LOCAL AREA DISCUSSION GROUPS
LISTING OF EXTENDED ABSTRACTS

Monday Orals
MS as an Integrated Technique in Problem Solving
Biochemistry
Ion Molecule Reactions & Chemical Ionization
Future Leaders in Mass Spectrometry
Mass Spectrometry in Surface & Materials Science
Biochemistry
Ion Molecule Reactions & Chemical Ionization
Future Leaders in Mass Spectrometry

Monday Posters
Instrumentation
Inorganic/Elemental Analysis
Electrospray & Thermospray
Laser Desorption/Plasma Desorption
FAB/Flow FAB
Polymers
Clusters

Tuesday Orals
The Mechanism of Electrospray Mass Spectrometry
FT/MS and Ion Traps
Peptides & Proteins
Instrumentation
Computational
FT/MS and Ion Traps
Peptides & Proteins
Isotopic Techniques Biomedical/Geochemistry

Tuesday Posters
Pharmacology/Drugs
Environmental
MS/MS & Ion Activation
Ion Activation/Dissociation
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Wednesday Orals
Reactive Collisions & Complexes and Their Analytical Applications 893
FAB/Flow FAB 903
Laser Desorption/Plasma Desorption 923
Inorganic/Elemental 941

Wednesday Posters
Biochemical 983
Isotope Ratios 1069
Fuels & Geoscience 1083
Computational 1113
Surface Science 1141

Thursday Orals
Electrospray & Thermospray 1159
MS/MS and Ion Activation 1179
Environmental 1199
The Use of PC Workstations for Off-Line Processing of MS Data 1221
Electrospray & Thermospray 1235
MS/MS and Ion Activation 1257
Environmental 1276
MS & Ion Chemistry of the Atmosphere & Beyond 1281

Thursday Posters
LC/MS 1300
Peptides & Proteins 1364
FTMS & Ion Traps 1479
Reaction Mechanisms 1580
Ion Molecule Reactions & Chemical Ionization 1578

Friday Orals
Issues In Environmental Chemistry 1639
LC/MS 1653
Pharmacology/Drugs 1671
Instrumentation 1691

INDEX OF AUTHORS 1713
INDEX OF KEY WORDS 1730
MINUTES OF THE ASMS BUSINESS MEETING 1754

INTEREST GROUP AND WORKSHOP REPORTS
Academic Laboratory Managers, "Manufacturers' Forum" 1766
Biomedical Interest Group 1768
Biotechnology Workshop, "The Changing Role of Technology in Biomedical Research" 1780
Desorption Ionization Workshop, "Sample Manipulation in FAB Mass Spectrometry" 1782
Environmental Interest Group, "Methods for Environmental Field Analysis" 1763
Fundamentals of Quadrupole Ion Traps Workshop 1764
Fundamentals Workshop, "Mass Spectrometry & Gas-Phase Chemistry of Fullerenes" 1765
History of Mass Spectrometry Interest Group 1767
Isotoplic Applications Workshop, "Isotopic Analyses of Noble Gases" 1769
Measurements & Standards Committee, "Nomenclature for Mass-to-Charge Ratio" 1770
Young Mass Spectrometrists Interest Group 1772

1991 ASMS CONFERENCE ATTENDEES 1774
INTRODUCTION

This volume represents the official record of the annual meeting and is designated as the Proceedings of the 39th ASMS Conference on Mass Spectrometry and Allied Topics.

The extended abstracts contained in the Proceedings provide brief descriptions of the research presentations made at the meeting and include both oral and poster contributions. In addition, reports from workshops and interest groups and the ASMS business meeting are included.

Special thanks are given to Hank Fales for overseeing the arrangement of the technical program and Judith A. Watson and her staff of Professional Association Management for coordinating the printing and distribution of the Proceedings.

Richard M. Caprioli
Editor and Member-at-Large
ASMS Board of Directors

CITATION NOTICE

This volume contains the extended abstracts of papers presented at the 39th ASMS Conference on Mass Spectrometry and Allied Topics. The material is not copyrighted and appearance of material in this volume does not jeopardize the author's right to publish the information in scientific journals.

Reference to individual abstracts contained in this volume should be cited as follows:

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

ASMS BOARD OF DIRECTORS

President
Robert C. Murphy
The Natl Jewish Center for Immunology & Respiratory Med.
1400 Jackson Street
Denver, CO 80206

Vice President for Programs
Henry M. Fales
National Institutes of Health
Building 10, Room 7N 318
Bethesda, MD 20892

Vice President for Arrangements
Robert L. Lattmer
The BFGoodrich R&D Center
9921 Brecksville Road
Brecksville, OH 44141

Secretary
Veronica M. Bierbaum
Department of Chemistry
University of Colorado
Boulder, CO 80309-0215

Treasurer
P. Jane Gale
Bristol Myers Squibb
Post Office Box 191
New Brunswick, NJ 08903-0191

Member-at-Large (Publications)
Richard M. Caprioli
Analytical Chemistry Center
University of Texas HSC
Houston, TX 77225

Member-at-Large (Education)
Robert J. Cotter
Johns Hopkins University
Department of Pharmacology
Baltimore, MD 21205

Member-at-Large (Measurements and Standards)
Michael T. Bowers
Department of Chemistry
University of California
Santa Barbara, CA 93106

Past President
Ronald A. Hites
SPEA 410 H
Indiana University
Bloomington, IN 47405

Executive Director
Judith A. Watson
Post Office Box 1508
East Lansing, MI 48826
(517) 337-2548

INTEREST GROUP COORDINATORS

Academic Lab Managers
Thomas R. Sharp
Pfizer Central Research
(203) 441-5932

Biomedical Applications
Steven A. Carr
Smith Kline & French
(215) 270-6550

Computer Applications
David E. Smith
Perkin-Elmer Nelson
(408) 725-1107

Desorption Ionization
Kenneth L. Busch
Georgia Inst. of Technology
(404) 894-4030

Elemental Analysis
Robert (Sam) Houk
Iowa State University
(515) 294-9462

Environmental Applications
Marcus Wise
Oak Ridge Natl Laboratory
(615) 574-4867

Fundamentals
Robert R. Squires
Purdue University
(317) 494-7322

History of Mass Spectrometry
Alfred L. Yergey
National Institutes of Health
(301) 496-5531

Instrumentation & Ion Physics
Ben S. Freiser
Purdue University
(317) 494-5270

Isotopic Applications
E. L. (Larry) Callis
Los Alamos Natl Laboratory
(505) 667-9888

LC/MS & Related Topics
Ross C. Willoughby
Extral Corporation
(412) 857-5708

Physical Organic
Douglas F. Barofsky
Oregon State University
(503) 737-1769

Surface Science
John A. Chakel
Charles Evans & Associates
(415) 369-4567

Young Mass Spectrometrists
John Stults

MASS SPECTROMETRY AS AN INTEGRATED TECHNIQUE IN CHARACTERIZATION OF PROTEINS.

Peter Roepstorff
Department of Molecular Biology
Odense University, DK 5230 Odense M, Denmark.

Mass spectrometry has since 1985 been an integral part of the protein studies in the Protein Research Group at Odense University. At that time the first plasma desorption mass spectrometer was physically placed in the protein research laboratory, and not as other mass spectrometers, in a dedicated mass spectrometry laboratory. The mass spectrometric data were found to be highly complementary to the data obtained by conventional methods in protein chemistry, and the sensitivity was soon developed to be adequate, i.e. in the low picomole range. The very informative data combined with the robustness of the instrument, ease of operation and a high sample throughput quickly placed mass spectrometry in a central position in our protein studies. After a few years doubling of the instrument capacity was needed and recently the plasma desorption mass spectrometers have been supplemented with laser desorption and electrospray instruments.

Our mass spectrometers do not have dedicated operators. The philosophy adapted is that any researcher (student, post doc, guest, technician and even professor) can use the mass spectrometers as they would use for example UV-spectrometers and pH-meters. In the last few years, on average 20 persons have operated the instruments on a daily basis. For each instrument one person is responsible for instruction, trouble shooting and maintenance. This is only possible if the mass spectrometers are robust, reliable and equipped with extensive safety controls to eliminate operator errors, and if sample preparation is simple and well understood, reproducible and gives results at the "first shot".

The concept described above is essential for the full integration of mass spectrometry in a protein study. In general, the mass spectrum of any sample can be available within less than an hour with consumption of only low picomole quantities. Nearly all other methods to characterise a sample will be more time and sample consuming. Therefore, molecular weight determination by mass spectrometry has become the first choice to characterize any peptide or protein preparation in terms of identity and purity and to serve as a guideline for further investigations.

The protein research in our group comprises:
* primary structure determination
* characterization of post translational modifications
* structure/function studies
* protein engineering

In any of these fields the first measurement carried out once the protein is isolated is the determination of a reasonably accurate molecular weight, preferably within a few Dalton. PDMS is generally adequate for proteins up to 10 KDa, but is too inaccurate and also often fail beyond that. Based on literature and our own limited experience it seem as if LDMS and ESMS might fulfill the needs up to at least 100 KDa. ESMS has the further advantage that it seems to disclose the presence of minor components in the sample.

In protein primary structure determination a general strategy for the inclusion of mass spectrometry has been developed (1). The strategy is based on the combined use of molecular weight determination by mass spectrometry specific enzymatic cleavages, peptide separation by HPLC and sequencing by automatic Edman degradation. This scheme with slight variations is followed in all our protein sequencing.
Structure determination of protein variants, such as natural mutant proteins, isoenzymes, and artificial variants induced by protein engineering is gaining increasing actuality. For this a combined approach based on peptide mapping by HPLC and mass spectrometry is used once the sequence of the original protein is known. This "two dimensional", mapping approach has been found extremely efficient for locating the enzymatically derived subpeptides carrying the variation because chromatographically silent variants normally are disclosed by mass spectrometry (e.g. Leu → Val) and the mass spectrometrically silent variants from the chromatographic data (e.g. Lys → Gln or Glu within the error of the mass determination). Only variants silent in both dimensions need sequencing (e.g. Leu → Ile). This mapping strategy has, for example, been successfully applied to hemoglobin variants consuming as little as 2 µl of blood (2), and to isoforms of fatty acid binding proteins (3).

To our surprise the inclusion of mass spectrometry in the protein studies has shown that post translational modifications are much more frequent than we expected. On a rough estimate between half and one third of the proteins we have investigated are modified. Mass spectrometry is essential not only to reveal the presence of modified amino acid residues, but also to determine the nature of the modifying group. The structure determination of a heavily post translationally modified protein from the locust cuticle is an example of the integrated use of mass spectrometry for such studies (4).

Although the sensitivity of the mass spectrometric techniques is comparable with most of the advanced "wet" biochemical techniques, improved sensitivity is always desirable. However, a major improvement can be obtained if the integration of mass spectrometry in the biochemical process can be used to increase the overall sensitivity of a given project. This is already partially fulfilled with the present state of integration, but a further improvement might be obtained if mass spectrometry is used in combination with early analytical separation procedures, such as gel- and capillary-electrophoresis, or to characterize proteins in rather crude extracts. Both possibilities now seem to be in reach (5,6) and should place mass spectrometry as an indispensable integral element in protein studies.

Complete carbohydrate characterization of a glycoprotein entails determining the primary structures and points of attachment of the oligosaccharide moieties. The primary structure of an oligosaccharide is defined by the following structural elements: the glycosyl residue composition; the linkage positions; the anomic configurations, absolute configurations and ring-forms of the constituent residues; the sequence of residues; and the attachment positions of any non-carbohydrate moieties (e.g., phosphate). Further complexity is introduced by the biosynthetic processing of glycoprotein oligosaccharides, which results in heterogeneous populations of structurally related oligosaccharides at individual glycosylation sites within a particular glycoprotein. In general, no single analytical method is capable of complete oligosaccharide structure elucidation; as a result, carbohydrate structure elucidation is usually carried out using several complementary methods. This lecture describes the use of mass spectrometry in conjunction with other physical (NMR), chemical (β-elimination), enzymatic (glycosidase and protease digestion) and chromatographic (high-pH anion exchange) methods to perform carbohydrate analysis of glycoproteins.

Recombinant human DNase (rDNase) is a glycoprotein with molecular weight of 30,000 and two potential sites for Asn-linked glycosylation. Approximately 10-20% of the N-linked carbohydrate of rDNase can be released by digestion with endo-β-N-acetylglucosaminidase H (endo H). When analyzed by high-pH anion exchange (HPAE) chromatography, the endo H-susceptible oligosaccharides were found to contain acidic functional groups. The acidic groups were found to be phosphate monoesters, as demonstrated by: (i) the isolation of mannose-6-phosphate after acid hydrolysis and (ii) shift in HPAE retention position to that of neutral oligosaccharides after treatment with alkaline phosphatase. After dephosphorylation, the endo H-susceptible oligosaccharides co-eluted in HPAE chromatography with two high-mannose structures (Man$_5$GlcNAc and Man$_6$GlcNAc) and one hybrid structure (NeuAcGalGlcNAcMan$_5$GlcNAc) whose structures had been determined by $^1$H NMR at 500 MHz. Liquid secondary ion mass spectrometry (LSIMS) of the p-aminobenzoic acid ethyl ester (ABEE)-derivatized oligosaccharides confirmed the underlying oligosaccharide structures and demonstrated that they were mono-phosphorylated. Collision-induced dissociation (CID)-MS was performed on the ABEE-derivatized Man$_6$GlcNAc structure to determine which mannose residue was substituted with phosphate (Fig. 1). This spectrum gave series of ions from both the reducing- and nonreducing termini that were consistent with: (i) attachment of phosphate to a linear hexose-hexose sequence (B- and C series corresponding to P-hex- and P-hex-hex-), and (ii) that the non-reducing terminal hexose residues are in a branched arrangement (X-, Y- and Z series corresponding to loss of one hexose and three hexoses, but not loss of two hexoses).

From the combined results, we conclude that the phosphate group in the Man$_6$GlcNAc structure is attached to the 6-position of the non-reducing terminal mannose residue of the Man$_6$(1-2)Man$_5$(1-3)Manβ(1-4)GlcNAc arm.
Recombinant tissue plasminogen activator (rt-PA) is a fibrin-specific plasminogen activator that is used in thrombolytic therapy in the treatment of myocardial infarction. The N-linked oligosaccharides of t-PA have been extensively characterized by several groups. Recently, a novel type of O-glycosylation was reported to occur in the EGF domain of urokinase (Kenzer et al., Biochem. Biophys. Res. Commun. 171, 401-406). We used a combination of protease- and glycosidase digestions, chemical degradation and MS to demonstrate that O-linked fucose is also present in the EGF domain of t-PA produced by several mammalian cell lines (Harris et al. Biochemistry 30, 2311-2314). The presence of O-linked fucose in t-PA was demonstrated by analysis of tryptic- and chymotryptic peptides containing Thr-61. Atmospheric pressure ionization (API) mass spectrometry was used in conjunction with carbohydrate analysis to demonstrate that fucose was covalently linked to the peptide(s). The nature of the linkage was confirmed to be O-glycosidic by the observation of destruction of Thr-61 under conditions that promote β-elimination. The linkage between fucose and threonine was found to be susceptible to α-fucosidase digestion and, therefore, has the α anomeric configuration. To examine whether O-fucosylation of t-PA was dependent on the type of mammalian cell used for expression, we examined t-PA produced in Chinese hamster ovary (CHO), Bowes melanoma and human embryonic kidney cells by reversed-phase HPLC peptide mapping and by API-MS of isolated peptides. All three cell lines were found to fucosylate Thr-61, suggesting that this is a cell-line-independent modification.
MASS SPECTROMETRY AS AN INTEGRATED TECHNIQUE IN LIPID RESEARCH

Phospholipids are one of the principal components of cell membranes. They exist as a complex mixture of molecular species containing a variety of head groups and fatty acyl moieties. The physical and chemical properties of cell membranes are largely dependent on their phospholipid composition, and especially on their polyunsaturate content. Upon proper stimulation, polyunsaturated fatty acids are released from phospholipids and metabolized through various oxygenative pathways to form extremely potent bioactive compounds, such as prostaglandins and leukotrienes. Therefore, alterations in polyunsaturate content or metabolism can result in modification of cell functions which may in turn yield many pathological consequences. Our research is focused on the composition and metabolic functions of the polyunsaturates, with particular emphasis upon their modulation by ethanol or diet.

In order to investigate changes in phospholipid composition, a technique which can efficiently analyze phospholipid molecular species was developed using thermospray LC/MS. Molecular ion species, and mono- and diglyceride fragments, as well as head group ions which are distinctive to each phospholipid class, are produced using the filament-on thermospray technique, as is shown in Figure 1 for 18:0, 18:1-PS. Therefore, information concerning the fatty acyl composition and class identity can be readily obtained by analyzing thermospray spectra. In conjunction with on-line reversed phase HPLC, phospholipid molecular species can be separated and detected. This approach enables rapid and efficient analysis of phospholipids from complex biological mixtures. An example is shown in Figure 2 for changes in phosphatidylcholine composition in red blood cell membranes after dietary manipulation. The changes resulting from a fish oil diet, which are a loss of w-6 molecular species and an increase of w-3 species, can be readily observed from the ion chromatograms. In addition to its use to compositional studies, this technique has great potential in the investigation of phospholipid metabolic pathways such as transacylation, desaturation-elongation, decarboxylation, phospholipase reactions or molecular rearrangements, using stable isotope-labeled phospholipids.

It has been shown that ethanol modifies the production of oxygenated fatty acid metabolites by various mechanisms such as lowering levels of polyunsaturates or directly affecting various oxygenative pathways. Docosahexaenoic acid (22:6w3) is the main polyunsaturated fatty acid in brain, and it has been shown that the level of this fatty acid decreases with ethanol treatment. Since it was believed in previous reports that arachidonic acid (20:4w6) is lipoxygenated in the brain, it was therefore thought possible that 22:6w3 could also be subject to lipoxygenation in brain. This, in turn, raised the possibility that the effect of ethanol upon brain could be mediated by one or many of the oxygenated metabolites formed from 22:6w3. When 22:6w3 was incubated with the rat brain homogenate or slices, various hydroxylated 22:6w3 was observed. They were characterized using thermospray LC/MS, GC/MS and chiral phase HPLC with the aid of standards, which were prepared by reactions with soybean lipoxygenase and platelets as well as autooxidation. However, stereochemical analysis by chiral phase HPLC indicated that they were mainly racemic mixtures. Similar results were obtained for arachidonic acid. This indicated that hydroxylation occurs in the brain, not by lipoxygenation but by peroxidation. When endogenous production of various hydroxylated compounds were measured in the presence of deuterated standards, using NCI-MS after pentafluorobenzyl derivatization, hydrogenation and trimethylsilylation, subnanogram levels of peroxidation products were observed from the 1 g of brain tissue.
Figure 1. Thermospray spectrum of 2 µg of 16:0, 18:1-PS. DG=diglyceryl fragment resulting from the loss of the head group from the intact molecule MG= monoglyceryl fragment resulting from the loss of either fatty acyl group from the diglyceryl fragment.

Figure 2. Ion chromatograms reconstructed with diglyceride ions of major phosphatidylcholine molecular species of rat erythrocytes obtained after feeding a corn oil or fish oil diet for 21 days. To separate molecular species, an Ultrasphere-ODS column (4.6 mm x 7.5 cm, 3µ) and a mixture of methanol:hexane:0.1M ammonium acetate (500:25:25) was used with a flow rate of 1 mL/min.
Arginine Isotopic Ratio Measurements Using a Perfluoroalkyl-oxazolinone (FOX) Derivative

Arginine metabolism is of interest because of its relation to the urea cycle, the immune response (nitric oxide formation) and overall nitrogen balance. A simplified, mass spectrometric analysis of stable-isotopically labeled arginine would be useful in the investigation of its in vivo metabolism.

Typically α-acyl, alkyl esters have been used for amino acid GC/MS analysis, but these undergo extensive fragmentation in an El source with losses of the guanido and acid moieties. Cyclized-guanido and TBDMS derivatives fared no better, thus requiring the use of CI sources for the analysis of various and multiply-labeled arginine analogues. Previously, this laboratory and others have reported the use of 2-perfluoroalkyl-3-oxazolin-5-one (FOX) derivatives of phenylalanine for GC/MS analysis. This derivative gave a strong molecular ion in El and was useful for both various labeled mole fraction and analyte concentration determinations. Additionally, the derivatization was a simple, one-pot procedure, minimizing necessary sample work up and avoiding loss of the more volatile amino acid derivatives.

Modification of the previously reported derivatizing reagent mixture of acetonitrile (CH₃CN) and perfluoroacyl anhydride (in this case, trifluoroacetic anhydride, TFAA) was required in order to avoid problems associated with heating amidines and guanidines in the presence of CH₃CN. 1,2-dichloroethane was substituted in a 4:1 (v:v) ratio with TFAA. Optimal reaction conditions for 250 μL of plasma were determined by comparing GC peak area ratios of the derivatized arginine with a known amount of added external standard, N-TFA, norleucine methyl ester. The final procedure required heating the isolated amino acids with 100 μL of the 4:1 reagent at 100°C for 120 minutes. No other preparatory steps were necessary.

PCI and NCI analysis of the derivative show very strong ions at m/z 445, (M+H)⁺, and 444, M⁺, indicating the compound is a dTFA, FOX structure, most likely guanido-N,N-diTFA, FOX-arginine. The largest (or near largest) fragment by EI-MS is m/z 375, (M-CF₃)⁺; this effectively allows all labeled arginine compounds to be observed by a single ionic species.

Single calibration curves for guanido-¹³C-; 5,5-d₂- and guanido-¹⁵N₂, 5,5-d₂-arginine in the range of 0 to 1% (except d₂, range = 0 to 21%) were prepared as aqueous solutions, derivatized and measured by GC/EI-MS. Linear regression results of isotopic mole fractions versus the appropriate m/z area ratios were r² = 0.994 / limit of detection (LOD) = 0.996/1.4%; and 0.997/0.6% respectively. Multiple isotope calibrants were prepared with various mixtures of the above labeled compounds and measured. Calibration of area ratios versus mole ratios was accomplished using an inverse multivariate (P matrix) method. Correlation coefficients for ¹³C- and d₂- compounds were 0.959 and 0.981 respectively; the ¹⁵N₂, d₂-arginine signal area was unaffected by the presence of either other analogue.

It was shown that arginine concentration could also be determined by this method. Homoarginine was used as an internal standard and arginine/homoarginine molar ratio standards were prepared in the range of 0.225 to 2.05. The standards were derivatized and measured in the above manner with homoarginine showing an (M-CF₃)⁺ ion at m/z 309. Linear regression of analyte/internal standard molar ratios versus m/z area ratios gave an r² of 0.991. Five 250 μL aliquots from a single plasma pool were then taken and a known amount of the internal standard added. Concentration determinations in replicates of seven gave the following results (mean±sd): 14.6±0.5, 15.1±0.7, 15.1±0.7, 14.6±0.5, and 15.4±0.3 μmol/100mL. Inte-
sample coefficient of variation (CV) is 4.0%. HPLC analysis gave an arginine concentration of 15.1 μmol/100mL.

To ten aliquots of the same plasma pool were added various amounts (in duplicate) of guanido-13C-arginine. Analysis was made in triplicate (except sample 1B, in duplicate only) and the results are given in the table below.

Furthermore, measurements of plasma isotopic mole fractions were made at different time points from a subject undergoing infusion of equal amounts of guanido-13C- and guanido-15N2, 5,5-d2-arginine. The values were divided into fasting and fed groups, averaged and are reported with their standard deviations below. The values are statistically the same.

The F0x derivative of arginine was investigated as a possible alternative to N-acetyl, Nε-acetyl esters. This derivative offers the advantages of one-pot formation with minimum sample work-up time and detection of the entire molecule by GC/EI-MS. Various and multiply-labeled arginine analogues were detected and accurately quantitated either as individual or multiple analytes. Additionally, with an internal standard plasma free arginine concentration could be determined.

DETERMINATION OF PHOSPHOLIPID PRECURSORS OF ARACHIDONIC ACID INVOLVED IN LEUKOTRIENE BIOSYNTHESIS USING STABLE ISOTOPE LABELLING AND FAST ATOM BOMBARDMENT TANDEM MASS SPECTROMETRY.

Kathleen Kayganich and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine, Denver, CO 80206

For the past thirty years there has been extensive investigation into the biochemistry of the arachidonic acid (AA) cascade of metabolites. This is primarily because of the potent biological activities of many of the AA metabolites, such as prostaglandins, thromboxane, and the leukotrienes. These oxidative metabolites of AA have been implicated as mediators of many physiological and pathophysiological processes, such as inflammation and platelet aggregation. In the late 1960's it was determined that most cellular AA is esterified in the sn-2 position of glycerophospholipids (1) and also that activation of phospholipase A2, which liberates AA from phospholipids, was necessary for the production of AA metabolites (2). Therefore it is generally accepted that these bioactive substances are produced from the action of cyclooxygenase or 5-lipoxygenase on AA released from cellular phospholipids. However, no one has ever shown there to be a direct link between any specific phospholipid molecular species and AA metabolites. There are numerous molecular species of phospholipids in mammalian cells containing AA that could serve as precursors to the prostaglandins and leukotrienes, which has made it difficult to determine the identity of an exact phospholipid precursor. To investigate the source of arachidonate we are using negative ionization fast atom bombardment and tandem mass spectrometry to follow incorporation of stable isotope labelled AA into phospholipid molecular species in cultured mast cells and correlating the isotopic enrichment of the arachidonate-containing molecular species with the isotopic enrichment of leukotriene B4 (LTB4) that is produced upon stimulation of the labelled cells.

METHODS

Cell Culture Conditions- D8-AA was added to the culture medium of virally-transformed murine bone marrow-derived mast cells (1 x 10⁶ cells/ml) to achieve a fatty acid concentration of 2 μM. Anti-dinitrophenol (DNP)-IgE was added to the cells (1μg/ml). After appropriate incubation times with labelled fatty acid, the antigen stimulus, DNP-albumin, was added to activate the cells to initiate leukotriene biosynthesis. Figure 1 illustrates the protocol for a typical experiment, including the lipid isolation procedures.

Figure 1. Protocol for D8-AA incorporation into cultured mast cells, stimulation of labelled cells, and isolation of lipids. Following stimulation, the cells are centrifuged. The LTB4 is isolated from the supernatant by reverse-phase HPLC using a gradient from 55% methanol/H2O (pH 5.7) to 100% methanol. Cellular phospholipids are separated according to polar head by normal phase HPLC using a hexane:isopropanol:H2O gradient (30:40:3.3 to 30:40:7).

Mass Spectrometry- Collision induced dissociation (CID) of the [M-H]- ions from phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine, or the [M-CH3]- ion from phosphatidylcholine molecular species, yields abundant carboxylate anions that correspond to the fatty acids esterified on the glycerol backbone of the phospholipids. Isotopic enrichment of each potential precursor phospholipid molecular species was determined using selected reaction monitoring for the decomposition of the [M-H]- (or [M-CH3]- for GPC) ion to the arachidonate anion (m/z 303) for each molecular species and its D8 analog, which gives rise to m/z 311 upon CID. The ratio of the intensities of the ions at m/z 311 to m/z 303 then represents the ratio of labelled to unlabelled arachidonate-containing molecular species
that are potential leukotriene precursors. A Finnigan TSQ70B triple quadrupole mass spectrometer, equipped with a fast atom gun was used to obtain all the phospholipid mass spectra. The fast atom gun was operated at 1 mA with xenon accelerated to 6kV. Diethanolamine was used as the liquid matrix. Selected reaction monitoring was carried out with argon (0.5 mtorr) as the collision gas and a collision offset energy ($E_{i\text{a}}$) of 30 eV. The stable isotope enrichment in the leukotrienes was determined by measuring the ratio of the product $D_8$-LTB$_4$ to the product LTB$_4$ by electron capture negative ionization GC-MS of its pentafluorobenzyl ester-trimethylsilyl ether derivative. A Finnigan SSQ70 quadrupole mass spectrometer equipped with a Varian 3400 gas chromatograph (10m x 0.2mm DB-1 capillary column) was used for selected ion monitoring of the [M-PFB] ions.

RESULTS
Representative data is shown in figure 2. The isotopic enrichment of the phospholipid molecular species in 2(a), as assessed by the ratio of the relative abundance of m/z 311 to that of m/z 303 is 0.32. The enrichment of the LTB$_4$, as assessed by the peak height ratio of m/z 487 to 479 is 0.64. The greater enrichment of the LTB$_4$ indicates that this particular molecular species, which is less enriched, could not have been the sole precursor of the AA that was converted to the LTB$_4$.

CONCLUSIONS
The combination of negative ion FAB and tandem mass spectrometry using selected reaction monitoring can be used to assess the enrichment of stable isotope labelled arachidonic acid into cellular phospholipid molecular species. Using these techniques we have been able to follow the incorporation of labelled AA into the 23 major arachidonate-containing molecular species of cultured mast cells. No conclusive correlations between the isotopic enrichment the phospholipid molecular species and that of LTB$_4$ have been found at this time.

ELUCIDATION OF PRIMARY STRUCTURE AND MICROHETEROGENEITY OF PULMONARY SURFACTANT ASSOCIATED SP-C LIPOPROTEINS WITH CYSTEINYL-THIOESTER-PALMITATE RESIDUES

Faculty of Chemistry, University of Konstanz, P.O. Box 5560, D-7750 Konstanz, FRG; Byk Gulden Pharmazeutika, P.O. Box 5500, D-7750 Konstanz, FRG;

Pulmonary Surfactant is a complex phospholipid-protein mixture secreted by alveolar type II pneumocytes. Among the three major surfactant associated proteins known thus far, the low molecular weight (4 kD) SP-C protein exerts important biological functions in normal respiration, predominantly by reducing surface tension at the air-liquid interface of bronchoalveoli. Mature SP-C, derived from a large (197 aa) protein precursor consists of a relatively hydrophilic N-terminal sequence with two adjacent Cys residues, followed by an extremely hydrophobic C-terminal transmembrane domain. SP-C sequences were previously obtained from cDNA data (1), while conventional protein-analytical methods proved difficult or unfeasible due to its extreme hydrophobicity. The complete amino acid sequences and primary structures of SP-C isolated from human, bovine, rat and canine lung were elucidated in this study, using 252Cf plasma desorption (PDMS) and fast atom bombardment mass spectrometry (FABMS) in combination with selective degradation reactions. Of particular interest was the identification of the bis-palmitoylated, cysteinylthioester structure of SP-C, which was established by selective deacylation and mass spectral analysis.

Several forms of human and bovine SP-C proteins were isolated from lung lavage by Sephadex LH60 chromatography and final HPLC purification, and subjected to PDMS and FABMS analysis. PD spectra yielded abundant molecular ions with high (sub-pmol) sensitivity as shown in Fig. 1 (left) for a bovine protein (m/z 4068). Molecular ions of natural SP-Cs occurred as \([M+Na]^+\), in contrast to \([M+H]^+\) ions for alkali salt-free recombinant SP-C, and were established by formation of \([M+NH_4]^+\) ions, or other alkali ion adducts. The exact molecular weight determinations were confirmed by FABMS analysis and revealed several microheterogeneous proteins, which were significantly larger compared to molecular weights derived from cDNA sequences. Covalent palmitoylated, Cys\(\gamma,\delta\)-thioester-linked structures were identified by direct PDMS analysis after selective cleavage with DTT/NH\(_4\)HCO\(_3\) (pH 8), yielding molecular ions deacylated by one and two palmitoyl residues (Fig.1; right). Palmitate was found as the only fatty acid incorporated. N-Terminal sequences and palmitoylation were further determined by combined Edman degradation/PDMS of stepwise truncated proteins (2). Notably, the direct identification of the hydrophobic regions (Arg\(^{11}\) to Leu\(^{30}\)) was obtained by sequence-specific carbenium fragment ions in the PD spectra (s. Fig. 1). The structure determination, complemented by amino acid analysis, is in accord with the recently reported palmitoylated structure of porcine SP-C (3). Thus, human SP-C consists predominantly of two proteins (34/35 residues) due to a frayed (Phe/Gly) N-terminus, while bovine SP-C showed heterogeneity by an additional N-terminal Leu and by Val/Leu exchanges in positions 21 and 22. A recombinant, non-palmitoylated human SP-C was analyzed and showed an identical sequence. By contrast, natural canine SP-C was identified as a mono-palmitoylated protein with a -Pro-Cys(palmitate)-Phe-Pro-
sequence. Of particular interest is the mass spectrometric identification of fatty acid-deacylation as a specific pathophysiological structure alteration in SP-C from patients with alveolar proteinosis (4).

Fig.1: PDMS analysis of bovine SP-C and primary structures of human and bovine SP-C proteins. Left, complete spectrum of bovine SP-C with sequence-specific fragment ions in the insert; right, direct PDMS analysis after stepwise depalmitoylation with DTT/NH$_4$HCO$_3$ (pH 8, 60 and 120 min).
Rapid Recovery of Biological Compounds from Electrophoretic Gel Slices for Subsequent Analysis by Matrix-assisted Laser Desorption Fourier Transform Mass Spectrometry

J. C. Dunphy, R. L. Hettich, and M. V. Buchanan, Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831, and K. L. Busch, School of Chemistry, Georgia Institute of Technology, Atlanta, GA, 30332

Slab gel electrophoresis is a widely used method for the high-resolution separation of large biopolymers. Mass spectrometry, with its increasing applications in biotechnology, has recently emerged as a highly-selective detector for gel electrophoresis. Our work has focused on rapid and sensitive mass spectral techniques for analyzing biomolecules separated by agarose and polyacrylamide gels. Our approach has been to develop methods to extract nucleotides and oligonucleotides from the gel matrix prior to examination by matrix-assisted laser desorption FTMS. The accurate mass measurement and collision-induced dissociation capabilities of FTMS provide both structural and sequence information for normal and modified oligonucleotides.

Agarose gel electrophoresis is commonly used for the separation of nucleic acids and their restriction enzyme cleavage products. For initial studies, agarose gels were prepared in 8.2 mM tris-phosphate buffer, and standards of oligonucleotides made up in the same buffer solution were electrophoretically introduced into the gel. For recovery, a procedure originally developed by Thuring et al. [Anal. Biochem., 66, 213 (1975)] was adapted for use with mass spectrometry. In this "freeze-squeeze" procedure, the gel slice to be analyzed is excised, frozen for a few seconds in liquid nitrogen, and then manually squeezed between two pieces of Parafilm to recover the interstitial gel fluid. Experiments using radiolabelled 14C-adenosine monophosphate indicated that recovery from the gel is typically greater than 50%. The drop of extracted fluid containing the analyte is mixed with 2-pyrazinecarboxylic acid, which is used a laser desorption matrix, and transferred to the probe tip for examination by LD-FTMS. This entire extraction procedure requires less than 5 minutes. High-quality mass spectra of nucleotides and oligonucleotides can be obtained with as little as 100 picomoles of sample originally applied to the gel.

For polyacrylamide (PAGE) gels, which are typically used for large oligonucleotide and protein separations, the "freeze-squeeze" procedure is not effective due to the high density of the PAGE gels. A modified electroelution procedure has been developed to rapidly recover biomolecules from PAGE gel slices by using the fabricated device shown in Figure 1. An electrical potential of +/-30 to 60 V is applied to a platinum wire electrode to extract the biological analyte from the gel into a buffer solution. Because gel-warping and loss of spatial resolution are not important in this case, electrical currents larger than those typically employed for electrophoretic separations are used for rapid extractions ( < 5 minutes) of analytes from the PAGE gels. The buffer solution into which the analyte will be extracted from the PAGE gel does not need to be identical in composition or concentration to the buffer solution in the gel. Studies of recovery efficiencies and detection limits for the electroelution of PAGE gels indicated that picomoles of analyte could be introduced to and subsequently extracted from these gels, which is similar to results observed for the "freeze-squeeze" method for agarose gels. An additional feature of the freeze-squeeze and electroelution recovery methods is that the analyte is recovered in solution and many other types of analyses can be performed on the sample, such as electrospray MS or other spectroscopic methods.

After a biomolecule has been extracted from a gel, it can be examined and characterized with matrix-assisted laser desorption FTMS. As an example, the isomeric dimers d(5'-CT-3') and d(5'-TC-3') were electrophoretically introduced into agarose gels (500 picomoles of each dimer) and extracted with the freeze-squeeze method. The resulting extracts were mixed with the laser matrix (2-pyrazinecarboxylic acid) and examined by 266 nm laser desorption FTMS. The negative ion spectra observed for these two isomers revealed molecular weight information as well as some fragmentation. However, the collision-induced dissociation spectra of the (M-H)+ at m/z 530 for each isomer, shown in Figures 2 a-b, provided detailed structural information and revealed fragment ions which could be used to differentiate the isomers.

* Research sponsored jointly by the Office of Health and Environmental Research, U.S. Department of Energy under contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc. and by the Laboratory Graduate Participation Program under contract DE-AC05-76OR00033 between the U.S. Department of Energy and Oak Ridge Associated Universities.
Electrospray ionization dramatically extends the capability for mass spectrometric analysis of proteins and oligopeptides. The facile production of multiply charged molecular cations extends the range of mass analysis, permitting the use of conventional mass analyzers of limited m/z range. Measurement of relative molecular mass for proteins of greater than 100 kilodalton have been demonstrated, and in favorable cases precision of measurement may be better than 0.005%.

Additionally, efficiency for collisional dissociation of multiply charged molecular ions is significantly enhanced permitting the production of informative singly and multiply charged product ions. We have employed these techniques for the qualitative examination of mixtures of oligopeptides and proteins from a variety of sources. These have included mixtures of proteins obtained as subfractions from the purification (e.g. gel permeation chromatography or polyacrylamide gel electrophoresis) of biological materials, and mixtures of oligopeptides derived from the partial or complete digestion with specific proteases. We have demonstrated the applicability of electrospray ionization mass spectrometry and tandem mass spectrometry in the analysis of mixtures of bovine eye lens proteins, and the products of partial trypsinolysis of mutant calmodulins.

Although we have observed a wide variation in the electrospray ionization response among proteins of different provenance in both model and applied studies, we have so far not observed substantial discrimination in electrospray ionization among similar constituents in the analysis of mixtures. We note particularly that this is the case for tryptic fragments of proteins. This absence of significant discrimination greatly facilitates analysis particularly in the evaluation of the homogeneity of protein preparations and proteolysis based "mapping" experiments. Mass measurement precision and accuracy (typically ± 0.05 % to ± 0.005 %) from the electrospray ionization mass spectrum of the constituents of protein and oligopeptide mixtures are superior to those obtainable by techniques such as denaturing gel electrophoresis. Such increased accuracy and precision can dramatically enhance specificity of the analysis. Additionally the mass spectral resolution permits the confident distinction among species unresolved by conventional techniques. In electrospray ionization, with the increase in the relative molecular mass of the majority of analytes, there is generally an increase in the extent of multiple charging, and an increase in the number peaks (i.e. different charge states) in the spectrum. In the analysis of mixtures of proteins, these increases result in significant spectral congestion, which places higher demands on m/z resolution required for successful analysis, reduction in the ability of the method to accommodate complex mixtures and may reduce the dynamic range of the analysis.

The electrospray ionization of mixtures of proteins may be interpreted by inspection in which the association among the peaks observed in the mixed spectrum are computed to identify the overlapping distributions of multiply charged ions. Alternatively, computer algorithms may often be applied which recognize the harmonic relation among the peaks in the spectrum and deconvolute the data to provide an uncomplicated view of the composition of the mixture. An example of a mixed spectrum amenable to either approach is shown in Figure 1 for the electrospray ionization mass spectrum of an HPLC subfraction of the βL fraction of bovine lens crystallin obtained by gel permeation chromatography. The manual approach permits the recognition of three principal constituents of relative molecular mass 20,080.5 ± 3.0, 23,194.7 ± 3.5 and 24,244.4 ± 1.9 daltons respectively. These values are in good agreement with those obtained by computer deconvolution shown in Figure 1(b). It is arguable that these data are potentially more accurate since they arise from a treatment of the full array of mass spectral information. The success of this latter approach depends on the presence of a sufficient number of peaks in the spectrum to represent the
harmonicity of distribution of multiply charged ions. Where the mixtures contain constituents affording few peaks in relatively low charge states (or where the mixture contains such materials together with constituents showing a number of higher charge states) the peak assignments still rely on the manual approach and incur a somewhat greater uncertainty. As the number of charge states decreases, the possibilities of misassignment increase. Where the constituents mixtures vary widely in size and thus in charge state of the distributions of molecular ions, we have found that “high” versus “low” charge state ions may be distinguished by evaluating their relative efficiencies in the production of secondary electrons in pulse counting ion detection experiments. The physical basis of this differential behavior of multiply charged ions in the production of secondary electrons is the object of present investigations. However, this observation suggests the possibility of the crude classification of ions according to their charge state which might facilitate the interpretation of mass spectra of complex mixtures.

Enterobacter agglomerans is a gram-negative bacterium commonly present in field cotton. This bacterium is known to produce lipopolysaccharide (LPS), a type of endotoxin. Inhalation of cotton dust containing LPS may lead to byssinosis, a pulmonary disease afflicting textile mill workers exposed to cotton fiber and dust in the workplace [1]. The toxic activity of LPS is thought to originate from a portion of the molecule called "Lipid A" [2,3] which is liberated from LPS via gentle acid hydrolysis. The exact structure of Lipid A produced by E. agglomerans has not been previously elucidated. Many of the known Lipid A's contain two glucosamine moieties joined by an ether linkage. Fatty acid ester and amide side chains are usually present on each sugar moiety, and one or more phosphate groups is typically attached. Many varieties of Lipid A may be produced by a single bacterium.

The goal of this study is to identify the molecular weights and ester-linked side chains present on the various Lipid A's produced by E. agglomerans. Plasma Desorption Mass Spectrometry (PDMS) has been performed on treated LPS preparations containing monophosphoryl Lipid A. The PDMS instrument used was a BIO-ION 20 (BIO-ION Nordic, Uppsala, Sweden). Positive and negative ion spectra of the Lipid A mixture suggest that at least four different Lipid A structures are present. The average molecular weights of the four monophosphorylated neutral molecules are 1973, 1957, 1734, and 1718 daltons. In the positive ion mode, sodium adducts of these molecules are observed, whereas in the negative ion mode, (M-H)^+ ions appear. Fragmentations are quite abundant in both positive and negative ion modes, and the observed ions correspond to the presence of ester-linked lauroyl, myristoyl, and hydroxymyristoyl side chains.

If the Lipid A is taken through a dephosphorylation step prior to PDMS analysis, desorption characteristics in the positive ion mode improve dramatically, and the signal-to-noise ratio increases significantly relative to phosphorylated Lipid A. The positive ion spectrum of dephosphorylated Lipid A is shown in Figure 1. Postulated empirical formulas for the observed peaks are given in Table 1 along with proposed side-chain losses from A4, B4, C4, and D4 (the four dephosphorylated analogs of the above listed monophosphorylated neutral molecules, respectively).

The combined information provided by positive and negative ion mass spectra reveal that E. agglomerans monophosphoryl Lipid A having a molecular weight of 1957 daltons appears to be structurally similar to a well-characterized Lipid A produced by Salmonella minnesota (also 1957 daltons) [4]. Moreover, the E. agglomerans monophosphoryl Lipid A having a molecular weight of 1718 daltons appears to be structurally similar to a well-characterized Lipid A produced by Escherichia coli (also 1718 daltons) [5]. The two Lipid A structures having molecular weights of 1973 and 1734 daltons differ from the above structures (respectively) in that each appears to contain an additional oxygen atom on a fatty acid ester side chain attached to the distal subunit.

CHARACTERIZATION OF SOLUBLE NOD-GENE-DEPENDENT FACTORS FROM RHIZOBIUM MELiloti CULTURES. E. Morrey Atkinson1, *Kym F. Faul12, David W. Ehrhardt1, Kenneth Conklin2 and Sharon Long1. 1Department of Biology, Stanford University, and 2Department of Psychiatry and Biobehavioral Sciences and the Neuropsychiatric Institute, UCLA School of Medicine, Los Angeles, California.

The symbiotic relationship between plants of the family Leguminosae and soil-borne Rhizobium bacteria is responsible for a major proportion of planet Earth's annual conversion of atmospheric nitrogen to organic nitrogen. This crucial component of the Nitrogen Cycle takes place in multicellular root nodules which harbour a population of bacteria. Root nodule formation is a complex process in which microscopic extensions of the epidermal cells (root hairs, which are normally involved in water and nutrient uptake) are distorted and invaded by bacteria: plant and bacterial cell division then takes place resulting in the formation of a morphologically distinct nodule usually visible to the naked eye.

Wild type (effective at initiating nodulation) and mutant strains (ineffective at initiating nodulation, so-called nod gene mutants) of Rhizobium meliloti were available. We therefore chose a novel approach to isolating the compound(s) produced by the bacteria which are responsible for root hair deformation and root cell division. This approach involved comparison of the chromatographic profiles of extracts of both strains in which we sought compounds in the culture supernatant from the wild type strain which were absent in the culture supernatant from the nod gene mutant strain.

Reverse phase high pressure liquid chromatograms of butanol extracts revealed the presence of a major peak of UV absorbing material in supernatants of the wild-type Rhizobium which was absent in the extracts from supernatants of nod gene mutants (Figure 1A). Biological tests revealed that this material caused root hair deformation and root cell division when applied to alfalfa seedlings. Further chromatography in the presence of a quaternary ammonium ion-pair reagent resolved the peak of UV absorbing material into several components (Figure 1B). Final purification of the resulting fractions was achieved in the absence of ion-pair reagent (Figures 1C & D). FAB mass spectrometry of the resolved materials was highly informative but required caution in interpretation. For example, mass spectra on two fractions at a relatively early stage in the purification (estimated on the basis of UV adsorption profile at around 70% pure) suggested the presence of two non-sulfated analogues of the compound reported at about the same time by Lerouge et al* (Figures 2A & C). However, mass spectra on the final purified fractions clearly indicated the presence of a sulfate moiety on each compound from the loss of 80 mass units from the molecular ions, and in one case showed the presence of an additional saccharide unit which had not previously been evident (Figures 2B & D).

Although final structural elucidation is awaiting the results of our on-going NMR and chemical degradation studies, the mass spectral data are consistent with the presence of two major components and at least two minor components in the original peak of UV absorbing material. One of the major components is assigned as an acetylated analogue of the compound isolated and structurally characterised by Lerouge et al* (Figure 3A); the other major component is assigned as the pentameric form of this modified saccharide (Figure 3C). The location of the additional acetic moiety on the non-reducing end of these two molecules is inferred from the FAB mass spectral pattern, but exact positional assignment of this acetate group has yet to be achieved. Two of the minor components of the mixture appear as the corresponding de-acetylated forms of the major components in which the additional acetate on the non-reducing end is missing (Figures 3B & D): the mass spectra of one of these peaks is identical to that of the compound reported by Lerouge et al (Figure 3B). Activity of these compounds in root hair deformation and root cell division assays is currently being assessed.

The Investigation of Oligosaccharides in an External Source Quadrupole Fourier Transform Mass Spectrometer
Carlito B. Lebrilla, Lambert Ngoka, and James Carroll
Department of Chemistry, University of California, Davis, CA 95616

An external source quadrupole Fourier transform mass spectrometry (QFTMS) instrument has recently been constructed in our laboratory and a program initiated to develop a method for the structural elucidation of oligosaccharides. Ions are produced in a liquid-secondary ion mass spectrometry source and are injected into the analyzer cell, which is in a differentially pumped chamber, using a single stage quadrupole guide. The quadrupole guide functions only as a broad band mass filter allowing sampling of most of the ions created in the cell. The analyzer cell is contained in a homogeneous region of a 3 Tesla superconducting magnet.

Although oligopeptides have been well studied with the QFTMS technique, oligosaccharides have not been explored. A separate investigation is warranted due to the importance of oligosaccharides in cancer research and the large difference between the two classes of compounds when analyzed mass spectrometrically. Oligosaccharides pose unique problems for mass spectroscopy. Sensitivity is often poor. Fragmentation is unpredictable (abundant in some cases and nearly absent in others). Derivitization is often necessary to obtain fragmentation.

Experiments have been performed on a series of underivatized oligosaccharides from monosaccharides to a heptasaccharide (maltoheptaose, m/z 1152). Samples are dissolved in water and placed on a copper probe tip. The sample is bombarded with a Cs+ beam having 10 KV of energy. Strong parent and fragment ions are observed. Figure 1 shows a representative cation (2a) and anion (2b) spectra of the FAB/FTMS of a tetrasaccharide maltotetraose. No attempts have been made to filter out the matrix ions. However, the spectra are nearly matrix free. Both spectra show cleavages only along glycosidic bonds. In addition, pseudomolecular peaks (clusters of matrix and the oligosaccharide parent), which are commonly observed in FAB/MS of underivatized oligosaccharides, are absent. The weak matrix background and the extensive fragmentation is a consequence of the relatively long time scale involved with this method. The time between ion formation and detection are at least several milliseconds long and can be as long as several minutes. During this time matrix clusters and oligosaccharide ions decompose. This is illustrated in the spectra of lactose (Figure 2) in which the ions are injected for a period of 5 msec and detected at 1 msec (2a) and 10 msec (2b) after the injection period. A significant decrease is observed for the protonated diglycerol species (G_2H^+) when the detection delay time is lengthened. When large oligosaccharides are analyzed a similar effect is observed with the parent ions. Protonated and sodiated maltotetraose, formed by adding NaCl in the oligosaccharide solution, decrease in intensity as the detection delay time is lengthened from 2 to 7 msec. Interestingly, the decrease of the protonated species occurs more rapidly than the sodiated species. We believe that both effects are due to unimolecular decomposition. FAB ionization provides sufficient energy for the metastable decay. The decomposition is, however, slow and is observed best during long detection times.

Oligosaccharides do not produce the same high sensitivity as the similarly massed oligopeptides. Nonetheless, 6 μg of underivatized compound is readily observable. High resolution is obtained in both the anion and cation mode. A resolution of 16,000 (FWHH) for the sodiated maltotetraose (m/z 689) and 85,000 for the anion of maltose (m/z 341).

APPLICATION OF FAST ATOM BOMBARDMENT MASS SPECTROMETRY TO BIOCHEMICAL STUDIES OF SECOND MESSENGERS: I, CYCLIC NUCLEOTIDES

Russell P Newton, A Gareth Brenton, Terence J Walton, Frank M Harris, James I Langridge, Andrea M Evans and Dipankar Ghosh

Biochemistry Research Group, School of Biological Sciences and Mass Spectrometry Research Unit, University College of Swansea, Swansea SA2 8PP, United Kingdom.

Cyclic nucleotides play a central role in mammalian cellular regulation and are consequently a major topic of current research interest. Each of the naturally occurring cyclic nucleotides contains a ribose ring, a heterocyclic base (BH) and a cyclic phosphate moiety, linked to the ribose ring at positions 3' and 5' or 2' and 3', with the former isomers having regulatory functions and the latter being merely products of nucleic acid degradation. One cyclic nucleotide, adenosine 3', 5'- cyclic monophosphate (cyclic AMP) mediates the action of a large number of hormones and neurotransmitters, leading to its description as a second messenger; a second cyclic nucleotide, guanosine 3',5'- cyclic monophosphate (cyclic CMP) acts in the visual cycle of the mammalian eye and as a mediator of atrial natriuretic peptide.

While not ideally susceptible to EI or CI mass spectrometric analysis, cyclic nucleotides yield useful protonated molecular ions on fast atom bombardment (FAB) MS, and characteristic fragments can be generated by collisionally induced dissociation (CID) and mass-analysed ion kinetic energy spectrum scanning (MIKES).

This provides a rapid means of differentiating the two isomeric forms of cyclic nucleotides: MIKES analysis of the protonated molecular ion from 3',5'- isomers produces spectra containing major fragments at BH* +28 and BH* +42, while that from 2',3'- isomers contains a much weaker BH* +42 fragment due to the substitution of the 2' position of the ribose ring (1,2).

![Fragmentation of 3',5'- cyclic nucleotides leading to formation of diagnostic ions.](image)

By application of this procedure to partially purified extracts of animal and plant tissues, in addition to the previously demonstrated cyclic AMP and GMP, cytidine-, uridine-, inosine- and deoxythymidine 3',5'- cyclic monophosphates (cyclic CMP, -UMP, -IMP and -dTMP respectively) have been shown to be endogenous compounds (3-5). FABMS and CID/MIKES analysis of the products of putative cytidylyl cyclase activity, an enzyme reportedly capable of the synthesis of cyclic CMP, has confirmed the identity of cyclic CMP as one of the products and, in addition, has identified 4 novel side products of the reaction, cytidine 3',5'- cyclic pyrophosphate, cytidine 2'-0-phosphate-3',5'- cyclic monophosphate, cytidine 2'-0-glutamyl-3',5'- cyclic monophosphate and cytidine 2'-0-aspartyl-3',5'- cyclic monophosphate (6). In addition to studies of naturally occurring cyclic nucleotides, FABMS/CID/MIKES analysis has been used to confirm the structure of synthetic cyclic nucleotides, for example dibutyryl cyclic nucleotides which are capable of permeating cell membranes and are used in studying the metabolic effects of the administration of exogenous cyclic nucleotides (7). More recently, cyclic nucleotide derivatives synthesized for radioimmunoassay have been subject to MS analysis, and in addition to confirming the position of succinylation and the maintenance of the integrity of the cyclic phosphate and heterocyclic base moieties, monitoring of peak heights of the diagnostic ions emanating from reactants and products of the reaction has facilitated the optimization of the reaction (8).
The latter approach indicates the validity of quantitation by FABMS; this has been used to monitor the reactions catalysed by cyclic nucleotide phosphodiesterases (9,10) and cyclic nucleotide-responsive protein kinase (8). In the case of the former, the activity was determined from

\[
\frac{[\text{NMP}]}{[\text{cNMP}]} E = \frac{[R_{BH_2} + R_{BH_2+28} + R_{BH_2+42}]}{[R_{BH_2} + R_{BH_2+28} + R_{BH_2+42}]} \times \frac{[\text{NMP}]}{[\text{cNMP}]} (m/z MH^+}
\]

where \( R_n = I_n/I_n^0 \); \( I_n = \text{peak intensity at } m/z_n \text{ in the MIKE spectrum}; \)

\( \Delta I = \text{change in peak intensity at } m/z \text{ in MIKE spectrum spiked with standard and } [\text{NMP}] \) and

\( [\text{cNMP}] \) are the concentrations of substrate and product spike and the rate of reaction from

\[
\frac{[\text{NMP}]}{[\text{cNMP}]} E \times \frac{[S_0]}{[S_0] - [\text{NMP}]} \text{ at zero time}
\]

and \( t = \text{length of incubation} \)

Close correlation between kinetic parameters determined by conventional radiometric assays and by this mass spectrometric method has been obtained.

The authors gratefully acknowledge support from The Wellcome Trust, SERC and the Royal Society.

Acyl-Coenzyme A (CoA) compounds are intermediates in the catabolism of fats and branched-chain amino acids. The ability to differentiate isomeric acyl-CoA’s and to elucidate the structure of novel species is important in the study of certain metabolic disease states which result from enzymatic blocks in these catabolic pathways. Mass spectrometry, and the combination of chromatography and mass spectrometry, have been demonstrated to be useful in the study of acyl-CoA compounds. This report summarizes a study whose objectives were to understand the mass spectrometric behavior of acyl-CoA compounds, to identify optimum analytical modes, and to develop strategies for isomer differentiation and structure elucidation.

Experimental

A significant number and variety of acyl-CoA compounds were investigated during this study. These included acyl groups of varying chain length (C2-C18), unsaturation, branching, and functional group content (hydroxy-, carboxy-, keto-). The analytical modes investigated included FAB +/-, thermospray +/-, and electrospray +. Both quadrupole and magnetic sector instruments were employed in this study. Tandem mass spectrometry (MS/MS) studies with FAB and thermospray were accomplished on a triple quadrupole instrument (VG Trio-III) using 15eV argon collisions.

Results

Examples of the FAB and thermospray behavior of octanoyl-CoA, which is representative of these compounds, are shown in Figures 1 and 2 respectively. Molecular ion species for all compounds studied were more favorably generated by FAB than by thermospray, in both positive and negative ion mode. The electrospray spectra obtained appear similar to the FAB spectra. Although the [M-H]⁻ ion can show greater relative abundance in FAB than the [M+H]⁺ ion, it was found that in general negative ion mode had no significant advantages over positive ion mode. CID MS/MS studies on [M+H]⁺ ions generated by FAB showed little utility for either isomer differentiation or structure elucidation. However, several successful analyses were accomplished by performing CID MS/MS on the [M+H]⁺-507 ion generated by FAB or thermospray (m/z 387 for octanoyl-CoA) or the acylium ion generated by thermospray. An example is presented in Figure 3 which shows MS/MS spectra derived from 3-ketooctanoyl-CoA and an unknown which was identified as 3-ketovalproyl-CoA. The relative abundance of m/z 57 located the position of the keto group in this species.
Figure 1. Positive and negative ion FAB spectra of octanoyl-CoA.

Figure 2. Positive and negative ion thermospray spectra of octanoyl-CoA.

Figure 3. CID MS/MS spectra of the [M+H]^+ - 507 (m/z 401) ion produced by FAB from 3-ketoocctanoyl-CoA and an unknown (3-ketovalproyl-CoA).
Mass spectrometric analysis of top monolayers of biological surfaces can be achieved using the technique of static secondary ion mass spectrometry (SIMS). Static SIMS employs low primary ion doses \((10^{10}-10^{12} \text{ ions/cm}^2)\) which maximize formation of molecular or structurally significant ions. Static SIMS analyses using KeV primary ion beam energies typically penetrate only \(10-50A\) into the sample. A novel instrument configuration incorporates a high performance time-of-flight (TOF) mass spectrometer with ion image capabilities. The distribution of secondary ions emitted from the sample surface can be determined to lateral resolutions approaching \(2000A\).

A sample of rabbit adrenal tissue was fixed, shock-frozen and cryomicrotomed. After freeze-drying overnight, positive ion mass spectra and ion images were acquired of both the adrenal medulla and cortex. An abundant molecular ion for epinephrine at \((M+H)^+\) 184 could be observed in spectra from the adrenal medulla and cortex. However, the ion image of the medulla region revealed regions of higher concentration of ions for epinephrine, while the ion image of the cortex showed a uniform distribution of epinephrine ions. Only the central part of the medulla would be expected to have higher concentrations of epinephrine. The bulk concentration of epinephrine in the rabbit adrenal is approximately 0.3 ppmw.

Figure 1. This figure shows the structure of spiperone and positive-ion mass spectra of spiperone deposited on a Si wafer in a solution of MeOH (top), and mixed into gelatin and deposited on a Si wafer (middle and bottom). The samples were dried prior to analysis.
In order to further evaluate applications of this technique to biological systems such as freeze-dried soft tissue, analysis of a series of standard compounds in a variety of tissue-like matrices are being performed. These analyses will determine the dependence of ion yields from various types of compounds on the general chemical composition of the matrix and the role of non-specific binding of compounds to the matrix.

Mass spectral data of spiperone, which binds dopamine receptors, epinephrine, and a neuro-active compound of the elemental composition $C_{27}H_{35}N_6O_5F_3$ in three matrices were presented. These compounds were first dissolved in MeOH or H$_2$O and then mixed with either commercial gelatin, Matrigel™ or a 20% aqueous brain homogenate. Analytical concentrations ranged from $10^{-3}$-$10^{-5}$ M wet weight. Each sample was deposited as a drop on a Si wafer and dried at room temperature prior to analysis. Matrigel™ is a solubilized basement membrane, containing type IV collagen, heparin and proteoglycans as well as other connective tissue proteins. Gelatin is a solubilized form of connective tissue collagen and contains less carbohydrate than Matrigel™. The brain extract was prepared by homogenizing human brain tissue in 5 volumes ice cold H$_2$O (5 ml/g) with a tissue homogenizer. This mixture was centrifuged at 15,000 x g for 30 min and the supernatant removed. Typical positive-ion spectra of spiperone in gelatin and aqueous brain homogenate are shown in Figures 1 and 2.

Spiperone ran similarly in all three matrices over the concentration range of analysis. Epinephrine was just detectable over the background in either gelatin or Matrigel™, but could easily be observed in the aqueous brain homogenate over the $10^{-3}$-$10^{-5}$ M range. Compound #275 produced more abundant ions at the same concentration in gelatin compared to Matrigel™. An approximately linear relationship was observed between molecular and fragment ion abundance and concentration of these analytes over the range analyzed. The analyses demonstrate that physiologically relevant levels of the three compounds can be detected in these matrices.

A Pulsed Electron Beam, Variable Temperature High Pressure Mass Spectrometric Determination of Proton Affinity and Entropy Differences from Proton Exchange Equilibria of Compounds Ranging in PA's from N$_2$ to H$_2$S

J.E. Szulejko and T.B. McMahon, Department of Chemistry, Guelph-Waterloo-Centre for Graduate Work in Chemistry (GWC)$^2$, University of Waterloo, Waterloo, Ontario N2L 3G1, CANADA.

The Proton Affinities [PA] of weakly basic compounds (N$_2$ to H$_2$S) have been measured on a newly constructed High Pressure Mass Spectrometer [HPMS] incorporating several novel features$^1$. The system consists of a large vacuum chamber containing the high pressure ion source coupled to a VG 70-70 mass spectrometer whose geometry is now BE (reversed geometry). The mass spectrometer has a collision cell between the electric and magnetic sectors permitting Collision Activation Spectra of mass selected ions from the high pressure ion source to be performed. In the future, laser induced decomposition of ions will also be implemented. The mass resolution capability is much larger than most HPMS apparatus and is sufficient to resolve HCO$^+$ and C$_2$H$_5^+$. This has permitted the proton exchange equilibrium between CH$_4$ and CO to be measured in one step and in many instances, suppress interferences from isobaric ions.

The proton exchange equilibria thermochemical data derived from van't Hoff Plots; Ln(K$_w$) v 1/T; of the compounds studied in the present work are presented in Table 1 and the PA data summary in Table 2. It is apparent by inspection of Table 2, that the present PA scale does not reproduce either the 298K appearance energy [AE] data or the high level ab initio 298K proton affinities over the entire range. The PA difference between CO and C$_2$H$_4$ does not reproduce the AE data or the ab initio calculations. If the PA scale is anchored relative to CO, then ∆PA between CO$_2$, CH$_4$, N$_2$O, CO and C$_2$H$_4$ is in good agreement with the AE data and ab initio calculations as appropriate. A similar conclusion is reached for C$_3$H$_8$, H$_2$O and H$_2$S, if the PA scale is anchored to C$_2$H$_4$. This discrepancy of 3.5 kcal mol$^{-1}$ between the AE data and the current HPMS results in the ∆PA of CO and C$_2$H$_4$ has been previously observed by McMahon and Kebarle$^3$ in 1985. The $\Delta G^\circ_{298}$ for the overall reaction; CH$_4$ + C$_2$H$_4$ $\rightarrow$ C$_2$H$_5^+$ + CH$_4$ from the present work; -26.4 kcal mol$^{-1}$ is in excellent agreement with the 1985 McMahon and Kebarle$^3$ result of -26.5 kcal mol$^{-1}$. One possible source of this mismatch may be heat capacity effects on AH and AS derived from van't Hoff Plots covering disparate temperature ranges. For example, $\Delta H_{298} = -10.4$ kcal mol$^{-1}$ may be estimated from heat capacity effects for the proton transfer between N$_2$ and CO$_2$ as opposed to $\Delta H_{298} = -10.8$ kcal mol$^{-1}$ derived from the high temperature data. On the other hand, the overall ∆S for HCO$^+ +$ H$_2$O $\rightarrow$ H$_3$O$^+$ + CO is -0.4 cal mol$^{-1}$ K$^{-1}$ in excellent agreement with the estimated 298K entropy difference of -0.4 cal mol$^{-1}$ K$^{-1}$ from isoelectronic/neutral species. The $\Delta H$ of -21.0 kcal mol$^{-1}$ is in serious disagreement with the AE $\Delta H$ of -24.6 kcal mol$^{-1}$ however. High level ab initio calculations support the AE proton affinity differences between H$_2$O, C$_2$H$_4$, CO and CO$_2$ which is at variance with the data presented here. In our laboratory, work is in progress to resolve this serious discrepancy between the HPMS data with AE measurements and ab initio calculations and to firmly establish absolute proton affinities in the low basicity region.

</table>
The amide formed by substitution of the hydroxyl group on an amino acid with an amino group is more similar in structure to an amino acid involved in a peptide bond than is the parent amino acid. In order to better understand processes relevant to the mass spectrometry of peptides, we have studied unimolecular decompositions of gas phase protonated amides with FTMS. The initial investigation examined the chemistry of the simplest amide, formamide (Lin, Hung-Yu; Ridge, D. P.; Uggerud, E. The Unimolecular Chemistry of Protonated Formamide. Fourier Transform Mass Spectrometry and \textit{Ab Initio} Quantum Chemical Calculations. Submitted.) Reaction channels open to protonated formamide include CO loss and water loss, with CO loss the lower energy process. Quantum chemical calculations indicating the O-protonated molecule as the most stable and significant barriers to the decompositions described above were consistent with the experimental results.

Studies of glycinamide and lysinamide, obtained as the hydrochlorides, required a different experimental sequence than employed for examinations of the liquid formamide. For these studies, the reference base was admitted to the analyzer of the FTMS 2000 by a pulsed valve sequence. Ions were formed by electron impact, and ion-molecule reactions to form BH\textsuperscript{+} allowed to occur. The source was then cleared of any amide ions formed from amide neutral from the heated solids probe, and all ions other than the desired BH\textsuperscript{+} ejected from the analyzer. The conductance limit potential was lowered for an appropriate time to transfer the ionic reactant from the analyzer to the source, where ion-molecule reaction products were measured for a variety of reaction times. Reference bases used in these studies included nitrogen, methane, ethylene, methanol, ammonia, and methylamine.

Evaluation of the energetics of the proton transfer processes required measurement of the proton affinities of the amides studied. The proton affinity of glycinamide (GA) obtained by bracketing was

\[
\text{PA (ethylamine)} = 217 \text{ kcal/mol} < \text{PA (GA)} < \text{PA (n-butylamine)} = 218.4 \text{ kcal/mol.}
\]

This was in good agreement with the theoretical value of 215.3 kcal/mol determined by \textit{ab initio} quantum chemical calculations, and exceeds the PA of glycine by \textless 5 kcal/mol. The proton affinity of lysinamide determined by bracketing was

\[
\text{PA (tripropylamine)} = 234 \text{ kcal/mol} \sim \text{PA (lysinamide).}
\]

Protonated glycinamide (GAH\(^+\)) was found to exhibit two decomposition channels (only ionic products shown):

\[
\text{GAH}^+ \rightarrow (\text{GAH} - \text{CO})^+ \\
\text{GAH}^+ \rightarrow (\text{GAH} - \text{CO-NH}_3)^+
\]

Loss of CO was the lower energy process. For the systems studied, these decomposition products from the initial reactions of protonated base with neutral amide reacted further. The temporal data indicated that final products were deuterated and/or protonated amide. Kinetic data were fitted to the appropriate function to obtain an estimate of branching ratios for the two decomposition products. The difference in proton affinity between the reference base and the amide under study was used as the upper bound on the internal energy in the amide in the proton transfer process. As the internal energy deposited in the reaction decreased by a factor of ~2, the branching ratio (CO and ammonia loss relative to CO loss only) decreased by a factor of 40.

Similarly, two reaction channels were observed for protonated lysinamide (LAH\(^+\)):

\[
\text{LAH}^+ \rightarrow (\text{LAH} - \text{NH}_3)^+ \\
\text{LAH}^+ \rightarrow \text{C}_5\text{H}_{10}\text{N}^+
\]

The C\(_5\)H\(_{10}\)N\(^+\) ion appears to be analogous to the product originating in part from the R-group in lysine electron impact and chemical ionization mass spectrometry. Loss of ammonia is the lower energy process. Computations similar to those described above for glycinamide indicated that as internal energy deposited varies approximately threefold, the branching ratio (C\(_5\)H\(_{10}\)N\(^+\) relative to ammonia loss) was reduced by a factor of 15. The dissociative proton transfers observed for all three amides studied to date occur at lower internal energies for the two amino acid amides than for formamide.

Questions relating to site of protonation remain. Deuterium incorporation in some fragment ions which arise from ammonia loss indicate that deuterium-hydrogen exchange occurs rapidly in some of the protonated products. The absence of water loss from GAH\(^+\) or LAH\(^+\) suggests that the amine and/or amido sites are more basic than the oxygen in the larger amides; preliminary \textit{ab initio} calculations indicate that amino protonation is 8 kcal more stable than O-protonated glycinamide.
We have successfully coupled a laser to a conventional high-pressure mass spectrometer. The new instrument is shown in Figure 1. A pulsed Nd-YAG laser (30 mJ) is used to generate the metal ions inside the high pressure source. The ions are quickly thermalized by the high pressure (7 torr) of the bath gas. A ligand of interest, present in small concentration in the bath gas, is allowed to react with the metal ions. Multichannel scaling is used to time resolve the reaction (Figure 2). The equilibrium constant is measured from the ratio of the two traces and the pressure of the ligand. The temperature is varied and a van't Hoff plot is constructed (Figure 3). The slope and the intercept give the $\Delta H^o$ and the $\Delta S^o$ respectively for the reaction studied.

Using the newly built instrument, we have studied the interaction of weak ligands on the aluminum cation. The results are presented in Table 1. Generally speaking, the aluminum affinity increases monotonically with increasing proton affinity. We have successfully calculated the CO$_2$ and N$_2$ enthalpy changes using GAUSSIAN 90. In the case of carbon dioxide, the small entropy change is the result of a large amplitude, low frequency Al$^+$-O=C=O bending mode.

Following our initial success, we studied the reaction of organic ligands on Al$^+$. The first ligand binds very strongly and so we studied the second clustering reaction. Table 2 summarizes our findings.

The entropy changes are quite large. The data and several theoretical calculations suggest that the L-Al$^+$-L bond angle is very small (<90°). This causes a large steric hindrance and makes the $\Delta S^o$ strongly negative as shown on the right. For example, diethyl ether has several rotational modes that are hindered and thus the negative entropy change is very large. Acetonitrile, on the other hand, does not have hindered rotation and exhibits a small (normal) entropy change. The second dimethylether appears to bind to the polarized methyl of the first ether rather than on the aluminum. This is why the entropy and enthalpy changes are so small.

CHEMISTRY AND PHOTOCHEMISTRY OF DOUBLY CHARGED TRANSITION METAL IONS

Yasmin A. Ranasinghe, Dorothy Y. Hill, Timothy J. MacMahon and Ben S. Freiser, Department of Chemistry, Purdue University, West Lafayette, IN 47907.

Reactions of monovalent transition-metal ions with organic molecules in the gas phase have been the focus of intense investigation over the past 10 years and have involved a multitude of mass spectrometric techniques. The study of doubly charged metal ions, however, has really just recently gotten underway. Tonkyn and Weisshaar in their benchmark paper reported bond insertion and hydride transfer reactions in addition to charge transfer with Ti$^{2+}$ reacting with small alkanes in a flowing afterglow mass spectrometer. Since then, Fourier transform mass spectrometer (FTMS) has been used to monitor the reactivity of a variety of dipositive early transition metal ions including Nb$^{2+}$, LaFe$^{2+}$, Zr$^{2+}$, Ta$^{2+}$, La$^{2+}$ and Y$^{2+}$. Of particular interest is the comparison of reaction mechanisms and kinetics, as well as bond energies between the doubly charged ions and their singly charged counterparts. Kinetic energy release measurements on the reaction of M$^{2+}$ (Nb,Ta,V) with benzene to form M$^+$ and C$_6$H$_{12}^+$ obtained by studying the trapping voltage dependence of product ion intensities, has provided information on energy transfer and reaction dynamics. Photodissociation studies of these doubly charged species also holds great promise as a method for distinguishing ion structure and determining M$^{2+}$ ligand bond energies. In this talk a brief survey of this work will be presented.

As an example, Figure I shows the mass spectra obtained when LaC$_2$H$_2^{2+}$ is irradiated with light from a 2.5 kW Hg-Xe arc lamp and passed through various cut-off filters. Several photodissociation products are evident and their threshold appearance energies can be measured, yielding bond energy information. In particular, the bond energies of the acetylene, ethene and the propene ligands to La$^{2+}$ and Y$^{2+}$ are compared with the theoretical calculations in Table I. One of the fascinating results from these studies is that in some cases singly charged metal ions bind as strongly or more strongly to the ligand than the doubly charged metal ion. A simple explanation for this is that, since La$^{2+}$ has only one valence electron it binds solely by electrostatic attraction, whereas La$^+$ has two valence electrons and can insert into multiple bonds.

Ion / molecule Reactions of Ions Derived from $V_2O_5$: a FT-ICR / MS Study

Keith J. Fisher, Derek R. Smith and Gary D. Willett
School of Chemistry, The University of New South Wales, P.O.Box 1, Kensington, New South Wales, Australia 2033.

Introduction

$V_2O_5$ is a very important catalyst used in the oxidation of a variety of organic and inorganic molecules. Various mechanisms have been proposed for its catalytic activity. The activity may be related to surface properties or to intrinsic properties of the vanadium/oxygen bonding system. Gas phase ion/molecule reactions can remove the influence of the macroscopic surface and yield information about the reactivity of vanadium and the vanadium/oxygen systems.

The oxidation of olefins and benzene derivatives has been proposed to initially involve the formation of $\pi$ complexes. To test this proposal we have studied the reactions of $V^+$ and $VO^+$ with benzene and benzene derivatives.

The oxidation of oxygen containing molecules such as alcohols is proposed to initially involve hydrogen bonding of the molecules to the $V_2O_5$ surface. Hydrogen bonding of an alcohol to a surface $V-O$ might be simulated by the study of ion/molecule reactions of $VO^+$ or $V_2O_5^+$ with alcohols. Thus we have studied the reactions of $V^+$, $VO^+$, $V_2O_5^+$ and $V_3O_8^+$ with alcohols.

Experimental

Mass spectra and ion/molecule reactions were studied using a Spectrospin CMS-47 FT-ICR mass spectrometer, equipped with a 4.7 T magnet. A cylindrical ICR cell with titanium plates (radius 30 mm x 60 mm) was used in an ultra-high vacuum chamber maintained at $10^{-9}$ mbar by a Balzers-330 turbomolecular pump.

Ions to be studied were isolated by a double ejection technique after a delay to allow thermal equilibration.

Pressed samples of $V_2O_5$ were prepared on cylindrical satellite tips which were introduced into the cell using a direct insertion probe. With the sample in the cell and a base pressure of $<1 \times 10^{-8}$ mbar, reagent gases were introduced to give an uncorrected pressure of $5 \times 10^{-8}$ mbar.

Laser ablation generation of the required ions was performed using a Nd-YAG laser (1064 nm, Spectra Physics DCR-11) focused to an area of 0.01 m.m.$^2$. In the Q-switched mode the pulse width was 8 ns producing a maximum energy at the sample surface of ~1600 MWcm$^{-2}$.

Results

$V^+$ and $VO^+$ form addition complexes with benzene and substituted benzenes. Our initial analysis of the first order kinetic rate of the disappearance of the ions showed that $VO^+$ reacted faster than $V^+$, but
fitting the kinetics for the formation of the monobenzene adduct indicated similar rates for each ion. The formation of the bis-benzene adducts occurs at an appreciably slower rate for \( \text{VC}_6\text{H}_6^+ \).

\[
\begin{align*}
\text{k}_1 & \quad \text{k}_2 \\
\text{V}^+ + \text{C}_6\text{H}_6 & \rightarrow \text{VC}_6\text{H}_6^+ \rightarrow \text{V(C}_6\text{H}_6)_2^+ & \text{k}_1=0.42, \text{k}_2=0.45 \text{ s}^{-1} \\
\text{VO}^+ + \text{C}_6\text{H}_6 & \rightarrow \text{VOC}_6\text{H}_6^+ \rightarrow \text{VO(C}_6\text{H}_6)_2^+ & \text{k}_1=0.43, \text{k}_2=0.015 \text{ s}^{-1}
\end{align*}
\]

Reactions of \( \text{V}^+ \), \( \text{VO}^+ \), \( \text{V}_2\text{O}_5^- \) and \( \text{V}_3\text{O}_8^- \) were carried out with methanol and ethanol and their deuterated derivatives. \( \text{V}^+ \) initially formed \( \text{VO}^+ \) at a much faster rate with methanol than with ethanol. Most of the reactions up to 2 s involved simple addition products. At longer reaction times products such as \( \text{VO}_4\text{C}_5\text{H}_8^+ \) and \( \text{VO}_4\text{C}_7\text{H}_{15}^+ \) were observed for the reaction of \( \text{V}^+ \) with methanol. Although we have not yet determined the structures of these ions, it is evident that the increased carbon content above the 1:4:1 (C:H:O) ratio in methanol suggests elimination of \( \text{H}_2\text{O} \) and possibly carbon-carbon bond formation.

\[
\begin{align*}
\text{V}^+ + \text{MeOH} & \rightarrow \text{VO}^+ \rightarrow \text{VO(CH}_3\text{OH})^+ \rightarrow \text{VO(CH}_3\text{OH})_2^+ & \text{VO}_4\text{C}_5\text{H}_8^+ \\
\text{V(OCH}_3\text{)}_3^+ & \rightarrow \text{V(OCH}_3\text{)}_2^+ \rightarrow \text{V(OCH}_3\text{)}_3^+ & \text{VO}_4\text{C}_7\text{H}_{15}^+
\end{align*}
\]

The anions \( \text{V}_2\text{O}_5^- \) and \( \text{V}_3\text{O}_8^- \) also react with methanol and ethanol to form addition products such as \( \text{V}_2\text{O}_5(\text{EtOH})^+ \), but again at longer reaction times unusual products are produced.

\[
\begin{align*}
\text{V}_2\text{O}_5^- + \text{MeOH} & \rightarrow \text{V}_2\text{O}_5(\text{MeOH})^- \rightarrow \text{V}_2\text{O}_5(\text{MeOH})(\text{CH}_2)^- \\
\text{V}_2\text{O}_5^- + \text{EtOH} & \rightarrow \text{V}_2\text{O}_5(\text{EtOH})^+ \rightarrow \text{V}_2\text{O}_5(\text{EtOH})(\text{C}_2\text{H}_4)^-
\end{align*}
\]

**Conclusions**

Positive ions derived from \( \text{V}_2\text{O}_5 \) form \( \pi \) complexes with benzene and some of the alkyl substituted benzenes. \( \text{V}^+ \) and \( \text{VO}^+ \) appear to form monobenzene adducts but the interaction of the second benzene is faster with the less sterically hindered \( \text{VC}_6\text{H}_6^+ \). This supports catalytic mechanisms that suggest \( \pi \) bond formation to be an initial step in the reaction of unsaturated molecules with \( \text{V}_2\text{O}_5 \).

The interaction of \( \text{V}^+ \) with methanol to form \( \text{VO}^+ \) and \( \text{VOMe}^+ \) suggests that an exposed vanadium might form a V-O bond as a first step. Addition products such as \( \text{VO(EtOH)}^+ \) might be formed by hydrogen bonding or coordination of the oxygen to the vanadium. The elimination of \( \text{H}_2\text{O} \) forming unsaturated carbon species may also aid oxidation. Thus hydrogen bonding may be an important step in the reaction of alcohols with \( \text{V}_2\text{O}_5 \) but a more definite answer must await collisional activation studies of some of the observed ions.
REACTIONS OF Si\(^+\) WITH CH\(_3\)SiH\(_3\), CH\(_3\)CH\(_3\) AND CH\(_3\)CHD\(_2\)

K. P. Lim and F. W. Lampe
Department of Chemistry,
The Pennsylvania State University
University Park, Pennsylvania 16802

Eighteen years ago, in a beam study of the formation of SiCH\(_3\)^+ in collisions of Si^+ ions with CH\(_3\)SiH\(_3\), Mayer\(^1\) observed that the peak in the kinetic energy distribution of SiCH\(_3\)^+ appeared at very low energies and was independent of the kinetic energy of the reactant Si^+. Such a characteristic is often observed in H'-abstractions from silanes which proceed by a direct process that approaches spectator stripping. If CH\(_3\)SiH\(_3\) is replaced by CH\(_3\)SiD\(_3\), still only the product SiCH\(_3\)^+ is observed, thus confirming the direct nature of the reaction. By analogy to H'-abstraction these results could be explained by a direct H\(_3\) (or D\(_3\)) transfer to the attacking Si^+ ion but this does not seem to us to be very likely. Indeed, we much prefer an alternate explanation in which the reaction proceeds via an inversion process as depicted in (1), viz.

\[
\text{Si}^+ + \text{CH}_3\text{SiH}_3 \rightarrow \text{SiCH}_3^+ + \text{SiH}_3
\]  

Since the masses of the attacking particle and the leaving particle are not very different, SiCH\(_3\)^+ would, within our energy resolution, be formed with zero kinetic energy and no scrambling of H-D would occur.

We were interested in learning if a methyl derivative with chemically identical but physically different ends would exhibit the inversion phenomenon on both ends and towards that end we studied the reaction of Si^+ with CH\(_3\)CH\(_3\) and CH\(_3\)CHD\(_2\). The major product of the reaction of Si^+ with C\(_2\)H\(_6\) at a collision energy of 1.0 eV is SiCH\(_3\)^+ with smaller amounts of SiC\(_2\)H\(_4^+\), SiC\(_2\)H\(_5^+\), SiH\(_4^+\), SiH\(_2^+\) and C\(_2\)H\(_5^+\).

Replacement of CH\(_3\)CH\(_3\) by CH\(_3\)CHD\(_2\) leads to the result shown in Figure 1, namely at 1.0 eV collision energy all three possible isotopic variants, namely SiCH\(_3\)^+ (m/z=43), SiCH\(_2\)D\(_+^+\) (m/z=44) and SiCHD\(_2^+\)

![Fig. 1. Product Spectrum from Reaction of Si^+ + CH\(_3\)CHD\(_2\) at 2.0 eV (Lab.).](image)

(m/z=45) are formed. However as the collision energy is varied, as shown in Figure 2, a dramatic change occurs in the relative abundance of these products. Increasing energy decreases the intensity of SiCH\(_2\)D\(_+^+\) relative to the intensities of SiCH\(_3^+\) and SiCHD\(_2^+\) while at the same time the ratio of i(SiCHD\(_2^+\)) to i(SiCH\(_3^+\)) remains essentially constant at 0.84±0.07.
These results indicate that SiCH$_3^+$ and SiCHD$_2^+$ are formed by the same mechanism and that this mechanism is different from that responsible for the formation of SiCH$_2$D$^+$. Since formation of SiCH$_2$D$^+$ involves some H-D scrambling and is the dominant process at low collision energy, it is tempting to conclude that SiCH$_2$D$^+$ is formed via a long-lived collision while SiCH$_3^+$ and SiCHD$_2^+$ are formed by a direct process either one analogous to the inversion shown in (1) or to a stripping reaction. However, examination of the kinetic energy distributions of the three isotopic product ions shown in Figure 3, reveals that all three product ions are formed in processes that yield the product ion kinetic energy distributions characteristic of either the spectator stripping model or the modified stripping model. All three product ions are therefore formed in direct processes and not in processes involving a long lived complex. The direct formation of SiCH$_3^+$ and SiCHD$_2^+$ by direct processes is easy to visualize but the mechanism by which the H-D exchange on the methyl group occurs to form SiCH$_2$D$^+$ remains obscure.

SEQUENTIAL REACTIONS OF SiD\textsubscript{2} WITH SiD\textsubscript{4}

W. D. Reents, Jr., M. L. Mandich, and K. Raghavachari

AT&T Bell Laboratories
600 Mountain Ave.; Murray Hill, NJ 07974

The reactions of SiD\textsubscript{2} and its product ions with SiD\textsubscript{4} have been examined experimentally and theoretically. A Fourier transform ion cyclotron resonance mass spectrometer was used to measure the reaction rates and product distributions. Critical transition state and intermediate structures were determined with high level ab initio calculations. Phase space calculations were used to make a quantitative comparison between the experimental and theoretical findings.

Ion/molecule reactions of SiD\textsubscript{2} and Si\textsubscript{2}D\textsubscript{4} with SiD\textsubscript{4} were studied at 300K with 1 - 4 x 10\textsuperscript{-7} torr of silane. The reaction of SiD\textsubscript{2} with SiD\textsubscript{4} proceeds at 1.3 ± 0.2 times the Langevin collision rate (K\textsubscript{L}) to produce SiD\textsubscript{3}, Si\textsubscript{2}D\textsubscript{3}, and Si\textsubscript{2}D\textsubscript{4} in the amounts of 0.54, 0.07, and 0.39, respectively. The reaction of Si\textsubscript{2}D\textsubscript{4} with SiD\textsubscript{4} proceeds at <0.005 K\textsubscript{L}. This is a terminal species in the sequential reactions with silane; its only reaction is slow silicon isotope exchange (0.20 ± 0.07 K\textsubscript{L}) with silane.

Theoretical calculations for the reactions of SiD\textsubscript{2} and Si\textsubscript{2}D\textsubscript{4} with SiD\textsubscript{4} were examined at the 6-31G* level with second order perturbation theory. The relative energies of the critical transition states and intermediates along the reaction path are displayed in Figures 1 and 2. The transition state energies are listed in Table I.

The calculated reaction pathway for the reaction of SiD\textsubscript{2} with SiD\textsubscript{4} is shown in Figure 1. There are two transition states, TS2 and TS3, which lead to different Si\textsubscript{2}D\textsubscript{3} isomers. The higher energy transition state, TS3, leads to the lowest energy isomer of Si\textsubscript{3}D\textsubscript{4}. Formation of SiD\textsubscript{3} and Si\textsubscript{3}D\textsubscript{3} are slightly exothermic or thermoneutral. However, there is an endothermic barrier to form Si\textsubscript{3}D\textsubscript{3}.

The calculated reaction pathway for the reaction of Si\textsubscript{2}D\textsubscript{4} with SiD\textsubscript{4} is shown in Figure 2. The two isomers of Si\textsubscript{3}D\textsubscript{3} may be distinguished experimentally by their reactivity. The higher energy form, D\textsubscript{z}SiSiD\textsuperscript{+}, reacts with SiD\textsubscript{4} to form Si\textsubscript{3}D\textsubscript{4} whereas the lower energy form, D\textsubscript{2}SiSiD\textsuperscript{+}, is unreactive with SiD\textsubscript{4}. The transition state for insertion from the D\textsubscript{2}SiSiD\textsuperscript{+} isomer, TS3, is slightly endothermic and thus inhibits rapid silicon isotope exchange.

Phase space calculations provide a means to quantitatively compare the experimental and theoretical results for the reactions of SiD\textsubscript{2} and Si\textsubscript{2}D\textsubscript{4} with SiD\textsubscript{4}. Phase space calculations use ab initio calculated vibrational and rotational frequencies for the critical structures to evaluate the dependence of transition state energies on reaction rate and product distribution. Limiting these rates and distributions to the measured values provides either unique values or upper bounds to the values for the transition state energies. The ab initio and phase space values are compared in Table I. The agreement, within 6 kcal/mol, confirms the accuracy of the experimental and theoretical values.

Tetracyanoethylene (TCNE) has been shown to be a particularly effective trap for hydrocarbon free radicals and hydrogen atoms that are produced in the e-beam irradiation of a hydrocarbon buffer gas, such as methane or isobutane, in a chemical ionization ion source. The products of these radical-TCNE reactions then attach thermal electrons and appear in the electron capture mass spectrum (ECMS) of TCNE, as shown in Figure 1. While the radical-TCNE reactions that lead to these ions have previously been thought to occur in the gas phase, we provide evidence here that all of the ions in Figure 1 are produced by reactions on the walls of the ion source prior to EC.

(1) We have determined the EC rate constant of TCNE by pulsed high pressure mass spectrometry (PHPMS): it is $1.2 \times 10^{-7}$ cc s$^{-1}$. Since the rate constants of gas phase radical-neutral reactions can not exceed $1 \times 10^{-10}$ cc s$^{-1}$, it is unlikely that a gas phase radical reaction could compete effectively with EC by TCNE.

(2) In measuring the electron impact spectrum of TCNE following use of the ion source for CH$_4$/ECMS, we observe in Figure 2 an unexpected H-adduct ion. This ion is clearly due to a wall related reaction of TCNE where the ion source walls have retained H atoms after exposure to irradiated methane.

(3) When TCNE is introduced to the ion source by gas chromatography, the unexpected ions persists in time after the TCNE has passed through the ion source, as shown in Figure 3. Clearly, wall-relative processes are responsible for this.

(4) In 3 torr isobutane buffer gas, the ECMS spectrum of TCNE shown in Figure 4 is obtained. By using a pulsing sequence in which the e-beam is "on" for 100 ms and "off" for about 1 second, the temporal profile of these ions have been measured and are shown in Figure 5. Inspection of these profiles indicates that the ions of the type $(M+R-CN)^-$ are formed immediately at the start of the "on" period. This is because the neutral precursors of these ions are being formed continuously during the "off" period by reactions with radicals that are attached to the walls of the ion source. The ion of the type $(M+R)^-$ has a completely different time profile. Its intensity starts at zero and becomes non-zero only after the e-beam has been "on" for several milliseconds. This indicates that this ion is being formed by a prior reaction of TCNE with gas phase radicals.

In view of these results, it is concluded that all of the unexpected ions of the type $(M+R-CN)^-$ in Figure 1 are formed by wall-related reactions. These are thought to be formed by the following reaction sequence:

$$\text{wall} \quad \text{e} \quad \frac{\text{M}}{} \quad \rightarrow \quad (\text{M}+2\text{R}) \quad \rightarrow \quad (\text{M}+\text{R-CN})^- + \text{RCN}$$

in which R is either H, CH$_3$, or C$_2$H$_5$. The ion CH(CN)$_2^-$ is thought to be formed along with $(M+H-CN)^-$ in a branched EC reaction of the species $(R+2H)$. Second generation ions of the type $(M+2R-2CN)^-$ are formed by a repetition of the above sequence following neutralization of $(M+R-CN)^-$ on the walls of the ion source.

Several generalizations regarding sulfur vs. oxygen reactivity have emerged from previous studies in our laboratory: sulfur and oxygen anions of comparable basicity exhibit similar nucleophilicity in $S_N2$ reactions;\(^1\) in contrast, sulfur is considerably less efficient in inducing elimination (E2) reactions;\(^2\) hydrogen/deuterium exchange in acid-base systems containing sulfur is less facile than in comparable oxygen systems.\(^3\)

To further explore the intrinsic reactivity of sulfur in the gas phase, we have carried out studies of sulfur-34 labeled anions by employing our Tandem Flowing Afterglow-Selected Ion Flow Tube.\(^4\) $^{34}\text{S}^-$, $\text{H}_3^{34}\text{S}^-$, $\text{D}_3^{34}\text{S}^-$, and $\text{CH}_3^{34}\text{S}^-$ have been generated in the flowing afterglow source from unenriched precursors and cleanly injected into the reaction flow tube for study.

The reaction of $\text{H}_{34}^-$ with hydrogen sulfide (eq. 1)

$$\text{H}_{34}^- + \text{H}_2 \rightarrow \text{H}_3^2\text{S}^- + \text{H}_2^{34}\text{S}$$

proceeds with ~50\% efficiency, indicating that complete equilibration has occurred within the ion-dipole complex. Similar results are obtained for the analogous reaction of $\text{H}_{18}^-$ with $\text{H}_2^{18}$, which undoubtedly has a larger complexation energy and longer lifetime.

The reaction of $\text{S}_{34}^-$ with hydrogen sulfide shows isotope exchange, proton transfer and hydrogen atom transfer pathways (eq. 2):

$$\text{S}_{34}^- + \text{R}_2\text{S} \rightarrow \text{S}_{32}^- + \text{R}_3\text{S}$$

The product branching ratios, however, indicate that proton abstraction dominates over H-atom abstraction and equilibrium is not achieved in the intermediate complex. In contrast, the corresponding reaction of $\text{O}_{18}^-$ with $\text{H}_2^{16}$ proceeds exclusively by isotope exchange with a reaction efficiency of 50\%.\(^8\)

The sulfur-34 anion exhibits isotope exchange with carbon disulfide (eq. 3) in only 18\% of the collisions:

$$\text{S}_{34}^- + \text{C}_2\text{S}_2 \rightarrow \text{S}_{32}^- + \text{C}_2\text{S}_{34}$$

This suggests that the $\text{CS}_3^-$ adduct is not formed with unity efficiency. In contrast, the corresponding reaction of $\text{O}_{18}^-$ with $\text{C}_2\text{O}_2$ indicates addition and complete equilibration occur on every collision.\(^8\)
The reactivity of H$^{34}$S$^-$ with carbon disulfide (eq. 4) is lower (1.1% efficiency) than that of $^{34}$S$^-$, suggesting a barrier to intramolecular proton transfer.

$$\text{H}^{34}\text{S}^- + \text{C}^{32}\text{S}_2 \rightarrow \text{H}^{32}\text{S}^- + \text{C}^{34}\text{SC}^{32}\text{S} \quad (4)$$

This is supported by a slightly reduced exchange efficiency for reaction of D$^{34}$S$^-$ with CS$_2$.

The D$^{34}$S$^-$ anion undergoes slow isotope exchange with ethylene sulfide (eq. 5):

$$\text{D}^{34}\text{S}^- + \text{CH}_2=\text{CH}_2 \rightarrow \text{D}^{32}\text{S}^- + \text{CH}_2=\text{CH}_2 \quad (5)$$

This process, which presumably occurs by ring opening, deuteron transfer and ring closure, was masked in the corresponding reaction of D$^{18}$O$^-$ with ethylene oxide where fast reactive pathways exist.$^7$

The preparation of isotopically labeled sulfur ions also allows us to probe the competition between reactive pathways. For example, a study of the reactions of $^{34}$S$^-$ and CH$_3^{34}$S$^-$ with methyl thioacetate (eq. 6,7) indicates that BAC2 rather than SN2 processes occur.

$$\text{O} \quad \text{CH}_3\text{C}^{34}\text{S}^- + \text{CH}_3\text{C}^{32}\text{S} \quad (6)$$

$$\text{CH}_3\text{C}^{34}\text{S}^- + \text{CH}_3\text{C}^{32}\text{SCH}_3 \rightarrow \text{CH}_3\text{C}^{32}\text{S}^- + \text{CH}_3\text{C}^{34}\text{SCH}_3 \quad (7)$$

In summary, our studies of sulfur-34 labeled anions indicate a lower intrinsic reactivity of sulfur relative to oxygen. Sulfur-containing systems have lower ion-dipole complexation energies, resulting in shorter lifetimes and less available energy for inducing intramolecular rearrangements. Moreover, in the sulfur systems, the proton or atom transfers must occur over larger distances. These factors give rise to the reduced exchange efficiencies and the incomplete equilibration which we have observed for the reactions of sulfur-34 labeled anions.

Functional group interactions can enhance specific reactive or dissociative channels of gas-phase ions by altering ion stabilities. For example, hydroxyl groups are strong hydrogen bond acceptors, so these functional groups play important roles in mediating the ion chemistry of hydroxy-containing compounds. In this work, selective ion/molecule reactions and dissociative chemistry of a series of diols of variable functional group separation are examined and compared to the behavior of monofunctional alcohols.

The ion/molecule reactions of interest included simple proton transfer and methylene substitution, both induced by dimethyl ether ions, CH₃OCH₂⁺. A Finnigan Ion Trap Mass Spectrometer was used to study the ion/molecule reactions of the diols and alcohols and to characterize product ions via low energy collisional activation. Typically, the reagent gas pressure (dimethyl ether) was 8.0 x 10⁻⁶ torr, and the helium buffer gas was 1.0 mtorr. The ion/molecule reaction period was about 20-50 msec, and the activation time during which the supplementary ac voltage was applied was 3 msec. The ac voltage was 400 mV, with q = 0.4. All samples were introduced via a heated leak valve system. Typical sample pressure was 8 x 10⁻⁷ torr.

In the ITMS, collisional activation of the protonated diols results in losses of one or two water molecules. No other dissociation channels are observed. At higher activating voltages, the loss of two molecules of water is favored. The extent of sequential dehydration is dependent on the functional group separation. Protonated 1,3-propanediol always shows a greater relative extent of double dehydration, likely due to the unfavorable thermochemical stability of the primary carbocation formed from dehydration of the protonated 1,3-propanediol in comparison to the secondary carbocation initially formed from dehydration of the protonated 1,2-diol.

Reactions of dimethyl ether ions with the diols and alcohols yield two products of interest: (M + H)⁺ and (M* + 13)⁺, via (M⁺ (CH₃O=CH₂⁺) - CH₃OH). Several observations about functional group participation are apparent. First, simple mono-functional alcohols do not undergo methylene substitution with dimethyl ether ions under any conditions. This indicates that the presence of two functional groups is necessary for formation of (M* + 13)⁺ product ions. Second, with increasing functional group separation, the abundance of product ions decreases. In fact, in the ITMS no product ions were observed for 1,4-pentanediol, and the relative abundance of (M* + 13)⁺ ions was low for 1,4-butanediol, but very high for 1,2-butanediol and 2,3-butanediol.

For each diol, the product ion at (M* + 13)⁺ was isolated and collisionally activated. For all the diols in which the hydroxyl groups are adjacent (1,2-ethanediol, 1,2-propanediol, 2,3-butanediol, and 1,2-butanediol), the major dissociation routes are via loss of formaldehyde and loss of formaldehyde plus water. However, for the diols in which the functional groups are separated (1,4-butanediol and 1,3-propanediol), very different dissociative behavior is observed. For those diols, losses of water, methanol, and CH₂=CHOH (44 amu) are observed. The CAD spectra for the (M* + 13)⁺ adducts of 1,2-propanediol and 1,3-propanediol are shown in Figure 1.

Proposed mechanisms for formation and dissociation of the (M* + 13)⁺ adduct is shown in Figure 2 for 1,2-propanediol. One of the oxygen atoms undergoes nucleophilic attack on the methoxy methyl ether cation, followed by a hydrogen shift from the hydroxyl group to the ether oxygen and elimination of methanol. This addition process results in the methylene ether product at (M* + 13)⁺. Formaldehyde is easily lost from this adduct, as shown in the next mechanism. This may be followed by dehydration to yield an alkenyl cation (net loss of 48 amu from (M* + 13)⁺). Analogous mechanisms can be formulated for the other diols with adjacent hydroxyl groups.

For the diols in which the hydroxyl group are separated, very different mechanisms are operative. Proposed mechanisms which involve cyclization of the diol are shown in Figure 3 (for 1,3-propanediol). Again, initially one hydroxyl oxygen atom attacks the methoxy methyl ether cation with subsequent elimination of methanol. In this case, however, the resulting methylene ether may cyclize, forming a favorable six-membered ring protonated dioxane system. The dissociative routes of this (M* + 13)⁺ adduct ion include dehydration, loss of methanol, and elimination of 44 amu.

To test the validity of the mechanisms and product structures suggested, 1,3-dioxane was protonated and collisionally activated. Although the relative ion abundances are slightly different from those observed in the ITMS, the same mechanistic pathways were observed.
for the (M + 13)+ adduct of 1,3-propanediol, the mass-to-charge ratios of the fragments are the same. Models were not available for 1,4-butanediol and 1,5-pentanediol, however, the mechanisms suggested are consistent with the observed dissociation behavior—namely that dehydration may occur from a cyclic intermediate or transition state, methanol loss is observed, and loss of 44 amu is apparent.

Such functional group interactions are also important in mediating the reactive chemistry of more complex biomolecules containing multiple functional groups. For example, L-glucono-1,5-lactone, a sugar derivative that contains four hydroxyl groups and a cyclic ester group, demonstrates the formation of (M + 13)+ adducts provides structurally diagnostic information about the proximal positions of hydroxyl groups.

Functional group interactions play significant roles in the reactive and dissociative chemistry of simple diols. For example, mono-functional alcohols do not undergo methyne addition with dimethyl ether ions, and the extent of reactivity of diols is largely dependent on the close proximity of the two hydroxyl groups. Additionally, those diols with large separation of the hydroxyl groups demonstrate the capability for forming stable heteroatomic ring structures upon methyne addition. Finally, the gas-basicities of diols reflect the ability of the hydroxyl groups to favorably interact through the formation of more linear hydrogen bonds.

LINEARIZATION OF FT/ICR/MS

Peter B. Grosshans and Alan G. Marshall

Depts. of Chemistry (P.B.G.; A.G.M.) and Biochemistry (A.G.M.),
The Ohio State University, 120 W. 18th Avenue, Columbus, OH 43210.

Elsewhere, we derived the spectral positions of all of the frequency-domain peaks (fundamentals, harmonics, and sidebands) associated with the motion of a trapped ion when all three fundamental modes are excited [1]. The unwanted peaks may obfuscate the interpretation of FT/ICR mass spectra, particularly ion abundance measurements. An axially excited ion is known to induce a smaller signal at the fundamental ICR orbital frequency than an ion with the same cyclotron orbital radius with little or no axial motion [1]. Furthermore, Laude [2] has given a cogent demonstration of how the combination of phased axial motion and frequency-sweep excitation results in errors in measuring relative ion abundances. By "shimming" the rf excitation field (electric field more spatially homogeneous), Wang and Marshall [3] and Hanson et al. [4] were able to reduce mass-discriminatory axial ejection during frequency-sweep excitation. In general, many problems associated with conventional ICR ion traps are traceable to the non-linearity of their excitation and detection fields.

From Reciprocity [1], if it is possible to shim or linearize the excitation electric field, it should be possible to linearize the detected signal from an ion. In fact, a pair of infinite parallel plates simultaneously linearizes the excitation electric potential field and the differential charge induced between them. The advantages of this linear behavior are: 1) the post-excitation cyclotron radii of ions with the same m/z are equal and determined solely by the rf excitation spectral magnitude at their ICR frequency (i.e., independent of the amplitudes of the magnetron and trapping oscillations); 2) excitation of the trapping oscillation is not possible and excitation of the cyclotron and magnetron motions can be performed only at the corresponding frequencies (i.e., not at harmonics or combination frequencies); 3) even for an ion with all three fundamental modes excited, only two peaks, at the cyclotron and magnetron frequencies, will be observed (no sidebands or harmonics); and 4) the magnitude of the signal at the fundamental ICR frequency of an ion is linear in ICR orbital radius and independent of the amplitudes of the trapping and magnetron oscillations.

Here, we present the design for a finite ion trap which mimics the desired linear behavior of a pair of infinite parallel plates: i.e., simultaneously linearizes the excitation and detection fields. Although reasoning based on Reciprocity suggested the proper circuit (shown in Figure 1), the proof of linearity in the excite field and received signal does not rest on this theorem. Two cross-sections through the linearized trap are shown with the electrical elements connecting the various electrodes. To achieve linearity, excitation and detection must be performed over the entire interior surface of the trap. Resistors to the side shim and end shim/trap plates provide a separate electrical route for applying/holding DC potentials. The capacitors serve to voltage-divide the excitation potential and to current-divide the received signal to produce the desired linear behavior. Experimental tests of this novel trap will be presented in a forthcoming manuscript.

The authors thank Steve Foster for helpful discussions. This work was supported by NSF (CHE-9021058) and The Ohio State University.

LASER STUDIES OF SOLVENT EFFECTS ON PHOTODISSOCIATION AND GEMINATE RECOMBINATION IN $I_2(CO_2)_n$ CLUSTER IONS

*James R. Gord, John M. Papanikolas, Vasil Vorsa, and W. C. Lineberger,
Department of Chemistry and Biochemistry, University of Colorado, and
Joint Institute for Laboratory Astrophysics, University of Colorado and
National Institute of Standards and Technology, Boulder, Colorado 80309-0440.

We have employed a tandem time-of-flight (TOF) mass spectrometer in conjunction with nanosecond and picosecond laser systems to study the effects of stepwise solvation on the photodissociation and geminate recombination of an $I_2$ chromophore embedded in a cluster of CO$_2$ molecules. Cluster ions are generated by using an ion source in which a pulsed supersonic expansion of CO$_2$ seeded with $I_2$ is crossed with a continuous 1 keV electron beam. Attachment of low energy secondary electrons to $I_2$ produces $I_2$, from which larger cluster ions grow in the expansion via ion-molecule reactions. The resulting anionic clusters, $I_2(CO_2)_n$ (n≤55), are extracted from the expansion and accelerated into the tandem TOF mass spectrometer by using a pulsed electric field. A standard two-field Wiley-McLaren TOF forms the first stage of the tandem mass spectrometer and focuses the mass-selected cluster ion beam at the first spatial focus where the ions can interact with a pulsed laser. A single field reflectron forms the second stage of the spectrometer and refocuses the ion beam at an off-axis detector located at the second spatial focus.

Nanosecond laser pulses are generated by using the frequency-doubled output of a Quanta Ray GCR-3 Q-switched Nd:YAG laser to pump a Spectra-Physics PDL-1 pulsed dye laser. Irradiation of mass-selected cluster ions with nanosecond laser pulses induces photodissociation of the $I_2$ chromophore. Cross section measurements indicate that the photodestruction cross section for $I_2$ is ~2.5×10$^{-17}$ cm$^2$ at 720 nm. Furthermore, $I_2$ is the only important chromophore in these cluster ions at 720 nm, and its electronic structure is not significantly perturbed by CO$_2$ solvation. Photofragmentation of these cluster ions with the nanosecond laser produces two types of fragment ions: "caged" photofragment ions, $I_2(CO_2)_k$ (k<n), in which the surrounding CO$_2$ solvent molecules induce geminate recombination of the photodissociated $I_2$ chromophore, and "uncaged" photofragment ions, $I^-(CO_2)_m$ (m<n), in which an iodine atom has escaped from the cluster ion. Calorimetric arguments based on the number of CO$_2$ molecules evaporated from the cluster ion and the typical binding energy of a CO$_2$ molecule to the cluster ion indicate that the photodissociated $I_2$ chromophore in the "caged" photofragment ions has recombined and that the vibrational energy of the recombined $I_2$ has been largely transferred to the solvent bath. The quantum yield for recombination, or "caging fraction," is strongly dependent on cluster ion size, ranging from zero for n≤5 to unity for n≥16.

Time-resolved studies of the photodissociation/geminate recombination dynamics were performed by using picosecond laser pulses at 720 nm. These were generated in a cavity-dumped Coherent 702 dye laser synchronously pumped by a Quantronix 416 mode-locked frequency-doubled Nd:YAG laser. Amplification by using a Spectra-Physics PDA pulsed dye amplifier pumped with the frequency-doubled output of a Quanta Ray GCR-3 Q-switched Nd:YAG laser produced output pulses of ≤3 ps duration and 1 mJ pulse energy. These pulses were split to create identical pump and probe pulses for use in time-resolved pump-probe experiments. Irradiation of a mass-selected cluster ion with the pump pulse induces photodissociation of $I_2$. Following recombination and vibrational relaxation of the photodissociated $I_2$, a second photon can be absorbed; however, if the probe pulse interacts with the cluster ion prior to recombination and relaxation, the cluster ion will be transparent at 720 nm, and a transient bleach will be observed in the production of two-photon fragment ions. By monitoring this transient bleach, we have investigated the cluster ion size dependence of the timescale for recombination. These data can be modeled by using a simple sequential two-photon absorption mechanism in which the transient bleach is represented by a single exponential recovery:
In this model, $\sigma$ is the photoabsorption cross section at 720 nm, $F_n$ is the caging fraction for a given parent cluster ion at this wavelength, and $r$ is the absorption recovery time which characterizes the duration of the transient bleach and, therefore, the time required for recombination and vibrational relaxation to occur.

Our recent transient bleaching data suggest that the absorption recovery time for $I_2(CO_2)_n$ ($n=9-11$) is of the order 30 ps, while $r$ is considerably faster, of the order 15 ps, for $I_2(CO_2)_n$ ($n=13-17$). This difference in recovery time may indicate a change in the mechanism of recombination or vibrational relaxation in these cluster ions. Some insight into these recombination dynamics is provided by lowest energy structures generated in recent Monte Carlo and molecular dynamics simulations which suggest that CO$_2$ molecules begin to appear in "capping" positions along the I$_2$ internuclear axis for cluster ions of this size. These "capping" CO$_2$ molecules limit the range of motion experienced by the iodine atoms, thereby accelerating the recombination process.

Future studies will employ femtosecond laser pulses and two-color pump-probe experiments to evaluate the contributions of geminate recombination and vibrational relaxation to the observed transient bleach. In addition, other solvent systems, such as Xe, N$_2$O, CS$_2$, and OCS, and other chromophores, such as ICl$^-$ and IBr$^-$, will be investigated.

Currently research is underway in our laboratory to determine the primary structure of all the gene regulatory factors of the sea urchin embryo. The 100-150 proteins involved in the early stages of embryonic development will be isolated and their amino acid sequences determined by mass spectrometry and DNA sequencing techniques. To date, several proteins have been isolated by affinity chromatography and SDS-PAGE. Protein levels in these gels are typically less than 100 pmol. We have developed a general sequencing strategy that will enable us to obtain partial amino acid sequence on many of these proteins starting with 100 pmol or less sample in SDS gel slices. The following paper describes new methodology utilizing capillary HPLC coupled with electrospray ionization on a Finnigan TSQ-700 triple quadrupole mass spectrometer.

The combination of packed capillary HPLC with tandem mass spectrometry has the potential to redefine approaches for molecular analysis of proteins. As much as 50% of a protein's amino acid sequence can be characterized in the time required to perform three cycles of automated Edman degradation at sample levels below those currently required by commercial sequenators. Figure 1 illustrates the configuration used in our laboratory for coupling capillary HPLC with on-line UV detection with electrospray tandem mass spectrometry. A 0.1% trifluoroacetic acid/acetonitrile solvent system was employed for all experiments.

Typical results obtained using this capillary HPLC-MS system are displayed in Figure 2. The reconstructed ion chromatogram is from a capillary HPLC-MS analysis of a tryptic digest of a DNA polymerase (90,000 Da) isolated from thermophilic bacteria. The early eluting peaks are peptides in the mass range 500-5000 Da and the later eluting peaks are large partially digested fragments (7000-40000 Da). The large fragments are detected and the spectra are easily deconvoluted.

Protein tryptic digests were analyzed at sample levels as low as 800 fmol and shown in Figure 3 is a base peak plot from an analysis of 800 fmol of a tryptic digest of β-lactoglobulin. Collision activated dissociation (CAD) was used to obtain amino acid sequence information on peptides at the 5 pmol level. Displayed in Figure 4b is a capillary HPLC-MS/MS CAD mass spectrum recorded on (M+2H)2+ ions of a 15 residue peptide generated from a 5 pmol injection of a tryptic digest of myoglobin. Ions of type-Y" and type-B are labeled. Predicted fragment ions for the 15 residue tryptic peptide are shown in Figure 4a. Those fragment ions observed in the mass spectrum are underlined.

This technique is compatible with in situ digestion of proteins bound to membranes or in SDS-PAGE gel slices. Figure 6 is a base peak plot from a capillary HPLC-MS analysis of an in situ digestion of a DNA binding protein from embryonic sea urchin nuclear extract. Peptides were generated directly from proteolysis of protein in SDS-gel slices following the procedure of Ward et. al. with the following modification. Extractions were performed with 5% acetic acid for 12 h and were repeated 3 times. No organic solvent was used in the extraction buffer.

Using a capillary C4 HPLC column coupled with electrospray, proteins were analyzed at the low pmol level. Displayed in Figure 5a is a plot of the signal from a UV detector using the Chro program run on a DECstation 2100 (The same computer that is used to acquire data on the TSO-700) for the analysis of a mixture of 3 proteins; 1) 3.5 pmol of γ-bungarotoxin, 2) 3.5 pmol of uteroferrin, 3) 1.5 pmol of horse heart cytochrome C, using a homemade capillary C4 column (320 μm x 15 cm). The RIC from this analysis is shown in Figure 5b and the strip chart plot of the UV signal is in Figure 5c.

This communication presents results on a RIMS analysis of thorium. Thorium is of interest for geochronological and geochemical purposes. The measurement of uranium series disequilibrium is a well established and valuable approach for geochronological studies: disequilibrium between $^{234/238}\text{U}$ and $^{230}\text{Th}$ can be used to date samples younger than 350,000 years. Both continuous wave (cw) and pulsed lasers were utilized in this study for resonantly exciting and subsequently ionizing thorium. In the case of the pulsed laser RIMS experiments, two excimer laser-pumped dye lasers were used in conjunction with a 0.4 m time-of-flight mass spectrometer. The cw RIMS experiments used an Ar$^+$ laser-pumped dye laser and a second Ar$^+$ laser in combination with a single magnetic sector mass spectrometer (NBS 12-90 design).

Experiments performed with the pulsed RIMS apparatus were aimed at determining the autoionization state structure and re-determining the ionization potential (IP). By tuning one dye laser to a resonance and scanning the second laser such that the total energy was equal to or above the IP, over 150 autoionization states were determined. The IP was re-determined to be $6.311 \pm 0.002$ eV ($50000 \pm 20$ cm$^{-1}$). In addition, the typical cross section for ionization of an autoionizing state was determined to be $1 \times 10^{-15}$ cm$^2$.

Figure 1 is a RIMS spectrum of $^{232}\text{Th}$ obtained by scanning the wavelength of a cw dye laser such that two photons of the dye laser have sufficient energy for ionization of thorium. The peaks in the spectrum correspond to excited states of thorium. This spectrum demonstrates both the sensitivity and selectivity of cw ionization for RIMS. The sensitivity is evidenced by the intensities of the peaks in the scan ranging over four orders of magnitude. The selectivity of RIMS is evidenced by the ability to use any of the transitions observed in fig. 1 for resonance enhancement. Because each element has a unique set of excited states this ability discriminates against isobaric interferences. Several of the more intense transitions were selected for the experiments described below.
Further experiments included having a cw dye laser in resonance with one of several strong transitions and using the mid-UV lines (333-364 nm) of an Ar$^+$ laser for the ionizing step in the ionization process. This method of ionization provides the elemental selectivity desired with the dye laser in combination with the increased power for ionization of the Ar$^+$ laser. The Ar$^+$ laser provides approximately 80 times the ionizing power of the dye laser (4 W vs. 50 mW) and hence, should translate directly into increased ion yield. However, the ion signal did not in all cases increase by a simple factor proportional to the ratio of the laser powers.

Figure 2 shows three plots of enhancement versus Ar$^+$ laser power. Enhancement is defined as: $\text{Enh.} = \frac{\text{signal w/(Ar}^+\text{ and dye)}}{\text{signal w/dye only}}$. The linear increase in RIMS signal with increasing Ar$^+$ power demonstrates the lack of saturation and hence, the potential of increasing the ion yield by simply increasing the ionizing laser power. The differing enhancements for a given Ar$^+$ power level for each of the three transitions are a direct reflection of the autoionization state structure for thorium. If the sum photon energy of dye and argon lasers is in resonance with an autoionizing state, as we believe is the case here for some of the transitions utilized, its increased ionization cross section will contribute to an enhanced ion yield to the extent that the resonance occurs. Clearly, the knowledge of the autoionizing state structure is important for performing a RIMS experiment in order to maximize ionization efficiency and minimize sample size.

Because of thorium's relative scarcity in geologic samples, there is considerable interest in increasing ionization efficiency and decreasing sample size. Through the use of the Ar$^+$ laser in combination with a relatively low power cw dye laser, samples as small as 25 ng of $^{232}\text{Th}$ have been analysed and with ionization efficiencies approaching 1%. We believe higher ionization efficiencies will be obtained in the near future which will in turn enable the use of smaller samples.

2Linear Instruments Corporation, Reno, Nevada 89523

A rapid scanning UV-Vis detector linked with fiber optics to a heated, remote flow cell has been coupled in series with a single stage quadrupole mass spectrometer. The chromatographic effluent from the exit line of the UV-Vis flow cell was routed into the source of a Finnigan 4023 GC-MS system, making use of a convenient hole in the transfer line oven which had originally been intended for use with a jet separator. The UV-Vis detector was a modified version of a commercially available instrument originally designed for use with HPLC. Vapor phase UV spectra and full scan mass spectra were acquired for a number of test samples, including Aroclors 1221 and 1254, gasoline, diesel oil, methyl anisoles, nitrotoluenes, and closely related PAH isomers of environmental and toxicological interest. The primary advantage of the technique is that it allows the unambiguous identification and differentiation of closely related aromatic compounds which often cannot be identified by the use of mass spectrometry alone. Isomeric PCB's, methyl anisoles, methyl naphthalenes and benzopyrenes can all be readily distinguished from one another using "on the fly" gas phase UV spectra. This has practical application wherever one has to deal with complex mixtures of aromatic hydrocarbons which can be separated on a GC column. The combined system has a linear dynamic range of about $10^4$, with UV detection limits of < 1.0 ng (s/n=3/1) when operating in the full scan mode (190-360 nm, 2 nm increment, 1.0 sec/scan) using unsubstituted biphenyl as a test solute.

Above: UV spectra normalized to the same intensity. All peaks with adequate s/n in this 1.0 ul sample yield unique UV spectra, although mass spectra of many isomeric mono and disubstituted PCBs show subtle differences at best.
Above: simultaneous mass and UV spectra were acquired for a 1/400 hexane dilution of Aroclor 1221. Both instruments were operated in the full scanning mode. GC program: 30h1, 120h3, 120-280 at 3°C/min, transfer line and UV flow cell 280°C, 1.0 meter X 0.32 mm retention gap with 30 meter X 0.32 mm DBS column. The exit line from the UV flow cell consisted of a 0.53 mm i.d. X 40 cm length of deactivated fused silica tubing, which was routed directly into the mass spec ion source.
Matrix assisted laser desorption time-of-flight mass spectrometry (MALD-TOF/MS) is a technique capable of molecular weight determination of high mass biomolecules. The high mass capability of the TOF experiment lead us to investigate the compatibility of MALD-TOF/MS with flowing sample introduction systems. We have made some progress with liquid sample introduction in the continuous flow mode using 3-nitrobenzyl alcohol. In order to better understand the requirements for optimizing this experiment, our attention shifted toward understanding the mechanism for MALD. Figure 1 presents a pictorial view of our proposed mechanism. The steps include: 1) photon absorption to produce an ensemble of $S$; 2) internal conversion of some $S$ species results in heating of a localized region; 3) the rapid heating causes ejection of "cluster species" from the surface, e.g., $[(S_0)_n-S]$ or $[(S_0)_n(A_n)_m-S]$ where $A$ represents analyte molecules; 4) the enhanced acidity of $S$ (relative to $S_0$) results in proton transfer to yield $[(S_0)_n(A_0)_m-AH^+-S']$; 5) evaporation of the cluster yields solvated adducts, $[(S_0)_n-AH']$ and $[(S_0)_n-S']$ or intact analyte molecular ions $[A+H]^+$. The proton transfer will be quenched if $S_0$ decays by radiative or non-radiative pathways, e.g., $S_0---A$. Coupling of electronic energy transfer can be eliminated by using matrices where the adiabatic transition energy ($E_t$) for the matrix molecules is less than that for the analyte (Figure 2). In general, pumping of high energy transitions, $S_0---S_0$ will be less effective for MALD because of electronic energy transfer and the coupling of these states to the triplet manifold. For example, the types of molecules that work best for

\footnote{Cheshnovsky, O.; Leutwyler, S. Chem. Phys. Lett. 1985, 121, 1.}
MALD, polar aromatics, the higher lying electronic states are more strongly coupled to the triplet manifold,\(^2\) this will be advantageous only if the acidity of the \(T,\) state is sufficient to promote the proton transfer reaction. Note: There are some cases where the acidity of the triplet is greater than the acidity of the singlet state.

Collisionally activated dissociation (CAD) mass spectra have been widely used for structural characterization of organic isomeric ions. The optimum approach for using CAD to determine the relative proportions of gaseous isomeric ions in mixtures has been studied by several groups.

McLafferty et al. proposed methods for determining the isomeric composition of an ionic mixture based on the superposition principle and Beer's law. Bowers et al. concluded from their study that "the present method of quantitative structural analysis based on the superposition principle cannot generally be expected to yield reliable results". The assumption made by Bower et al. dictated that the collision cross-section be the same for both isomers. McLafferty et al. pointed out that the general validity of this assumption had not been demonstrated experimentally. Recently, Kim et al. suggested that multiple collision (low transmittance) conditions are unreliable, as scattering cross sections may be different between isomers, and proposed a quantitative method using CAD cross sections at zero pressure limit. In contrast, a study presented here indicated that multiple collision conditions introduced much less variety of CAD cross sections than that at single collision conditions for isomers with unequal scattering cross sections. However, comparative evaluation of these approaches has been hampered by the difficulty of preparing standard mixtures and by the lack of other analytical methods for gaseous isomeric ions. For the latter, we have recently shown that neutralization-reionization (NR) mass spectra forming both positive ion (NR) spectra and negative ions (NR spectra) can provide independent quantitative determinations. The present study describes the application of these complementary techniques to the quantitation of the C₂H₄O⁺ and C₄H₆⁺ ions, and evaluates the accuracy of these methods using comparison of the independent CAD, NR and NR results. The isomeric compositions reported here are calculated from the corresponding CAD or NR spectral data and relative cross sections of the reference ions measured with relatively high precision using our new personal computer system.

The C₂H₄O⁺ ions generated from butane-1,3-diol were reported by CAD studies to consist of structures of CH₃CH=O⁺ (e⁻) and CH₂=CHO⁻ (f⁻), and the proportions of these two isomers [e⁻]:[f⁻] were 1:1 measured by McLafferty et al. and 64%:34% by Kim et al. Recently, the structures of seven possible C₂H₄O⁺ isomers and their corresponding ions have been established by the neutralization-reionization techniques, which allows to evaluate these analytical methods more definitively using CAD, NR and NR spectra. In consistent with previous studies, only e⁻ and f⁻ ions have been observed from unimolecular dissociation of ionized butane-1,3-diol by both NR and NR methods. The proportions of isomer e⁻ by CAD, NR and NR measurements, are 50%, 44% and 45%, respectively, in good agreement with McLafferty's results. Obviously, Kim's results were outside the experimental error.

The mixtures of the isomeric cations vinylacetylene (a⁺), butatriene (b⁺), methylene cyclopropane (c⁺), and cyclobutadiene (d⁺) from 13 different precursors have been analyzed by both NR and NR techniques. For ionized benzene, 1,5- and 2,4-hexadiyne, 1,3- and 1,4-cyclohexadiene, 1,3,5-hexatriene, 2,4,6-cycloheptatrienone and cyclooctatetraene that apparently produce the same [a⁺]/[c⁺] ratio; the average of the NR values for c⁺ is 69.3% ± 2.1% and that of NR values is 65.5% ± 5.2%. For mixtures of four C₄H₄⁺ isomers formed from 13 different precursors, the deviation from the average for the individual NR and "NR" measurements of the most abundant...
for C₄H₄⁺⁺ isomers produced from 13 different precursors indicate the high reliability for this determination utilized CAD and NR methods based on the superposition principle and Beer's law.

Introduction

Interest in radio frequency (rf) powered glow discharges continues to grow as is evidenced by the steadily increasing numbers of presentations at national meetings. This is not surprising given the benefits of such a discharge. RF discharges allow the direct analysis of nonconducting, as well as conducting, materials due to the d.c. bias which develops at the sample surface. Thus no dilution is required and possibilities of contamination of the sample are reduced because mixing with a conducting host matrix is not necessary. Isobaric interferences remain a limiting feature in glow discharge mass spectrometry. One possibility in dealing with such interferences in mass spectrometry is to increase the available resolution. In this work we detail major improvements in the interfacing of an rf glow discharge source to a double focusing mass spectrometer, which is able to resolve many atomic and molecular interferences.

Experimental

We have coupled an rf glow discharge to a double sector mass spectrometer (VG-9000). In order for such an interface to be successful, three electrical systems must be accommodated: 1) the rf system, 2) the high voltage accelerating potential, and 3) the grounded shielding system. The electrical, source, and probe design developed allows the efficient coupling of the rf potential to the sample, and thus supports a stable rf discharge. Isolation electronics maintain the division of the rf and high voltage systems while the high voltage necessary for extraction of the ions is efficiently coupled to the sample and the discharge cell. Equally important is the complete shielding of all rf carrying components and cables. Previous attempts at such an interface, utilizing an isolation transformer to reference all components to the high voltage accelerating potential, have led to inadequate shielding of the rf noise. With the new design signal-to-noise levels have been greatly increased ($\approx 10^4$).

The source, shown below, couples to the VG-9000 directly without mass spectrometer modifications. Samples (<3/16") and rf power are introduced via a direct insertion probe (21" x 1/2"). The stainless steel portion of the cell serves as the anode and is screw mounted to the boron nitride portion. The boron nitride allows cryo-cooling, high voltage insulation, and maintains an o-ring vacuum seal around the probe assembly. The discharge cell geometry efficiently restricts the discharge to the sample surface.
Results

The electrical system discussed above is capable of sustaining a stable discharge for both conducting and nonconducting species. Bias voltages as high as 600V have been observed and increase with increasing rf powers (15-45 watts typically). These bias potentials support the efficient atomization of solids for subsequent ionization within the discharge.

The analytical capabilities of this technique are demonstrated in the mass spectrum of strontium (3.85%) in NIST SRM 1412 multicomponent glass (shown below).

![Mass spectrum of strontium](image)

Of note is that noise limits have been greatly reduced over previous attempts of coupling the rf source to the VG-9000. The source and electrical design have resulted in 75 ppm limits of detection for strontium for a single scan. Analyte ion currents as high as $10^{-11}$ have been observed in conducting materials with single ppb detection limits having been obtained. These LOD’s (2σ) are obtained based on mass spectra acquired at a resolution of approximately 1200 with single scans and a 200 mS integration time. The observed differences in LOD’s for conducting and nonconducting species are not due to fundamental limitations in the analyses of nonconducting materials, but instead, current limitations in the source design. The source design to date has limited optimization of the plasma parameters and thus LOD’s comparable to the d.c. source are expected after minor changes in the source design are complete. Analytical characteristics of both nonconducting and conducting sample types are expected to be similar.
Trace Analysis of Atoms and Molecules on Surfaces Using Ion Beams

Nicholas Winograd
Department of Chemistry
Penn State University
152 Davey Laboratory
University Park, PA 16802

Mass spectrometric detection of species desorbed from ion–bombarded surfaces has become an important methodology for trace analysis studies. Analysis of the desorbed ions forms the basis of fast atom bombardment mass spectrometry (FABMS) or secondary ion mass spectrometry (SIMS). Our efforts have been focused on utilizing multiphoton resonance ionization (MPRI) spectroscopy to ionize the neutral flux of particles (1). This approach offers several unique advantages when compared to other related methods. First, ion–beam desorption, as opposed to laser or thermal desorption, is extremely efficient at selectively removing molecules from only the top layer of a solid (2). This characteristic means that the signals are specific to the surface concentration of the analyte. As an additional bonus, the theory of ion/solid interactions is highly developed (3). This important fundamental aspect allows valuable mechanistic insight into the nature of the desorption event. Second, MPRI detection offers selective ionization by use of relatively low–power pulsed lasers (4). The low–power requirement allows the use of a large ionization volume. This aspect of the technique results in more efficient sampling than with ionization schemes based on electron impact or focused lasers. Third, the pulsed nature of the radiation adds another dimension of selectivity provided by the built–In availability of a time–of–flight (TOF) mass spectrometer detector. These detectors exhibit inherently very high transmission efficiency. Finally, MPRI can be an extremely efficient means of producing ions.

For atomic species, Hurst has shown that ionization efficiencies approaching 100% are possible for those atoms in resonance with and spatially overlapping the photon field (5). In our experiments, we have elucidated a number of factors which need to be considered in order to maximize the value of MPRI ionization. These include ion pulse width, laser beam cross section, ionization scheme and minimization of SIMS ions as a source of background (4). With proper care, we will show that it is possible to determine surface concentrations of impurities with sub–zeptomole detection limits. At present, these measurements are only feasible for well–defined targets such as high purity silicon. But a number of factors aimed at allowing the study of more complex matrices will be considered.

Special problems arise when attempting to utilize this technology for the detection of molecules on surfaces using ion beam induced desorption. Computer simulations as well as a limited number of experimental studies suggest that the molecules desorb in a variety of highly excited vibrational and rotational states, with the largest population remaining in the ground–state electronic manifold. Two approaches have been successfully pursued in connection with other desorption schemes that will likely have relevance to the ion–beam–induced desorption technique. In one scheme, the molecules are first entrained and cooled by a supersonic jet of a noble gas (6). The advantage of this step is that the target molecules are cooled into a single spectroscopic state. The MPRI process can then be highly selective and efficient. A disadvantage is that only a very small fraction of the molecules can be trapped into the jet, dramatically reducing the sensitivity. In a second approach, the molecules are ionized directly by a laser tuned to a wavelength associated with an electronic transition of the molecule. Since there are a high density of occupied vibrational and rotational states in the ground–state manifold and since each of these states can connect with a real level in the excited–state manifold, a degree of selectivity is lost. This simplified scheme, however, offers major advantages in sensitivity due to the increased sampling efficiency. There have already been elegant experimental demonstrations of attomole detection limits when this mode of operation is coupled to laser desorption (7).
Here we demonstrate that it is possible to achieve attomole detection limits for desorbed neutral molecules even within the framework of the above limitations. For rigid molecules such as polycyclic aromatic hydrocarbons (PAH), it is possible to detect primarily molecular ions by postionization with two photons of wavelength between 266 and 280 nm. The signal intensity linearly follows the surface concentration of the PAH to detection limits of ~1 femt mole. For more fragile molecules such as tryptamine, tryptophan, phenylalanine and serotonin, the base peak in the mass spectra are characterized by fragment ions formed by losses of the amine side chains. Even with this fragmentation, however, it is possible to achieve sensitivity limits that are many orders of magnitude greater than for secondary ion mass spectrometry, without preparing the samples in special matrices. For serotonin, detection limits of 40 femt moles on the surface of a silicon target are achievable. The results also yield a linear relation between the serotonin base fragment ion intensity and the known surface concentration.

Finally, we will offer a number of suggestions for reducing these detection limits further, and will examine the possibility of utilizing this new technology in submicron molecular imaging.

THE IN SITU CHARACTERIZATION OF MATERIALS USING SECONDARY ION MASS SPECTROMETRY-RECENT ADVANCES

RICHARD W. LINTON
Department of Chemistry- CB3290, University of North Carolina Chapel Hill, NC 27599-3290

The SIMS technique has become a highly versatile tool for the chemical characterization of solid surfaces, particularly as additional analytical capabilities have been incorporated in the traditional classes of instruments for dynamic (elemental depth profiling) and static (molecular monolayer) measurements. As outlined in Figure 1, many of the recent advances center on sector field (SF) or time-of-flight (TOF) instruments incorporating imaging or laser post-ionization schemes to improve lateral spatial resolution, selectivity, or sensitivity. As is illustrated by the paper in this symposium by Winograd, the TOF-SIMS instruments have been especially suited to the use of resonant and non-resonant ionization involving pulsed lasers. A commercial SIMS instrument based on these features was recently introduced by Perkin Elmer-Physical Electronics Division known as the SALI (Surface Analysis by Laser Ionization). Paralleling the prior developments in the use of ion microscope or microprobe SF instruments operating in the dynamic SIMS mode (e.g., the Cameca IMS 3-F and IMS 4-F instruments), similar imaging approaches have recently been incorporated in TOF-SIMS instruments operating in the static mode. The presentation by Chakel in this symposium illustrates the combined microscope and microprobe capabilities of a TOF-SIMS instrument recently developed by Charles Evans and Associates. For both SF and TOF instruments, the microscope mode permits the simultaneous stigmatic imaging of areas on the order of 100 μm in diameter with approximately 1 μm lateral resolution. The microprobe sources, such as the field emission liquid metal ion source, provide improved lateral resolution (in the 50 nm range), but are usually restricted to smaller image fields as a consequence of analysis time considerations. Pulsed microprobes utilized in TOF instruments are further constrained by space charge and pulse width considerations that may degrade lateral and mass resolutions, respectively (1). To date, there has been little reported effort to combine both the imaging and post-ionization modes in a given SIMS measurement.

Because of the TOF emphasis of other SIMS presentations in this symposium, I will focus on recent developments in the SF techniques. Of special significance are advances involving three-dimensional (3-D) image depth profiling, incorporating digital image acquisition and processing techniques in SF ion microscopes. This has been a subject of extensive investigation in my research group beginning in the early 1980s (2). In recent years, detection systems generally have utilized microchannelplates (MCP) coupled to either resistive anode encoders (RAE) or phosphor screen/charge coupled device (CCD) assemblies (3,4). We have been particularly interested in various aspects of the CCD approach including: 1) development of intelligent image acquisition systems to optimize the trade-offs between detection sensitivity and spatial resolution, 2) quantification of 3-D data including corrections for detector non-linearities, matrix effects, and interfacial ion yield transients, 3) visualization of 3-D data involving the application of volume rendering techniques, 4) application of pattern recognition techniques to SIMS image data. Image acquisition and quantification issues will be illustrated using applications to dopant characterization in electronic materials (5). Organic applications include the 3-D characterization of spatially modified materials such as patterned arrays of electrically conductive polymer films, or labelled antigenic sites within biological tissues. The use of immuno-gold/silver staining of selective antibodies allows 3-D mapping of antigenic sites within complex biological matrices.

ORGANIC SURFACE ANALYSIS AND ION MICROSCOPY WITH TIME-OF-FLIGHT SECONDARY ION MASS SPECTROMETRY (TOF-SIMS)

J. A. Chakel, C. M. John, P. M. Lindley, R. W. Odom and B. Schueler, Charles Evans & Associates, 301 Chesapeake Dr., Redwood City, California 94063.

Mass spectroscopic analysis of the top monolayers of organic or inorganic surfaces can be achieved using the technique of static SIMS (TOF-SIMS). The low primary ion doses used in static SIMS ($10^{10}$ to $10^{12}$ ions/cm$^2$) are sufficient to generate secondary ions from the surface for mass analysis while minimizing the damage of the surface. The secondary ions formed are often molecular ions or structurally significant fragment ions indicative of the chemical structure of the surface.

A unique configuration of static SIMS instrumentation incorporates a high performance TOF mass spectrometer that provides both high mass resolution and high mass range analysis. The TOF-SIMS instrument can perform mass resolved ion image analysis. With the ion microscope analysis mode, a uniform Cs$^+$ primary ion beam impinges on the entire sample analysis area (typically 60 or 200 micrometer in diameter). Secondary ions thus formed are focused through the TOF mass spectrometer preserving their spatial origin and a magnified ion image is projected onto a position sensitive detector. Lateral distributions can be determined down to resolutions of 1 to 3 micrometer. For higher lateral resolution, an ion microprobe analysis mode is required. With this technique, a microfocused (2000Å beam diameter) Ga$^+$ beam is rastered over the sample surface. A unique feature of this mode is the ability to define custom raster patterns in order to obtain mass spectra from irregularly shaped features or particles. Up to four separate "region of interest" spectra can be acquired simultaneously. A low energy electron charge compensation system permits the analysis of insulating surfaces.

This technique has been used to study the surface of polymeric films, monolayer films, composite materials, treated papers and biological tissues. A representative polymer spectrum for poly (ethylene terephthalate) is shown in Figure 1. The base peak is C$_7$H$_4$O$^+$ at m/z 104. A monomer, dimer and trimer species can be seen at m/z 193, 385 and 577, respectively. The probable ion structures for the peaks labeled with dots in Figure 1 are shown in Scheme 1. Biological analyses including evaluating the relative ion yields and detection limits for biologically active compounds (neurotransmitters and pharmaceuticals) incorporated into different matrices were performed and are presented in Paper MOC 12:15 (C. John, et al.).

\]
We are using negative ion photoelectron spectroscopy to study neutral and anionic coordinatively unsaturated transition metal species in the gas phase. Anions are prepared from stable organometallic precursors in a flowing afterglow ion-molecule reactor, and mass-selected by a 90° sector magnet. Use of a sector magnet in place of the Wien filters employed in previous instruments of this type provides a ten-fold improvement in mass resolution. The mass-selected ion beam is intersected by an argon ion laser beam, and the resulting photoelectrons are energy analyzed at a resolution of 5 meV (40 cm^{-1}).

Multiple metal-metal bonding can be examined in its clearest form in the bare transition metal dimers. Chromium dimer, in particular, has been the subject of numerous experimental and theoretical studies. Since the ground state of the Cr atom has a high spin 3d^{5}4s^{1} configuration, a closed shell configuration for Cr$_{2}$ would lead to a formal bond order of six. Consistent with this picture, Cr$_{2}$ is known to have a $^{1}$E$_{g}^{+}$ ground state and a bond length of only 1.6788 Å. However, other results belie the simple picture of a hextuple bond in Cr$_{2}$. For example, the bond dissociation energy (D$_{0}$) of Cr$_{2}$ is only 1.44±0.05 eV (33.2±1.2 kcal/mol), actually lower than the 2.01±0.08 eV bond energy of the singly 4s-4s bonded Cu$_{2}$ molecule. The bonding picture is complicated by the 3-times greater size of the 4s than the 3d orbital in atomic chromium, which may cause the 4s-4s interaction in Cr$_{2}$ to be repulsive at the optimum distance for 3d-3d bonding. Modified GVB calculations by Goodgame and Goddard predict that the ground state of Cr$_{2}$ has a double minimum potential energy curve, dominated by five covalent 3d-3d bonds at short internuclear distance, and by a single 4s-4s bond at long distance.

We report the 488 nm photoelectron spectrum of Cr$_{2}^{−}$. The electron affinity of Cr$_{2}$ is 0.506±0.006 eV. Vibrational levels up to v=6 in the $^{1}$E$_{g}^{+}$ ground state of Cr$_{2}$ fit a Morse potential with $\omega_{e}=479\pm2$ cm$^{-1}$ and $\omega_{e}X_{e}=13.5\pm1.0$ cm$^{-1}$. This anharmonicity constant is unusually large: $\omega_{e}X_{e}$ values for all other neutral homonuclear first row transition metal dimers measured to date fall in the range 1-4 cm$^{-1}$. An excited electronic state of Cr$_{2}$ with a vibrational frequency of 580±20 cm$^{-1}$ is observed 14,240±30 cm$^{-1}$ above the ground state. For Cr$_{2}^{−}$, we obtain $\omega_{e}=470\pm25$ cm$^{-1}$, $\omega_{e}X_{e}=20\pm10$ cm$^{-1}$, and r$_{e}=1.705\pm0.010$ Å.

Perhaps the most intriguing feature of the photoelectron spectrum is the appearance of a weak vibrational progression of Cr$_{2}^{−}$ comprised of more than 12 peaks from 5100 to 6700 cm$^{-1}$ above the 0-0 transition. Surprisingly, the peak spacings are only 130±10 cm$^{-1}$, and they exhibit no detectable anharmonicity! This low-frequency, harmonic vibrational progression displays an intensity profile noticeably more irregular than that expected for the...
The photoelectron spectrum of a diatomic. Furthermore, the intensity profile changes dramatically when the argon ion laser is tuned from 488 nm to any of the other lines strong enough to be used in this experiment. However, the separation between each peak and the 0-0 transition remains unchanged. These observations suggest a one-photon process involving a resonance of the laser with one or more metastable states of the anion. This resonance allows us to probe regions of the Cr$_2$ potential curve which would normally be inaccessible due to negligible Franck-Condon overlap with the anion ground state.

The 130 cm$^{-1}$ vibrational interval observed here is close to the 110 cm$^{-1}$ value predicted by Goodgame and Goddard$^5$ for the singly 4s-4s bonded, "long-bond form" of the Cr$_2$ ground state. However, the 130 cm$^{-1}$ progression appears only 0.6 eV above the 0-0 transition, and displays no detectable anharmonicity over a 0.2 eV range. In contrast, the MGVB calculation$^5$ predicts the 4s-4s well to be bound by only 0.3 eV, and to lie 1.6 eV above the 3d-3d well. In addition, we measure an unusually large anharmonicity ($\omega_0x_0 = 13.5 \pm 1.0$ cm$^{-1}$) for the "short-bond" region of the potential. These results suggest the need for improved calculations of the ground state potential energy curve of Cr$_2$.

(II) Group VI Metal Tricarbonyls

The photoelectron spectra of Cr(CO)$_3^-$, Mo(CO)$_3^-$ and W(CO)$_3^-$ show vibrational activity in the symmetric modes of the C$_3V$ neutral molecules. Although the extra electron is the lone occupant of a degenerate pair of orbitals in the d$^7$ anions, the spectra provide no evidence for a Jahn-Teller distortion. The neutral molecule symmetric CO stretching frequencies are measured to be 2000±10 cm$^{-1}$ in all three species, about 120 cm$^{-1}$ lower than in the stable metal hexacarbonyl complexes. Surprisingly, the spectra also show activity in the MCO bending vibration. Since the active modes in these direct photodetachment spectra are those associated with differences between the equilibrium geometries of the anion and the corresponding neutral molecule, this observation suggests that the MCO bonds are slightly bent in the anions, and possibly also in the neutral molecules. The electron affinities of Cr(CO)$_3$, Mo(CO)$_3$ and W(CO)$_3$ are determined to be 1.36, 1.34 and 1.87 eV, respectively.

Field desorption and laser desorption mass spectrometry have been used to determine the molecular weights of highly branched polymers (dendrimers). These materials are unusual polymers because the synthetic scheme is designed to yield a product having a single molecular weight, rather than a wide distribution of molecular weights. During the synthesis, a branched "core" is modified by the symmetrical addition of linear or branched appendages (Scheme 1). When polymers of this type were first synthesized by Newkome et al., they were dubbed "arborals" because of their tree-like structures (1). The present study involves polymers having a silicon backbone, which have interesting physical properties and a reactive surface that makes them potentially useful synthetic intermediates (2). Electron ionization may be used to determine the molecular weights of the 'core' and 'add-on' reagents, but the volatility of the products is too low to allow EIMS characterization without decomposition. Field desorption ionization has been used to determine molecular weights of first- and second-generation polymers (M, 5-10 kD).

In the electron ionization mass spectra of the add-on blocks and the core units the high-mass ions corresponded to (M-H)\(^+\) and (M-CH\(_3\))\(^+\). Similarly, in the positive-ion field desorption mass spectra, the high mass ions were M\(_a\), (M-H)\(^+\) and (M-CH\(_3\))\(^+\). Some loss of branches also occurred. In the FD mass spectra of the larger compounds, multiply-charged ions were observed as well as abundant singly-charged ions (Fig. 1). The multiply-charged peaks arose by losses of hydrogen, methyl or variously-sized branches, or combinations of these. The most abundant ions in the negative ion field desorption mass spectra were the (M+Cl)\(^+\). In all these spectra, peaks at 74 u above and below the major ions were observed. These reflect the presence of minor components differing in mass by Si(CH\(_3\))\(_2\)O, that are probably result from scrambling that occurs on heating or after long storage.

Because thermal decomposition made it impossible to determine the molecular weights of the third generation products by field desorption, these values (M, 16-20 kD) were determined by laser desorption. LD/TOF mass spectra of the first- and second-generation products were also acquired to provide reference spectra. The laser desorption spectra show cationized molecular ion peaks, some fragmentation via branch loss, and doubly-charged ions (Fig. 2).

There is strong support for a mechanism by which foreign antigen is internalized by an antigen presenting cell and proteolytically processed to generate a number of fragments which are selectively presented by class II major histocompatibility complex (MHC) molecules for recognition by T cells. To assess the role of antigen processing and to circumvent the difficulties in isolating antigenic fragments in vivo we have developed a cell-free processing system. Mass spectrometry has been utilized as a method for rapidly analyzing the proteolytic products of a model antigen, *Staphylococcus aureus* nuclease (Nase), generated under conditions analogous to those present in the in vivo "processing-compartment." Nase was treated with an acidic endoprotease, cathepsin D under varying conditions of time and pH. The resulting digests were (I) characterized by Frit-FAB LC/MS to identify the fragment sequences and (II) assessed for antigenicity using a T cell recognition assay. We have previously identified 5 regions of Nase as T cell determinants in BALB/c mice (I-Ad and I-Eα) (1). In digests carried out over 1, 2, 4 and 18hr, immunogenic fragments were detected as assessed by the recognition of specific T cell hybridomas and the potential fragment sequences were identified solely by LC/MS. Fragments containing the immunodominant (61-80) and minor (112-130) epitopes were identified. Shorter digestion times (0, 15 and 30min) required the use of electrospray ionization to analyze peptides whose molecular weights exceeded 2400 amu (the effective upper mass limit of the Frit-FAB experiment). This latter technique proved effective in generating exact mass assignments for the higher molecular weight peptides, and was corroborated by an exact mass measurement on the intact Nase, producing a Mr of 16,812 +/- 0.002%.  

DETERMINATION OF GLYCOPROTEIN GLYCOTYPES AND GLYCOFORMS BY ESI-MS

Vernon Reinhold, Bruce Reinhold, Thomas Covey

and PE SCIEX, Thornhill, Ontario, Canada L3T 1P2

Carbohydrate chains attached to proteins modulate the chemical and biological properties of the resultant conjugate in numerous ways. These glycan chains have been shown to be of three major types, (glycotypes), high mannose, complex, and hybrid. In addition, each chain displays a polymorphic character that has more recently been characterized as a glycoform distribution, (e.g., Man₃₋₉GlcNAc₃₋₉). Thus, glycoproteins are characterized by considerable microheterogeneity and yield, as a signature, an envelope of molecular weights. The nature of this polymorphic distribution can have considerable bearing on product viability and concerns of quality control, especially for those companies involved in protein-based pharmaceuticals. Batch-to-batch monitoring of glycosylated products, in a cost-effective manner, is a challenging and necessary obligation that biotech firms are preparing to undertake.

We have considered this problem of glycoform characterization by proteolysis, glycopeptide isolation, and profiling these fractions using ESI-MS. Reverse phase HPLC fractionates primarily on the basis of peptide structure with perturbations in retention due to glycan residues. Thus, direct characterization of these fractions can provide an unperturbed measure of glycan distribution. In addition to an envelope of glycoforms the mass intervals provide further insight to glycotyep. As an example of this approach Figure 1 is an ESI-MS analysis of three eluting glycopeptide fractions obtained from ovomucoid. The spectra show doubly charged glycopeptides with mass intervals indicating polylactosyl or complex type glycans. Fraction $22$ is a major peak which was followed by fraction $23$. From the spectra it is clear that the separation is one of glycoforms with the peptides identical. In contrast, fraction $24$ indicates a different peptide, however, the glycotyep appears to be identical. This simple and rapid survey of rHPLC fractions greatly facilitates glycoprotein characterization.

CHARACTERISATION OF OLIGOSACCHARIDES AND GLYCOPROTEINS BY MATRIX-ASSISTED LASER DESORPTION MASS SPECTROMETRY (LDMS).

The pattern of glycosylation is now recognised as being crucial to the biological activity of glycoproteins. However, structural elucidation of the constituent oligosaccharides is extremely difficult because of their complexity. This paper examines the use of LDMS to characterise these compounds.

Samples examined were intact glycoproteins and glycopeptides with molecular weights up to 150 kDa and oligosaccharides containing from 9 to 19 monosaccharide units. All compounds were examined in the underivatised state and, in addition, the oligosaccharides were examined as permethyl and peracetyl derivatives. For recording the spectra, 50 fmole - 10 pmole of the sample in 0.1 µl of water was mixed with the matrix solution (0.5 µl in the centre of the stainless steel target and allowed to dry at room temperature. The matrix consisted of sinapinic acid (10 nmole) for the glycopeptides and 3-amino-4-hydroxybenzoic acid (10 nmole) for the oligosaccharides. These were dissolved in a mixture of acetonitrile (70%) and water (30%) to which had been added 0.1% trifluoroacetic acid. The targets were loaded into a Finnigan Lasermat time-of-flight mass spectrometer and ions were produced with a 337 nm pulsed nitrogen laser with a power density of around 10^6 W/cm².

The spectra of the oligosaccharides, both derivatised and underivatised, were characterised by [M + Na]⁺ ions (Fig. 1) which were often accompanied by [M + K]⁺ ions in low concentration. No fragmentation was observed. Unlike the spectra of proteins, multiply charged and multimeric ions were not evident. These features make the technique ideal for mixture analysis. Mass measurement accuracy was usually to within 0.1% using a prerecorded calibration file, or better than 0.5 mass units when an internal calibration standard was present. The most accurate results were obtained with the laser power set to just above that required to produce a signal. With higher powers, adduct formation often caused an increase in measured mass; this effect occurred to a similar extent with all similar compounds in a mixture.

There appeared to be little correlation between sample loading and recorded peak intensity. This was the result both of the non-homogeneous drying of the slide and to saturation of the signal at sample loadings in excess of about 30 pmole. Peak intensities varied considerably with successive shots but more accurate values of the intensity could be obtained by summing up to about 20 shots. Sugars with similar structures gave similar responses allowing an internal standard to be used for quantitative measurements. Under these conditions it was found that very accurate quantitative measurements could be made over a wide concentration range as the behaviour of the internal standard exactly reflected that of the sample, both in peak intensity and in adduct formation. Fig. 2 shows a calibration curve for a biantennary oligosaccharide (coded NA-2, [M + Na]⁺ = 1664.5) containing nine monosaccharide residues, using its fucosylated analogue as the internal standard, over the range 3 - 125 pmole. Derivatisation as either the peracetyl or permethyl derivative gave similar results although the sensitivity was increased by about a factor of about ten. Sialylated sugars (underivatised) gave lower responses than neutral sugars and tended to form adducts containing multiple sodium atoms.
Glycopeptides gave good responses, but again tended to form complex adducts with alkali metals, particularly at high concentration. Adduct formation also increased with laser power. Fig. 3 shows plots at two laser powers of measured mass against sample concentration for human transferrin oligosaccharide (4134.5 Da) in a matrix consisting of sinapinic acid to which had been added a low concentration of sodium iodide in order to encourage \([M + Na]^+\) formation. The graph shows a linear correlation between measured mass and peak intensity. The y intercept corresponds to the mass of the \([M + Na]^+\) ion showing that the most accurate mass measurements are obtained at low sample loading. The use of an internal calibration compound with more intense peaks ensures high mass measurement accuracy.

As an example of the application of the technique to a biological sample, Fig. 4 shows the spectrum of bovine pancreatic ribonuclease. The peak at 13,683 Da corresponds to the unglycosylated protein and the peak centred around 14,000 Da appears to be a photochemically produced adduct with the matrix. The other cluster of peaks starting at 14,900 Da correspond to glycopeptides containing the sugars (GlcNac)_2(Man)_7 at Asn-34. Following hydrazinolysis and reacetylation, the released sugars were re-examined by LDMS and gave the spectrum shown in Fig. 5. The ratios of these peaks agreed to within ±1% of those measured by three other, non-mass spectrometric techniques.

Carcinogenic polycyclic aromatic hydrocarbons such as benzo(a)pyrene are known to bind covalently to DNA in vivo following metabolic activation. Projected strategies for assessing individual exposure and risk require detection and identification of these adducts at environmentally induced levels. To this end we have constructed a time-of-flight mass spectrometer and are investigating both pulsed liquid secondary ion mass spectrometry (LSIMS) using a liquid metal ion (LMI) source and matrix assisted laser desorption/ionization with regards to their sensitivity in this analysis.

Details of the liquid metal ion LSIMS ionization source have been described previously (1). Briefly, a liquid metal ion column directs a focused, 0.1-10 nA, beam of 0-25 keV positive ions onto an area of ≤10 μm in diameter. Samples are deposited on a target wire (~25 μm diameter) and the primary beam is swept across it. The sample droplets are 100-300 μm in diameter. In this way the secondary ionization event is defined in time by the sweep rate and the target diameter. Acceleration voltages of 8-10 kV are typically used. Post acceleration up to 10 kV is possible.

Alternately, the third harmonic of a Nd-YAG laser is used to deliver 10 MW/cm² pulses of 355 nm photons onto a target area of ~50 μm diameter. Samples are deposited onto the end of a 2 mm diameter sample probe. An acceleration voltage of 15 kV is used.

The model compound used, 7,8,9-trihydroxy-10-(N²-deoxyguanosyl)-7,8,9,10-tetrahydrobenzo(a)pyrene (dG-BaPDE, MW 569), was synthesized from the ±-anti-7,8-diol-9,10-epoxide metabolite of BaP and calf thymus DNA. The adduct was isolated chromatographically following enzymatic digestion of the intact adducted DNA.

Preliminary experiments were performed with the LMI source and wire sample probe fitted onto a Kratos MS-50 double focusing sector instrument. No dG-BaPDE peaks were observed from 140 pmoles of sample until the glycerol matrix was acidified with 5% trifluoroacetic acid (TFA). The molecular ion region was dominated sodium adduct ions (Fig. 1a). Furthermore, peaks corresponding to the aglycone fragment, loss of the deoxyribose moiety, can be seen for both the mono- and di-sodiated molecular ions, (Fig. 2). Following the reported use of p-toluenesulfonic acid (p-TSA) to suppress metal adduct ions in FAB analysis of nucleotides (2), 0.2 N p-TSA was used to acidify the matrix and significantly decreased sodiation of the molecular ion (Fig. 1b).

The LMI-LSIMS source on the time-of-flight mass analyzer produced useful spectrum from 65 pmoles dG-BaPDE in glycerol/p-TSA. A signal to background of ~5:1 for the (M+H)+ ion as well as observable aglycone fragment can be seen (Fig. 3).

The use of cinnamic acid derivatives in matrix enhanced laser desorption has been shown to produce high quality spectra of proteins at 355 nm (3). Despite the complexity of the matrix spectra in the low mass range and the relatively poor resolution of the instrument at this stage of development, we have observed peaks corresponding to (M+H)+ and (AH₂)+ with good signal to background from 1.5 pmoles of dG-BaPDE (Fig. 4).

Confirmation of the structure of recombinant proteins is especially important for drugs which are approved for clinical use. Currently, biotechnology companies use peptide mapping with UV detection to monitor recombinant products. Laser Desorption Mass Spectrometry (LD-MS) in conjunction with narrow bore HPLC and chemical and enzymatic degradation provided a fast and sensitive method to confirm the primary structure of Interleukin-2 using only 10 μg of starting material.

**Summary of Results:**

* The native material is homogeneous (but may be a dimer in solution)
* The DNA derived sequence can be verified with high specificity
* Methionine is present at the amino terminus; it seems partially oxidised
* There is no glycosylation at Thr 3
* There are 3 cysteines
* The disulfide bond is between Cys 58 and Cys 105
* The disulfide bond becomes scrambled under tryptic digest conditions

APPLICATION OF TANDEM MASS SPECTROMETRY TO THE ELUCIDATION OF THE STRUCTURES OF CARCINOGEN-NUCLEOSIDE ADDUCTS: IDENTIFICATION OF CHARACTERISTIC FRAGMENTATION PATHWAYS

J.O. Lay, Jr., M.S. Bryant, and M.P. Chiarelli
National Center for Toxicological Research, Jefferson, AR 72079, and University of Arkansas at Little Rock, Little Rock AR, 72204.

We have developed an analytical strategy based on FAB ionization and tandem mass spectrometry for the analysis of nanogram to picogram levels of unknown carcinogen nucleoside adducts. This strategy involves: (1) derivatization with TMS groups to increase the analyte signal levels using FAB ionization; (2) the use of constant neutral loss scans to detect selectively the derivatized modified nucleosides; and (3) the use of daughter ion scans to probe the structure of the carcinogen modified base moiety (BH$_2^+$ ion). We have presented preliminary data regarding the feasibility of the first two elements of our analytical approach. Specifically, we have demonstrated that FAB is a sensitive desorption ionization methodology for the TMS derivatives of arylamine modified nucleosides (1), and that constant neutral loss scans can be utilized to identify the protonated molecules of TMS derivatives of carcinogen nucleoside adducts (2). Additional work using constant neutral loss scans, selected reaction monitoring, and isotope dilution methodologies for the analysis of low picogram levels of adducts is presented elsewhere (3). Unfortunately only limited evidence regarding adduct structures has thus far been obtained. The objective of this work is to demonstrate that tandem mass spectrometry can be used to obtain specific data regarding the structures of the adducts detected using the TMS derivatization and constant neutral loss scanning strategy described above.

Tandem mass spectrometry provided little additional structure-specific information when the protonated molecules were mass selected for MS/MS studies. Furthermore, with TMS derivatives, uncertainty regarding the location of the TMS groups, and the existence of isomeric TMS derivatives caused additional problems. However, significant structure specific fragmentation was observed from collisionally activated BH$_2^+$ ions. Fortunately, except for the tris-TMS derivatives, the protonated molecules from all of the derivatized nucleosides showed principally underivatized BH$_2^+$ fragment ions.

Model C-8 substituted deoxyguanosinyl [N-(deoxyguanosin-8-y1)-4-aminobiphenyl (dG-C8-ABP) and N-deoxyguanosin-8-yl]-2-aminofluorene (dG-C8-AF)], and C-8 substituted deoxyadenosinyl [N-(deoxyadenosin-8-y1)-4-aminobiphenyl (dA-C8-ABP)] adducts gave different and characteristic fragment ions and neutral losses using low energy MS/MS with a triple quadrupole instrument. Nine specific neutral losses, attributed to cleavage within the base moiety with retention of charge on the carcinogen containing fragment, were observed with the deoxyguanosine adducts but not with the deoxyadenosine adduct. Four fragments attributed to loss of the carcinogen moiety were also observed only with the deoxyguanosine adducts, whereas five fragment ions were observed with adducts from the same carcinogen and different nucleosides. The latter were attributed to loss of most of the base moiety with retention of the charge on the carcinogen containing fragment. Preliminary data suggest that the BH$_2^+$
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Fragment from other types of adducts (N\textsubscript{2}-substituted for example) also give unique fragment ions after collisional activation (data not shown). All of the fragments listed above (and tabulated below) can be attributed to the loss of even electron species (small neutrals) from the BH\textsubscript{2}\textsuperscript{+} fragment parent ion. This result is consistent with the use of low collision energies (about 50 eV) for the MS/MS experiments.

These data suggest that FAB and tandem mass spectrometry can be used to provide significant structure-specific data for carcinogen modified nucleosides. Furthermore, the tandem mass spectrometry step can be incorporated directly into an overall analytical strategy used to determine experimentally the adduct's molecular weight.

GCMS STUDY OF GLUCOSE METABOLISM IN MAMMALIAN CELLS

Yong Y. Lin, Bruce M. Gillum and Charles E. Wright
NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314

INTRODUCTION:

The method utilizing stable isotope and GCMS has been developed for the study of glucose metabolism in mammalian cells. Uniformly labeled \(^{13}\)C\(_6\)-glucose was used to study its metabolism via pyruvate dehydrogenase complex and TCA cycle. By the GCMS-SIM analysis of the glucose metabolites and their isotopomers, the glycolysis, glycogenolysis, and glyconeogenesis in the cells can be estimated. \(^{1-13}\)C-glucose was used to examine the formation of \(^{13}\)C-lactic acid and \(^{12}\)C-lactic acid, from which the metabolic flux through the pentose phosphate pathway can be calculated. The developed method was used to examine the glucose metabolism in cultured human cell lines.

METHODS:

Cultured human fibroblast and lymphoblastoid cells were incubated with 10 mM \([1-^{13}\)C\(_6\)]-glucose (for pentose phosphate pathway study) or 10 mM \([U-^{13}\)C\(_6\)]-glucose (for glycolysis and glyconeogenesis study). The resultant metabolites; glucose, lactic acid, aspartic acid, glutamic acid, and \(\gamma\)-aminobutyric acid were analyzed for their \(^{13}\)C-isotope distributions. Volatile derivatives of the metabolites were made as the following: glucose to the aldonitrile pentaacetate, lactic acid to 2-heptafluorobutoxy-propionyl propylamide, and amino acids to their N-trifluoroacetyl-butyl esters.

GCMS-SIM analysis were performed in CH\(_4\)CI(for glucose and lactic acid derivatives) and in NH\(_3\)Cl(for amino acid derivatives) by monitoring the base peaks showing in the following table:

RESULTS:

Metabolism of \([1-^{13}\)C\(_6\)]-glucose in the fibroblast and lymphoblastoid cell lines obtained from Alzheimer disease (AD) and their age-matched controls were examined. The glycolysis of \([1-^{13}\)C\(_6\)]-glucose via pentose phosphate pathway will lose the \(^1\)C-carbon and result in production of non-labeled \(^{12}\)C-lactic acid, while the glycolysis by direct rout will retain the \(^{13}\)C-carbon in the lactic acid; therefore, the flux to the pentose phosphate pathway can be estimated from the ratio of \(^{12}\)C/\(^{13}\)C in the lactic acid (1). The results (Table 1) indicates that the flux to the pentose phosphate pathway is significantly decreased in fibroblast cells of AD (FA-5 and FA-6). The increase in the flux to pentose phosphate pathway can be achieved by the addition of an artificial electron acceptor, phenazinemethosulfate, to the system (cell line FN-6a).

Metabolism of \([U-^{13}\)C\(_6\)]-glucose in the above cell lines were studied, and the abundance of the
isotopomers in the resultant glucose and lactic acid were shown in Table 2. Analysis of the dilution and distribution of the isotopomers in glucose and lactic acid reveals that the glycolysis of the exogenous glucose appears to be the only metabolic activity observed in the cells, since little or no isotopic dilution was observed with $^{13}$C$_1$ glucose or with $^{13}$C$_3$ lactic acid. In addition, little or no recycling of glucose from gluconeogenesis is indicated, since no significant metabolic enrichment could be observed with $^{13}$C$_1$, $^{12}$C$_2$, and $^{13}$C$_3$ glucose (2).

INTRODUCTION

Epidemiological studies suggest a role for diet in the etiology of many human cancers. Among the heterocyclic amine food mutagens thus far isolated, 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) has been identified in fried beef and fish at levels up to 15 µg/kg (1). The compound is mutagenic in bacteria (2) and has been shown to cause lymphomas when administered in the diet to mice (3). To assess possible human exposure to this compound, we have developed a GC/MS method for measuring PhIP in urine. This study reports on the application of this method to a preliminary study in rats.

EXPERIMENTAL

Internal Standard  A d5-labelled PhIP internal standard was prepared by reaction of d5-phenyl alanine and creatinine, with subsequent purification by HPLC. Methane Negative Ion Chemical Ionization (NICI) mass spectra of the bis-pentafluorobenzyl (BPFB) derivatives of d5-labelled and unlabelled PhIP, are shown in Fig. 1.

![Figure 1: Methane Negative Ion Chemical Ionization mass spectra of A) BPFB-PhIP, and B) BPFB-PhIP-d5](image)

Treatment of Rats with PhIP  Ten 7-week old male Sprague Dawley rats (average weight 211 g) were divided into two dose groups and placed in metabolic cages. One group received a single oral dose of 50 µg PhIP (-250 µg/kg bw) dissolved in 0.5 ml H2O containing 15 µl DMSO and 2 µl 0.1N HCl to aid solubility. The control group received only solvent. Urine and feces were collected every 24 h for 4 days and stored at -80°C.

Extraction of PhIP from Urine  PhIP was extracted from urine using a modification of a procedure described by Murray et al. (4) for MelQx in urine. After addition of d5-PhIP internal standard, PhIP was extracted from 10 to 300 µl aliquots (0.5 or 2% of 24 h urine volumes) of urine (pH 9) with ethyl acetate, extracted into 0.1N HCl and finally extracted from basic aqueous solution with ethyl acetate. Samples were then taken to dryness with a speed vac evaporator.

Formation of BPFB-derivatives  To obtain volatile, electron-capturing derivatives, the PhIP residues were treated for 1 h at 30°C with 400 µl of a 5% solution of pentafluorobenzyl bromide in acetonitrile and 100 µl of diisopropylamine (4). After reduction to dryness under a stream of N2 at 30°C, the residue was dissolved in 0.1N HCl and cleaned up with hexane before extraction from basic aqueous solution with ethyl acetate.
Gas chromatography/mass spectrometry (GC/MS) analyses were carried out on a Hewlett Packard (HP) 5890 gas chromatograph coupled through a heated interface (300°C) to a HP 5988A mass spectrometer. Chromatographic separation was achieved on a HP-1 fused silica capillary column (12 m x 0.2 mm id). After splitless injection at 180°C, the column oven was heated to 290°C at 30°C/min and then at 10°C/min to 320°C. The mass spectrometer was operated in the negative ion chemical ionization mode with a methane source pressure of about 1 Torr and source temperature of 250°C. Quantification was by selected ion monitoring of the (M-PFB)- ions of the BPFB derivatives of PhIP (m/z 403) and d5-PhIP (m/z 408) as shown in Fig. 2.

**Figure 2:**

Selected Ion Monitoring Chromatograms for

A) BPFB-PhIP-d5 (int std), and

B) BPFB-PhIP in the urine of a rat treated with 50 μg PhIP.

**Figure 3:**

Mean daily excretion of PhIP in the urine of 5 rats treated with a single oral dose of 50 μg PhIP. Standard deviation is expressed by error bars.

**RESULTS AND DISCUSSION**

Figure 3 shows the mean urinary excretion of PhIP for 5 rats treated with a single 50 μg oral dose of PhIP. About 0.6% of the total dose was excreted in the first four days after treatment. About 55% of this amount was excreted during the first 24 h. For rat urine, the method has a detection limit of about 2 pg (~1 ng PhIP excreted/24 h) and should be able to detect a single oral dose of ~200 ng PhIP in rats.

Work is underway to improve the sensitivity of the method using immunosaffinity cleanup and to extend the method to matrices other than urine.

ROOT ESSENTIAL OIL COMPOSITION FROM ARISTOLOCHIA ASCLEPIADIFOLIA (ARISTOLOCHIACEAE)

George R. Waller, Oklahoma State University, Stillwater OK 74078, Lorenzo Sagrero-Nieves, Instituto de Ciencias Basicas, Xalapa 91000, Veracruz, Mexico, and Richard P. Sgaramello, International Flavor and Fragrances, Union Beach NJ 07735

The genus Aristolochia, a member of the Aristolochiaceae (1) is distributed in tropical and subtropical regions of the world. Aristolochia asclepiadifolia Brandegee is an endemic plant of Veracruz State, Mexico. The species is a vine 30-10 m long and is locally called "guaco". The root is very aromatic and some people of the region use alcoholic infusions to combat the venoms of scorpions and snakes and for dysentery. The work reported describes the chemical composition of the essential oil of the root of Aristolochia asclepiadifolia, in which 38-83 compounds were identified in 1986-1990.

The vegetal material (root) was collected from random lianas (vines) in the final fruiting stage growing near Actopan, Veracruz in June of each year. The plant is perennial and a voucher specimen is deposited at Instituto de Ecologia Herbarium, Xalapa, Veracruz, Mexico. Approximately 600 g of the ground root was subjected to steam distillation for 6 h in an all-glass system containing no stopcock grease. The distillate was saturated with sodium chloride (Baker, certified reagent grade) and extracted with ethyl ether, ACS-certified reagent grade. The extract was dried over anhydrous magnesium sulfate, filtered, and freed of ether and the essential oil stored at 0°C until analyzed.

Capillary gas chromatography (CGC/MS/DA) analysis was carried out with a Kratos MS-50 mass spectrometer in the electron ionization mode, coupled with a HP 5880 gas chromatograph using a methylsilicone fused silica column 50 m x 0.32 mm. The samples were analyzed using 1.5 μl injections with the splitter turned off and the oven at 50°C, programmed at 2°C/min to 225° and held there for 60 min. The helium flow rate was 1.8 ml/min. Results were acquired and analyzed with a Kratos DS-55 data system (2). Identification was based on comparison of known with unknown spectra, visual interpretation of the fragmentation patterns, and relative retention times are compared to a proprietary IFF standard index (comparable to Kovac's Indices).

Preliminary study of essential root oil of A. asclepiadifolia reported identification in years 1987 and 1988 of 38 compounds (3) with the presence of vanillin. In years 1989 and 1990 eighty-three compounds were identified; between 170-180 compounds were detected and all of the compounds not identified were sesquiterpenes (MW=204) and sesquiterpene alcohols (MW=220). The freshly prepared essential oil for 1986 possessed the characteristic fragrance evaluation as being: dry — sweet, woody, fir balsam absolute, fresh — mate absolute, fig leaf absolute; comment: — smells like compounds of many absolutes → very pleasant; organoleptic quality — similar to already established natural essential oils. The 1988 oil was similar in fragrance evaluation; however, the 1989-90 essential oils did not have the same fragrance, probably due to the absence of vanillin and like presence of more sesquiterpenes and sesquiterpenoids.

A representative CGC/MS/DA reconstituted tracing of the steam volatiles from the 1989 oil of A. asclepiadifolia is shown in Fig 1. Major compounds were linalool and its oxides, α-bisabolol, and guaiol and isomers; followed by vetiverol, β-selinene, ledol, terpinel (4- and α-plus other isomers and their acetates), pogostol, borneol and its esters are shown in Table 1. Of particular interest was the absence of vanillin, the presence of β-caryophyllene and the identification of more sesquiterpenes and sesquiterpenoids in the 1989-90 oils.

The root essential oil from A. asclepiadifolia is shown on a yearly basis and we are unable to pinpoint the reason. Of particular interest was the ability to biosynthesize vanillin and the lack of enzymes required for its production was noteworthy. There are probably a number of factors involved such as genetics, environmental, or other factors unknown.

Metabolites of aromatic compounds in bile of fish exposed to weathered crude oil

Donald W. Brown, Margaret M. Krahn, Douglas G. Burrows, Tracy K. Collier, Catherine A. Wigren, Gina M. Ylitalo, Sin-Lam Chan, and Usha Varanasi

Environmental Conservation Division
Northwest Fisheries Science Center
2725 Montlake Blvd. East
Seattle, WA 98112

The Exxon Valdez spilled about 11 million gallons of Prudhoe Bay crude oil (PBCO) into Prince William Sound (PWS), AK, in March, 1989. Aromatic hydrocarbons and heterocyclic compounds such as dibenzothiophenes and their alkyl substituted homologs are abundant in PBCO. We wanted to determine if fish were exposed to these aromatic compounds (ACs) as a result of the spill.

Studies have shown that fish take up ACs from their environment. ACs are readily metabolized and the metabolites are excreted in bile. Our goal was to determine specific metabolites of petroleum-related ACs in bile as definitive evidence of exposure. A halibut was injected with weathered PBCO collected from PWS 11 days following the spill to serve as a positive control in the determination of oil exposure in feral fish. Bile was collected 48 hrs post injection, and the metabolites in 100 μL of bile were hydrolyzed using β-glucuronidase with sulfatase activity. The hydrolyzed (non-conjugated) metabolites were extracted into dichloromethane and the extract was cleaned up by HPLC size exclusion cleanup (Krahn et al., J. Chromatogr. 437:161-175, 1988). The metabolite fraction was analyzed by GC-MS using a 30 m DB-5 capillary column. Three μL were injected splitless at 80°C; the split valve opened after 0.5 min; the oven programmed @ 4°C/min to 300°C; 45-450 amu scanned per sec.

More than 150 metabolites were identified as alcohols or phenols in the PBCO-injected halibut (Table 1); however, a solvent-injected halibut had low levels of a few metabolites. An ion chromatogram of the phenanthrene metabolites from the bile is shown in Figure 1. Spectra of 9-anthracenemethanol standard and of C1-, C2-, and C3-substituted phenanthrene-OHs (PHN-OH) from the bile are shown in Figure 2.

This work provided a reference pattern for the successful determination of metabolites of petroleum-related ACs in bile samples from fish captured in PWS (Krahn et al. in preparation).

ANALYSIS OF AN EGYPTIAN MUMMY RESIN BY FAST ATOM BOMBARDMENT
MASS SPECTROMETRY AND GC/MS.

Mark L. Proefke and Kenneth L. Rinehart
School of Chemical Sciences,
University of Illinois at Urbana-Champaign, Urbana, IL 61801.

Recently, an Egyptian mummy was acquired by the University of Illinois World Heritage Museum. A portion of the resinous material recovered from its wrappings was subjected to mass spectrometric analysis to determine its composition and to assist in determining the mummy's age. Since the resin sample was expected to contain any of several di- or triterpenoic acids, fast atom bombardment (FAB) was chosen as the mass spectrometric ionization technique due to its ability to produce strong molecular ions with these polar, nonvolatile compounds. The low resolution FAB mass spectrum of the resin acids isolated by base extraction is shown in Figure 1. No peaks were observed above m/z 400, indicating a lack of triterpenoic compounds. The molecular formula obtained from high resolution measurements of peaks m/z 299, 315, and 331 (Table 1) contained twenty carbons, characteristic of diterpenoic acids. The molecular formula of the largest peak, m/z 315, contained one more oxygen and two less hydrogen atoms than the common diterpenoid dehydroabietic acid, 1 (Scheme I), suggesting that this unknown acid may be an oxo derivative. The location of the oxo group was determined to be on C-7 by comparison of analogous FABMS/MS daughter ions of the m/z 315 peak to EI fragments and structures of methyl dehydroabietate reported by Enzell and Wahlberg[1]. The presence of 7-oxodehydroabietic acid, 2, was confirmed by comparing the FABMS/MS spectrum of the methyl ester of the unknown with that of an authentic sample. The m/z 299 and 331 peaks were determined by FABMS/MS to be due to two additional oxidation products of dehydroabietic acid, Δ[double bond]6-dehydroabietic acid, 3, and 15-hydroxy-7-oxodehydroabietic acid, 4. The three peaks at m/z 253, 269, and 285 corresponded to loss of COOH and H from the three parent acids. The presence of these characteristic diterpenoids indicates that the base of the mummy resin is a pine pitch obtained from one or more species of conifers.

A problem appeared in determining the mummy's age in that the decorations on the mummy's wrappings suggest that it is from the Roman period of ancient Egypt (100 - 350 A.D.), while a carbon-14 date of 190 B.C. places the mummy in the Ptolemaic period. GC/MS of the neutral fraction identified a series of n-alkanes with chain lengths of 19 to 33 carbons. The finding of similar amounts of odd and even hydrocarbons as shown in Figure 2 suggests a petroleum product as their source as opposed to an insect or plant wax. The only petroleum product available in Egypt at this time was bitumen, a highly oxidized and weathered asphalt imported from regions surrounding the Dead Sea. The use of bitumen in mummification has often been debated; however, its use in later mummies, such as this mummy from the Roman period, has been documented[2]. Confirmation of the addition of bitumen was obtained by trace metal analysis of the resin sample. The elements vanadium, nickel, and molybdenum are characteristic of petroleum products such as
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

...bitumen [2]. The presence of 65.9 ppm vanadium, 33.4 ppm nickel, and 17.4 ppm molybdenum in the sample support the addition of an ancient carbon source such as bitumen and would explain the inconsistent carbon-14 date obtained for this mummy.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Sarah Wisseman of the University of Illinois Program on Ancient Technologies and Archaeological Materials for the mummy resin sample and the invitation to participate in this program; Dr. Curt Beck of the Amber Research Laboratory, Vassar College, for authentic samples of dehydroabietic acid and 7-oxodehydroabietic acid; and the University of Illinois Mass Spectrometry and Microanalytical Laboratories.

Support for this work was provided in part by a grant from the National Institute of General Medical Sciences (GM27029) and in part by the University of Illinois University Scholars Program. M.L.P. would like to thank the Department of Education for fellowship support.

[Diagram of Scheme I]
A PENTAQUADRUPOLE STUDY ON THE GAS-PHASE REACTIVITY OF ACYLIUM AND OXONIUM IONS AND SOME SULFUR ANALOGS

Marcos N. Eberlin and R. G. Cooks, Purdue University, Department of Chemistry
West Lafayette, IN, 47907.

Acylium and oxonium ions constitute two of the most important classes of gas-phase ions. To explore their chemistry, various acylium ions (a) R=H, CH₃, C₂H₅, n-C₃H₇, Ph, p-CH₃O-Ph, p-NO₂-Ph, OH, OCH₃, Cl, NHCH₂N(CH₃)₂, α-β unsaturated acylium ions (b) R,R'=H, CH₃, i-C₃H₇, and (c), oxonium ions (d) R=H, CH₃, C₂H₅ and (e) X=O and some sulfur analogs (e) X=S, (f) R=H, NH₂, CH₃ and (g) were prepared and mass-selected. Their ion/molecule reactions with isoprene and 1,3-dioxolanes were studied in a pentaquadrupole mass spectrometer (Figure 1). This instrument is particularly useful for studies of ion/molecule reactions since two separated reaction regions are available so that either ion/molecule reactions or collision dissociation can be performed in each region when applying any of the fifteen MS³ scans available.

Acylium ions (a) react with isoprene by two competitive reactions, proton transfer and [4+2*¹] Diels-Alder cycloaddition at the CO triple bond (Scheme 1), as exemplified for the acetyl cation in Figure 2, the cycloaddition reaction leading to m/z 111. The other products are due to proton transfer (m/z 69) and subsequent reactions involving protonated and neutral isoprene. The relative extent of these two reactions is greatly affected by the nature of the substituent group (R). The α-β unsaturated acylium ion (b, R,R'=H) react mainly at the double bond, the adduct having enough internal energy to fragment by CO loss. The C≡O⁺ moiety acts as an olefin activating group. Substitution at the C≡C double bond favors cycloaddition at the C≡O⁺ triple bond. Ion c reacts with isoprene at the C≡N double bond to form an abundant cycloaddition product. This product does not fragment by loss of CO as expected by the low stability of the nitronium ion which would be generated.

Scheme 1

The thioacetyl cation (f, R=CH₃) also reacts predominantly by [4+2⁺] cycloaddition. Contrary to the behavior of oxonium ions, which undergo proton transfer reactions, the sulfonium ions react with isoprene to give mainly the cycloaddition products. Acylium (Figure 3), oxonium, thioacylium and sulfonium ions undergo a reaction with 1,3-dioxolanes which formally corresponds to oxirane addition. The mechanism of reaction for acylium ions is assigned as initial O-acylation of the dioxolane, followed by loss of an aldehyde and recyclization.

The sequential product MS² scan was applied to obtain structural information on the ion/molecule products, which helped both in assigning reaction mechanisms, as well as in characterizing these ions. For instance, the fragmentation to the benzoyl cation (m/z 105) displayed in the MS² spectrum of the cycloadduct of ion e (Figure 4), which occurs in a process involving phenyl migration, allows its identification as the product of reaction at the C=N double bond. Also, the structures of the oxirane addition products in the reaction with 1,3-dioxolanes is revealed by the fragmentation displayed in the MS² spectra. The similarity of the MS² spectra for acylium and thioacylium ions with the CID product spectra of ions h shows that this is the product structure while comparison with the CID product spectrum for O-methylated 1,3-dioxolane indicates that oxonium ions yield a mixture of ions (i) and (j). The reactivity with isoprene and 1,3-dioxolanes allows easy characterization of these important gas-phase ions.
Ions with formally separated radical and charge sites (distonic ions) are of wide current interest. However, the knowledge on the properties of distonic ions is almost exclusively limited to highly excited and short-lived species. For example, thus far the ion-molecule reactions of only three β-distonic ions have been investigated (1-3).

We have used a dual cell FT-ICR mass spectrometer to synthesize and study long-lived distonic ions with one or more heavy atoms between the charge site and the radical site. For all the distonic ions that have a protonated heteroatom, fast proton transfer dominates the bimolecular reactions. These distonic ions behave like the corresponding even-electron ions, i.e., the β-distonic isomer of ionized ethanol shows reactivity similar to that of protonated ethanol, the distonic form of ionized trimethyl triphosphate behaves like protonated trimethyl triphosphate, and the distonic isomer of ionized ethyl acetate behaves like protonated γ-butyrolactone. The distonic ions that are not acids, e.g., the ring-opened form of ionized trimethylene oxide (CH₂CH₂O=CH₂⁺) and the ring-opened form (4) of ionized cyclobutanone (CH₂CH₂CH₂C=O⁺) undergo radical type atom and group abstraction reactions with ketones, aldehydes, H₂S and dimethyl disulfide. Bond formation occurs at the radical site of the ion in these reactions. Evidence for one of the reactions is presented in Figure 2 that compares the CAD spectra of two reference ions (b, c) to that (c) of the product ion from hydrogen atom abstraction from acetone by CH₂CH₂CH₂CO⁺ (Figure 1).

Overall, most of the distonic ions studied are clearly less reactive than their conventional radical cation counterparts. Bimolecular reactions involving neutral reagents with low ionization energies and relatively high proton affinities or low homolytic bond energies (e.g., dimethyl disulfide, cyclohexanone, trimethyl phosphite) proved to be useful in distinguishing distonic ion structures from conventional radical cations. For example, while the unrearranged molecular ions of organic ketones undergo charge exchange at collision rate with dimethyl disulfide, the ring-opened isomer of the molecular ion of cyclobutanone preferentially abstracts a CH₂S-group in a radical type reaction (k⁺/k⁺CH₂S = 0.4), accompanied by slow dissociative electron transfer (Figure 3).

DISTINGUISHING PROTONATED PROPYLENE OXIDE AND PROTONATED PROPANAL IN FT-ICR

Peiping Lin and Hilkka Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47907

The intrinsic stability of protonated epoxides is of wide interest, in part because of the great importance of acid-catalyzed reactions involving opening of an epoxide ring in solution, in biological systems, and in chemical ionization mass spectrometry. The energy barrier of the isomerization of protonated propylene oxide to protonated propanal has been estimated to be very low. Distinguishing these two isomers has not been successful.¹

Multistage mass spectrometry experiments with a dual-cell Fourier transform ion cyclotron resonance device were employed to generate the \([C_3H_7O]^+\) isomers with different amounts of internal energy through the use of a series of reagents ions with various gas-phase acidities. The relative stabilities and the structures of the ions generated in these proton-transfer reactions were examined using energy-resolved collisional activation experiments (Argon, 5-100 eV lab.) and ion-molecule reactions with H₂S.

The energy-resolved mass spectra of the epoxide ion are strongly dependent on the exothermicity of the proton transfer reaction used to generate the ion. Protonated propanal does not show similar sensitivity. Both qualitative and quantitative differences are seen in the data for the different isomers. However, the spectra observed for the epoxide ion with average internal energy over 4.5 kcal/mol were similar to those of the protonated propanal (see Figure). This supports the earlier estimation² that the barrier for ring-opening of protonated propylene oxide is about 5 kcal/mol. The dissociation products of protonated propylene oxide and protonated acetone are similar when only a few activation collisions are employed. This suggests that under these conditions, protonated propylene oxide undergoes ring opening to give an intermediate \(\text{CH}_2\text{CH(OH)}\text{CH}_3\) which is common with protonated acetone. In analogy with earlier results obtained by others on protonated ethylene oxide,³ protonated propylene oxide reacts with H₂S by an exothermic reaction with an activation energy of about 4 kcal/mol. This reaction involves loss of H₂O from the collision complex. Protonated propanal does not react with H₂S.

Electrophilic aromatic substitution (EAS), unlike nucleophilic substitution, proceeds largely by a single mechanism (1). This mechanism, known generally as the arenium ion mechanism, involves electrophilic attack to yield an arenium ion (sigma complex) followed by the departure of the leaving group in the final step (2). Although most electrophilic aromatic substitutions are thought to proceed via the arenium ion mechanism, the participation of Pi-complex intermediates on the potential energy surface can play a role, though to what extent is still up for debate.

One supposition emerging from this debate is that the transition state for EAS is not a rigidly fixed one always resembling the arenium ion. Instead, the transition state may be earlier on the reaction coordinate and resemble starting materials as an oriented Pi-complex. This was found to be the case for gas-phase EAS of alkylated benzenoid species (3).

Our interest in this mechanistic chemistry has motivated the present study in which the scope is to access whether Pi-complexes play a role in the gas-phase EAS of heteroaromatics species such as thiophene, furan, and pyridine.

MS/MS experiments were performed on a Kratos MS-50 Triple Analyzer of EBE geometry, utilizing a high pressure chemical ionization source to conduct bimolecular reactions in the gas phase. Three types of experiments were performed: (a) the heteroaromatic was reacted with alkyl carbenium ions so as to perform gas-phase EAS, (b) alkyl heteroaromatics were protonated via chemical ionization to form identical mass ions to those formed in the aforementioned experiments so as to make direct comparison, and (c) the alkylated heteroaromatic compounds EI spectra were obtained so as to catalog the fragmentation processes intrinsic to the radical ions. In each of the above type of experiment, the ions of interest were collisionally activated and their MIKES spectra obtained.

The protonated alkyl heteroaromatic ions were found in all cases to differ from the corresponding ions formed via gas-phase EAS, which is unlike the case between protonated alkyl benzenes and their corresponding gas-phase EAS analogs. This is readily explainable in that the CI protonation of alkyl heteroaromatics will most probably protonate at the heteroatom, generating a sigma complex. That the ions formed via gas-phase EAS are different from the protonated alkyl heteroaromatics means either that the sigma complex formed via protonation of the heteroatom is not equivalent to the sigma complex formed in EAS, or that the ions formed in EAS are a composite of sigma complex ions and other ionic contributors.

The ions formed via gas-phase EAS share some of the features of the protonated alkylheteroaromatics, but possess two salient fragmentation processes that are unique: loss of a neutral alkene, and loss of the entire alkyl group as a carbenium ion. These two processes trade off as a function of alkyl group chain length -- the longer the alkyl group the greater the propensity for alkyl carbenium ion loss.

The interpretation of the above two findings draws heavily from previous work. The loss of the alkene is most probably a process intrinsic to a sigma complexed species (3, 4). The loss of the alkyl carbenium ion is most probably intrinsic to a Pi-complex (3). The interplay between the two fragmentation processes is logical in that the extent of Pi-complex formation should be a function of incipient carbenium ion stability. The implication then being that both sigma and Pi-complexes potentially play a role in the gas-phase EAS of heteroaromatic compounds.
THIOPHENE + CARBENIUM ION DISSOCIATION PATHWAYS AS A FUNCTION OF CHAIN LENGTH

A GAS-PHASE STUDY OF THE REACTIONS OF PROPENE AND CYCLOPROPA NE RADICAL CATIONS WITH NEUTRAL ETHYLENE

David L. Vollmer, R. N. Hayes and M. L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588.

Early ion-molecule studies have principally dealt with homogenous (i.e., reaction of a radical cation with its corresponding neutral) systems[1,2]. The goal of this study is to understand the mechanism of gas-phase products formed in mixed systems of small olefin and cycloalkane radical cations with other olefins. These reactions are of particular interest because they may react to form a distonic ion (i.e., charge-radical site separate radical cation).

Three tools were used to obtain kinetic and structural information of the reaction products. First, Fourier Transform Mass Spectrometry (FTMS) coupled with a pulse valve interface was used to determine changes in the reactants and products with respect to time. Second, chemical ionization mass spectrometry was used to determine if a covalent product could be collisionally stabilized. Third, tandem mass spectrometry combined with charge stripping was used to determine the structure of the products formed in a high pressure source.

The FTMS experiment was used to study the kinetics of the reactant and product ions. Ethylene was introduced into the FTMS cell at a constant pressure of 1x10⁻⁷ torr with propene pulsed in at a partial pressure of 2x10⁻⁷ torr. The ionization beam was turned on 100 msec after the pulse event so as to achieve maximum reactant ion population. All ions except for those of propene were ejected 300 msec after ionization in order to eliminate any interfering ion-molecule reactions occurring within the cell. The kinetics were investigated by varying the delay time between the ejection and excitation.

The relative abundance of the propene radical cation (m/z 42) decreased while the m/z 55, 41, and 67 ion abundances all increased from 5 msec to 10 sec (See Figure 1). The m/z 55 and 41 ions are probably second order reaction products with the m/z 67 ion appearing around 2 sec as a higher order reaction product.

Tandem mass spectrometry combined with collisional activation has showed the adduct possesses a significant degree of covalency. When C₃H₆ radical cations from either propene or cyclopropane are reacted with ethylene in separate experiments, a product, C₅H₁₀⁺, is formed which fragments upon collisional activation to give the following structurally significant ions: m/z 69 [M - H]⁺, m/z 55 [M - CH₃]⁺, m/z 42 [M - C₂H₄]⁺, and m/z 41 [M - C₂H₄]⁺ (See Figure 2).

Unfortunately, CAD is not informative in terms of distinguishing the ion-molecule reactions from the appropriate model compounds. Charge stripping has been shown to be more effective than CAD in differentiating C₅H₁₀⁺ isomers[3,4].

The charge-stripping experiments were performed in the narrow scan mode from m/z 30 to m/z 36 with diatomic oxygen as the collision gas. The results correspond nicely with those of Holmes; most of the C₅H₁₀⁺ isomers and the two ion-molecule products are distinguishable (See Figure 3). The propene-ethylene charge-stripping mass spectrum closely resembles that of 2-methyl-2-butene spectrum; the presence of a doubly-charged molecular ion is particularly distinctive. The cyclopropane-ethylene spectrum is similar to that of 1,2-dimethylcyclopropane which also shows a doubly-charged molecular ion.
On the basis of the charge-stripping experiments, we propose that the C$_3$H$_6$ radical cations react with neutral ethylene to form a distonic intermediate that isomerizes by 1,2-H$^+$ and 1,2-H shifts (See Figure 4). The propene-ethylene mechanism is in good agreement with Bower's earlier study of propene-propene[2].

Introduction

Gas phase polymeric ions are formed via consecutive addition-elimination (condensation) reactions between unsaturated parent ions with their precursor compounds. One interesting possibility that has not been explored yet is the study of ionic polymerization within van der waals (vdw) clusters of the monomer molecules. The reaction can be initiated following the ionization of a neutral cluster beam formed in a supersonic expansion. Addition and elimination reactions can take place within the ionized clusters resulting in a product ion distribution which reflects both the stability of the polymeric ions and the kinetics of the reaction.

Experimental

Neutral clusters, generated by pulsed adiabatic expansion in a supersonic cluster beam apparatus, were ionized by EI and subsequently mass analyzed in a quadrupole mass spectrometer.¹

Results

Figure 1 displays a segment of the cluster spectrum which includes ions smaller than the dimer, C_{10}H_{16}^{+}. The ions observed are consistent with their formation by eliminative ion-molecule reactions between isoprene radical cation and neutral isoprene within the clusters. These ions are similar to those observed by Kaschers and Cooks from their ion-molecule reactions after 300 ms reaction time in an ion trap². These ions are the characteristic fragment ions observed in the daughter spectrum of limonene, which is formed by a Diels - Alder reaction of isoprene radical cation with its neutral molecule. A magic number has been observed for C_{14}H_{21}^{+} ion and attributed to a stable cyclic structure which can be derived from a series of ion-molecule consecutive addition-elimination reactions. Our results suggest that cationic polymerization of isoprene proceeds via the formation of the stable dimer C_{10}H_{16}^{+} which, most likely, has a structure similar to limonene and can undergo further addition reactions to generate larger ions.

Figure 2 displays a representative segment of a typical 70 eV EI mass spectrum of a cluster beam of vinyl chloride. The precursor ions C_{2}H_{3}Cl^{+} and C_{2}H_{3}^{+} undergo condensation ion/molecule reactions with neighboring C_{2}H_{3}Cl molecules in the cluster with subsequent elimination of neutral species such as HCl, Cl, CH_{2}Cl and C_{2}H_{2}. We observe that the elimination reactions initiated by C_{2}H_{3}Cl^{+} terminate after three successive steps; each involving elimination of HCl or Cl. The product ions are of the general formula C_{6}H_{k}Cl^{+}, k=9-13. These ions can rearrange to some stable structures and this may account for the lack of further elimination reactions.

ISOTOPE EFFECTS FOR BASE-PROMOTED, GAS-PHASE PROTON TRANSFER REACTIONS

Joseph J. Grabowski and Xueheng Cheng
Department of Chemistry, Harvard University
Cambridge, MA 02138

Proton transfer reactions are among the most basic, the most common and the most important of chemical transformations; despite their apparent simplicity we still have much to learn about this most fundamental of all chemical processes. Active interest in understanding the underlying principles of organic proton transfer reactions continues because of efforts being made to develop the theory of elementary chemical processes, because of the resurgence of interest in mechanistic organic chemistry and because of the dynamic role played by proton transfers in biochemical transformations. As organic chemists, we have used the flowing afterglow technique to gain an appreciation of the fundamental issues involved in reaction mechanisms by examining such processes in a solvent-free environment under thermally-equilibrated (300 K) conditions. Recent characterization of the facile production of both acetate and the monoenolate anion from the interaction of hydroxide or fluoride with acetic acid reinforces the idea that we have much yet to learn about proton transfers/proton abstractions in general [1]. Earlier work by Riveras and co-workers [2] on competitive H vs D abstraction from a-d-toluences and by Noest and Nibbering [3] on competitive H vs D abstraction from α,α,α-,δ-δ-acetone, in combination with the acetic acid results, challenged us to assemble a comprehensive picture of the competitive nature of proton transfer reactions for anionic base-promoted processes.

We have carried out a broad survey of the "order-of-magnitude" isotope effects that one will see for a large number of systems. Here, we will concentrate on anion-induced proton abstraction reactions from a binary mixture of acetone and δ-δ-acetone, from α,α'-δ-δ-acetone and from α,α,α,-δ-δ-acetone. Such systems allow us to examine inter- vs intramolecular isotope effects, to examine the intramolecular isotope effects for a 1,3 competitive system and to consider isotope effects for hydrogen vs. deuterium on a common carbon center. It quickly became apparent that the bases used should be classified according to structure, not just according to exothermicity. Data for three classes of anions interacting with the binary mixture of acetones are shown on the next page. The first graph describes localized heteroatomic anions (RX-) and shows that there is essentially no isotope effect when the reaction is reasonably exothermic while the isotope effects rises rather abruptly to a value of ca. 1.7 for a thermoneutral reaction. The second graph is for localized carbanionic bases (symbolized HnC-) and shows that the isotope effects are considerably larger here than in the first case; kH/kD is about 1.5 for exothermic reactions and rises more gradually to a much higher value for thermoneutral reactions. These latter reactions are also a bit slower than those represented in the first graph. The final graph is for delocalized carbanions and is divided into two parts; benzylic anions give an isotope effect of ca. 5-7 while allylic anions give a value in the 1.5-3 range. All-in-all, these data demonstrate the sensitivity of isotope effects as a probe of the detailed nature of proton abstraction reactions and promise to provide considerable insight into the dynamics of these fundamental reactions.

DETERMINATION OF GAS PHASE BASICITIES OF CARBENES
BY FT/ICR MASS SPECTROMETRY

Charles W. Ross III†, Zhenmin Liang‡, Matthew S. Platz† and Alan G. Marshall†,§

Departments of Chemistry† and Biochemistry,§ The Ohio State University
120 West 18th Avenue, Columbus, Ohio 43210

For about 20 years, experimental techniques such as ion cyclotron double resonance (ICDR) have made it possible to quantitate the gas-phase thermochemistry of proton transfer reactions. By comparing the solution and gas-phase basicities, one can distinguish the intrinsic molecular basicity from solvation effects. Moreover, heats of formation and bond dissociation energies are in turn helpful in determining molecular stabilities and energetically favorable reaction pathways.

Carbenes, R–C–R', are important short-lived intermediates in condensed-phase organic synthesis, photochemistry, and atmospheric chemistry. For example, cyclopropenylidene is the most abundant hydrocarbon in Interstellar space, and other carbenes have been detected in Interstellar and circumstellar space [2,3]. Although proton affinity (PA) and gas phase basicity (GB) have been determined for a wide variety of organic compounds [1], such data on carbenes have to date been limited to a few chloro- and fluorocarbenes [4-6].

In this abstract, we report the formation and detection in a Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometer of several protonated carbenes, CHRR', produced by electron ionization of neutral precursors provided by Professor M. S. Platz. The electron energy is set just above the appearance potential of the carbonium ion. The ions are then transferred from the source region of a dual ion trap to the analyzer region, where a stored waveform Inverse Fourier transform (SWIFT) rf excitation ejects all ions except the protonated carbene. Since the concentration of gas-phase neutral carbene, CRR', is vanishingly small, the gas-phase basicity, GB = ΔGrx = RT loge Keq, cannot be determined directly from the equilibrium constant, Keq, for the reaction.

\[ \text{CHRR'}^+ + B = \text{CRR'} + \text{BH}^+ \] (1)

In which B is a volatile reference base. It is therefore necessary to "bracket" the gas-phase basicity by reacting the protonated carbene with a series of reference bases of different known basicities, to determine the threshold basicity at which BH' is observed (i.e., the forward reaction shown in Eq. 1). A gaseous neutral reference base is injected into the analyzer region of the chamber by means of a pulsing valve, and allowed to react with the protonated carbene for hundredths to tens of seconds, after which the product ions are excited and detected. If BH' is observed (Eq. 1; Figs. 1,2), then one infers that the basicity of the carbene is lower than that of the reference base. In this way, the gas phase basicities of several carbenes have been determined. In cases for which the reference base exhibits self-protonation, thereby obscuring the confirmation of proton transfer from the carbonium ion, deuterated precursors were employed. Our proton affinities are: dichlorocarbene, 196.1±0.2; dimethoxycarbene, 171.3±3.3; and phenylcarbene, 173.0±1.7 kcal/mole respectively (Fig. 3); the latter two values are still being refined. This work was supported by NIH (GM-31683) and Ohio State U.

MASS INDEPENDENT ISOTOPE EFFECTS IN THE FORMATION OF $OJ^+$

K.S. Griffith and G.I. Gellene
Department of Chemistry and Biochemistry
University of Notre Dame
Notre Dame, IN 46556.

Motivated by relevance to interstellar and upper atmosphere chemistry, the termolecular association reaction:

$$O_2^+ + O_2 \rightarrow Oj^+$$

has been the subject of experimental and theoretical investigations for almost thirty years. In 1963, Curran (1) reported an appearance potential for $Oj^+$ produced in reaction 1 of 16.9± 0.1, almost 5 eV greater than that of ground state $O^+$. On the basis of this observation Curran suggested a role for the metastable $a^4\Pi_u$ electronic state of $Oj^+$ in reaction 1, although no consideration was given to the origin of the unusual requirement of electronic excitation for the production of a cluster ion. Unfortunately, no notice of the $Oj^+$ appearance potential seems to have been taken by other workers in subsequent kinetic studies of $Oj^+$ formation leaving the detailed nature of the apparent electronic energy requirement unknown. Very recently, Smith et. al. (2) observed formation of $Oj^+$ by reaction 1 where the $Oj^+$ was produced by a resonance-enhanced multiphoton ionization (REMPI) scheme which is known to produce only electronic ground state ions. Thus the results of Smith et. al. can be compatible with those of Curran only if REMPI and near threshold electron ionization (EI) produce ion state populations which differ in some critical aspect affecting the kinetics of reaction 1 and this difference is preserved in "thermalizing" collisions of the ions. The present work addresses this question by reexamining the threshold EI production of $Oj^+$ paying particular attention to the production of cluster ions containing a single $^{17}O$ or $^{18}O$ atom from $O_2$ molecules with a natural abundance isotopic distribution.

The intensity $^{32}Oj^+$ and $^{64}Oj^+$ (denoted $I_{32}$ and $I_{64}$ respectively) as a function $E_e$ is shown in Figure 1. As $E_e$ is increased above the $O_2$ threshold, $I_{32}$ initially increases substantially faster than does $I_{64}$ indicating that the simple kinetic description: $d[Oj^+]/dt = k_1[O_2][O_2]$ is not valid at low $E_e$. This is a remarkable result considering that for $E_e < 16$ eV, no electronically excited states of $Oj^+$ can be produced and the vibrationally excited levels of the ground electronic state produced are efficiently relaxed to the $v = 0$ level under our ion source conditions. Further evidence that the ionizing conditions have a significant effect on clustering efficiency is provided by the pronounced increase in $I_{64}/I_{32}$ at $E_e = 19-20$ eV in qualitative agreement with the results of Curran.

Fig. 1 Intensity of $Oj^+$ and $Oj^+$ as a function of ionizing energy.

Fig. 2 Intensity ratios of isotopically substituted $Oj^+$ as a function of ionizing energy.
The intensities of O$_j^+$ ions containing one $^{17}$O (les) or one $^{18}$O (lee) relative to the intensity of the all $^{16}$O containing species ($^{16}$O$_4$) as a function of $E_e$ is shown in Figure 2 where the dotted lines indicate the expected ratios based on natural isotopic abundance. At low $E_e$ reaction 1 shows a strong kinetic isotope effect with the the intensity mixed isotopic O$_j^+$ ions approaching a ten fold enhancement relative to natural abundance expectations near threshold ($E_e \approx 12$ eV). Furthermore the enhancement is mass independent with the $^{16}$O$^3$/$^{16}$O$^4$ ratio always observed to have its natural abundance value. As $E_e$ is increased, the $^{16}$O$^3$/$^{16}$O$^4$ and $^{16}$O$^4$/$^{16}$O$^6$ ratios continually decrease and natural abundance values are observed for $E_e \geq 40$ eV. The most dramatic change in the $^{16}$O$^3$/$^{16}$O$^6$ and $^{16}$O$^6$/$^{16}$O$^8$ ratios occurs near the threshold $O_2^3(a^3\Pi_g)$ production ($E_e \approx 16$ eV) suggesting that the $E_e$ dependence of the kinetic isotope effect in reaction 1 results from the increasing participation of $O_a^3$ originally produced in the $a^3\Pi_g$ as $E_e$ is increased. Phenomenologically, the results indicate a strong kinetic isotope effect favoring mixed isotopic cluster ion formation when the $O_2^3(a^3\Pi_g)$ is produced by $E_1$ directly and little or no kinetic isotope effect when the $O_2^3(a^3\Pi_g)$ arises from relaxation of metastable $O_2(a^3\Sigma_u^-)$.

A fundamental understanding the results requires that the following three points be addressed: (1) A characteristic of the $O_a^3(a^3\Pi_g)$ ions must be identified which can give rise to largely varying state specific values of $k_1$. (2) The effect of this characteristic on $k_1$ must be strongly isotopic dependent. And (3) the population distribution of ions with regard to this characteristic must depend on the details of ion formation and must be largely preserved in a collision environment. Termolecular association reactions are generally considered to consist of two bimolecular energy transfer reactions. Ordinarily all of the reactions are considered to occur on a single Born-Oppenheimer surface correlating with ground state products. However, there is no rigorous reason why this should be so. If, for a particular set of collision conditions, the O$_2^3$/O$_2$ collision preferentially took place on a repulsive surface, then the (O$_j^+$)* collision complex would be very short lived and cluster formation would be inhibited. We have developed a permutation-inversion (PI) symmetry group appropriate for correlating rotational-vibrational-electronic-translational wave functions for O$_2^3$/O$_2$ with the electronic wave functions of (O$_j^+$)*. The specific correlation depends on whether the angular momentum quantum numbers $J^+ - S^+$ for O$_j^+$, N for O$_2$, and L for their relative orbital motion are even or odd as listed below.

Considering that the ground state of O$_j^+$ in C$_{2h}$ symmetry is B$_u$, Table I indicates that indicates that O$_j^+$ ions in a state with $J^+ - S^+ = odd$ having an odd L collision with an O$_2$ molecule will access the ground electronic state of O$_j^+$ and lead to termolecular association more efficiently than any other type of collision. This restriction vanishes when one of the diatoms is isotopically heteronuclear. Due to this symmetry restriction the kinetics of reaction 1 depends critically on isotopic composition and mode of ionization.

OBSERVATION OF A HIGH ENERGY METASTABLE STATE OF O$_2$ FOLLOWING O$_2$/ALKALI METAL CHARGE EXCHANGE

K.S. Griffith and G.I. Gellene, Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556.

The title reaction has been studied previously by several groups$^{1-3}$ using neutralized ion beam techniques which were sensitive only to dissociative processes. In those experiments the primary neutralization products were identified as the $^1\text{P}_0$ Rydberg levels which rapidly predissociate. We have investigated this reaction using a neutralized ion beam technique which is sensitive to both dissociative and nondissociative products. Briefly, ions formed by electron ionization in a high pressure source are accelerated to 5 keV and magnetically mass-resolved. The ions then enter a neutralization chamber containing a few mTorr of metal atoms (Na or K). Both neutrals and ions exit the chamber, and the ions are deflected by a pair of electrostatic plates. The neutral beam, which spreads as species dissociate, travels to a translatable detector, which samples the intensity as a function of the angle ($l(\theta)$ vs $\theta$). Metastable products show up as a spike of intensity centered around $\theta=0$. A typical profile is shown in Figure 1.

Our results for the dissociative products are in complete agreement with previous work. Surprisingly, however, undissociated O$_2$ in a long-lived metastable state was also observed. By measuring the dependence of the normalized intensity of the metastable ($I_m/1^0$) as a function of time after formation, a dissociative lifetime of $\sim$2.8 $\mu$s was obtained (See Figure 2).

---

**Figure 1** $l(\theta)$ plotted as a function of $\theta$. O$_2$ from 5:1 Ar:O$_2$ neutralized on K.

---

**Figure 2** $\ln$ of normalized metastable intensity as a function of time. O$_2$ from 5:1 Ar:O$_2$ neutralized on K or Na. Slope $=-(\tau)^{-1}$, which gives a lifetime of the metastable, $\tau \sim 2.8$ $\mu$s.
Because the metastable relaxes dissociatively, it cannot be identified with any of the known metastable states of O$_2$, all of which lie below the first dissociation limit. The ion states which could be responsible for the metastable species include O$_2^+$ ($^4\Pi_u$) and O$_2^+$ ($^2\Sigma^+_g, v=1,2$). To examine the role of different ion states in the metastable formation, various mixtures of Ar and O$_2$ were used. The ion source has a resonance time of 0.4 µs, and this allows the ions to undergo quenching reactions before exiting the source; thus by varying the Ar/O$_2$ ratio, we can alter the amount of O$_2^+$ ($^4\Pi_u$) and O$_2^+$ ($^2\Pi_g, v=1,2$) exiting the source. In all cases, the normalized intensity of the metastable remained constant, indicating that the metastable species is not produced through either O$_2^+$ ($^4\Pi_u$) or O$_2^+$ ($^2\Pi_g, v=1,2$). However, these results did not exclude high vibrational states of the ground state. To test the effect of high vibrational excitation in the ion on metastable production, a mixture of Xe and O$_2$ was used. Xe is an excellent quencher of both O$_2^+$ ($^4\Pi_u$) or O$_2^+$ ($^2\Pi_g, v=1,2$), and the charge transfer from Xe$^+$ to O$_2$ is very efficient. These conditions allow us to maintain the O$_2^+$ signal intensity even near threshold for production, while eliminating the ion states we are not interested in. By varying the ionizing electron energy, we can vary the high vibrational excitation. In Figure 3, the normalized metastable intensity is plotted as a function of ionizing electron energy. It is easily seen that high vibrational excitation favors production of the metastable.

Finally, we have investigated the possibility that the metastable species is a high Rydberg level of O$_2$. In order for a Rydberg level to account for the ~ 2.8 µs lifetime, the principle quantum number $n$ must be greater than 10. By attempting to field ionize the metastable species, it was determined that $n$ could not be greater than 14. Thus, for a Rydberg level to explain the observation of a metastable species, $n$ must be between 10 and 14, and not greater than 14. Since these energy levels are so closely spaced, this is extremely unlikely.

No previously observed state of O$_2$ can account for the observations made in this investigation. Currently we are considering Rydberg-valence and valence-valence interactions in the energy region of the first Rydberg levels of O$_2$ as a possible explanation.

FORMATION AND CHARACTERIZATION OF CROWN ETHER COMPLEXES IN THE GAS PHASE

Simin Maleknia, Jeff Liou and Jennifer Brodbelt

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA, 02139
Department of Chemistry, University of Texas, Austin, TX 78712

The chemistry of macrocycles is important in understanding principles of host-guest chemistry in molecular recognition. In particular, crown ethers and their complexes are useful for modeling biologically relevant transport processes, and enzyme catalysis. Several mass spectrometric analysis of crown ethers and complexes have been reported. The present study compares the mass spectrometric characterization of crown ethers and their gas phase chemistries to several perfluorinated analogues.

Collision induced dissociation of protonated crown ethers, produced by chemical ionization, proceeded by successive losses of ethylene oxide units, and the assumption was made that the fragmented ions retained a cyclic structure. Perfluorinated crown ethers produced an abundant molecular ion in the negative mode and dissociated by the loss of \((C_2F_4O)_n\) units. The loss of two or more ethylene oxide units were more favorable than the unit loss, and the same trend held for the perfluorinated molecules.

Reactions with \(O_2\), \(CO\), and \(CO_2\) were examined since perfluorinated compounds show a high oxygen carrying capacity. Several crown ethers, acyclic ethers, and their perfluorinated analogues were tested and only the perfluorinated crown ethers produced adducts with oxygen. These oxygen adducts fragmented by loss of \((C_2F_4O)\) units, which indicated that these adducts are not just held by electrostatic forces but the bonding is at least as strong as ether linkages. A less abundant fragment series from the loss of the oxygen was also observed (Figure 1).

Some aspects of the negative ion chemistry of crown ethers have been investigated by ion/molecule reactions of halide ions. Abundant halide adducts were produced in the negative chemical ionization mode for a series of ethers, their perfluorinated analogues, and a thio ether \((1,4,7,10,13\text{-pentathiacyclopentadecane})\). The highly electronegative perfluorinated crown ethers only reacted with the fluoride ions, and CAD of the fluoride adduct proceeded only by loss of \((C_2F_4O)\) units. Other ethers examined showed adducts with all halides, however, the iodide and bromide adducts dissociated only to the halide anion. The fluoride adducts showed several crown-related fragment ions and the loss of \(HF\) was also observed. The effects of halide size and gas phase acidity are the properties that are under consideration for rationalization of the CAD behavior. The acidity of fluoride is substantially higher than the acidities of the other halides, so it has the greatest favorability of abstracting a proton from the crown ethers, resulting in \((M-HF)^-\).

Crown ethers have been investigated for alkali metal binding in solutions. The present study has focused on the size selectivity of crown ethers in the gas phase. LSIMS was used to form complexes of crown ethers and alkali metals. Collision induced dissociation of \([\text{alkali metal}]\text{halide}^+\) complexes of several crown ethers revealed that as the cavity size of crowns increase the binding ability for larger alkali metals increase. Another approach used the kinetic method to investigate the binding preference of the crowns with alkali metals. Crown ether adducts of mixed alkali metal dimers were generated in LSIMS mode by appropriate mixing of halide salts. This study suggested that the binding preference of crown ethers was highly correlated with cavity sizes. Table 1 summarizes data for 18-crown-6 and 15-crown-5. The solution stability constants in methanol or water for these crowns show the highest binding toward potassium, then cesium and sodium.

Gas phase recognition of ammonium and related substrates were examined by the formation of adducts of crowns with ammonium hydroxide, methyl amine, methyl hydrazine, and tosyl hydrazine. Collision induced dissociation techniques were used at collision energies of 0.4 keV and 7 keV. At high collision energies these complexes showed fragments indicative of strong interaction of the amine site with the crown ethers. Also, fragmented adducts of \((\text{crown} + 16)^+\) and \((\text{crown} + 32)^+\) were observed with methyl hydrazine and tosyl hydrazine, respectively. These fragmented adducts were not observed at low collision energies; however, the presence of a metastable ion suggested the strong binding of crowns and the amine sites.
ACKNOWLEDGEMENTS

We gratefully acknowledge the MIT Mass Spectrometry Facility and the Robert A. Welch Foundation for generous support of this research. Prof. Brodbelt extends thanks to the ASMS for a Young Investigator Award.
On the basis of current or planned work in several laboratories it is quite clear that the next major frontier in structural mass spectrometry involves the maturing of tandem mass spectrometry and the development of greater sensitivity, specifically the improvement in the signal-to-noise ratio, especially in terms of background noise. Several new instrument designs are in the developmental stage, e.g., multi-sector instruments with spatial array detectors and time-array detectors, Fourier transform ion cyclotron resonance (FTICR), quadrupole ion traps, and sophisticated time-of-flight instruments. Each instrument design possesses specific advantages, in terms of operating parameters and range of experiments, but it is too early to evaluate in detail the specific advantages/disadvantages of a particular instrument concept.

In this paper we describe a new instrument under development in our laboratory. The instrument incorporates a high resolution magnetic sector as MS-I (Kratos MS-50) and a reflectron time-of-flight (TOF) as MS-II. The instrument design is mechanically simple, operator friendly, and takes advantage of the high efficiency of pulsed ionization and time-domain data acquisition. Of particular importance is the applicability of this instrument concept to pulsed ionization/excitation methods such as matrix-assisted laser desorption and multiphoton ionization/dissociation.

The tandem magnetic sector/reflectron time-of-flight (TOF) instrument is shown in Figure 1. The instrument consists of a Kratos MS-50 and a home-built reflectron time-of-flight. The instrument is equipped with a continuous or pulsed 30 keV Cs+ ion gun (Phasor Scientific), an excimer laser (Questek model 2440) for performing pulsed laser desorption and/or photodissociation, and a Laser Science, Inc. cartridge type N2 laser (model VSL 337 and VSL 337ND). Time-of-flight spectra can be obtained by using a time-to-digital converter (TDC) (LeCroy model 4208 TDC), a 350 MHz digital oscilloscope (LeCroy model 9450), or a transient recorder (LeCroy model TR8828D 200 MHz digitizer). All of the TOF data acquisition modules are interfaced to PC/AT computers by using a National Instruments GPIB mainframe card. Event sequenceing for the various experiments is controlled by a EG&G Princeton Applied Research digital delay generator model 9650.

The reflectron TOF currently in use has a total flight path of 0.5 meters and the reflection angle
is approximately zero degrees. The advantages of a colinear reflectron are high ion transmission and high mass resolution in comparison to that obtained with larger (5°-20°) reflecting angles. The colinear arrangement is also convenient for positioning detectors to detect both neutrals and ions. For example, neutrals formed by metastable ion dissociation reactions, collision-induced dissociation (CID), or photodissociation in the region between MS-I and MS-II are detected by a microchannel plate detector (detector #2) positioned behind the reflectron. Ions are detected by the microchannel plate detector (detector #1) positioned at the entrance to the reflectron TOF.

Tandem MS-TOF Instrument

Figure 1.
Introduction

Fast atom bombardment tandem mass spectrometry of lithiated oligosaccharides has been shown to be a useful technique to determine the linkage position of disaccharides and oligosaccharides [1]. The monolithiated species of various selected disaccharides show a distinguishable pattern in the product ion scan [2]. As reported earlier, gentiobiose, the β-1,6 linked disaccharide, shows product ions of m/z 289, 259 and 229 which correspond to two-carbon (C2), three-carbon (C3) and a four-carbon (C4) chain neutral losses of the reducing end. Lactose, the β-1,4 linked disaccharide, shows only a C2 and a much less intensive C4 neutral loss. Laminaribiose, the β-1,3 linked isomer, forms only an ion at m/z 259 corresponding to a C3 neutral loss. The loss of the C3 neutral species producing a product ion at m/z 259 can be explained only if one considers a rearrangement prior to bond cleavage in the open hydroxy-aldehyde form of the reducing end of the disaccharide. The rearrangement consists of keto-enol tautomerization such that the carbonyl function is transposed from C1 to C2. Once the carbonyl group is located at the C2 position one can postulate a six membered ring transition state from which a retro-aldol rearrangement can be invoked thus giving the ion of m/z 259 [3]. Compared to single bond cleavages the steps involved in the rearrangement are clearly more time consuming. The various product ion scans of monolithiated laminaribiose and nigerose were presented and discussed.

Experimental

The instrument used in this work was a VG ZAB2-EQ [3] equipped with collision cells in the 1st, 2nd and 3rd field free region. A Cs+-gun operated at 25 kV was used to bombarded the sample. The acceleration voltage was 8 kV.

The samples were dissolved in water with a small amount of Li2CO3. The mixture was then added to a dithiothreitol/dithioerythreitol matrix (3/1).

Results and discussion

Figure 1 shows the various CID product ion scans of the monolithiated molecular ion of laminaribiose. The B/E scan represents the product ion scan in the 1st field free region. The ion of m/z 259 is absent. The rearrangement has not yet occurred during this short time. In the 2nd field free region scan, MIKE scan, the ion of m/z 259 is present. The ions of m/z 229 and m/z 215 in the B/E and the MIKE scan can be explained by high collision energy induced two bond cleavages. 18O-labelling studies of laminaribiose did show that the C4 neutral loss giving m/z 229 can take place either on the non-reducing or the reducing end of the disaccharides. The 18O-labelling experiments further showed that the C5 neutral loss giving rise to the m/z 215 takes place on the non-reducing end. Because the quadrupole product ion scan represents low energy CID processes, the C4 and the C5 neutral loss never show up in this scan.

Both the β and α 1,3 linked isomers gave the same results. The time frame of the experiment is shown in Figure 2. The time taken for an ion to arrive at a given part of the mass spectrometer is given by equation

\[ t = d \left( \frac{m}{2zeV} \right)^{1/2} \]

\[ \text{d} : \text{distance} \]

\[ m : \text{mass of a single ion} \]

\[ z : \text{charge of the ion} \]

\[ e : \text{elementary charge} \]

\[ V : \text{accelerating voltage} \]

Thus the time for the precursor ion to arrive at the gas cell of the 1st field free region is 2 μs. The precursor ion passes the MIKE cell at 55 μs and it arrives after 75 μs at the quadrupole gas cell. Corresponding to the above discussed product ion scans the rearrangement takes place within 50 μs of flight between the 1st and 2nd field free region. The time needed for the rearrangement in laminaribiose and nigerose is therefore about 50 μs.
Conclusion
The C3 neutral loss in laminaribiose and nigerose involves keto-enol tautomerization to form the carbonyl group in the C2 position in the hydroxy-aldehyde form of the reducing end of the disaccharide. Product ion scans from the 1st, 2nd field free region and in the quadrupole mass analyzer clearly showed that the rearrangement takes place in the gas phase between the 1st and the 2nd field free region of the mass spectrometer.

MATRIX CHEMISTRY AND BACKGROUND IONS IN FAB AND LIQUID SIMS

Kenny A. Caldwell and Michael L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304.

FAB MS and FAB MS/MS are established analytical techniques. The success of FAB (or liquid SIMS) for producing molecular weight information belies a significant understanding of the chemical events that occur upon keV particle bombardment. Based on ions observed in the low resolution spectrum of neat glycerol, and subsequent OH⁺ CIMS of irradiated glycerol, Field concluded that keV particle bombardment of glycerol produces new molecular species via recombination of matrix derived radicals (1). This conclusion was substantiated by GCMS analysis of bombarded glycerol (2).

We have used accurate mass measurements to assign elemental compositions, and MS/MS to characterize the "peak at every mass" background ions produced by keV particle bombardment of neat FAB matrices (3). Based on these experiments, we have identified a mechanism which accounts for the major background ions observed in glycerol and other common FAB matrices.

Iodization of the matrix radical recombination species produces parent or precursor background ions. These ions along with H⁺-bound matrix cluster ions lose stable neutrals such as H₂O and H₂CO to produce product background ions at lower mass. These relatively low mass, covalent species produce higher mass background ions by clustering with matrix molecules (3).

The matrix chemistry outlined above has two major analytical implications. The matrix derived free radicals may react with stable analyte derived free radicals, giving rise to additional peaks in the mass spectrum, possibly confusing a qualitative analysis. This could possibly lead one to conclude that the compound is "impure". Secondly, background ions increase the limit of detection for MS/MS and target compound analysis, reducing the appeal of quantitative FAB.

The FAB analysis of the herbicide atrazine illustrates the importance of understanding matrix chemistry. The FAB spectrum of the pure compound in 2-hydroxyethyl disulfide (HEDS, molecular weight = 154) shows abundant analyte specific ions in addition to the protonated atrazine molecular ion at m/z 216 (see figure 1). These ions (marked with a dot) can be accounted for by considering a mechanism based on the coupling of analyte derived radical species with matrix derived radical species.

The top of figure 1 shows a mechanism for the formation of a molecular species with a mass of 257 which upon protonation forms the ion at m/z 258. The proposed structure is supported by the elemental composition determined by accurate mass measurements and the MS/MS spectrum (not shown) obtained on a Kratos MS-50 TA.

Now consider m/z 292. Loss of H⁺ from atrazine produces a radical A₂₋. Combination of A₂₋ with H⁻ produces a molecular species with a mass of 291, which upon protonation produces the ion at m/z 292. Loss of H⁺ from HEDS produces a matrix radical H₁₁₋. Combination of H₁₁₋ with the atrazine A₁₉₀ radical produces a molecular species with a mass of 333, which is protonated to yield the ion at m/z 334.

The ion at m/z 182 corresponds formally to substitution of the Cl on the triazine ring with H, followed by protonation, i.e., A₁₉₀ + H⁺. Beam induced halogen substitution reactions have been reported previously (4-6). A free radical mechanism was also used to account for the substitution in references 4-5. An alternative reduction mechanism is presented in reference 6.

Analogous free radical reactions also occur in the analysis of atrazine in other FAB matrices. The reaction scheme to produce m/z 334 is especially important in the FAB analysis of atrazine in a DTT/DTE matrix. This matrix consists of a mixture of dithiothreitol and dithioerythritol both of which have terminal SH groups; the elemental compositions are the same as that of HEDS.

Figure 2 shows a narrow scan over the m/z 216 region of the FAB spectrum (R = 12,000 for 2A-2D and R = 10,000 for 2E & 2F, Kratos MS-50 TA, Kratos FAB source) for several matrices. Both glycerol and 3-nitrobenzyl alcohol (not shown) have background ions which completely overlap the region at which the atrazine protonated molecular ion appears. This point in the window is demarcated with a tic mark. Because thioglycerol contains a S heteroatom, the mass defect of both the matrix and, consequently, the matrix derived background ions is increased. Thus the background ions at m/z 216 in the neat thioglycerol are shifted to lower mass, and appear to the left in the mass window.

Both DTT/DTE and HEDS contain two sulfur atoms. This increases the overall mass defect of these matrix molecules even further than for thioglycerol. This has considerable importance in the trace analysis of atrazine by FAB. The background ions in HEDS are clearly removed from the atrazine region and the peak from the addition of 340 pg of atrazine to the FAB probe tip is also shown in figure 2D. The best detection limits are obtained in the DTT/DTE matrix, and the peak from the addition of 20 pg of atrazine to the probe tip is shown in figure 2F.

Finally, we have also observed matrix analyte free radical chemistry occurring upon Cs⁺ ion bombardment.

A FAB AND MS/CA/MS STUDY OF ERYTHROMYCIN A AND A SERIES OF RELATED MACROLIDE ANTIBIOTICS

Denise K. MacMillan and Michael L. Gross  
Midwest Center for Mass Spectrometry  
University of Nebraska-Lincoln  
Lincoln, NE 68588-0304

Schering-Plough Corporation  
Bloomfield, NJ 07003

The mass spectrometric study of thermally labile materials is facilitated by soft ionization techniques such as FAB and SIMS. Both MS/MS and MS/CA/MS provide structural information often unavailable from the simple FAB experiment. We have used these techniques and two tandem sector instruments (Kratos MS-50 TA and VG ZAB-T) to characterize a series of 11 macrolide antibiotics that includes erythromycin A, tylosin, and mycinamicin II. All of the antibiotics studied incorporate from one to five sugar units attached to a 12-, 14- or 16-membered lactone aglycone. At least one of the sugars is an amino sugar. The molecular weights of the glycosides included in this study range from 700 to 1300 u.

The structure of erythromycin A is typical of this class of antibiotics (Fig. 1). Attached to the 14-membered lactone aglycone are two sugar units, desosamine, the amino sugar, and cladinose. The molecular weight of erythromycin A is 733.5 u.

We acquired the low resolution FAB and SIMS mass spectra of the antibiotics as protonated [(M + H)+] and cationized [(M + Li)+, (M + Na)+, and (M + K)+] species to determine the molecular ion. The antibiotics were desorbed from a 3-NBA matrix and 3-NBA saturated with the appropriate salt. High resolution peak matching experiments were performed to confirm the atomic composition of the molecular species. Neither of these techniques give much structural information about the glycosides, however. Characteristic fragmentations are observed in MS/MS spectra, instead. The MS/MS spectra yield information about the structure of the ion of interest, but only if high levels of collisional activation (CA) are employed. Our experiments indicate that the main beam must be reduced by 50-80% with the appropriate pressure of collision gas for some fragment ions to be generated. Metastable ions yield fewer fragment ions than collisionally activated precursor ions.

The MS/CA/MS spectrum of protonated erythromycin A (Fig. 2A) exhibits peaks indicative of bond cleavage accompanied by H rearrangement at the site of the glycosidic oxygen. As a result of this process, the non-amino sugar is lost from the glycoside as a neutral fragment, but the amino sugar is observed as a charged species. Cleavage occurs to either side of the glycosidic oxygen. Loss of H2O is also observed to occur from the (M + H)+ species. Eliminations from the backbone of the aglycone ring are not observed.

Cationized erythromycin A species all produce spectra which are strikingly different from those produced by the protonated species. As is demonstrated in the MS/CA/MS spectrum of (Erythromycin A + K)+ in Fig. 2B, numerous peaks are observed at high mass, but only minor ions appear in the low mass region of the spectrum. Small, neutral molecules are eliminated from the cationized species via cycloreversions of the sugar entities, cleavages to either side of the glycosidic oxygen accompanied by H rearrangement, and H2O loss. Portions of the aglycone ring are also
removed from the cationized species. The same fragmentation patterns are observed for the (M + Lj)+ and (M + Na)+ ions.

![Diagram](image)

Fig. 2: MS/CA/MS Spectra of Erythromycin A

The sharp contrasts observed between the spectra of the (M + H)+ and (M + metal)+ ions of erythromycin A may be the result of differing charge sites. The tertiary amine has high proton affinity, and thus, may hold the proton tightly fixed on the amino sugar. This interpretation is consistent with the observed fragmentations of the (M + H)+ species. The amino sugar appears as a charged entity, but the second sugar is lost as a neutral molecule.

Association of a metal ion with the macrolide occurs on the lactone rather than one of the sugars. Elimination of low molecular weight, neutral molecules from the sugars can occur with the charge remaining on the aglycone portion of the antibiotic. The absence of low mass peaks in the spectra of cationized erythromycin A suggests little metal ion interaction with the sugar portions of the macrolide.

The fragmentation patterns of Erythromycin A are also generally observed for the other macrolides studied here. For all (M + H)+ ions, the amino sugar is observed to be a protonated species and the predominant peak in the MS/CA/MS spectrum. Other fragments include those resulting from loss of H2O and the non-amino sugar. The (M + metal)+ ions all exhibit loss of low mass neutral fragments from the sugar entities and parts of the aglycone.

In conclusion, the molecular ion of macrolide antibiotics can be identified through a combination of low resolution FAB and high resolution peak matching experiments. Structural information about this class of compounds is best obtained with MS/CA/MS techniques. Differences in fragmentation from the (M + H)+ and (M + metal)+ ions occur because the charges are located on different portions of the macrolide molecule.
Molecular Epitope Identification in Protein Antigens by Mass Spectrometric Peptide Mapping Analysis of an Immobilized Immune Complex

D. Suckau, D. Bitter-Suermann* & M. Przybylski

University of Konstanz, D-7750 Konstanz and Medizinische Hochschule*, D-3000 Hannover, Germany

Monoclonal antibodies are powerful tools in biochemistry and medicine. A monoclonal antibody (mab) is specific for a single biomolecule such as a protein, and binds to a specific region on its surface. Current methods for the identification of antigenic sites on proteins depend on panels of peptides or variant proteins as antigenic probes (1). More recent approaches employed partial proteolysis of immune complexes (2,3), revealing a) a general resistance of antibodies towards proteolytic enzymes; b) protection of antigens against proteolytic degradation by a bound antibody; and c) stability of the immune complex after proteolysis of the antigen. But due to major restrictions of the employed techniques, a reliable method of accurate epitope identification is still needed.

Mass spectrometric methods are presented, which are capable of rapidly identifying epitope sequences within a few amino acid residues. Crosslinking of the monoclonal antibody to the insoluble carrier sepharose, allowed the separation of mab-bound molecules from unbound by sedimentation. Two different ways of immune complex formation were developed: 1) the antigen is allowed to bind to the mab, and the resulting immune complex is partially digested by trypsin - this approach is termed "EPITOPE EXCISION"; b) the mab is challenged even by complex mixtures of peptides, resulting in selective binding of only the antigenic peptides - this approach is termed "EPITOPE EXTRACTION". After removal of the supernatant, which can be analyzed separately (non-epitope fraction), the epitope bearing peptides are remaining bound to the immobilized mab and are selectively removed from the mab by the lyotropic agent 4 M MgCl₂ (epitope fraction). Fractions were purified by RP-HPLC and analyzed by ²⁵²Cf-plasma desorption mass spectrometry (PDMS). These methods (4) were applied to the identification of an epitope located on the C-terminus of the complement protein C³a (9 kD), which is recognized by the mab h453 (5).

Fig. 1: PD-Mass spectrometric epitope identification on guinea pig C³a (gpC³a) applying the EPITOPE EXCISION method: 6.4 ng des-Arg⁷⁸-gpC³a was bound to h453 and treated with 0, 5 and 45 ng trypsin respectively (30 min, RT). Epitope
peptides were separated from the mab by treatment with 4 M MgCl₂. Chromatograms of the epitope fractions (right) and the PD-spectrum of the fraction at 23.7 min (left) are shown. The spectrum identifies the C-terminal octapeptide gpC3a(70-77) as epitope peptide and Arg⁶⁹ as tryptic cleavage site (solid arrowhead). In contrast, cleavage in free gpC3a occurred at Arg⁷⁰ (open arrowhead). This change in trypsin specificity can be explained by steric hindrance of trypsin access due to the epitope-bound mab a few amino acid residues downstream.

To further characterize the C-terminal part of the epitope, EPITOPE EXTRACTION analyses were performed using the synthetic peptides hC13 and hC14 and their proteolytic degradation products, which contain the sequence of antigenic human des-Arg⁷⁷-C3a, i.e. ASHLGLA (for sequences see insert).

Fig. 2: EPITOPE EXTRACTION analysis of a) hC13 and hC14; b) tryptic peptide fragments of hC13 and hC14 without and c) with additional digestion by carboxypeptidase B. After binding of the peptide mixtures to immobilized h453, supernatants (non-epitope fraction) and MgCl₂-eluates (epitope fraction) were chromatographed and all eluting peptides analyzed by PDMS, identifying a single antigenic structure, hC14-(1-7), i.e. ASHLGLAGKGKGG (m/z 809). C-terminal elongation of this sequence completely abolished antigenicity. This change in trypsin specificity can be explained by steric hindrance of trypsin access due to the epitope-bound mab a few amino acid residues downstream.

Conclusion An entirely new epitope mapping approach is presented, which allows an accurate description of antigenic structures. The use of an immobilized antibody provides the basis for the antigenic classification of peptides even in complex mixtures. A main feature of the methods presented, is the direct structural identification of molecular species bound to an antibody by mass spectrometric peptide mapping, which prevents experimental artifacts observed with traditional assays (ELISA), e.g. caused by unknown antigenic contaminations. Moreover, the epitope excision method enables the identification of an antigenic structure from a single immune complex and allows access even to the knowledge of steric conditions in the antigen-antibody-protease complex. This method will greatly reduce the number of structures to be tested in fine specificity studies (e.g. using site-directed mutagenesis), and may even be applicable to the complex analyses of assembled topographic sites.

COLLISION-INDUCED DECOMPOSITIONS OF PEPTIDE ANIONS CATIONIZED WITH CALCIUM

Lynn M. Treesch and Jeanette Adams: Department of Chemistry, Emory University, Atlanta, GA 30322.

We recently presented the collision-induced decomposition (CID) spectra of FAB-desorbed \((M + Ca^{2+} - H)^+\) complexes between peptides and alkaline earth metal ions (1,2). Our results allowed us to deduce the location of the alkaline earth metal ion in the fragmenting complexes from our proposed mechanisms of decomposition (2,3). The most abundant fragment ions arise from complexes in which the metal ion is preferentially bonded to a deprotonated amide group. We also investigated complexes between peptides and alkali metal ions and found that the alkali metal ion binds preferentially to amide carbonyls (1,3-5). The fragmentation patterns of both these complexes change with metal ion size and amino acid sequence, thus providing evidence for intramolecular chelation of the metal ions. Here, we report the study of decompositions of anionic \((M + Ca^{2+} - 3H)^-\) complexes between 45 peptides and calcium, with the intent to provide further evidence of intramolecular chelation between peptides and metal ions in the gas phase.

The CID spectrum of \((M + Ca^{2+} - 3H)^-\) complexes shown in Fig. 1 for VAAF displays characteristic fragmentations observed for complexes containing only aprotic amino acid residues. The important fragment ions are C-terminal \((x_{n-m} + Ca^{2+} - 2H)^-\) and \((y_{n-m} + Ca^{2+} - 2H)^-) ions in which Ca\(^{2+}\) is most likely at the C-terminal carboxylate group. Losses of side chains (see cleavage of Phe in Fig. 1, labelled -Phe) are also abundant.

Spectra of \((M + Ca^{2+} - 3H)^-\) complexes of VIHN, AEKAA, and YGGFL (Fig. 2) show characteristic fragmentations for peptide complexes that contain protic amino acids. Fragmentations yield \(x_{n-m}\) and \(y_{n-m}\) ions and losses of amino acid side chains. In addition, however, decompositions also produce N-terminal \((c_{n-m} + Ca^{2+} - 2H)^+\) fragment ions. The \(c_{n-m}\) ions are observed in spectra of peptides that contain at least one His (Fig. 2A), Glu (Fig. 2B), Tyr (Fig. 2C), or Asp. Losses of amino acid side chains dominate spectra of peptide complexes that contain other protic side chains such as Arg, Ser, Thr, and Asn (see Fig. 2A, labelled -Asn).

The mechanism for formation of \((c_{n-m} + Ca^{2+} - 2H)^+\) ions appears to be the same as that proposed earlier for \((c_{n-m} + Ca^{2+})^+\) ions (2,3). The \(c_{n-m}\) ions arise from cleavages through OCN(H)-C(H)R bonds, require transfer of an \(\alpha\)-hydrogen from an R group on the departing neutral to the amide N of the fragment ion, and are inhibited by proline in the \(n-m+1\) position. Calcium is located at a deprotonated amide towards the N-terminus and distant from the reaction site. Formation of \((c_{n-m} + Ca^{2+} - 2H)^-\) ions also requires at least one more amide bond and a protic side chain that are deprotonated and involved in binding calcium. The necessity for multiple binding sites for calcium in \((c_{n-m} + Ca^{2+} - 2H)^-\) ions provides support for intramolecular chelate complexes.

OPEN CELL GEOMETRIES FOR FOURIER TRANSFORM MASS SPECTROMETRY

Steve C. Beu and David A. Laude, Jr., Department of Chemistry and Biochemistry,
The University of Texas at Austin, Austin, TX 78712-1167

A variety of cell designs have been employed for Fourier transform mass spectrometry (FTMS) with the most common being of cubic, rectangular, and cylindrical geometry. All implementations of these designs to date have employed trap electrodes oriented perpendicular to the excite and detect electrodes. Such orientation results in a closed cell exhibiting several disadvantages for the FTMS experiment including restricted access to the cell interior and reduced gas conductance through the cell. Perhaps the most significant disadvantage of such designs is the inhomogeneous electric fields which result from the termination of field lines on adjacent electrodes. This effect causes significant field curvature and thus introduces an undesirable radial component to the trapping field and axial component to the excitation field. The radial trapping field component induces magnetron motion and induces a negative shift in the cyclotron frequency, and the axial excitation field component results in axial ejection of ions during excitation. In this work we present an alternative “open” cell geometry achieved by employing trap electrodes which are a linear extension of the geometry defined by the excite and detect electrodes. In contrast to closed cells, this open cell geometry offers several advantages including easy access to the cell interior, improved gas conductance through the cell, and significantly reduced electric field inhomogeneities. The absence of physical barriers along the cell axis simplifies the introduction of externally generated charged particles or laser beams, and the improved conductance through the cell region shortens pressure transients associated with laser desorption and pulsed gas introduction. The efficient injection of externally generated ions is also facilitated in that the possibility of trapping surface interactions are eliminated, as well as interactions with magnetic field inhomogeneities associated with paramagnetic trap plate materials. Improved electric field homogeneity results in smaller trap potential induced cyclotron frequency shifts and reduced axial ejection associated with excitation fields.

An example of this open cell design approach is presented in Figure 1 for cells of both square and circular cross section. This design results in a cell with three tandem colinear sections consisting of two trapping sections and one excite/detect section. The length of the trap extensions will determine the maximum centerline trapping potential achieved for a given applied potential, with length/width (aspect) ratios as small as 1/15 yielding effective potential wells. However a more effective ratio of 1/1 results in a trap potential maxima that is 92% of the applied potential and located essentially at the center of the extension. The length of the trapping potential well is then easily determined as the distance between trap extension centers. If the aspect ratio of the excite and detect electrode assembly is also 1/1, and the length of the cell is taken as the length of the potential well, then the overall aspect ratio of the cell is 2:1. Aspect ratios of greater than 1/1 are typically referred to as elongated cells. A field map showing the trapping field isopotential contours for such a cell is presented in Figure 2 along with a corresponding map for the closed elongated cell of the same aspect ratio. That this open cell design is capable of generating suitable trapping potential wells is demonstrated in Figure 3 where the centerline trapping potential for both the open and closed elongated cells are compared. It should be noted that although the closed cell exhibits a slightly deeper effective well, the open cell geometry results in significantly smaller peak radial electric fields.

Isopotential contours for the excitation fields of both the open and closed elongated cells are presented in Figure 4. While the closed cell offers a more homogeneous radial excitation field as averaged over the length of the cell, the open cell exhibits axial field gradients that are approximately 1/2 that of the closed cell. This results in reduced axial ejection during excitation, as is demonstrated with perfluorotributyl amine (PFTBA) spectra presented in Figure 5. Further modification of the open cell design can eliminate ejection entirely. If the trapping extensions are cut into quadrants corresponding to the excite and detect plates, the excitation waveform can be superimposed on the trap potentials applied to those trap extension segments which are colinear with the excite plates. As demonstrated in Figure 6, the resulting excitation field is homogeneous over the entire trapping potential well, thus significantly improving excitation performance of the open cell as compared to closed cell designs.

Another advantage of the open cell design is the increased experimental versatility which may be realized by extending the open-colinear section concept to more than three sections. For example, with the appropriate application of trapping and excitation potentials to different sections, a five section cell could be configured to perform as a single cell of variable aspect ratio, or as a tandem cell. Such a configuration is shown schematically in Figure 7.

Resonant Excitation for GC/MS/MS in the Quadrupole Ion Trap via Frequency Assignment Pre-Scans and Broadband Excitation

Nathan A. Yates and Richard A. Yost, Univ. of Florida, Gainesville, FL 32611-2046
Steven C. Bradshaw and David B. Tucker, Finnigan Corporation, San Jose, CA 95135-1991

Two of the quadrupole ion trap's most notable features are ultra-high sensitivity as a gas chromatograph/mass spectrometer (GC/MS), and versatility as an efficient tandem mass spectrometer (MS/MS). GC/MS/MS would seem to be the obvious next step, and although GC/MS/MS has been demonstrated with the ion trap, several issues need to be resolved before GC/MS/MS becomes a routine mode of analysis. The combination of GC and MS/MS in the ion trap is complicated by the interdependence between operating parameters that affect MS/MS and the ion population in the trap at any given time. In particular, as the number of the ions within the trap change during the elution of a chromatographic peak, the proper setting of the resonant excitation frequency shifts. Figure 1 illustrates this shift in a plot of the parent ion intensity for 134* of n-butylbenzene against resonant excitation frequency for three different ion densities. As the number of ions in the trap increases, the excitation band shifts to lower resonant excitation frequencies. This often results in the loss of daughter ion production over part or all of the GC peak.

We have developed two techniques that correct for the shift in resonant frequency in real-time. The first technique applies a frequency-assignment pre-scan that automatically determines the resonant ion frequency for a subsequent MS/MS scan. The second approach eliminates the need for exact frequency assignment by exciting a range of frequencies simultaneously with a broadband excitation signal.

The frequency-assignment pre-scan (Figure 2) rapidly measures the secular frequency of an ion's motion with a frequency scan acquisition. Data obtained by scanning the resonant excitation frequency across a 10 KHz (1.7 amu) range (Figure 3). As the synthesizer passes over the an ion's resonant frequency, power is absorbed and the ion is ejected from the trap to the detector. Appropriate resonant excitation frequencies are obtained by calculating the average ejection frequency for increasing and decreasing frequency scan acquisitions; averaging the scans corrects for additional frequency perturbations that are caused by the amplitude of the frequency scan. Less than 100 μs is required for accurate frequency assignment, which we believe will be fast enough to perform MS/MS over a chromatographic peak. In practice, the frequency-assignment pre-scan takes 1-2 additional seconds for communication between the data system and the instruments embedded microprocessor; the elimination of these delays is possible with additional software modifications.

Broadband excitation applies an excitation signal that has a bandwidth of approximately 10 KHz (1.7 amu at q=0.3) during the CAD stage of an MS/MS experiment. Thus, the excitation of the parent ion is independent of slight shifts in the ions secular frequency of motion. In addition, the broadband excitation scan function is faster and less complex than the frequency-assignment pre-scan. Broadband excitation is found to be an effective method for resonant excitation during the GC/MS/MS experiment and is a significant
step towards routine GC/MS/MS on the quadrupole ion trap. Figure 4 shows the GC/MS/MS results for n-butylibenzene; note that daughter ions 91' and 92' are observed over the entire chromatographic peak. One potential disadvantage of the broadband excitation technique is that it places strict requirements on the mass selection step; if unit mass-selection is not achieved and multiple m/z ions remain following isolation, broadband excitation may produce an ambiguous daughter spectrum containing daughter ions from multiple parent ions.

Determining Effective Ion Energies in a Quadrupole Ion Trap Mass Spectrometer

Cecilia Basic, Richard A. Yost and John R. Eyler
Department of Chemistry, University of Florida, Gainesville, Florida 32611-2046

We are conducting a series of experiments which should lead to the determination of the energy of the ions stored in a quadrupole ion trap mass spectrometer (QITMS). As the QITMS sees increased use as a routine analytical mass spectrometer, it is becoming more important to understand - if not ultimately to control - the energy deposition processes occurring in the ion trap. To this end, we have utilized a series of chemical “thermometer” reactions in an effort to characterize the energies of the ions in the QITMS.

The first two chemical “thermometers” studied were the ion-molecule reactions,

\[
\text{Ar}^+ + \text{N}_2 \rightarrow \text{Ar} + \text{N}_2^+ \tag{1}
\]

and

\[
\text{O}_2^+ + \text{CH}_4 \rightarrow \text{CH}_3\text{O}_2^+ + \text{H} \tag{2}
\]

Flow-DRIFT experiments have shown that the rate coefficients, \(k\), for these reactions vary with centre-of-mass kinetic energy, \(K_E\).[1,2] Thus, determination of \(k\) for these “kinetic thermometers” on the QITMS leads to a value for the \(K_E\) of the reacting ion-molecule pair. An effective temperature, \(T(K)\), can be derived by transforming to \(K_E\) and applying the relation \(K_E = 3/2kT\) (assuming a Maxwell-Boltzmann distribution for the ion energies).

The second type of chemical “thermometer” utilized is based on determination of the equilibrium constant, \(K_{eq}\), for a proton transfer reaction. Given knowledge of either the \(\Delta G\) or \(\Delta H\) for the reaction, an effective temperature, \(T(K)\), can be obtained from these “thermodynamic thermometers” via the relation, \(\Delta G = \Delta H - T\Delta S = -RT\ln K_{eq}\) assuming \(\Delta S = 0\) or estimating it as appropriate. The two proton transfer equilibria studied were those between protonated toluene and ethyl benzene and between n-diethyl amine and n-dipropyl amine,

\[
\text{C}_7\text{H}_9^+ + \text{C}_8\text{H}_{10} \rightarrow \text{C}_8\text{H}_{11}^+ + \text{C}_7\text{H}_8 \tag{3}
\]

and

\[
[(\text{n-Et})_2\text{NH}]^+ + [(\text{n-Pr})_2\text{NH}]^- \rightarrow (\text{n-Et})_2\text{NH} + [(\text{n-Pr})_2\text{NH}]^+ \tag{4}
\]

The effective temperatures obtained from the four “thermometers”, both without and with He buffer gas (added to a total pressure of \(1\times10^{-4}\) torr) in the QITMS are given in Table 1. The result for the \(\text{Ar}^+ / \text{N}_2\) “thermometer” without He buffer is the average obtained over an \(\text{Ar} / \text{N}_2\) pressure range of \(1\times10^{-6}\) to \(1\times10^{-3}\) torr (\(\text{Ar} / \text{N}_2\) pressure ratio varied from 10:1 to 1:10). Both the \(\text{O}_2^+ / \text{CH}_4\) and toluene/ethyl benzene temperatures without He buffer were obtained at a pressure of \(5\times10^{-6}\) torr (50:50 neutral ratio). The result for the amine “thermometer” without He is the average value obtained over the pressure range \(7\times10^{-7}\) to \(5\times10^{-5}\) torr (2:1 n-diethyl:n-dipropyl amine ratio).

Results to date show that the kinetic “thermometers” give ion temperatures a factor of 10 higher than those obtained with the thermodynamic “thermometers”. Without He buffer gas, a temperature of approximately 3500K is given by both the \(\text{Ar}^+ / \text{N}_2\) and \(\text{O}_2^+ / \text{CH}_4\) “thermometers”, while the toluene/ethyl benzene and the n-diethyl/n-dipropyl amine “thermometers” result in temperatures on the order of 300K. In all cases somewhat of a cooling effect is seen upon addition of the He buffer gas.

The reason for the ten-fold difference in temperature between the kinetic and thermodynamic “thermometers” is as yet unclear; we suspect, however, that it may lie in the transformation from \(k\) to \(T(K)\). It is interesting to note that if the temperature-variable SIFT DRIFT data available for the \(\text{O}_2^+ / \text{CH}_4\) “thermometer” (providing a direct measure of \(T(K)\) from \(k\) [3]) are utilized instead of the flow-DRIFT results, temperatures on the order of 560K are obtained. These are not only in better agreement with the thermodynamic “thermometers”, but are in good agreement with the 600-700K temperature range reported previously for the ions in a QITMS [4] utilizing the temperature-variable SIFT DRIFT \(\text{O}_2^+ / \text{CH}_4\) “thermometer”.

While we have yet to determine the absolute values for the temperatures of the ions stored in a QITMS, trends in ion temperatures obtained with the \(\text{Ar}^+ / \text{N}_2\) “thermometer” as a function of the \(q\) of the \(\text{Ar}^+\) ion (Figure 1) indicate that the “thermometer” is indeed probing ion energy.

The great analytical potential of electrospray ionization for analysis of both light and heavy molecules has led us to retrofit an existing HP 5988A (Hewlett Packard, Palo Alto, CA) quadrupole mass spectrometer with a commercially available electrospray source and a compatible high energy dynode (HED) detector. Our evaluation of this instrumental configuration included a qualitative comparison of electrospray spectra with those in the literature and assessments of sensitivity and mass accuracy. We determined that this retrofitted configuration using multiple suppliers can provide excellent analytical capabilities for electrospray mass spectrometry. The HED detector (Phrasor Scientific, Duarte, CA) gave an optimal signal at a dynode voltage of -7.5 kV which represented an increase of two orders of magnitude over a conventional conversion dynode electron multiplier. The high mass sensitivity was improved with the HED as well. The electrospray source (Vestec Corporation, Houston, TX) replaced the existing Hewlett Packard EI/CI source with no modification necessary.

A glutathione and a glucuronide were used to test the sensitivity of this configuration. Methanol content of the infusion solvent had little effect on sensitivity of the molecular ion detected between 1.0 and 0.01 nmol. A lower limit of 780 fmol per scan was detected for both the glutathione and the glucuronide. This represents a concentration of 0.01 nmol of solution undergoing continuous infusion in the syringe. The mass accuracy for all samples tested is within a 0.02 - 0.005 percent error range.

Manipulation of electrospray parameters can provide additional spectral information. On increasing the block/repeller voltage, fragmentation was found to occur which was similar to that of high energy collision induced dissociation. Proteins of molecular weight exceeding the mass range of the quadrupole (2000 D) was were found to yield singly and multiply charged fragment ions (Figure 1).

High molecular weight compounds could be analyzed with the addition of 20 - 30 percent acetic acid. An example is alcohol dehydrogenase from yeast of mass ~ 74 kDa which has up to 70 positive charges (Figure 2). Analysis of glycoproteins and protein mixtures were also found to be feasible. Negative ion electrospray of compounds such as nucleotides resulted in multiply charged negative ion distributions. Analysis of real samples such as the P-17 fragment of the gag protein from the HIV-I virus gave comparable results to test compounds.

Alzheimer's disease (AD) is neuropathologically characterized by deposits of amyloid, the senile plaque in cerebral blood vessels and the neuropil. The senile plaque is a fibrillar extracellular deposit primarily composed of a ca. 4-kilodalton peptide, β/A4, derived from the amyloid precursor protein (APP) (Fig. 1.A). The 42-43 amino acid β/A4 peptide includes 14 amino acids of the transmembrane domain and 28 amino acids of the adjacent extracellular domain of APP. However, the biochemical events responsible for the generation of β/A4 from APP are not clear. Studies performed in cultured cell have documented that APPs have a short intracellular half-life and are posttranslationally modified both by N- and O-linked carbohydrate and by tyrosine sulfation. Full-length molecules are detected on the cell surface, and proteins lacking the transmembrane and cytoplasmic domains are secreted into the medium. Similar events occur in vivo.

Recently, we identified a domain of APP that was necessary and sufficient for this constitutive cleavage event. We provided compelling evidence that this constitutive cleavage occurs in the extracellular domain, within the β/A4 peptide (Fig. 1.B). Subsequently, Esch et al. confirmed these molecular biological studies by chemically identifying unique carboxyl- and amino-terminal residues of the secreted and membrane-retained fragments respectively. However, the precise cleavage site was indeterminate because a lysine residue (Fig. 1.B), which normally resides between the identified termini of secreted and membrane-retained fragments, was not detected in this analysis.

To define the precise APP cleavage site that leads to secretion, we have now generated a Chinese hamster ovary (CHO) cell line that overexpresses the human APP-770. The soluble APP-770 (SAPP-770) was purified from the conditioned medium of these cells by Mono Q HR5/5 anion exchange FPLC and analyzed by SDS/PAGE with silver staining and immunoblotting. The purified SAPP-770 was chemically digested with cyanogen bromide (CNBr). Peptides were separated by Vydac C-18 reverse-phase HPLC (Fig. 2A). The peptide contains carboxyl-terminal residues of SAPP-770 were
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Identified by plasma desorption mass spectrometry (PDMS) (Fig. 2B and 2C) and verified by Edman degradation (Fig. 3) and in situ carboxypeptidase Y digestion on PDMS sample foil (Fig. 4).

A portion of the reverse-phase HPLC profile of peptides generated by CNBr digestion of SAPP-770 is shown in Figure 2A. This region of the chromatogram was selected for analysis because a synthetic 16 amino acid peptide, DAEFRHDSQYEVHHQK, had retention time of 66 minutes under identical chromatographic conditions. To confirm that an authentic CNBr generated C-terminal peptide of SAPP-770 fractionated in this region of the chromatogram, we tested each of the fractions by PDMS. This initial PDMS survey revealed that fractions 66 and 67 of the chromatogram (Fig. 2A) contained peptides with molecular weights appropriate for a CNBr generated C-terminal peptide of SAPP-770. Figure 2B depicts the PDMS analysis of fraction 66 showing a strong peak of m/z 1955.6 and a weaker peak of m/z 1827.1. Similarly, Figure 2C depicts PDMS analysis of fraction 67 showing peaks identical to fraction 66 but with reversed intensity. These two [M+H]+ ions of 1955.6 and 1826.9 are correspond to the molecular weights of CNBr digest of SAPP-770 with the sequence DAEFRHDSQYEVHHQ (calculated m/z = 1955.6) and DAEFRHDSGYEVHHQ (calculated m/z = 1826.9), respectively. Note that the predicted difference in hydrophobicity of these two peptides is reflected by the respective retention on the reverse-phase column.

![Figure 3 Edman degradation of C-terminal CNBr derived peptides of SAPP-770. Amino acids of the highest yields are shown at each sequence cycle](image)

The Edman degradation analysis (Fig. 3) revealed that fractions 66 and 67 do contain peptides with amino acid sequences that matched the APP sequence. The in situ carboxypeptidase Y digestion on PDMS sample foil (Fig. 4) further confirmed the C-terminal amino acid sequence of the ion m/z 1955.6 is ...QK by the mass difference of between the original and first digest ions, and between first and second digest ions.

These data provide the evident that the primary site for the membrane associated cleavage of APP-770 is immediately N-terminal to leucine 688, thereby generating a secreted molecule (i.e., SAPP-770) with a C-terminal lysine residue. A postcleavage event involving exopeptidase removal of lysing 687 would then give rise to secreted molecules with a C-terminal glutamine residue (as predominate in fraction 67).

A METHOD FOR BACKGROUND REDUCTION IN A SUPERSONIC JET/MULTIPHOTON IONIZATION REFLECTRON TIME-OF-FLIGHT MASS SPECTROMETER

Alan P.L. Wang and Liang Li*
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2, Canada

Multiphoton ionization mass spectrometry (MPIMS) combined with supersonic jet spectroscopy (SJS) is a powerful technique for trace analysis and for the determination of chemical structures. In the past few years, in an effort to extend both the MPIMS and the SJS method for the study of thermally labile biochemicals, pulsed laser desorption (LD)[1,2] and, more recently, fast atom bombardment (FAB)[3] have been used to vaporize these molecules. In the LD or FAB experiments, a pulsed laser (e.g., CO2 laser) or a FAB gun is used to desorb molecules from a sample substrate placed close to the nozzle orifice. The resulting neutral molecules are then entrained into a pulsed supersonic jet which prevents them from thermal decomposition through collisional cooling and carries them into a time-of-flight mass spectrometer (TOFMS) where MPI takes place. Both LD and FAB/SJ-MPI mass spectrometry methods have been applied for the detection of a variety of biochemicals[1-3].

As in most other mass spectrometry techniques, high-intensity background can cause some problems in SJ-MPIMS. This is particularly true for FAB and LD/SJ-MPIMS. In these techniques, the nonvolatile molecules are first vaporized and then carried into the ionization region of the TOFMS. During this process, samples may condense on the wall of the vacuum chamber and the electric lens assembly of the TOFMS. These molecules and their decomposition products will eventually become the background for the analysis of other samples or the same sample in the next run. This cross-contamination can become quite severe in light of the fact that the turn-around time of the system is usually very short (i.e., less than 5 minutes) and a large number of samples can be analyzed in a given time period. Due to the possible overlapping of the molecular ion and fragments with the background signals, the sensitivity for the detection of molecules of interest is often reduced, and also the structural information obtained from the mass fragmentation pattern suffers.

In this report, we describe a method for background reduction in FAB and LD/SJ-MPIMS. This method involves (1) the use of an ion deflector in a supersonic jet/reflectron TOFMS, and (2) the optimization of the time delay between the sample pulse and the ionization laser pulse, to selectively detect the sample ions from background interference. Note that the ion deflector placed above the acceleration plate is commonly used in supersonic jet TOFMS for controlling the trajectory of ions from the ionization region to the detector. Now if the sample in the jet expends to the ionization region at a velocity perpendicular to the acceleration field or ion flight axis, the ions generated from the sample(sampling-ion packet) will have different linear velocity from the ions originated from the background molecules(background-ion packet). Thus they will travel to the detector with different trajectories. If there is a sufficient spatial separation between these two ion packets when they arrive at the detector, then, by selection of a proper ion deflector voltage, the sample-ion packet can be selectively detected by the detector. We show here that in our linear-type TOFMS, it is difficult to use the ion deflector to reduce the background in FAB and LD/SJ-MPI experiments. However, we demonstrate that the background can be significantly reduced by using the ion deflector in a reflectron TOFMS.

In this study, the linear velocity difference between the sample molecules in the jet and the background molecules is first examined. Then a computer simulation is performed to study the ion trajectories of the ions entrained into the TOFMS with various initial linear velocities or initial kinetic energies. The simulation indicates that, because the ion flight distance is doubled in the reflectron TOFMS, the spatial separation of the sample-ion packet and the background-ion packet can also be doubled. Moreover, with the reflectron TOFMS, the initial kinetic energy differences among the sample ions can be partially compensated for by applying proper voltages to the reflector to focus the sample ions, which results in a narrower energy distribution within the sample-ion packet. The reflector will also compensate, to some extent, for the energy differences among the background ions. The combination of the longer flight distance and less diffused sample-ion packet enhances the spatial separation between the two ion packets. Thus it becomes possible to selectively detect the sample ions.
The application of this background reduction method for FAB and LD/SJ-MPIMS is illustrated in Fig. 1. Figure 1A is the mass spectrum of aniline (m/z=93) and background obtained by using laser ionization at 266 nm with an ion deflector voltage of 70 V. Figure 1B shows the mass spectrum of 9,10-dimethylanthracene obtained by using laser desorption for sample volatilization with MPI at 266 nm. The deflector voltage is also set at 70 V. Note that the molecular ion peak (m/z=206) is superimposed on the background. This problem makes the quantification difficult. The mass spectra shown in Fig. 1C and D are obtained under the same conditions as in Fig. 1A and B, respectively, except that the ion deflector voltage is set at 0 V. As Fig. 1C and D show, the background is now significantly reduced, and the small fragment ion (m/z=191) from the loss of CH$_3$ from the molecular ion peak can be clearly identified. This example represents a typical experiment for background reduction performed in FAB and LD/SJ-MPI studies of nonvolatile chemicals. This method has now been routinely used in our lab.

ORGANIC SECONDARY ION YIELD MEASUREMENTS WITH A PULSED, TIME-OF-FLIGHT MASS SPECTROMETER

T.Y. Yen, E. Barofsky, and D.F. Barofsky
Department of Agricultural Chemistry
Oregon State University, Corvallis, OR 97331

We are investigating the processes of desorption and ionization from liquid matrices by bombarding nucleosides, nucleotides, and a few other organic molecules with pulses of energetic (keV) metal ions in a time-of-flight (TOF) mass spectrometer. The instrument has been described in detail elsewhere [1,2]. Briefly, positive primary ions of In, Ga, Bi, Au, or Si are generated and accelerated to kinetic energies of 10-50 keV in a focusing liquid metal ion (LMI) column. The LMI column is coupled to the mass spectrometer's ion source through a Wien filter that separates the various ionic species in the primary beam according to their isotopic identities and charge states. We have detected down to 50 femtomoles of gramicidin-S (1141.4 Da) and 15 picomoles of various nucleotides (Figure 1) in the positive ion mode with this instrument. These detection limits are about 50 times better than we observe using conventional FAB techniques.

We are studying the physical processes of ion ejection by measuring the relative secondary ion yields of nucleosides and nucleotides from glycerol matrices bombarded by the different ionic species at our disposal. All samples were prepared in water solution (0.025-0.25 μg/μL); 0.2 μL of sample solution were mixed with 5 μL of glycerol before being loaded into the mass spectrometer.

Typical secondary ion yield data from our measurements are shown in Figures 2-6. Yield in these figures is defined as the total number of secondary ions detected divided by the total number of impinging primary ions. Specifically, Figure 2 and 3 show the secondary ion yields obtained respectively by bombarding 40 ng samples of various deoxynucleosides and 50 ng samples of different deoxynucleotides with In and Bi ions. Figure 4 shows the secondary ion yield of deoxyguanosine monophosphate (dGMP) as a function of the energy of the primary ions. Figure 5 and 6 show the secondary ion yields (normalized with respect to the yield from In⁺ bombardment) respectively of deoxyadenosine (dA) and dGMP due to bombardment with In, Au, Bi, and some of their cluster ions.

The data presented in Figures 5 and 6 show that the relative ion production of protonated dA and dGMP secondary ions under polyatomic cluster ion bombardment is increased by up to 16 times over monatomic ion bombardment. Similar results for an organic analyte were obtained by Salehpour et al. when they bombarded valine on a solid substrate with 800 keV to 3.7 MeV polyatomic C₇H₃⁺ (n=1,3,4,7; m=0,3,9,15) ions [3]. The data generated by bombardment with monoatomic In and Bi ions suggest that the secondary ion yield is proportional to the momentum of the primary ion. The very small change in secondary ion yields with energy probably reflects the facts that we are observing a nuclear sputtering phenomenon and that the energy range of our measurements (12-18 keV) was quite narrow.

THEORETICAL ANALYSIS OF THE EFFECT OF ELECTRIC FIELD INHOMOGENEITIES IN THE AREA OF WIRE MESH GRIDS ON RESOLUTION IN THE TIME-OF-FLIGHT MASS SPECTROMETER

Richard C. King, Robert Goldschmidt, and Kevin G. Owens*, Department of Chemistry, Drexel University, Philadelphia, PA 19104.

Laser ionization and laser desorption techniques are important ionization methods for the analysis of both synthetic and biological polymers. Recent work with matrix-assisted ultraviolet laser desorption has demonstrated its ability to generate intact molecular ion of large (upwards of 250,000 daltons) proteins and peptides. The time-of-flight mass spectrometer (TOFMS) meets the unique requirements of extended mass range and the ability to work with these pulsed ionization techniques, but typically suffers from relatively poor mass resolution. Higher mass resolution would provide unambiguous information about adduct formation and small subunit variations for these soft ionization techniques, and improved data on fragmentation and molecular structure when combined with harder ionization methods.

Most TOFMS employ ionization/acceleration regions defined by fine mesh metal grids. The resulting position dependent potential gradients degrade mass resolution by increasing the ion time of flight distribution. Results of mathematical modeling of the effects of changing the electric field difference across the grid and of grid mesh size are presented for several different mass ions. The importance of the effect is measured by calculation of the time-of-flight differences that are a result of ions passing through the grid.

The electric potential array calculated by SIMION2 was used to calculate the ion time of flight spread as a result of passing through wire mesh grids. Figure 1 shows the distribution of flight times for several ions of the same mass formed at the same time with the same initial kinetic energy at several positions along the grid. The time spread is a result of the position dependent electric fields, i.e. the curved equipotential lines shown in figure 2.

The time spread that results is mass dependant. Larger mass ions spend more time in different electric fields and thus spread further as they pass through the grid (figure 3). The initial velocity at the grid has a similar effect. The slower ions spend more time in different electric fields and thus have larger time spreads.
Another factor affecting the time spread is the electric field difference across the grid. The larger the electric field difference, the more the electric field punches through the grid. This gives larger electric field difference for each position along the grid and thus a larger flight time spread.

The time spread is also affected by the grid mesh size used. The larger mesh sizes have more wires per inch which results in more constant electric fields and smaller flight time spreads (figure 4).

The time variation due to the grid effects is compared to the flight time distributions created by the length of the initial ionization pulse, the initial velocity distribution, and the initial spatial distribution of ionization. The results suggest that the grid effects can be reduced while maintaining the high accelerations needed for enhanced detection of large ions. Preliminary results from a linear TOFMS designed to reduce these grid effects will also be presented.

A TIME-OF-FLIGHT MASS SPECTROMETER FOR PHOTODISSOCIATION STUDIES OF PEPTIDES AND PROTEINS

D. Shannon Cornell, Michael A. Duncan, Jonathan Amsler
Department of Chemistry, University of Georgia, Athens, Georgia 30602

Matrix assisted laser desorption is a powerful analytical method for making accurate molecular weight determinations of proteins as large as 300 kDa from sub-picomolar quantities of sample (1,2). Protein ions formed during the desorption process are primarily singly charged molecular species exhibiting little or no fragmentation. As a result, few deductions can be made concerning the structure of the protein molecule.

Structurally significant fragments of peptide molecular ions have been obtained through the use of laser photodissociation (3). Irradiation with laser light provides a convenient means of depositing discrete amounts of energy into a molecular ion. The amount of energy deposited is dependent on the laser wavelength, and not on the mass of the parent ion, in contrast to collisionally activated dissociation.

In order to investigate photodissociation of protein ions produced by matrix assisted laser desorption, we have designed and constructed the reflectron time-of-flight mass spectrometer shown in figure 1. Ions are desorbed from a stainless steel sample probe which fits flush with the repeller plate of a two stage acceleration region. After passing through an Einzel lens and beam steering optics, the ions are focused into a single stage, 59 cm reflectron consisting of 46 rings. The reflected ions then strike an electron multiplier tube for detection. The total flight distance is approximately 3 m. Fused silica windows located in the source and reflection regions are used to introduce ultraviolet light for photodissociation experiments.

In addition to providing increased resolution for molecular weight determinations, the reflectron offers some advantages for photodissociation experiments as well (4). At the acceleration voltages typically employed, 5-15 kV, ion lifetimes in the turning region of the reflectron are on the order of several microseconds. Comparing this value to a value of a few hundred nanoseconds for a 1 cm flight path just outside the initial acceleration region, one can see that timing concerns for the triggering of the photodissociation laser are less critical for photodissociation occurring in the reflectron. Another advantage over previous photodissociation experiments in a time-of-flight instrument (5) is the ability to selectively fragment a particular component of a mixture of compounds having comparable masses. At the turning point in the reflectron, ions having only slightly different masses will be sufficiently separated in time. There will then be little chance of the photodissociation beam overlapping any ion packet other than that having the targeted mass. This feature will be particularly useful for analyzing protein mixtures.

An important concern to be addressed by these experiments is whether large protein ions will photodissociate on the microsecond time scale of the experiment. Beginning at the turning point, the flight time for passage through the reflectron is 50-100 μs. Daughter ions formed away from the turning point or outside the mirror region will not be detected at their correct mass. Statistical bond dissociation may occur too slowly to be observed for truly large ions. Increasing the energy deposited into a parent ion by multiphoton photodissociation may be useful for increasing the rate of the photodissociation process, and will be investigated in future studies.

Figure 2. SIMION calculations of the trajectories of a m/z 5000 parent ion, and m/z 4000, 3000, 2000, and 1000 daughter ions from dissociations occurring at the turning point of the parent ion trajectory in the mirror region. The vertical lines represent the cross sectional view of the reflectron mirror. The parent ion enters along the top trajectory to the left, and exits along the bottom trajectory to the left. Lighter daughter ions are deflected closer to the central axis of the mirror, with m/z 1000 having the trajectory closest to the center.
Design and Performance of a New Linear TOFMS for Matrix Assisted Laser Desorption/Ionization

G.R. Kinsel, J. Grottemeyer, and E.W. Schlag
Institute für Physikalische Chemie, TU München, Lichtenbergstr. 4, D-8046 Garching, Germany.

Recently the success of matrix assisted laser desorption/ionization (LD/I) for introduction of high mass ions into the gas phase has focused attention on the linear Time-Of-Flight Mass Spectrometer (TOFMS). For a variety of reasons, including an unlimited mass range, high collection efficiencies and compatibility with pulsed ionization experiments, the TOFMS is the instrument of choice for performing these experiments. A major drawback of the TOFMS, particularly severe for LD experiments, is the relatively low resolution of the detected ion signals. Large distributions in the initial positions, velocities or times of ion formation may all lead to broadening of the detected ion signal and reduced signal resolution. Post Source Pulse Focusing (PSPF) is a method which has been proposed for improving the resolution of ion signals in a linear TOFMS [1, 2]. PSPF involves application of a compressing voltage pulse to a group of selected ions after they have been accelerated from the TOFMS source region using conventional electric fields. The only instrumental modification required is the addition of a separate voltage pulising region adjacent to the TOFMS acceleration regions.

A 2 m linear TOFMS has been constructed at this institute incorporating the necessary modifications for performing PSPF. A drawing of the source region design is shown in Figure 1. The source region consists of 2 adjustable static electric field acceleration regions and a 10 cm pulsed acceleration region. The pulsed acceleration field is defined by 10 plates spaced at 1 cm and a series of 10 1 kΩ resistors. The ion acceleration assembly is horizontally and vertically micrometer adjustable for maximizing the detected ion signals. In operation the ionizing laser fires and simultaneously triggers a digital delay generator and the 200 MHz data recording system. The ions created are accelerated through the source and secondary acceleration region. After an appropriate delay, determined by the highest mass ion to be focused, a voltage pulse is applied to the PSPF region. Under nominal conditions more than 80% of the mass spectra relative to the highest mass may be focused in the 10 cm region by the voltage pulse.

![Figure 1: Schematic representation of the source region design for a 2 m linear TOFMS incorporating a 10 cm Post Source Pulse Focusing region.](image-url)
Extensive theoretical modeling using the instrumental configuration described and a wide variety of ion formation conditions suggest that PSPF should allow significant improvement in the resolution of ion signals detected in the linear TOFMS, even when these ions are created with broad distributions in velocity or formation time. The ability of PSPF to compensate for the latter so called "start time errors" is a promising feature of this approach. In Figure 2 are displayed the typical unfocused and PSPF focused molecular ion signals for Zn Mesoporphyrin at m/z 656. The compound was introduced by 266 nm LD directly from the surface of the insertion probe. Clearly, PSPF produces a dramatic enhancement in ion signal resolution. In other initial experiments, similar results have been observed for gas phase and matrix assisted LD ion signals from smaller molecules. These results confirm the potential for PSPF to produce high resolution ion signals in a linear TOFMS.

**Figure 2:** The Zn Mesoporphyrin molecular ion signals at m/z 656 obtained by direct laser desorption at 266 nm. A) Static field operation without pulse focusing. The signal represents the sum of 20 laser shots. Resolving Power (50%) = 100. B) Molecular ion signal focused using Post Source Pulse Focusing. The signal represents the sum of 2 laser shots. Using Time-of-Flight Mass Spectral Data to Deconvolute Unresolved Chromatographic Peaks

G. E. Yefchak  
Meridian Instruments, Inc. 2310 Science Parkway, Okemos MI 48864  
R. Grix, K. L. McNitt, J. F. Holland

Department of Chemistry, Michigan State University, East Lansing MI 48824

Mass spectral detection in chromatography yields a three-dimensional data field (time, mass, intensity) which greatly enhances the ability to determine the presence of unresolved peaks, as illustrated in Fig. 1. Though the total-ion chromatogram (a) shows an unresolved doublet, analogous to two-dimensional (e.g., flame-ionization) detection, reconstructed ion chromatograms for masses unique to each compound (b) are resolved in time [1]. Thus it is most useful here to view chromatography/mass spectrometry data not as a series of mass spectra acquired over time, but rather as a collection of mass chromatograms acquired simultaneously.

Unfortunately, routine deconvolution of unresolved peaks and extraction of pure spectra for each component are often hindered by the inadequate spectral-acquisition rates available with scanning mass spectrometers. In addition, spectral "skewing" caused by the rapid changes in analyte partial pressure (i.e., the GC peak profile) during each scan interferes with normal spectral-deconvolution algorithms.

The problems of spectral-acquisition rates and spectral skewing are eliminated by the use of time-of-flight mass spectrometry (TOFMS) with time-array detection [2]. We have developed a set of deconvolution algorithms which analyze GC/TOFMS data to find the number of components, determine their retention times, and extract pure spectra for each component.

**Determination of Overlapping Peaks**

The intensities of those ions that correspond to any given compound eluting from the GC will rise and fall synchronously as the partial pressure of that compound changes in the ion source. We detect the presence of two or more components within a single chromatographic peak, then, by finding sets of ions that reach their maximum intensities at different retention times. We search each mass chromatogram, or reconstructed ion chromatogram (RIC), for local maxima and then tabulate, for each scan, the number of RIC's that reach their maximum intensities at that scan. This information is plotted in the form of a histogram to yield a "Peak-Position Plot" (PPP). The PPP indicates the number of compounds present and their corresponding retention times.

**Determination of Unique Masses**

For each compound located from the PPP, we must find a mass present in its spectrum but absent in the spectra of its nearest-eluting neighbors. Since a "unique mass" has its maximum intensity in the scan corresponding to the retention time, to identify unique masses we represent the intensities for a given mass \( m \) in the PPP scans prior to, at, and following the scan time of interest by \( I_{m,-1}, I_{m,0}, \) and \( I_{m,+1} \), respectively. The mass having the largest \( \Delta \) score, calculated as

\[
\Delta_m = \frac{2I_{m,0} - (I_{m,-1} + I_{m,+1})}{\max(I_{m,-1}, I_{m,0}, I_{m,+1})} \log I_{m,0},
\]

is chosen as unique for the corresponding compound. The log function discriminates against noise spikes.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Extraction of Pure Spectra

We assume that the shape of a unique-mass RIC represents the true elution profile for the corresponding compound. If so, the degree to which this profile matches other RIC's is related to the intensity of those other masses in the desired spectrum. We calculate cross-correlations between the unique mass RIC and all other RIC's; these values are then re-mapped to yield factors ranging from 0 to 1 such that values for masses unique to adjacent components vanish, as illustrated in Fig. 2. The factors are multiplied by the corresponding observed intensities, acquired at the elution time, to yield the deconvoluted spectrum. In detail, we first normalize each RIC to unit vector length over the region of interest by using the formula

\[ N_{m,s} = \frac{R_{m,s}}{\left( \sum_{i=a}^{b} (R_{m,i})^2 \right)^{1/2}}, \]

where \( N_{m,s} \) is the normalized intensity for mass \( m \) at scan \( s \), \( R_{m,s} \) is the raw intensity, and \( a \) and \( b \) are the first and last scan numbers, respectively, for the desired scan range. Cross-correlations are then calculated between the normalized RIC for the unique mass of interest, \( p \), and all other masses, \( q \), as

\[ \text{Corr}(p,q) = \frac{\sum_{s=a}^{b} N_{p,s} N_{q,s}}{\sum_{s=a}^{b} N_{p,s}^2}. \]

We identify the cross-correlation between the RIC for the compound of interest and that for the unique mass of the nearest-eluting species as \( C_{low} \) and linearly re-map the correlation values as

\[ \text{Corr}'(p) = \frac{\text{Corr}(p) - C_{low}}{1 - C_{low}} \]

to produce the desired factors.

Performance

Representative results are shown in Fig. 3. The total-ion elution profile, PPP, and unique-mass RIC's for a pair of nearly-coeluting compounds, obtained from TOFMS data acquired at a rate of 30 spectra per second, are shown in Fig. 3a. The deconvoluted spectra, shown in Fig. 3b–c, are virtually identical to those of the pure species. Note that the two retention times differ by 0.067 s—that is, only two spectral acquisitions! We have obtained similar results in cases where one component was present in as much as a 50-fold excess.

High Speed Analysis of Complex Mixtures by Gas Chromatography / Time-Of Flight Mass Spectrometry

R. D. MCLANE, J. ALLISON and C. G. ENKE, Department of Chemistry, Michigan State University, East Lansing MI 48824

G. E. YEFCHAK, Meridian Instruments, Inc., 2310 Science Parkway, Okemos MI 48864

R. GRIX, J. T. WATSON, and J. F. HOLLAND, Department of Biochemistry, Michigan State University, East Lansing MI 48824

In normal high resolution gas chromatography/mass spectrometry (GC/MS), the components of a mixture are separated chromatographically and then detected using a mass spectrometer. The key to this technique is the chromatographic separation—while the mass spectrometer serves to detect and identify the components. In cases where components elute nearly simultaneously from the chromatographic column, pure mass spectra (and thus identification) of the coeluting species may be obtained using deconvolution techniques. The resolving power of deconvolution depends on a mass spectral acquisition rate adequate for an accurate reconstruction of the elution profile. A typical scanning mass spectrometer only acquires a few spectra across the elution band of a component from a capillary column. Under these conditions, the shape of the elution profile cannot be determined, and the resulting mass spectra are skewed due to changes in the pressure of the analyte in the ion source during a single scan. In some cases, the scan rate can be increased, but at the cost of diminished sensitivity. With low capacity narrow-bore columns, the attainable mass spectral acquisition rate is limited by the need to maintain a detectable amount of analyte for each scan.

The combination of time-of-flight mass spectrometry (TOFMS) and time-array detection (TAD) allows spectral acquisition rates and sensitivities compatible with the chromatographic timescale, even when capillary columns are used [1]. In our instrument, which was designed and initially constructed by H. Wollnik et al. [2] and modified for GC/MS at Michigan State University, ions are made continuously and a portion of them are stored in the ion source. Every few hundred microseconds, these ions are pulsed out of the source, accelerated, drifted through a 1 m flight tube to a grid-free ion mirror and are reflected back to a detector. Each of the transient waveforms produced from the detector contains unskewed spectra data over the full mass range with unit resolution. A selected number of successive transients are summed to form each recorded mass spectrum. Up to 50 mass spectra are produced each second, allowing accurate determination of retention times and elution profiles. When two or more compounds coelute, mass spectral deconvolution can determine the presence of coeluting species and then provide an accurate retention time and pure mass spectrum for each compound [3].

The ability to perform effective deconvolution of the GC/MS data reduces the need to chromatographically resolve the components of a complex mixture. Thus, the analysis time can be reduced without sacrificing any information. We have reduced the chromatographic analysis time by shortening the chromatographic column and increasing the linear velocity of the GC carrier gas to provide the optimal combination of theoretical plates and analysis speed. Narrow-bore columns provide better resolution when operated under these conditions.

When this approach is applied to a 60-component mixture of volatile organic contaminants (VOC), the run time is reduced from 30 minutes to 80 seconds. Figure 1 shows the total ion chromatogram (TIC) for an 80 second analysis. Although a portion of the chromatographic resolution has been sacrificed, many of the components of this mixture still elute separately. Figure 2 shows an expansion of a region of the TIC with a Peak Position Plot (PPP) [2] from the deconvolution overlayed. The times when the elution profiles of a group of ions reach their maximum intensity (retention time) is displayed in this plot. A total of 22 compounds were located and identified in this 14 second region. Visual inspection reveals the presence of some compounds as irregularities in the shape of the elution profile, but species whose retention times differ by less than 0.1 s may not be noticeable. The PPP allows precise location of these compounds, even in an unknown sample. Pure mass spectra have been extracted for each of these compounds and they compare favorably with library spectra.

This approach reduces the GC/MS analysis time of complex mixtures with known or unknown composition by a factor of 10 or more without sacrificing any analytical information. The combination of TOFMS/TAD and mass spectral deconvolution can follow faster chromatographic technologies as they emerge, shortening analysis times even further.

The decreasing analysis times of modern separation methods have placed increasingly stringent demands on the temporal responses of injection, detection, and data acquisition systems. In particular, the mass spectral acquisition rates available with conventional gas chromatography/mass spectrometry (GC/MS) systems are not adequate for the sub-second peak widths achieved with high-resolution GC columns. To overcome this difficulty, we have developed a time-of-flight mass spectrometry (TOFMS) system for use with high-speed GC.

In order to serve as a useful detection system, the TOFMS instrument must have the following characteristics: a mass range 1-1000 u; unit mass resolving power throughout the entire mass range in each transient; acquisition of at least 30 spectra per GC peak; efficient ion storage between extractions; and source conductance adequate to maintain the integrity of narrow elution profiles. To achieve these goals, our system incorporates a novel source providing efficient ion generation, storage, and extraction as well as an open geometry for high conductance; an inhomogeneous-field ion mirror for mass-independent lateral and longitudinal ion focusing; an integrating transient recorder (ITR) for time-array detection of complete TOFMS transients. The flight tube, source, and mirror were originally designed and built by Wollnik and coworkers, and the ITR was designed at Michigan State University. A modified source, built at Michigan State, was designed to allow operation under GC conditions.

A dual multichannel plate (MCP) detector, designed and constructed by Wollnik and coworkers, uses two Galileo MCP plates mounted in a single, low-profile unit. Controllable voltages are applied to each surface of the plates. Current-to-voltage conversion is accomplished by a Comlinear E-220 amplifier. Time-array detection was performed with an ITR having 8-bit analog-to-digital converter (ADC) resolution and 5-ns time resolution. Transients are typically generated at 5 kHz and are digitized by the ADC. A user-specified number, n, of successive transients are summed to yield a mass spectrum with enhanced signal-to-noise ratio (S/N) and dynamic range. The spectral generation rate is equal to 5000/n.

A single transient obtained from analysis of residual gas is shown in Figure 1a; the sums of 2, 20, and 200 transients are shown in Figures 1b-d. The ionization, ion storage, and transmission efficiencies in the instrument are so high that as few as 20 transients must be summed to provide an adequate S/N. This leads to a potential spectral-acquisition rate of 250 spectra per second—more than adequate for capillary-column GC analyses. GC/MS data from mixture of hexanes is shown in Figure 2a. These data were acquired at the rate 100 spectra per second; yet the representative spectrum, shown in Figure 2b, is clearly recognizable.

Characterization of Storage Electron Ionization Sources for Time-of-Flight Mass Spectrometry

M. A. Puzycki, B. D. Gardner, J. Allison, C. G. Enke
Department of Chemistry, Michigan State University, East Lansing MI 48824
R. Grix, J. F. Holland
Department of Biochemistry, Michigan State University, East Lansing MI 48824
G. E. Yefchak
Meridian Instruments, Inc. 2310 Science Parkway, Okemos MI 48864

In GC/MS analysis, the analyte is continuously delivered to the source of the mass spectrometer. Thus, in a time-of-flight (TOF) mass spectrometer using pulsed extraction, the highest sensitivity is achieved with continuous ionization and storage of the ions between pulsed extractions. The novel source design of Wollnik, et al. 1 provides both high sensitivity and mass resolution across the entire mass range. Since the storage efficiency of such a source is directly related to sensitivity, it is important to understand and optimize the storage process.

To characterize the storage performance of the source, a model of ion behavior has been developed. We assume that the number of ions in the storage region, n, follows the rate equation \( \frac{dn}{dt} = k_F n - k_L n \), where t is time, and \( k_F \) and \( k_L \) are the formation and loss rate constants, respectively. Integrating Eq. 1 leads to the expression \( n(t) = \frac{k_F}{k_L} (1 - e^{-k_L t}) \). Thus, we expect the ion population to rise exponentially to a limit given by \( k_F / k_L \), and with a time constant given by \( 1 / k_L \) (see Figure 1). The longer the time constant is for the exponential approach to steady-state the greater the ion storage efficiency. The greater the value of \( k_F / k_L \), the greater the sensitivity.

Observations have indicated that alteration of the source geometry can significantly affect the storage capability. In order to identify the parameters critical for ion storage, we have systematically studied six different source geometries. For each source geometry, the ion storage effectiveness was evaluated in terms of the ion storage time constant. The time constant was obtained by fitting the theoretically derived equation for ion population (2) to the peak intensities (m/z = 44) at many source extraction periods. The maximum mass resolution and the formation rate constant were also measured for each configuration.

Tabulated below are the different geometries tested and their results. (See Figure 2 for a generic source design.)
Extracted ion volumes that are essentially field free (geometries having cages: A-D) are more efficient at ion storage and achieve better resolution. The production of a dense electron cloud appears to be critical to ion storage, (geometries A and D which have opposing linear filaments and geometry B which has a large circular filament). In addition filament alignment, often difficult to control, had a significant impact on the source storage efficiency.

Experiments have indicated that the storage of helium ions under GC conditions greatly decreases the number of analyte ions which can be stored in the source. Modeling shows that the application of a sine wave of the correct amplitude and frequency to one of the source grids causes low mass ions to be accelerated from the source storage region. High mass ions, on the other hand are not removed.

Comparison of the residual gas spectra obtained with and without the application of a 2MHz, 30Vpp "tickle" voltage, (see Figure 3a-b) reveals that up to 10 times more high mass ions are stored when the helium ions are continuously removed.

Figure 3a. Spectrum obtained without the tickle applied.

Figure 3b. Spectrum with the tickle voltage applied.

Comparison of storage time constants (1/kL) obtained with and without the application of the tickle voltage, (0.77 s and 0.27 s respectively) indicates that the analyte ion loss rate is substantially decreased when the helium ions are being selectively removed. (see Figure 4)

Figure 4. Effect of applying a tickle signal on the storage curve for analyte ions.

The capability of comparing a nitrogen chromatogram generated from a gas chromatograph (GC, Varian model 3400) linked to a thermal energy analyzer (TEA, Thermedics Inc. Model 610) with a total ion chromatogram (from a Finnigan-MAT Ion Trap Mass Spectrometer, ITMS) has provided a new means to screen and identifying trace levels of nitrogen-containing compounds in complex mixtures. Prior to the work described here, it has not been possible to simultaneously acquire TEA and MS data. What was needed was a viable GC-TEA/ITMS interface to combine the capabilities of both instruments.

INTERFACE: The TEA pyrolyzer is installed vertically on the GC oven box. A hole was drilled through the GC oven to insert the pyrolyzer transfer line. At the exit of the GC capillary, a glass "Y" connector with a split ratio of 1:1 was attached. Two six inch guard columns were attached to the fork side of the connector. The ends were then connected to two separate, low dead volume valves (MCV-1/100 control valve, Scientific Glass Engineering PTY. LTD). The control valves were placed in a specially machined heating block. A heating cartridge in the center of the heating block provided stable heating at variable temperatures (utilizing the alternate heater controller from the GC). The exit of one valve was connected to the ITMS interface (via capillary guard column), the other to the TEA interface. A complete schematic of the linked GC-TEA/ITMS system is shown on Figure 1. The GC carrier gas linear velocity did not change with respect to the ITMS when operating in GC-TEA/ITMS mode. Data acquisition for the TEA utilized a MLS A/D data acquisition card (Industrial Corporate Source, San Diego, CA) and a stand-alone PC. A variety of unique data manipulation software programs were designed to offer the user a full range of processing options.

RESULTS: The capability of the GC-TEA/ITMS to screen for and identify nitrogen-containing compounds is illustrated Figure 2. The peak retention times of only nitrogen-containing compounds from the TEA chromatogram (Figure 2A) have a corresponding peak in the TIC (Figure 2B). Explosives in a complex matrices can be seen easily with GC-TEA/ITMS (Figure 3). Figure 3A demonstrates how a sample of diesel fuel was screened for explosives using the TEA chromatogram. The TEA response for TNT can be confirmed by locating the corresponding peak in the TIC (by retention time, Figure 3B) and extracting the mass spectrum of TNT (Figure 4B inset). Once the nitrogen compounds are identified, and if there are several samples of this type, a MS/MS scan function can be generated for the target compounds. For example, single reaction monitoring (SRM) of TNT (Figure 3C inset), [fragmentation of m/z 210 (precursor ion) to m/z 164 (product ion)], removes all superfluous peaks contributed by diesel fuel from the TIC (Figure 3C). This clearly shows the analytical power of ITMS for linked GC-TEA/MS/MS.

Another application of this new system is its use for drug detection. Figure 4 illustrates how phencyclidine (PCP) can be detected (Figure 4A) and identified (Figure 4B inset) in marijuana extract. In addition to PCP we also identified 1,3-benzothiazole, a rubber product residue. A strong 1,3-benzothiazole TEA response (Figure 4A) facilitated the location of 1,3-benzothiazole on the TIC for mass spectral identification.

We have not attempted to perform quantitative studies or optimize detection limits for specific compounds. We are addressing these issues currently. Our results indicate that linking TEA with mass spectrometry will provide a new analytical tool to screen and identify trace levels of nitrogen compounds.

Supercritical fluid chromatography (SFC), with its complementary nature to gas chromatography (GC) and high performance liquid chromatography (HPLC), has become an increasingly widespread method of analysis over the past few years. For example, SFC has been applied to mixtures which are too low in volatility or thermal stability for GC, or which lack a good functional group for sensitive HPLC detection. Compilations of SFC applications have been published.

Historically, most detection for SFC has been performed with a flame ionization detector. As the routine use of SFC has grown, so has its combination with detectors which provide more informative knowledge of the analyte. Such is the case, for example, in supercritical fluid chromatography-mass spectrometry (SFC-MS). As the field has developed, many researchers in SFC-MS have moved to mass spectrometers that are able to capitalize on some of the inherent advantages of SFC. In particular, a move to higher mass range instruments, either quadrupoles, double-focusing sector, or Fourier-transform and more recently the Paul ion trap has been apparent. However, the quadrupole ion trap has the potential to deliver the advantages of high performance instruments without the disadvantages of being generally large, complex, and expensive.

Recently, we described a tandem quadrupole mass filter/ion trap mass spectrometer. Ions produced in a conventional ion source are transmitted from the quadrupole, with or without mass selection, into the quadrupole ion trap where they are further characterized. The combination of capillary SFC with an instrument allowing external ionization (see Figure 1) provides a number of distinct advantages. The instrument provides good sensitivity, the capacity for performing MS/MS experiments, traditional electron and chemical ionization, and it tolerates relatively high flow rates of mobile phase from the chromatograph.

The instrument was characterized and optimal experimental conditions determined with perfluorotributylamine, anthracene, and methyl docosanate. A sample of 80 femtomoles of anthracene provided a S/N of 20 (see Figure 2 and 3). Once the operating parameters were optimized, two less volatile mixtures were characterized. The first was a standard, 770-average-molecular-weight poly(dimethylsiloxane). The second was a derivatized surfactant for which the full structure was not known (see Figure 4), but was determined with the SFC-MS data.

INTRODUCTION
Collisional activation (CA) has become a very useful technique in tandem mass spectrometry for
inducing the characteristic dissociations of selected ions for fundamental and structural studies. The
principal advantages of high-energy CA lie with its generality and efficiency. Its versatility is manifest
in the ability to generate useful MS/MS data for almost all ionic species up to 2500da, including
biomolecules, without the need of constant instrumental optimization.

INSTRUMENT
The VG ZAB-T is a four-sector mass spectrometer of BEBE layout in which MS-II is of special
design featuring a wide-acceptance inhomogenous-field ESA coupled with either a conventional or a
six-inch microchannel plate (MCP) detector. The MCP detector, while not employed in the
experiments reported here, affords much greater efficiency in the generation of MS/MS spectra from
limited amounts of materials than does a conventional detector.

As a four-sector instrument, the ZAB-T makes possible the selection of precursor ionic species and
subsequent analysis of fragment species with greater than unit resolution in the same experiment, a
capability not possible on our three-sector instrument of EBE design. Such selectivity allows the study
of competing fragmentation pathways whose products would not be resolved otherwise. At the same
time, essential reproducibility of spectra between the two machines is maintained.

The wide energy acceptance of the ESA of MS-II coupled with a flexible collision cell between MS-I
and MS-II facilitates the generation of MS/MS spectra with varying collision energy without the
sacrifice of resolving power.

By using the opportunities afforded by the ZAB-T, we have begun reinvestigating prototypical systems
that exhibit charge-remote fragmentation. These systems were chosen because of the potential in
determining the nature of long hydrocarbon chains on molecules and because that capacity may be
enhanced by elevated high-energy CA.

EXPERIMENTAL
All experiments were carried out on the ZAB-T. Precursor ions were desorbed by Cs+ LSIMS,
accelerated to 10keV, and selected by MS-I with resolution >1000. CA was performed in the
collision cell between MS-I and MS-II with He as the target gas at 50% beam suppression. Collision
energy was 10keV except for the collision energy study in which the cell was floated to the
appropriate potential. Fragment ions were analyzed in MS-II with greater than unit resolution and
detected at the conventional detector.

RESULTS AND DISCUSSION
Collision Energy Study
CA at a variety of energies (lab frame) from 10keV down to 500eV were performed on the
n-dodecyltrimethylammonium ion. The intensities of the eight charge-remote losses (m/z 212 to m/z
116) and the major charge-related fragmentations (m/z 100 to m/z 41) were separately summed and
the sums were ratioed. The ratio of charge-remote/charge-proximate as a function of collision energy
is shown by graph in figure 1.

Since charge-remote fragmentation carries more structural information than charge-proximate
cleavages, the ratio of charge-remote/charge-proximate is a measure of information content for the
MS/MS spectra. Based on the energy available in the center-or-mass frame of reference, it is likely
that the high collision energy response which is increasing would prove to be more general than the
lower energy maximum and thus motivate the use of elevated collision energies for this class of CAD.
At 500eV collision energy, the charge-remote fragmentation for this species disappears except for the
equivalent loss of methane.

Mechanism
The MS/MS spectra showing charge-remote fragmentation of 7,7,8,8-d4 palmitic acid is shown in
figure 2. The pattern of fragmentation in this more detailed spectrum is still consistent with the
proposed 1,4-H2 loss resulting in C-C bond cleavage.1 The cleavages labelled a-e show the expected
progression in m/z. The intensities of b and c are depressed because of a proposed 1,4-HD
elimination in these cases. The significant minor peaks at m/z of 142, 144, 159, and 173 may be due
to mechanistic complications or some inaccurate labelling in the precursor.

Structural Determination
MS/MS spectra featuring charge-remote fragmentation were obtained for a series of long-chain fatty
acids (stearic, oleic, linoleic, linolenic, arachidonic, etc) and for a set of EETs (monoepoxy
eicosatetraenoic acid isomers derived from arachidonic acid). The spectrum for the 14,15-EET is
shown in figure 3.
Improved resolution revealed details previously obscured in MIKES spectra in the MS/MS spectra of these long-chain fatty acids: low-mass radical-ion series of formula \( \text{CH}_2(\text{CH}_2)_n\text{CO}_2\text{Li}_2^+ \) \((n=0, 1, \text{etc})\) which parallels the stability trends known for distonic ions (rapidly diminishing abundances for \( n>2 \)),\(^2\) and the splitting of peaks due to allylic and certain allylic-vinyl cleavages into doublets with the peaks corresponding to the closed shell ionic species dominant. The spectra are otherwise consistent with MIKES spectra and show the gaps in the peak patterns corresponding to the positions of double bonds\(^3\) and the prominent peaks corresponding to cleavage sites that are allylic to the proximate double bond and vinyl to the distal double bond of a homoconjugated pair.\(^4\)

For the EET's, the features corresponding to charge-remote fragmentation are present in the MS/MS spectra of these compounds and are useful in structural assignments even though they are not the most prominent features. Most prominent are the four major sequential peaks that correspond to cleavages about the epoxy group. The epoxy related cleavages are much enhanced over those for a simple long-chain epoxy acid. Also prominent are peaks corresponding to water loss and the low-mass radical-ion series.

**CONCLUSIONS**

The ZAB-T shows great promise as a tool for structural and fundamental studies. The range of molecular weights it can handle should make it useful for studying molecules of biological interest.

**REFERENCES**

The use of analytical instruments on manned spacecraft has been limited by the lack of sufficiently compact, space-qualified devices with the required specificity and sensitivity. Only recently, longer manned missions have been achieved on space shuttle operations and consequently, methods for analytical measurements of the spacecraft environment are of importance. For example, a rapid and routine method for monitoring the spacecraft environment for contaminants, is essential. To address this need as well as support research on board the spacecraft, we have designed a compact triple-sector MS/MS instrument, with an EBE configuration.

Several constraints are placed on the analytical mass spectrometer for operation in space applications. The three primary constraints are: power, size, weight and reliability. The EBE design constraints (which become design goals) are: (1) power consumption of less than 100 Watts, (2) less than 100 pounds, and (3) less than 2 cubic feet in size. Unfortunately, these constraints limit the mass range, resolution, and utility of various types of spectrometers. For example, a scanning magnet or a quadrupole were ruled out due to their excessive power requirements.

We have redesigned the already space-proven mass spectrometer used on the NASA Mars lander mission. This mass spectrometer is an accelerating voltage scanned mass spectrometer with a Nier-Johnson configuration. Modification of the source has been accomplished for improved transmission and simplified construction. This ion source is a hybrid of the original source and a source design of Matsuda, et al.\(^1\) employing an acceleration/deceleration region. The original and the modified sources were compared via modelling with SIMION under optimum focusing and extraction conditions for a given set of initial parameters. Comparing the off axis velocity and spatial divergence values, it is estimated that the new source is an order of magnitude more efficient.

Analysis of the instrument configuration revealed that the image and object distances as well as the shunts for the electric sector were accurate\(^3\). The image exit slit half-angle was calculated to be 3.7\(^\circ\).

The design of MS2 involves a lens system that will refocus the diverging beam exiting MS1 on to a microchannel plate (MCP) and allow control of the collision energy. This surface dissociation technique has been used successfully by Aberth\(^7\). The MCP has a length to pore ratio of 40 and a tilt of 1\(^\circ\) yielding an effective ion interaction with approximately 1100 pores.
A lens system system for collecting the resulting daughter ions is currently being designed however, the required vacuum system, power supply, and control circuitry have been designed. A diagram of the complete spectrometer in a custom vacuum housing is shown in Figure 1. MS1 has a fixed magnet and MS2 has a scanned electric sector (floated relative to MS1) for daughter ion analysis.

The power consumption is less than 250 Watts. The weight of the spectrometer is less than 100 pounds and it is approximately 2 cubic feet in size. The resolving power is 375 and currently employs fixed slits.

PERFORMANCE OF AN ATMOSPHERIC SAMPLING GLOW DISCHARGE IONIZATION SOURCE WITH A TRIPLE QUADRUPOLE MASS SPECTROMETER

Barry C. Grant, Douglas E. Goeringer, Kevin J. Hart, Scott A. McLuckey, and Gary L. Glish
Analytical Chemistry Division
Oak Ridge National Laboratory

Introduction

Atmospheric sampling glow discharge ionization (ASGDI) has been shown to be a highly sensitive ion source for the detection of organic compounds in air (1,2). We first interfaced this ion source with a home-built quadrupole/time-of-flight (QT) instrument (3). A second MS/MS instrument, a Finnigan ion trap mass spectrometer (ITMS), was then modified extensively to adapt the ASGDI source (4). We have recently interfaced an ASGDI source with a Finnigan TSQ 700 tandem quadrupole instrument. Part of the rationale behind this work was to adapt ASGDI in a very simple and inexpensive manner to a widely available state-of-the-art beam-type tandem mass spectrometer. In particular, we are interested in evaluating the ASGDI/TSQ 700 combination as an explosives vapor detector.

TSQ 700 Modification

An ASGDI ion source geometry was designed that would adapt directly to the TSQ 700 ionization region vacuum manifold. The modifications to the TSQ 700 include:

- removal of the normal EI/CI ion source and solids probe flange and replacement with the ASGDI source
- addition of a 1 cm tube extension to the first lens element for ion extraction
- addition of a 10 L/s roughing pump to evacuate the ASGDI source to 0.8 torr
- addition of a DC power supply to provide the 400 V, 10 mA for the discharge

Results and Discussion

An important application of ASGDI is the ionization of trace quantities of high explosives in air. We have therefore focussed our attention first on the negative ion performance of the ASGDI/TSQ 700 system. The negative ion mass spectra obtained with the ASGDI/TSQ 700 instrument are virtually identical to those obtained with the other instruments. The MS/MS spectra show qualitative differences, however. The major difference between the TSQ 700 and the QT is much poorer product ion resolution in the latter. Mass resolution is comparable for the TSQ 700 and the ITMS but collisional activation conditions are significantly different for the trapping instrument vs. the beam-type instruments. The major difference in the product ion spectrum is the relative intensity of the NO$_2^+$ product ion. This product ion can be the major ion in the beam-type instruments but is essentially absent in the ITMS spectrum.

The appearance of a large NO$_2^+$ in the MS/MS spectra acquired with the beam-type instruments can be useful in rapid screening for nitroaromatics via the "targeted product ion" mode of operation (5). In this mode, the first quadrupole is operated as a high pass filter (e.g., passing only ions of m/z > 150) and scanning the second analyzer to detect any product ions characteristic of a compound class. The product ions NO$_2^+$ and NO$_3^+$, for example, are characteristic of nitroaromatics and nitrate esters, respectively. It is therefore desirable to maximize NO$_2^+$ from the MS/MS of M of TNT for application of the targeted product mode of operation. The use of argon as a collision gas at pressures sufficient to attenuate the parent ion signal by 50 % and use of a laboratory collision energy of about 40 eV constitutes the best compromise between transmission and NO$_2^+$ production.

The performances of the three ASGDI/tandem mass spectrometers were compared under different MS/MS operating modes. In all cases an equal and constant flux of TNT was admitted into the instrument (maximum concentration estimated to be 1 ppb) and data were collected for two seconds. This normalized the analyte quantity sampled by each instrument. A quantitative measure of "signal/noise" for each
experiment was taken as the analyte signal (minus background signal) divided by three times the standard deviation of the background signal. For the beam-type instruments, the NO$_2$ product ion was used as the analyte signal whereas the product ion at m/z 210 was used for the ITMS data. Table I summarizes the "signal/noise" results acquired under various MS/MS operating modes. The various operating modes establish compromises between signal/noise and specificity via the normal trade-offs between resolution and transmission, duty cycle and scan length, etc. The most direct comparison to evaluate signal/noise at equal specificity comes from the data acquired with MS I resolution > 400 and MS II resolution maximized. For the TSQ 700 and the ITMS, MS II resolving powers are comparable. However, the resolution of MS II of the QT is at least an order of magnitude lower. The TSQ 700 provides slightly better signal/noise than does the QT and with much superior specificity. The ITMS, however, provides roughly an order of magnitude greater signal/noise with specificity at least as good as that of the TSQ 700. At the cost of specificity, however, the beam-type instruments can come closer to the performance of the ITMS. This is apparent in the numbers obtained using various forms of parent ion resolution degradation, including the targeted product ion mode. The TSQ 700 can approach the performance of the ITMS in the targeted product ion mode with a narrow scan (to improve duty cycle) over the m/z 46 product ion. An analogous procedure is not available for the QT.

Conclusions

The TSQ 700 can be fitted with an ASGDI source simply and with minimal expense (hardware costs < $10k). The ASGDI/TSQ 700 provides performance superior to that of the QT instrument both in terms of specificity and signal/noise (which should translate to lower limits of detection). The ASGDI/ITMS provides the best performance of the three instruments in terms of specificity and signal/noise. However, at degraded specificity the ASGDI/TSQ 700 can provide performance in MS/MS signal/noise comparable to that of the ASGDI/ITMS.

Table I
The field of ion-molecule chemistry is well established at relatively low pressures (<10 Torr) with thousands of rate coefficients having been measured. Conversely, of the few data that exist at pressures up to and exceeding atmospheric pressure, only a small fraction are quantitative. Studies of ion-molecule reactions under the collision dominated conditions at atmospheric pressure can provide a wealth of fundamental information with valuable application to environmental chemistry and trace analysis.

We are currently developing an ion mobility spectrometry (IMS) system which will allow measurement of ion-molecule reaction rate coefficients at atmospheric pressure and over a range of temperatures from ambient to 200°C.

IMS is a method of separating ionic species according to their drift velocity (or more correctly their mobility) through a neutral gas under the influence of an electric field and has been used to date essentially as an analytical tool. The present IMS is illustrated in Figure 1 and consists of a drift tube approximately 37 cm long and 9 cm diameter. Ions are produced by a 15 mCi $^{60}$Ni source and drift through a counter flowing drift gas, under the influence of an electric field towards the Faraday plate detector. Ions are admitted to the drift region in short bursts by pulsing the Bradbury-Nielson grid, then they are collected at the Faraday plate, amplified and recorded by a signal averager.

To study ion-molecule reactions, the drift gas is seeded with known concentrations of a reactant gas and the resultant modification of the ion arrival time spectrum can be modelled to obtain the rate data.

We report here two preliminary negative ion reaction studies under the IMS conditions given in Table 1:

1. Azulene in the source gas (to produce Az$^-$) and CF$_3$Br in the drift gas; shown in Figures 2A, 2B and 2C. The product ion has a higher mobility than the reactant ion. Figure 2D shows the spectrum obtained with CF$_3$Br in the source gas and pure $N_2$ as the drift gas. A pulsed e-beam high pressure mass spectroscopy (PHPMS) study of the reaction between Az$^-$ and CF$_3$Br revealed the product ion to be Br$^-$ and a rate coefficient $8.2 \times 10^{-10}$ cm$^3$ s$^{-1}$ is reported at 125°C in 3 Torr of Methane [1].

2. CFCl$_3$ in the source gas (to produce Cl$^-$) and CH$_3$Br in the drift gas; shown in Figures 3A, 3B, 3C and 3D. The product ion has a lower mobility than the reactant ion in this case. The reaction between Cl$^-$ and CH$_3$Br has been well studied and the product ion is known to be Br$^-$. From the PHPMS results of Caldwell et al. [2] a rate coefficient of $8.8 \times 10^{-12}$ cm$^3$ s$^{-1}$ can be determined at 125°C in 5 Torr of Methane.

The observed ion arrival time profiles are in agreement with those predicted by the analytical model of Woo and Whealton [3]. Thus with the ensuing addition of a mass spectrometer, reactant gas handling plant and source handling plant we will be able to quantitatively study many chemical systems of interest at atmospheric pressure.

GAS-PHASE ION CHEMISTRY USING A TROCHOIDAL ELECTRON MONOCHROMATOR

J.A. Laramée, B. Mahiou and M.L. Deinzer, Department of Agricultural Chemistry, Oregon State University, Corvallis, Oregon 97331.

A trochoidal electron monochromator/mass spectrometer has been constructed to perform environmental analyses for which it is ideally suited for such applications. The kinetic energy of the electron beam can be easily varied from 0.025 to 30 eV under computer control. No reagent gas is used to moderate the electron energy; consequently, the mass spectra are expected to be free from artifacts which arise from ion/molecule interactions and that vary with the nature of the analyte, and ultimately lead to spectral irreproducibilities (Laramee, 1986). The instrument can be applied to the solution of environmental problems which cannot be reached by other simple mass spectrometric techniques such as isomer differentiation of tetrachlorodibenzodioxins, polychlorodibenzofurans, and polynuclear aromatics. Although positive electron affinities can be measured by several techniques, an electron monochromator/mass spectrometer system is the only instrument for measurement of negative electron affinities. It can be used to investigate a wide range of chloro/fluro aliphatics. These compounds are responsible for the observed loss of O³ in the Antarctic vortex (Anderson et al., 1991).

The trochoidal electron monochromator was first brought to practice by Stamatovic and Schultz, 1970, and has since been used by several investigators (refs. in Christophorou, 1984). All electron optic components are made of 99.999% pure molybdenum. Non-magnetic stainless steel is used for the other vacuum system components. Electron scattering resonances for molecules which possess negative electron affinities are detectable since all scattered electrons have their axial velocity vector reoriented and do not have sufficient axial momentum to overcome a retarding barrier. Molecules with positive electron affinities which can form stable anions with respect to autodetachment are mass analyzed and detected (Figure 1).

The operating principle of the electron monochromator/MS is electrons emitted by a rhenium filament are confined by a magnetic field and analyzed by crossed electric and magnetic fields. This arrangement produces intense electron beams (~3 x 10⁷ A) at very low energies (0.025 eV). Electrons entering the crossed field off-axis move trochoidally towards the center of the end-cap electrode with a drift velocity of E x B/B². Excellent peak shape, determined by third and fourth moment analysis is obtained which compares well with the instrument function. Isotope measurement accuracy is excellent at ±1.2% for the 99% confidence level, and the system can be operated over a wide range of sample pressures without loss of energy resolution for an energy spread of ±0.28 eV. The highest energy resolution obtained thus far is ±0.07 eV.

We have begun to test the hypothesis that positional isomers can be distinguished on the basis of differences in their electronic manifolds which can be accessed by discrete energy electrons. The isomers 1,2,3,4-tetrachlorodioxin and 1,3,6,8-tetrachlorodioxin show differences in the electron energy (e_max) needed to produce the maximum amount of M'' (Figure 2). These attachment energies follow the same ordering as their calculated lowest unoccupied orbital energies, ca. 0.96 and 1.59 eV, respectively. Tetrachloronaphthalenes (Halowax) are another class of environmentally relevant compounds which are used in electrical insulating materials, cutting oils, textiles and paper. Although their mass spectra are identical, the isomer 1,4,6,7 tetrachloronaphthalene reveals an e_max of 0.34 eV, while 1,4,6,8 tetrachloronaphthalene has e_max equal to 0.50 eV. The technique of monoenergetic electron capture ionization indeed appears to be sensitive to isomer position as these two isomers differ by a single chlorine from the β-position to the α-position. These resonances in ion production with respect to electron energy are unique to each compound and furthermore, it is unlikely that the same resonances will be found for the same mass ions. For this reason, monoenergetic electron capture ionization should be useful for the analysis of environmental compounds (Watson, 1990).

Multiple resonances to form a stable M'' radical anion at m/z 123 from nitrobenzene were observed at 0.06, 3.3, and 6.9 eV. The two higher energy peaks could be formed from independent electronic states or different ion structures of the same mass. The mass spectrum of heptachlor obtained by broadband (0-3 eV) electron capture from the electron monochromator/MS system was compared to the spectrum obtained from the Finnigan 4023 mass spectrometer. A factor of 10 increase in relative abundance for the higher mass ions was observed using the electron monochromator (Figure 3).

THE 39TH ASMS CONFERENCE ON MASS SPECTROMETRY AND ALLIED TOPICS

ANALYSIS OF POLYCYCLIC AROMATIC COMPOUNDS BY SUPERCRITICAL FLUID CHROMATOGRAPHY-MASS SPECTROMETRY USING ATMOSPHERIC PRESSURE CHEMICAL IONIZATION

J.F. Anacleto, F. Benoit, R.K. Boyd, S. Pleasance, M.A. Quilliam, L. Ramaley and P.G. Sim

The analysis of polycyclic aromatic compounds (PAC) is of considerable importance due to concerns over the mutagenicity and carcinogenicity of many of these compounds. Because of the complexity of most PAC contaminated samples, methods of analysis that offer good chromatographic resolving power and selective and sensitive detection are required.

Supercritical fluid chromatography (SFC) is a complementary technique to both gas and liquid chromatography, which provides efficient separations of less volatile, higher molecular weight compounds with relatively short analysis times [1]. The difficulties in coupling SFC with mass spectrometry (MS) have been largely due to the pressure requirements of conventional mass spectrometers.

Atmospheric pressure ionization (API) MS is rapidly becoming a universal detection system for the separation sciences [2]. A rugged API-MS interface for the routine coupling of microbore packed-column SFC with a SCIEX API III triple quadrupole mass spectrometer has been developed [3]. The improved interface was designed to accommodate commercially available fused silica restrictors.

The atmospheric pressure chemical ionization (APCI) of PAC has been found to involve both charge and proton transfer reactions. The ratio of M⁺ to [M+H]⁺ ions will depend on the ionization energies and proton affinities of the analyte. Figure 1 illustrates that as the size of polycyclic aromatic hydrocarbons (PAH) increases, proton transfer becomes the predominant form of ionization. This reflects the increase in proton affinity with increasing PAH molecular weight. Nitrogen containing PAC (e.g. carbazole) produced predominantly protonated molecules while oxygen and sulphur heterocycles produced molecular ions.

The addition of chemical ionization modifiers to the make-up gas entering the source can be used to alter the reagent ion composition in the APCI plasma and therefore dictate the type of spectrum obtained. Benzene was used to promote charge transfer since trace compounds that have lower ionization energies than benzene, which is true for all higher molecular weight PAH, will readily transfer an electron to benzene radical cations. Proton transfer reactions were enhanced with the addition of water to the source. The two modes of ionization provided comparable detection limits for benz[a]anthracene of about 150 pg (signal to noise ratio of 2).

Using a photoionization detector for the off-line optimization of chromatographic conditions, SFC-APCI-MS was applied to the characterization of PAC in complex extracts from coal tar and hydrotreated tar sand oils. Ions corresponding to carbazole (m/z 168) and its alkylated homologues (m/z 182 to 490) were easily identified in a nitrogen-containing PAC fraction of a tar sand oil. Tandem mass spectrometric (MS/MS) experiments performed on the abundant [M+H]⁺ ions of the alkylated carbazoles showed the losses of neutral hydrocarbon fragments from the alkyl side chains.
Figure 1: SFC-APCI-MS background subtracted mass spectra of a test mixture of PAH.
Recent advances in the fabrication of ULSI devices has demonstrated the need for highly purified gases, with impurities at levels below 1 ppb. Consequently, the analysis of impurities in highly purified gases is becoming increasingly important in the semiconductor industry. Normal detectors utilizing GC and GC/MS techniques are not capable of detecting impurities at levels near 1 ppb. We have developed an Atmospheric Pressure Ionization Tandem Mass Spectrometer (API MS/MS) to measure trace impurities in ultrahigh purity nitrogen. This system has the capability of measuring sub-ppb levels of methane, water, oxygen and carboxdioxide in bulk nitrogen. In addition, utilizing the triple quadrupole feature of the analyzer, trace carbon monoxide can also be detected at levels below 1 ppb. This API MS/MS system utilizes a point to plane corona discharge at atmospheric pressure. The source is made of specially treated materials, and is heated, to avoid problems due to the adsorption of impurities on its surface. The triple quadrupole uses 3/4" diameter poles, and patented leaky dielectric endplates for enhanced transmission.

A mass dilution system along with a calibration gas was used to generate the calibration curves. The curves were obtained by monitoring the intensity at the indicated mass to charge ratio. The figures shown below demonstrate the linearity and the sensitivity for detecting the impurities in nitrogen. A linear regression analysis, with 99% confidence bounds, performed on the system response to varying concentrations of oxygen, indicate that the system has a detection limit of 50 ppt for oxygen in nitrogen. Experiments have also been performed on detecting trace impurities in argon, with similar results.
SINGLE-PHOTON IONIZATION MASS SPECTROMETRY WITH A VUV MOLECULAR HYDROGEN LASER SOURCE

Jeffrey W. Finch* and M. Bonner Denton
Department of Chemistry, University of Arizona, Tucson, AZ, 85721
*Department of Pharmacology, Medical University of South Carolina, Charleston, SC, 29425

A molecular hydrogen laser is characterized as a photoionization source for mass spectrometry. The laser, shown in Figure 1, is a Blumlein discharge apparatus, with a narrow discharge channel, 330 μm in height, and a low-inductance spark gap switch purged with nitrogen. Since the laser operates in a superradiant mode, there are no optical cavities or mirrors to align. Therefore, the laser is relatively simple to build and easy to operate. Details of the laser construction used in our laboratory have been previously discussed (1,2). The bottom Blumlein plate is wrapped with eight layers of .05" thick mylar dielectric and connected to a high voltage supply operating at 20 kV. With a hydrogen pressure of 45 torr inside the channel, the device outputs 160 nm (7.8 eV) photons from a series of Lyman transitions in the vacuum ultraviolet, with an average peak pulse energy of 30 μJ and a pulse duration of ~1 nsec.

For photoionization mass spectrometry, the laser is coupled to a linear TOF mass spectrometer (Figure 2) through a custom purge tube filled with He. The tube contains two CaF₂ windows sealed with o-rings at the ion source and the discharge channel. Ions are accelerated to 635 eV through a drift tube, 1.5 m in length, which contains a Galileo Electro-Optics Z-stack microchannel plate detector (~10⁸ gain) mounted at the end. Mass spectra are averaged over many laser pulses and stored with a LeCroy 9400A digital oscilloscope, which is linked to an IBM compatible 286 computer via an IEEE-488 interface. An ASYST version 3.0 software package was utilized for data acquisition and analysis. Samples are introduced as solutions through a heated inlet, or as solids using a direct insertion probe.

Types of compounds ionized at or below 7.8 eV include particular classes of molecules such as tertiary and aromatic amines, nitrogen heterocycles, pharmaceuticals, drugs of abuse, and polynuclear aromatic hydrocarbons (PAHs). The laser is a "soft" ionization source which produces only parent molecular ions for most of these compounds. For mixtures of photoactive species, this produces a simplified mass spectrum of only M⁺ ions as demonstrated in Figure 3, for a .5 μl injection of a mixture containing equal volumes of aniline (93), triethylamine (101), N,N-dimethylaniline (121), tripropylamine (143), tri-n-butylamine (185), and trihexylamine (269).

For PAHs, reproducible ion signals are obtained for averages over 500 laser pulses, with detection limits (S/N=3) in the 100 pg range. Selectivity and sensitivity for detection of PAHs in environmental samples is illustrated in Figure 4 for the analysis of a water sample from a drinking fountain spiked at 100 parts-per-trillion with pyrene (202), chrysene (228), benzo[a]pyrene (252), benzo[ghi]perylene (278), and coronene (300). 1 liter water samples of blank water and spiked water were mixed with 120 ml of isopropanol and aspirated through a 3 ml Bakerbond C₁₈ solid-phase extraction column (J.T. Baker, Inc.). Then the columns were eluted with 3 ml of hexane and the residues from the extracts were analyzed directly with an insertion probe on the laser/TOF instrument. Spectra for each sample were recorded by averaging over 200 laser pulses at two different heating times of the probe. While over 14 organic components were identified in a blank water sample extract by GC/MS, the photoionization mass spectra gave clear M⁺ ion signals for PAHs in the blank and spiked samples with a relatively low background from the sample matrix. This is attributed to the fact that the other organic components in the water sample identified by GC/MS have ionization potentials above the 7.8 eV laser threshold.

Selectivity of 7.8 eV photoionization has also been proven for screening of abused drugs spiked in pooled human urine samples. In this case, a simple solid-phase extraction step using a...
Bond Elut Certify column (Analytichem International) was applied, followed by direct analysis of the resulting solid residue with an insertion probe. Urine samples spiked at 200 ppb with cocaine, codeine, morphine, methadone, and phencyclidine yield photoionization mass spectra consisting of intense parent molecular ion signals for the drugs with a few signals from the matrix which do not interfere with identification of the M+ peak.

ENHANCED SENSITIVITY IN SFC-CIMS OF GLYCOCONJUGATES THROUGH SAMPLE DERIVATIZATION AND FOCAL PLANE DETECTION

Douglas Sheeley, Adrian Birchenough1, and Vernon Reinhold
Harvard University School of Public Health, Boston MA 02115
1VG Analytical Ltd, Manchester UK

Introduction

The importance of glycosylation in a variety of biopolymers has resulted in a more focused effort to understand carbohydrate structures. A detailed analysis of an oligosaccharide is however, complicated by numerous factors, foremost of which is an isomeric complexity coupled with the general problem in detecting sensitivity. Generally, several times more material is necessary for the detailed structural analysis of a carbohydrate than is the case for other biopolymers.

We have found that SFC-MS can provide an alternative approach to carbohydrate separations and molecular weight detection.1,2 When these materials are conjugated with groups possessing enhanced electron affinity, marked improvement in detection (femtomole) has been observed using negative ion chemical ionization.3 Further structural understanding has been realized through pre-column chemistry and related analyte derivatization.

It is the focus of this study to capitalize on these improvements by capturing this sensitivity and structural detail with a focal plane detector (VG ZAB2-SE-FPD equipped with a plane parallel electric sector and 40% coverage focal plane detector). Preliminary analyses comparing chemical ionization with fast atom bombardment indicated greater freedom for FPD signal amplification and hence smaller sample loading. SFC coupling would provide a similar matrix-free environment for NICI-MS-FPD analysis.

Results

In order to evaluate the relative sensitivities of the point detector (photomultiplier) and FPD, as well as the overall sensitivity of the FPD, a well characterized standard, PFBAB-labelled maltoheptaose, as a peracetylated derivative, was run under identical chromatographic conditions using each detector. Using the photomultiplier, at a resolution of 1000 ppm, scanning from 3000 to 300 amu, 80 femtomoles of PFBAB-maltoheptaose provides a selected ion plot with a signal to noise ratio of 25:1 and spectra with a signal to noise ratio of 50:1. This was commensurate with the initial studies done on a ZAB-SE.3 In previous work, the lower limit of detection was between 10 and 20 femtomoles for this compound.

Figure 1 shows the total ion chromatogram for an injection of 8 femtomoles, using the FPD, at lowest resolution (90°), with the micro-channel plate at 1.25keV and phosphor at 3keV. Signal to noise for this run is approximately 10:1. After peak processing, the spectrum in Figure 2 is obtained. Signal to noise is virtually 100:1.

These data were obtained under conditions where the FPD has not yet been fully optimized, but it is clear that this detector complements the features of SFC-MS well. The low background of SFC-NICIMS and concentration of ion current in the molecular ion are ammenable to the amplification possible with the FPD.

High Sensitivity Detection Effects upon FAB/SIMS Spectra

Julius Perel, Stephen A. Ruatta and John F. Mahoney
Phrasor Scientific, Inc., Duarte, CA 91010

High sensitivity detection investigations, originally undertaken to improve sensitivity at high mass, were found to provide significant improvement over the entire mass range. The investigations included increasing the ion impact energy and lowering the impact dynode work function to assure copious desorption/emission of negative particles. Improvement of signal and signal-to-noise has been demonstrated for a variety of ionization modes including EI, CI, Thermospray, FAB/SIMS, Electrospray, Particle Beam, etc. The enhancement of signal is sometimes dramatic, typically greater at high mass, and somewhat similar in effect for the different ionization modes. A few outstanding characteristics have been observed with Electrospray and FAB which will be discussed.

Electrospray spectra contain multiply charged ions which are advantageous in observing high mass sample on a limited range mass spectrometer. In addition, improvement in sensitivity for the multiply charged ions using the High Energy Dynode (HED) detector is greater than that for singly charged ions, revealing effects of impact ion mass upon signal enhancement.

The background noise typically observed in FAB/SIMS spectra measured on quadrupole mass spectrometers varies with the HED voltage differently than signal. This is probably due to the particular mix of particles desorbed during the ion (atom) surface bombardment. During the desorption process sample ions, liquid matrix ions and scattered primary ions/atoms are produced in the ion beam and focused toward the analyzer. The sample and its fragments along with matrix molecular ions make up the readable spectrum. The noise is composed of chemical noise (matrix fragments) which appears at each amu on the mass scale and scattered ions which are not mass analyzed. Chemical noise is generated by the desorption/ionization process and appears to the detector as signal. However, scattered ions having a higher energy than the others display characteristics that can be observed at the detector.

The tests reported in this abstract were performed on an HP5982 outfitted with a Cesium Ion Gun or a DIP Gun to produce the ions and an HED Detector used to increase detection sensitivity. Spectral signal was measured in the selected ion mode while the voltage to the dynode was varied between -8kV and +8kV. The general characteristics of molecular ion signal variation with HED voltage using gas and Cesium guns are similar to those reported in past HED studies (Ref. 1). However the non-mass analyzed background noise variation is distinctly different from the mass analyzed spectral signal (including sample, matrix, and chemical noise). Figure 1 shows the signal variation with voltage from +7kV to -8kV for the cesium ion peak. The minimum observed near -2kV and the maximum near -6kV have been observed many times previously. The structure in the vicinity of zero appears to be dependent upon the ion trajectory and the impact region within the horn of the CDEM (Ref. 2). A similar minimum occurs near -2kV in Fig. 2, which shows the variation of noise with HED voltage. In this case the maximum is a much sharper peak near -3kV with a steeper decline above this voltage. This region is not as well understood as is the region to the left of -2kV, which appears to relate to the structure near zero voltage in Fig. 1, while its spread is attributed to the higher energies and energy spread of the scattered ions generating the noise.

Figure 3 illustrates the exceedingly favorable effects of using HED voltage for moderately high mass FAB spectra. The signal increases, the noise decreases and both the signal and signal-to-noise increase by over two orders of magnitude.

Fig. 2. Noise variation with HED voltage during Cesium ion bombardment.

Fig. 3. Comparison of FAB spectra of Aerosurf with and without HED voltage showing a signal gain and signal-to-noise ratio gain of about two orders of magnitude.
The value of post mass filter acceleration devices in improving sensitivity has been demonstrated by Daley, Dietz, and others (1,2,3). These devices work by increasing the velocities of ions as they leave the mass filter, which increases the conversion of ions into electrons at the detector. Since all ions in a quadrupole mass spectrometer have similar energies (mv^2/2) and conversion of ions to electrons at the electron multiplier depends on velocity (v), higher mass ions provide lower signals with a standard electron multiplier and benefit more from the acceleration provided by a high energy dynode detector (HED).

Diagrams of an HED multiplier and a standard (non-HED) multiplier are shown in Figures 1 and 2, respectively. In the normal mode of operation, the high energy dynode is operated at 4-8 kV to accelerate ions leaving the quadrupole and to convert them into electrons, which are then accelerated into the horn of the multiplier. The dynode can also be operated at low voltage (0-255 V) to focus the ions directly into the horn of the multiplier. In the low voltage mode, the dynode resembles an "X-ray" lens and the HED shows sensitivities comparable to that of a standard multiplier.

The sensitivity improvement provided by the HED was determined by analyzing fourteen compounds with the HED operated in the standard, high-voltage mode, vs. with it operated in the low-voltage, "X-ray" mode. These studies were done with an HP5989A GC/LC/MS, operated in the El, Cl, particle beam (PB), and thermospray (TS) modes.

The HED produced sensitivity improvements of two to sixteen times in the positive ion mode, with the degree of enhancement increasing with molecular weight. In general, dividing the molecular weight by 100 provided a conservative estimate of the signal-to-noise enhancement provided by using the dynode at high voltage. For example, the HED improved sensitivity for 10 pg hexachlorobenzene (mass 284) by a factor of three, but improved sensitivity for hexaphenylbenzene (mass 534) by a factor of six. (See Figure 3.) The overall results are summarized in Table 1. Since the sensitivity gains were proportional to molecular weight, the HED proved especially beneficial for the LC/MS analyses of higher molecular weight compounds.

The growing popularity of very small and relatively low cost instrumentation for both residual gas analysis (RGA) and gas chromatography/mass spectrometry (GC/MS) has focussed attention on every area of the instrument. These seemingly unrelated techniques have a number of systems in common - one of the most important of which is the detector. Standard single channel electron multipliers (CEMs) are commonly used because of their excellent performance characteristics and stability even after repeated cycling between vacuum and atmosphere. The major thrust in recent years has been on reduced size and cost with little or no sacrifice in performance. Many CEMs suffer from the fact that they are relatively large devices (up to three inches long), and in some cases offer more performance than is really necessary (e.g. most RGA applications have little need for an analog gain of up to $10^7$ or more).

We have developed a compact ion detector based on a microchannel plate (MCP) which reduces the length of a typical detector by a factor of three while at the same time retaining many of the performance features of single channel detectors and offering the potential for even higher dynamic range than standard single channel devices. For higher gains required in some applications, a second MCP may be added.

Two variations of the detector are possible as shown in the figure below. The first is a device in which the MCP is located off-axis in order to reduce noise due to photons and neutrals emitted from the quadrupole. This detector would be operated in a manner similar to standard CEM detectors.

The second detector is based on an MCP with a 6mm center hole which allows an undeflected ion beam to pass through the detector. This undeflected beam may be collected in a faraday cup connected directly to an electrometer amplifier. For very small signals, the beam is deflected onto the MCP for amplification of $10^4$ to $10^7$ depending on the configuration. The deflection is accomplished by applying a high voltage to selectively electroded areas of the MCP detector. This has the potential advantage of allowing two or more detectors to be fabricated in a single housing. Initial experiments indicate that good sensitivity is obtained if the MCP voltage is kept high enough to accelerate the ions sufficiently into the detector. The device utilizes a common anode/faraday cup configuration for simplicity and cost savings.

Preliminary characterization data for both types of detector will be presented as well as recommendations for further improvements.
Direct Thermal Analysis of Materials Utilizing the Short Path Thermal Desorption System

Chris Baker, John Manura, Sandy Overton
Scientific Instrument Services
1027 Old York Rd., Ringoes, NJ 08551

This new technique permits the analysis of solid samples without the prior need for solvent extraction or other sample preparation. A variety of types of materials were analyzed including Food Products, Packaging Materials, Finished Manufactured Samples, Pharmaceuticals and Forensic Samples. The solid sample to be analyzed is inserted directly into the Glass Lined Stainless Steel (GLT) Thermal Desorption Tube. The new "Short Path Thermal Desorption System" was utilized to permit the direct sparging of the volatile and semi-volatile components from the solid samples directly into the GC injection port with subsequent GC and MS analysis. This technique permits the maximum sensitivity of analysis due to this direct injection technique.

The Scientific Instrument Services "Short Path Thermal Desorption System" was attached to the injection port of a H.P. 5971 MSD. A J&W DB-5, .25 mm x 25 meter, 0.25 u film thickness capillary column was used for this study. The GC was used in the splitless mode at a flow rate of 0.5 ml/min.

Desorption Tube for Direct Thermal Analysis

Experimental

One to 3 mg samples of the various solid samples to be analyzed were inserted into the GLT tubes between two quartz wool plugs. These tubes were then attached to the Short Path Thermal Desorption System and fitted with a syringe needle. The sample was flushed with helium carrier gas and then autoinjected into the GC injection port. The heating blocks were heated to the sparging temperature indicated and closed around the desorption tube to ballistically heat the sample to the set temperature. This combination of heat and flow sparge any volatiles or semi-volatiles into the GC injection port were they are subsequently trapped in a narrow band at the front of the GC column which has been cryo-cooled to -40° C. The sample is collected for 10 minutes after which the GC is programmed at 10° per minute up to 280° C, to elute the products which are subsequently analyzed via the Mass Spectrometer.
Results and Discussion

Food Products. Dried vegetative materials which are relatively low in moisture content can be analyzed via this technique. A wide variety of spices have been analyzed and the various terpenes, hydroxy-terpenes and sesquiterpenes identified. Samples containing high oil content such as peanuts can be analyzed by this technique instead techniques such as soxhlet extractions. Flavored candy samples can be analyzed directly to identify the artificial flavors and other additives.

Packaging Materials. Plastic food wraps, tapes, papers, cardboard, packaging containers, and other packaging products can be analyzed via this technique to identify the volatile components present that may be leached out in food products. With the increased use of recycled papers and with the increased concern over the leaching of chemicals, inks, preservatives and insecticides into food products, this technique is extremely versatile in identifying these materials.

Manufactured Products. Virtually any solid material can be analyzed via this technique. Samples analyzed include powdered laundry detergents, synthetic fibers, nylon rugs, wood products, plastics, waxes, and other finished manufactured products.

Forensic Materials. The direct thermal analysis technique lends itself to many areas of forensic analysis. Pharmaceutical samples can be analyzed to determine the residual solvents present. Materials from the scene of suspected arson crime scenes can be analyzed for accelerants.

Conclusion

The technique of direct thermal analysis utilizing the Short Path Thermal Desorption System has proven to be a valuable and versatile technique for the analysis of a wide variety of solid type samples. Due to the direct injection technique, the maximum sensitivity of analysis is possible and the labor time for sample preparation is minimized.
Improved Precision of Mass Spectral Response by Digital Control of Ion Energy and Mass Resolution

Adam J. Patkin, The Perkin-Elmer Corporation, 761 Main Avenue, Norwalk, CT 06859-0228
Anthony N. Duryea, Leybold Inficon Incorporated, 149 Delta Drive, Pittsburgh, PA 15238

Most GC/MS methods promulgated by the U.S. Environmental Protection Agency (EPA) require that the mass spectrometer be tuned in a specific manner. In particular, these methods require that the mass spectrometer be tuned to generate spectra of 4-bromofluorobenzene (BFB) and decafluorotriphenylphosphine (DFTPP) which meet specific relative intensity and resolution criteria. This may be a difficult and time-consuming task, requiring that the mass spectrometer be detuned from its optimal performance conditions. It is strongly desirable to avoid such time-consuming tasks in a production environment, so sample throughput can be maximized.

This paper describes a simple method of tuning the mass spectral response of a benchtop quadrupole mass spectrometer. It also demonstrates its applicability for satisfying EPA tuning protocols.

INTRODUCTION. In a quadrupole mass spectrometer the magnitude of the DC and RF voltages determines the mass and, in theory, a constant DC/RF ratio defines the resolution. A DC/RF ratio changing as a function of RF is often used for better control of mass resolution and intensity across the mass range. This is frequently achieved in hardware by increasing the DC by some fraction of the RF:

$$[DC] = [DC] + k[RF]$$

where $k$ is varied as a tuning parameter. Altering the $k$ parameter affects all masses in the spectrum.

The potential between the ion volume and the entrance aperture to the quadrupole rods, known as the ion energy, also exerts a strong influence on the spectrum. Increasing ion energy with mass is often applied to improve ion transmission from the ion volume to the quadrupole. This is usually performed linearly with mass:

$$E = a + b[RF]$$

where $a$ and $b$ are constants.

Together, the lens voltages, ion energy, and the DC/RF ratios define the observed relative ion intensities across the mass spectrum. The effects of the lens voltages interact, and adjusting one generally necessitates adjustment of others. This makes tuning a quadrupole mass spectrometer to match BFB or DFTPP somewhat problematic.

This paper demonstrates a method of defining the ion energy and DC/RF ratio at up to ten masses across the spectrum, and then ramping them in a piecewise linear manner. No changes to lens potentials are required. This allows the relative spectral intensity to be defined locally, with minimal effects elsewhere in the mass range. This technique, called OptiTune™ (Trademark of the Perkin-Elmer Corporation), allows the facile matching of reference spectra criteria.

EXPERIMENTAL. The ion optics were first tuned for optimal sensitivity across the mass range. The reference spectrum was then matched by DC/RF and ion energy adjustments alone.

These adjustments were made by observing the spectral intensities produced by a controlled leak of perfluorotributylamine (also known as PFTBA and FC-43) at ten of its characteristic masses (19, 50, 69, 131, 219, 264, 314, 414, 502, and 614). The ion energy and DC/RF ratio at each these masses were then modified.
so that DFTPP or BFB would yield a spectrum meeting EPA criteria upon injection. Once an acceptable DFTPP or BFB spectrum was obtained, the PFTBA spectrum was recorded.

EPA criteria may also be achieved by tuning the mass spectrometer to precisely replicate the recorded PFTBA spectrum.

RESULTS. DFTPP was chosen to demonstrate the effects of altering the DC/RF ratio at one mass of PFTBA.

Figure 1 shows the results of decreasing the DC/RF ratio and increasing the observed intensity of DFTPP's mass 275. Note that the spectrum has been simplified, by removing some masses (for heuristic purposes). Figure 2 displays the reverse, with a greatly reduced mass 275 intensity.

DISCUSSION. The optimal tuning of the mass spectrometer can usually generate a spectrum close to meeting the EPA criteria. Only small changes of relative intensity, typically less than 10 or 20 percent, are required for complete compliance. The displayed spectra in exhibit much larger variations in relative intensity for demonstration purposes. Smaller and more typical changes in intensity would have correspondingly smaller effects on the intensities of nearby masses.

There are two significant advantages to tuning by piecewise linear changes of the ion energy and DC/RF ratios.

First, the intensity response across the mass range can be adjusted locally, over a narrow mass window, without perturbing those mass intensities which may already meet the EPA criteria. This significantly reduces the need for iteration between tuning adjustment and injection of standards, thus saving time.

Second, the mass spectrometer operates at optimum voltages on its ion optics. Small drifts in voltage have minimal effect. In a conventional approach, the mass spectrometer would be de-tuned to meet the EPA criteria. Rather than operating at a maximum or minimum optimum for a particular voltage, the mass spectrometer operates where the response to a particular voltage may be sharply sloping. Small drifts in voltage now have significant effect.

CONCLUSIONS. This paper has demonstrated a novel approach to tuning a mass spectrometer to meet EPA criteria. The piece-wise linear fit of ion energy and DC/RF ratios allows:

- precise control of mass spectral response
- minimal interaction across the mass range
- much more flexibility than the conventional approach of varying only the slope of the DC/RF operating line or ion energy
- intrinsically more valid spectra than a software normalization based on PFTBA response.

MODIFICATION OF A QUADRUPOLE MASS SPECTROMETER FOR LIQUID SIMS

Stephen Boue, A. Kamel Harrata, and Richard B. Cole*

Department of Chemistry, University of New Orleans, Lakefront, New Orleans, LA 70148

The advent and refinement of liquid SIMS during the past decade offers the possibility for truly routine mass spectrometric analysis of polar, thermally-labile biomolecules. These types of compounds are not readily analyzed using classical ionization methods such as electron ionization and chemical ionization. Many older mass spectrometers were not designed to accommodate the liquid SIMS experiment. In this report, we have reconfigured one such instrument, a Hewlett-Packard HP5985A GC-MS, to perform liquid SIMS.

An important consideration in adapting the instrument was to keep the modifications relatively simple, such that any moderately equipped machine shop would be able to effectuate the changes. The modifications consisted of first welding a vacuum flange to the source-housing manifold to accommodate a commercially available focusing cesium ion gun (Antek model Cs-160-250B, Antek, Palo Alto, CA). Afterwards, a new secondary ion source block and secondary ion collection lens assembly were constructed. A sample probe with detachable tip was also fabricated.

Each constructed item was taken through an independent optimization procedure. The height of the added flange was positioned such that a minimum clearance (<1/4 inch) existed between the final lens of the cesium ion gun and the magnet yoke of the conventional EI/CI source. In this way, the mass spectrometer could be operated in the normal EI and CI modes without removing the cesium ion gun. The diameter of the added 'receiver' flange is 3/8 inch larger than the diameter of the ion gun mounting; this allows for manual centering of the primary ion beam.

Optimization of the aperture width, and placement of the added secondary ion collection lens has also been performed. Figure 1 shows the 3-dimensional plot of signal counts at peak maximum vs. lens distance from the probe tip vs. lens diameter. Four different lens distances and four lens diameters were evaluated. A 9 mm diameter lens placed at 6 mm from the target was shown to yield the greatest secondary ion signal. The target reservoir diameter was also empirically optimized; a 3 mm diameter resulted in the best secondary ion signal, as shown in Figure 2.

A conversion dynode detector (Phrasor HED, Phrasor Scientific, Duarte, CA) was purchased to replace the conventional electron multiplier detector in order to improve sensitivity especially at the higher mass end of the quadrupole analyzer (upper mass limit = m/z 1000).

The new capabilities for liquid SIMS have been demonstrated for various peptides, acyl carnitines, nucleosides, and glycoconjugates. Displayed in Figure 3 is the mass spectrum obtained for the peptide proenkephalin (Tyr-Gly-Gly-Pho-Met-Arg-Gly-Leu).

![Figure 2: Signal counts at peak maximum vs. probe tip reservoir diameter for four different probe tips.](image)

LASER PYROLYSIS GC/MS OF SINGLE COAL AND COAL MODEL PARTICLES

Waleed S. Maswadeh and Henk L.C. Meuzelaar
Center for Micro Analysis & Reaction Chemistry, University of Utah
Salt Lake City, Utah 84112

Laser pyrolysis GC/MS using an electronically pulsed cw CO₂ laser focussed at the center of a Paul trap type particle levitation device connected to a Paul trap type spectrometer (Finnigan MAT ITMS) by means of a short, ballistically heated capillary GC column (see Figure 1a) has proved to be a valuable technique for studying the devolatilization (pyrolysis + desorption) behavior of single, 100-150 μm sized coal particles at very high heating rates (10⁵-10⁶ K/s) [1,2].

A major advantage of the Paul trap type particle levitator, better known as EDB (Electro Dynamic Balance) is the absence of hot, adsorptive and/or catalytically active surfaces in the reaction zone. However, during the course of our experiments we encountered several serious disadvantages including difficulty in stabilizing irregularly shaped coal particles which causes the loss of many laboriously prepared and selected coal particles and introduces further problems when trying to obtain reliable optical images of single coal particles, e.g., for the purpose of temperature measurements. A second complication, encountered in trying to optimize experimental conditions, is the notoriously high interparticle heterogeneity in coals which is compounded by the unavailability of well defined coal model particles.

These experiences prompted us to design a modified experimental set-up, shown in Figure 1b, in which the EDB cell is replaced with a simple electron microscopy (EM) grid (400 mesh, 78% open) to support and stabilize particles while providing markedly improved collection efficiency for laser pyrolysis and desorption products, as illustrated in Figure 2. Comparison of the two GC/MS profiles in Figure 2 shows a high degree of qualitative similarity while illustrating the higher yield and improved signal to noise ratio of the EM grid technique. The improved signal quality is especially important for detecting and identifying minor components, e.g., reflecting subtle changes in pyrolysis mechanisms as a result of the high laser heating rate. Thus far, we have not detected any effect of the metal (copper; gold coated versions available) grid on the yield and composition of devolatilization products.

The need for coal devolatilization model particles of known composition provided the incentive to impregnate 100-150 μm sized Spherocarb particles (widely used for modeling coal char combustion behavior) with known quantities of coal-derived bitumen as well as soluble polymeric model substance, including fossil resin from Wasatch Plateau field (Utah) coal as well as recent Aspen lignin [3]. Preliminary results shown in Figures 3 and 4 illustrate the feasibility of this approach since characteristic pyrolysis products of resin and lignin are readily detected and identified among the devolatilization products from single, impregnated Spherocarb particles. Unfortunately, recent work by Sarofim and co-workers [4] has cast doubt on the presumptive homogeneity of Spherocarb particles with respect to density. This may limit the usefulness of impregnated Spherocarb particles for the development of reliable devolatilization standards in view of the potentially wide variation in absorptive and desorptive properties.

THE DETERMINATION OF STABLE ISOTOPE INCORPORATION BY GC-FI/MS

R.M. Milberg*, P. Beak, D.J. Allen*, and G. Lutz*
University of Illinois, School of Chemical Sciences, Urbana, IL 61801

INTRODUCTION

Combined gas chromatography-field ionization mass spectrometry (GC-FI/MS) has proven to be a useful technique in this laboratory for the determination of stable isotope incorporation in the study of mechanistic organic chemistry. The endocyclic restriction test is being developed here to determine the allowed reaction geometries for substitutions at various heteroatoms. This work provides the only experimental approach to the determination of reaction trajectories at non-stereogenic atoms. In order to determine if a reaction is intra- or intermolecular, double-labeling reaction experiments are employed with measurement of the isotopic distributions in the reactants and products by GC-FI/MS. This technique is extremely useful since conventional isotope ratio measurement techniques provide limited information when dealing with mixtures of small amounts of material. The electron ionization (El) spectra of many compounds examined posses a large (M-H)+ peak which interferes with H/D incorporation calculations.

HARDWARE AND METHODS

The GC-FI/MS isotopic incorporation measurements were performed using a VG 70-VSE mass spectrometer (VG Analytical, Ltd., Manchester, U.K.) employing a VG retractable, high temperature GC capillary column re-entrant and the new-style VG FI/FD ion source. The re-entrant is mounted in a bellows mechanism with a scissors jack motion device. This permits the end of the capillary GC column to be brought into direct proximity (within 1-2 mm) of the emitter wire in the FI/FD ion source. The re-entrant can be heated to over 400° for high boiling compounds. The re-entrant is completely retractable to allow the ion source to be installed and is adjustable in three dimensions for the optimal positioning of the end of the GC column with the emitter wire. The new-style FI/FD ion source is of an open design and does not have a source block which minimizes memory effects and background problems. The extraction focusing element consists of two parallel metal tubes which are internally heated. The small surface area of the tubes combined with the heating minimize condensation and surface reaction problems common to other type FI/FD ion source designs. Data were collected using electrical voltage scans over a narrow window around the molecular ion region.

EXPERIMENTAL RESULTS

The precision of the technique was measured by performing five consecutive GC-FI/MS runs of a mixture of equal amounts of N-isopropyl-3-phenylthiopropanecarboxamide and N-isopropyl-4-phenylthiobutanecarboxamide with 250 ng of each injected on the GC column. These are compounds whose product reactions have been examined with the aide of GC-FI/MS. The data indicate that the technique is reproducible to better than +/- 5%.

The reaction trajectory of the substitution of iodine by bromine in 3'(o-Bromophenyl)propyl-11-iodoundecanyl ether (Figure 1) has been examined employing double labeling experiments. Reactions in t-BuLi with subsequent reduction by MeOH were performed using the compound with natural abundance H and Br and with a 1:1 mixture of enriched compounds (o-Br and o-Br'/I'-D2). The GC-FI/MS data...
(Figures 2-3) indicate that the Br substitution is intermolecular and endocyclic because the products retain the label within the molecules with no evidence of products resulting from the intramolecular transfer of Br.

CONCLUSIONS

GC-FI/MS is an extremely useful technique for the determination of stable isotope incorporation applied to the study of reaction trajectories and kinetics. The technique is ideally suited to measuring incorporation in complex mixtures. GC-FI/MS is quite sensitive, as little as 10-50 nanograms of some compounds are needed. The technique provides measurements reproducible to better than +/- 5%, it is easy to perform, and does not suffer from the interferences present in EI since FI usually produces mainly molecular ions.

ACKNOWLEDGEMENT

The 70-VSE mass spectrometer was purchased in part with a grant from the Division of Research Resources, National Institutes of Health (RR 04648). The reaction trajectories research was funded by a grant to P. Beak from the National Science Foundation (CHE-875607).

An Automated Capillary GC Column Backflush System for Rapid GC/MS Analyses

J. G. Solch, J. H. Garrett, C. J. Reynolds, and T. O. Tiernan
Wright State University, Department of Chemistry and TCRP, Dayton, Ohio 45435

A current trend in GC/MS analysis is to achieve the detection and quantitation of large numbers of analytes in a single analysis in order to reduce overall costs. Considerable effort is also being expended on developing methods to analyze compounds having a wide variety of functional groups in a single analysis. The removal of all interfering compounds during sample cleanup procedures is not always possible when these encompass a wide variety of functional groups. Although high resolution mass spectrometry has been used to eliminate interferences arising from coeluting compounds which yield ions that can be mass resolved, this still does not obviate the need to remove residues which may result in degradation of column separation efficiency. In addition, the less-selective cleanup procedures and the long capillary GC columns which are typically used to achieve adequate resolution of many chemical components in such analyses often make it necessary to bake off the capillary column for extended periods of time after an analysis.

The objectives of the present work were to reduce or eliminate GC column bake-off time, to increase the time intervals between MS source cleanings, and to prolong the life of the GC capillary column by avoiding deposition onto the column of non-chromatographable residues.

Although the idea of using a capillary GC pre-column, and backflushing compounds having retention times greater than the analytes of interest, is well known, commercial systems which employ these methods are not readily available. Figure 1 shows a block diagram of an automated backflushing system designed at our laboratory. We have successfully employed this design to reduce turn-round time for a number of types of analyses on three different GC/MS systems. A backflush tee of the usual design is employed with this system.

Several advantages result from the use of this backflushing system. This system allows the removal of all peaks eluting after the analytes of interest, which can significantly decrease column bake-off time between analyses. Retention time characteristics of the analytical column are preserved since the pre-column prevents degradation of the primary analytical column by trapping non-chromatographable residues. This pre-column can be easily and inexpensively replaced. In cases where the capillary column is directly connected to the mass spectrometer, the intervals between required source cleanings are usually extended, since the late-eluting higher boiling compounds do not enter the source.

The backflush system described here has two limitations. First, installation of such a system requires replumbing the gas chromatograph during installation, which may void the manufacturer's warranty. Another possible problem concerns the column connection to the backflush tee. Since the connection between the pre-column and the analytical column cannot be a gas-tight connection, the solvent front from the injection can partially diffuse into the dead volume of the backflush tee connection. When redirection of the carrier supply occurs at the backflush time, a portion of the injection solvent that diffused into the dead volume will be redirected onto the analytical column. Under certain conditions, this re-introduced solvent peak can coelute with an analyte and represent an interference. However, a slight adjustment of the actual time of backflush will alter the elution time of the reintroduced solvent peak, and result in separating it from the analyte peak of interest.

The backflush system described here has been in continuous use on several GC/MS systems at our laboratory for a period of three years, and has functioned successfully in all cases.

In the past, detection of chromatographic peaks in a GC/MS system has generally relied on a set of simple rules which delimit the peaks. Problems that frequently arise from use of such simple rules include incorrectly drawn baselines; the beginning or end of a delimited peak may either be on the side of the peak or in the tail far from the peak center; drop markers which separate closely eluting peaks may either be missing or are arbitrarily inserted; and finally, peaks may be found in the background noise. Such problems are most severe with low signal-to-noise peaks and late-eluting peaks that are very wide. These problems result in inaccurate quantitation, and possibly, misidentification of the analytes in a GC/MS run.

The objective of the present work was to create a new rule-based GC/MS peak detection algorithm that would yield accurate, consistent quantitation of analytes in the GC/MS analyses of complex environmental samples. It was intended that this algorithm would also give accurate signal-to-noise values for each analyte delimited, and provide detection limits when the analyte was not found.

The peak detection algorithm processes the data (TIC, single ion, and so on) three separate times. The first pass determines the background noise, the second pass determines the baseline points, and the third pass finds all the peaks. Other data processing may also occur, such as Fourier smoothing, that yields better peak centroiding and more accurate separation of closely-eluting peaks. The present algorithm gives the analyst the option of setting variables that aid the peak detection algorithm. These variables are peak width, background noise, and a parameter for setting baselines. If no peak width is specified, the algorithm defaults to a peak width of five scans. Although the algorithm works well with this default value, it works even better if the actual peak width for an analyte is specified. The actual peak width is easily determined from a standard injection.

The determination of background noise is integral to achieving good peak delimitation with the algorithm. The background noise is found by looking at all the acquired data around the region of quantitation and determining the regions in which no peaks appear, and averaging those regions to determine an average background noise level. For TIC this noise level changes as run time increases. The analyst may set this to some default value if so desired, which is generally the case for full scan work, when the noise baseline for most masses is screened out by the GC/MS data acquisition. This part of the algorithm uses more than 50 rules.

After the background noise is determined, all the baseline points are predetermined before any actual peaks are delimited. The algorithm finds the baseline points in the regions that were determined to have no peaks present. The frequency cannot be greater than the peak width. A baseline point TIC value is close to the middle TIC for the background noise in the region in which it is set. The algorithm defaults to drawing relatively flat baselines. The analyst has control over the rate of change and number of baseline points, and may change these all the way up to a valley-to-valley baseline (skim) for all delimited peaks. This part of the algorithm uses more than 75 rules. At this point, the actual peak detection may be accomplished.

The algorithm searches for possible peaks on a scan by scan basis. When a possible peak is found, the starting and ending scans may be adjusted if chromatographic distortions are detected. The peak must then pass many requirements that include minimum height (signal-to-noise), minimum area, minimum peak width, and so on. If it passes all of the requirements, a peak packet is stored and the algorithm then searches for
another peak. This part of the algorithm uses more than 150 rules.

The rules for determining a peak include very few special-case rules that apply only to very specific sets of conditions. Most of the rules apply to the majority of the delimited peaks. A sample set of rules governing the determination of a drop marker is given below:

```java
if ( TIC apex - TIC start > 2 * minimum height ) |
if ( TIC present - TIC end >= 2* Minimum height ) |
   TIC next - TIC end >= 2 * minimum height ) |
if ( TIC present + minimum width / 4 > TIC end ) |
   if ( apex - start ) minimum width / 4 &&
      end - apex > minimum width / 4 )|
   if ( previous peak not dropped &&
      end - start >= minimum width ) |
      ( previous peak dropped &&
      end - start >= minimum width / 2 ) ) |
if ( TIC end > TIC end + 1 .. TIC end + minimum width / 4 ) |
   drop marker is inserted
```

As shown in this example, the minimum height, as determined by the noise and the width of the peak, are the only considerations. This is extremely important in the functioning of the algorithm.

This new algorithm has been successfully implemented in the MACH 3 software system of KRATOS Analytical. Additional refinements to the present set of rules will be made to further improve the ruggedness of the algorithm.
A Computer-Controlled Pressure Regulated Sample Inlet System
For Fourier Transform Mass Spectrometry

Shenheng Guan¹ and Patrick R. Jones
University of the Pacific, Chemistry Department, Stockton, CA 95211.

Fourier transform mass spectrometers are routinely used for ion-molecule reaction studies. They are usually equipped with leak valves for introducing gas phase samples at constant pressure. The sample inlet system should be continuously adjustable over an FTMS operating pressure range of $10^{-3}$ to $10^4$ torr. The sample pressure should be stable at the desired pressure for at least a few minutes for routine FTMS experiments. For two-dimensional FTMS experiments, the sample pressure has to be stable for several hours. In this work, a feed-back pressure control device was designed and constructed to achieve constant pressure over a long time period. As shown in Figure 1, a single board microcomputer is used to read the pressure from an ion pump and to drive a leak valve through a stepper motor. An assembly code program of the microcomputer was written to allow the operator to input the desired pressure, pressure tolerance, and response time. Once a START command is given, the device automatically increases (or decreases) to the desired pressure value in about five minutes. A stable pressure (within 5% over a 3 hour period) is maintained by the gas sample inlet system.

The algorithm for operation of the device is outlined in Figure 2. First, the ion pump current-to-pressure calibration table is loaded and several control parameters are specified by the user. These include the desired pressure ($P_d$), the pressure tolerance ($DP$), and the response time ($T$). $P_d$ is the pressure under which the experiment is to be conducted. $DP$ is the acceptable pressure range for the experiment. $T$ is the response time for the pressure change with the leak valve turning, a characteristic which has to be determined experimentally. For the configuration of our instrument, it is several seconds. After the parameters are set, the computer reads the current pressure ($P$) and compares it with $DP$. If $P - P_d < -DP$, the stepper motor turns the shaft of the valve 7.2° in the valve-open direction. If $P - P_d > DP$, the stepper motor turns the shaft the same amount in the valve-close direction. Otherwise, no signal is issued to turn the stepper motor. The controller uses this procedure to maintain the pressure between $P_d - DP$ and $P_d + DP$.

This device has been installed on our lab-built FTMS instrument for running two-dimensional FTMS experiments. This design provides a starting point for future automation of FT mass spectrometers.

INVESTIGATION OF A UNIQUE CHEMICAL BACKGROUND DERIVED FROM A CERAMIC PROBE TIP ASSEMBLY

Glaxo Inc. Research Institute, Five Moore Drive, Research Triangle Park, NC 27709

Introduction
An investigation was made into the identity, origin, and removal of a unique chemical background originating from the ceramic probe tip assembly of the VG 70 series mass spectrometer, observed under El conditions. The background was quite intense at ambient temperature, and significantly interfered with the analysis of unknowns at nanogram quantities. Subsequent shipments of the probe tip assemblies showed the same background ions. The background could be eliminated by heating the probe assembly in the vacuum lock, but was re-introduced upon brief (seconds) exposure to the laboratory atmosphere. A series of experiments were performed to understand and eliminate this problem.

Experimental
A VG 70VSEQ mass spectrometer was used to obtain El spectra of the untreated probe assembly and of the probe assembly after exposure to D2O and methanol. El spectra of boron oxide (Aldrich) were obtained by placing the sample neat in an alternative probe assembly consisting of a stainless steel base and ceramic tip. Methanol extracts of the boron nitride probe assembly base and boron oxide were analyzed using El and ammonia desorption chemical ionization (DCI). An Electroscan E20 electron microscope equipped with a Princeton Gamma-Tech Sili X-ray detector was used to obtain X-ray emission patterns and micrographs from two probe assembly bases. One probe base was untreated; the other had been sonicated in methanol for 30 minutes. Micrographs were obtained with the high resolution environmental secondary electron detector (ESD). X-ray diffraction patterns of boron nitride (Aldrich), boron oxide (Aldrich), and powdered probe assembly base were obtained using a Scintag XDS 2000 X-ray diffractometer with an 1800W copper X-ray source and an Ortec high purity germanium detector.

Results
The composition of ions in the background spectrum was determined using high resolution El mass spectrometry, and was found to contain boron, hydrogen, and oxygen. The base of the ceramic probe tip assembly used is made of boron nitride (BN) and was the source of the contamination.

Further investigation showed that the background spectrum could be altered by exposure to D2O and methanol. Application of a few drops of D2O to the probe tip assembly shifted peaks by 2 and 3 amu, as predicted by the proposed structures of fragment ions. Similar exchange of the active protons with methanol was demonstrated. This suggests that accidental exposure of the probe assembly to a protic solvent or other reactive species might introduce artifacts into a sample spectrum. Cleaning the probe assembly base by sonicating in methanol effectively removed the background but left the probe base extremely brittle and, therefore, unusable. A comparison was made between the probe assembly background and boron oxide, examining ambient temperature El spectra as well as El and ammonia DCI spectra of methanol extracts. Spectra from the two sources were similar, suggesting similarities in composition.

Electron scanning electron microscopy (ESEM) and energy dispersive X-ray (EDX) analysis were used to compare the surfaces of an untreated sample probe base and a base which had been sonicated in methanol. The X-ray emission spectra show that surface oxygen, chlorine, potassium, silicon, and carbon found in the untreated probe are removed during the cleaning step, leaving boron and nitrogen only. Cleaning with methanol removes the surface and exposes the internal crystal structure, shown by the micrographs.

X-ray diffraction patterns were obtained on a powdered BN probe base (untreated) and on boron nitride and boron oxide standards, to study the bulk material. The pattern for the probe base is identical to that of the boron nitride standard, and does not contain evidence that boron oxide may be present in the bulk material. This suggests that the background is primarily a surface phenomenon.

A solution was found in alternative materials. Two options which have been successfully used are a stainless steel probe assembly base (with ceramic tip) and a one-piece quartz probe tip assembly.
El mass spectra are shown of the following:

a) background from the ceramic probe assembly (accurate masses are shown),

b) the same background after exposing the tip to D₂O, and

c) the background after rinsing with methanol.
We have previously described a GC/GC/MS which utilized a flame ionization detector (FID) for detection of the GC effluent from the primary chromatograph (Ligon and May, J. Chromatogr. Sci., 24, 2 (1986)). This configuration required that 10% of the primary effluent be split to the FID which reduced ultimate MS sensitivity. Conversely, the splitting produced a 90% loss in FID sensitivity.

We have now modified our apparatus so that the FID is replaced by a photoionization detector (PID). In this configuration all of the primary effluent flows through the detector. The detection of minor components in the primary effluent is much enhanced. In addition, sample losses due to ionization in the PID are very small compared with the 10% loss of the FID. We have encountered only small losses in GC resolution in passing through the PID. In addition, we find that the PID cell is unaffected by the 10-20 PSI of internal pressure which it encounters during the secondary separation.

We have found that the relatively large quantities of material which reach the PID during 2D separation causes it to become contaminated relatively quickly. In addition, we find that using the standard 10.2 eV lamp, the PID is a relatively selective detector (e.g. poor response to saturated hydrocarbons) compared with an FID and this is a handicap in some analyses.

Laser desorption of neutral molecules in combination with multiphoton ionization and time-of-flight mass analysis has become a well-known technique to examine non-volatile, labile molecules [1]. Instead of multiphoton-ionization, it is also possible to use other ionization techniques, e.g. electron-impact (EI) ionization. EI is able to ionize molecules with higher ionization potentials, which can practically not be photon ionized with satisfying sensitivity. But on the other hand EI is said to be the less sensitive method, much more fragmentizing and therefore not so attractive for the analysis of labile species.

The measurements have been performed with a Bruker TOF-1 including EI ionisation unit. Neutral molecules are vaporized by pulsed infrared CO$_2$-laser radiation (10.6 μm, 10 μs). The desorbed intact molecules penetrate a pulsed supersonic jet (4 bar, 500 μs), which cools them and carries them into the ionization region. Here the neutral molecules are bombarded with 20 eV electrons for several μs. The ions produced are trapped in the focus of the electron beam. After the electron beam is switched off, the ions are pulsed into the TOF mass spectrometer. This technique allows resolutions of m/dm = 2000 (FWHH) and sensitivities not much less than that of multiphoton ionization (MPI). For samples with higher ionization potentials and exited states not matched by the photon energy, however, the sensitivity of EI-ionization is much higher than that of multiphoton ionization. The apparatus allows fast switching between both ionization techniques for direct comparison.

We have analyzed several peptides in the mass range up to 2000 u with the general finding that for all those species, where the molecular ion can be observed with multiphoton ionization (MPI), it also can be produced with electron impact ionization. EI often produces fragments similar to those produced by MPI, which leads to the conclusion that fragmentation is already "predecided" during desorption, although it is finally executed during ionization. For larger peptides, however, the fragments are more characteristic with MPI. Fig. 1 shows a complete raw data spectrum of Gramicidin D, the molecular ion is clearly seen. For Gramicidin S (see Fig. 2) the dimer and trimer are observed, too. The peptide PRO-LEU-GLY in Fig. 3 does not contain any double bonds, and therefore can not be ionized with MPI, if, as in our case, only laserlight in the range 230 - 300 nm is available.

The three stage ion source ND-jet-EI (Neutral Desorption - jet cooling - Electron impact Ionization) is well-suited to produce ions of labile, non-volatile compounds up to 2000 u. The success of this ion source is mainly based on the jet cooling of the desorbed ions as discussed in a parallel study [2]. EI ionization, when performed as described above, is a good and cheap alternative to multiphoton ionization. The best results can be obtained when EI and MPI are available, using the advantages of both methods alternatively.

SHORT CAPILLARY COLUMN GC/FID UNDER VACUUM OUTLET CONDITIONS AND ITS RELEVANCE TO GC/MS

Ulrich R. Bernier, Stacy-Ann Rossi, and Richard A. Yost
Dept. of Chemistry, University of Florida, Gainesville, FL 32611

Introduction
Short open tubular capillary columns can be employed in GC/MS when rapid separation is desired prior to mass spectral analysis. The effects of vacuum outlet operation are much greater for short columns (less than 10 meters) than for long columns. As the column length is decreased, the optimum velocity under vacuum outlet operation increases significantly. Thus, the most obvious advantage of short columns with vacuum outlet is the improved speed of analysis. Corresponding to this advantage is a loss in the number of theoretical plates by a factor of 8/9 versus atmospheric outlet operation.

The chromatographic performance of short columns may be studied by vacuum outlet GC/FID under approximately the same conditions as GC/MS. Previous theoretical calculations have shown that the pressure drop along a short column for a 100 torr outlet pressure closely resembles the pressure drop for subtorr outlet pressures [1]. Thus, the chromatographic performance (evaluated by Golay plots) of 140 torr vacuum outlet GC/FID and of GC/MS should closely resemble each other.

Experimental
Experiments with flame ionization detection were performed on a Varian 3400 GC with modifications to the injection port and detector tower to allow for both sub-ambient inlet and outlet operation. Experiments with MS detection were conducted on a Finnigan TSQ45 with a 9610 GC. The injection port was modified to allow for sub-ambient inlet operation. The comparison between GC/FID and GC/MS consisted of analyzing dodecane isothermally at 60°C, over a range of inlet pressures (linear velocities). A mixture of n-alkanes (C_{14}, C_{15}, and C_{16}) was analyzed by the GC/FID system by adjusting the inlet pressure for each chosen outlet pressure so as to run the chromatograms at the optimum carrier gas velocities.

Results and Discussion
The retention times of dodecane, analyzed by both GC/MS and vacuum outlet GC/FID (140 torr), showed excellent agreement between the two methods, as well as with theoretical expectations. An extra-column band broadening of 0.6 seconds was evident in the GC/MS data, whereas the GC/FID data appeared to have only a minor amount of band broadening. It is thought that the calculated linear velocities in the GC/FID study are lower than the linear velocity actually present; this deviation results due to the location of the pressure gauge, which is removed from the injection port (located between the split and injector buffer). Thus, the observed inlet pressure is less than the true pressure resulting in lower velocities when calculated by the Poiseuille equation:

$$u = \frac{3(r)^2P_0(P_0P - 1)^2}{32\eta L(P_0P - 1)}$$

where $u$ is the average linear velocity in cm/s, $r$ is the column radius in cm, $P_0$ is the outlet pressure in dyne/cm$^2$, $P$ is the ratio of inlet to outlet pressures $P_i/P_0$, $\eta$ is the
carrier gas viscosity in poise and L is column length in cm. By the analysis of plate height versus linear velocity (i.e. a Golay plot), one may find the optimum linear velocity and plate height at any given velocity. Figures 1 and 2 are the Golay plots for GC/FID and GC/MS respectively. On Figure 2, both theoretical Golay curves (with and without the 0.6 second band broadening) have been plotted along with experimental data.

Loss in resolution under vacuum outlet operation has been studied on the GC/FID system. A summary of the results, including running conditions (Table 1) and loss or resolution (Table 2) appears below. It is of interest to note that the chromatograms run at 400 and 140 torr required sub-ambient inlet pressures in order to achieve the optimum linear velocities. Table 2 presents the loss of resolution versus atmospheric outlet operation for the various chromatograms which were run at different outlet pressures. At 140 torr, the experimentally determined loss of resolution of approximately 6% is in excellent agreement with the theoretically predicted value of 6%. The chromatograms demonstrate the corresponding improvement in the speed of analysis (by a factor of 2).

Modeling of Diffusion and Sputtering Processes in a Glow Discharge Cell

A. Vertes, M. van Straaten and R. Gijbels

Department of Chemistry, University of Antwerp (UIA)
Universiteitsplein 1, B-2610 Wilrijk, Belgium.

Glow discharge (GD) cells are used both in optical and mass spectrometric ways of elemental trace analysis. In order to understand and describe one of the basic processes in a GD cell, a one-dimensional sputtering model was established [1] utilizing the Boltzmann equations for ions, neutrals and electrons [2]. A critical detail we have learnt from the model was the relative importance of redeposition processes due to back-diffusion of sputtered neutrals directed towards the sample surface.

Here we report the extension of the diffusion model into three dimensions providing the possibility of tracing both axial and radial processes for real cell configurations. The source term of the model couples the diffusion processes to sample erosion through thermalization profiles of sputtered neutrals. The diffusion equation, in cylindrical coordinates, for a steady state glow discharge plasma then becomes:

$$\frac{\partial n(r,z)}{\partial t} = D \left[ \frac{\partial^2 n(r,z)}{\partial r^2} + \frac{1}{r} \frac{\partial n(r,z)}{\partial r} + \frac{\partial^2 n(r,z)}{\partial z^2} \right] + J_0 F_r(z)$$

where $n(r,z)$ is the sputtered neutral atom density (atoms/cm$^3$), $D$ is the diffusion coefficient (cm$^2$/sec), $J_0$ is the sputtered atom flux (atoms/cm$^2$sec) and $F_r(z)$ (cm$^{-1}$) is the normalized thermalization profile of the sputtered neutrals. $J_0$ and $F_r(z)$ are calculated according to the sputtering model described in refs [1] and [2]. Solutions of this differential equation are sought with the aid of a computer code [3] using a finite difference method, together with the appropriate boundary conditions. In this way, the analytical performance of different simple cell designs can be investigated theoretically, assuming a constant ionization efficiency throughout the cell if it is coupled with a mass spectrometer. Overall, the performance of a cell is thought to be influenced by the axial transport whereas cell wall contamination may be correlated with radial spread of material.

Fig. 1 shows the sputtered neutral atom density variation in two different cell designs. The standard cell used in our mass spectrometer for analyzing flat samples has a "neck"-formed anode body to constrict the discharge to a part of the cathode sample. This design can simply be improved, by cutting off a part of the neck and by increasing the radial distance to the cell walls, as is shown in Fig. 1b. In this way, the axial diffusion profile of the sputtered atom number density shows a distinct increase of atom density close to the exit slit, situated at the back of the cell (Fig. 2). Also the diffusion flux towards the end of the cell increases by a factor of 2.5, which can be estimated from the slope of the diffusion profile close to the exit slit. Another possible improvement would be the use of a sampling cone immersed into the cell interior (not shown here). The disturbance of the equidensity lines in this case also creates a larger diffusion flux. Additionally, the distortion of the electrostatic fields outside the cell improve the focussing properties of the electrostatic lens system in a mass spectrometer. This feature will be illustrated elsewhere [4].

Glow discharge mass spectrometry (GDMS) has become a viable method for trace elemental analysis of solid conducting materials (1). In most applications of the technique, argon is used as the discharge gas. However, under certain conditions the argon complexes with various species to form complex ions that can result in isobaric interferences. One method of removing these interferences is to use an alternative discharge gas, such as neon, which will shift the m/e value of the complex ion. With the increasing application of GDMS, the use of neon discharges can be expected to proliferate and fundamental information on excitation processes in neon discharges would be valuable. Three ionization mechanisms have been most commonly reported to be responsible for the ionization of sputtered atoms; electron impact ionization, charge exchange ionization, and Penning ionization. Electron impact ionization results from an energy transfer from an energetic electron, charge exchange ionization can occur when an energy level for an ion of the rare gas directly overlaps with an energy level of the sputtered atom, allowing the transfer of an electron, and Penning ionization results from a potential energy transfer from an excited metastable state of the discharge gas.

Several previous studies of low pressure, low current argon glow discharges have shown the argon metastable atoms to significantly impact the extent of ionization in the discharge through the Penning ionization process (2,3). Neon discharges would be expected to behave in the same manner, but little direct evidence of Penning ionization in neon glow discharges has been presented. These experiments were designed to quench the metastable levels of the neon and measure the resulting decrease in ion emission from a sputtered copper population, employing a diode geometry glow discharge operating at 0.5-5 torr and 1-5 mA with an optical system discussed elsewhere (2,3). The results for the neon system were then compared to argon in an effort to determine if significant differences in excitation/ionization were present in the two discharge gases.

Methane was employed as the metastable quenching agent. As illustrated in Figure 1, low levels of methane added to a neon glow discharge results in the removal of the Ne* states without significantly impacting the ground state copper population. Under these conditions, the Penning ionization process should be removed, allowing ionization only through electron impact, assuming there is no energy overlap for charge exchange to occur. As shown in Figure 1, a reduction in ion emission signal also occurs with the introduction of methane, indicating the Ne* does play a role in the ionization processes in the glow discharge. Discharge pressure is also known to influence the population of various discharge species, and the pressure profiles of different species provide one method of illustrating the role of metastables in discharge ionization. Figure 2 shows the population of the ground state copper atoms and neon metastables as the discharge pressure is varied. The neon metastables show a peak at ~1.8 torr, while the Cu° population decreases linearly with increasing pressure for both a neon and 10% methane/neon mixture.
Figure 3A exhibits the effect of pressure on three copper ion emission signals for both pure neon and a 10% methane/neon mixture. The role of Penning ionization is clear in this figure, with the ion emission signal profiles in neon peaking at 1.8 torr, matching the behavior of the Ne* population (Figure 2). With methane present in the discharge, 3B, the ion signal is reduced, and the profile is closer to that of the copper ground state (Figure 2). These same transitions were monitored in argon and 10% methane/argon under as similar conditions as possible to compare directly the extent of ionization with each discharge gas. The results are presented in Figure 4A for pure argon and 4B for the methane mix, plotted relative to the maximum signal for neon. The neon provides significantly higher ion emission signals for these transitions and the enhancement is removed upon metastable quenching. This is most likely due to the role of Ne* in the population of the upper energy level of these transitions. The neon metastable has sufficient energy (16.62 and 16.67 eV) to populate these levels directly (15.91 -16.52 eV), while argon metastables (11.55 and 11.72 eV) will require supplemental energy and a less likely two step process to populate these levels. Penning ionization to these levels will be enhanced in neon, but as the metastables are quenched, so will the Penning ionization process, and the enhancement with neon will be removed. Zinc ion absorption data employing a transition originating from a ground state ion level (20 nm) showed no enhancement with neon, and the methane quenching effects were approximately equal for both discharge gases. These results indicate the enhancement holds for specific excited state ion levels, not necessarily the bulk ion population, a fact consistent with the postulated role of the neon metastable in the excitation/ionization processes in glow discharges. Further investigations include studying a possible energy level dependence on the neon enhancement, comparing other discharge gases and cathodes, and studies of laser excitation and depopulation in the discharge.

As an elemental analysis technique, glow discharge mass spectrometry (GDMS) combines the simplicity of design of the glow discharge ion source with the high sensitivity and selectivity of mass spectrometry. As with any technique, certain limitations have arisen to challenge existing methodology; an example of this can be found when considering the problem of isobaric interferences. Shown to be a universal problem in elemental mass spectrometry, isobaric interferences arise from several sources including overlapping isotopes, doubly charged species, and polyatomic ions; some typical glow discharge diatomic ion interferences include dimers, oxides and argides. Two schemes that have been used to deal successfully with these interferences are discrimination and suppression/elimination. The first of these is the approach of high resolution mass spectrometry. Although commercial instrumentation is capable of resolving \( m/\Delta m_w = 10000 \), the required resolution necessary to effect separation of these species from an analyte of the same nominal mass can range to an excess of 60000. 

Recently we have interfaced a glow discharge-ionization source to a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. Utilizing the ultra high resolution capabilities of the FTICR approach (resolution in excess of 100000), we are capable of more successfully addressing the problems that typical diatomic and polyatomic interferences pose in GDMS.

**EXPERIMENTAL**

Positive ions generated in the negative glow region of a coaxial cathode glow discharge were mass analyzed by a home-built FTICR mass spectrometer that employs Nicolet FTMS-1000 electronics in controlling a 4.50 cm x 2.54 cm x 2.54 cm ion analyzer cell. A series of four electrostatic lenses acts to focus and accelerate ions sampled from a 1.0 mm diameter ion exit orifice, and a cylindrical decelerator serves to slow the ion beam prior to injection into the analyzer cell. The trapping plates were dropped from +2V to ground for a period of 0.1 - 5.0 seconds to allow ions to be "injected" into the cell, and then raised back to +2V for the detection phase. In typical experiments ions with frequencies from 10 kHz to 2 667 MHz were excited and detected with a bandwidth of 2.667 MHz. Fifty time domain signals of 16 K data points each were accumulated, and the average time domain signal was apodized by a modified Blackman-Harris window function and zero-filled once prior to Fourier transformation. For higher resolution analysis, fifty time domain signals of 64 K data points each were averaged, and a standard heterodyne approach was employed.

**RESULTS AND DISCUSSION**

Although the FTMS approach holds the potential for both discrimination (with ultra high resolving power) and elimination (with a greater probability for collisional dissociation than the TSQ approach) of isobaric interferences, we are presently concentrating our efforts on the discrimination aspect. In a series of precursory studies, moderate resolution mass spectra were generated from a compacted silver cathode in an argon discharge. Figure 1 illustrates the 106 - 110 a.m.u. region of the mass spectrum with Ag\(^+\) indicated at nominal masses of 107 and 109. The observed resolution for 107 Ag\(^+\) is 5996 (full width at half maximum). Although this spectrum shows only moderate resolution, our highest resolution spectrum obtained to date, (Figure 2: \( m/\Delta m_w = 42549 \), for the Ar\(^+\) ion) demonstrates the possibility for using ultra high resolution to discriminate against glow discharge isobaric interferences.

One limitation to the GD-FTICR approach, thus far, is its poor sensitivity compared to other GDMS instruments. Since most isobaric interferences only begin to appear at the 100 ppm level, we are somewhat limited by our present detection limit of 25 ppm. However, we believe that the
future addition of a Bessel Box energy analyzer and quadrupole ion guide should help improve ion transport capabilities and lower the L.O.D by several orders of magnitude.

The analytical technique of trace elements is required to detect at least ppt level of impurities. However, various artifact ion species generated in the ICP interface are isobaric with the atomic ions from the elements to be determined, and thus the determination of trace quantities of these elements is not generally possible. Artifact ion species are formed by the reaction of carrier gas (Ar) and the oxygen originated from aqueous samples. We discuss the ICP-high resolution mass spectrometer which is able to identify the ion component at minimal intensity level.

Experimental

It is known that most of the artifact ions can be resolved from the elemental ions by operating the mass spectrometer at a resolving power of 10,000. For this purpose, we have developed an ICP-high resolution mass spectrometer (ICP-HRMS) based on the QQBQ.E geometry which has been used for organic mass spectrometer, which is able to obtain resolution up to 60,000 by EI. Data system program for ICP-HRMS has both low and high resolution measurement capabilities. The used torch assemblies, coaxial nebulizer and spray chamber are the same as conventional type. Radio frequency power 40MHz generator is ICP16L (Plasma Products Inc., USA). A new interface has developed to obtain high ion transmission efficiency and non-arching at high accelerating voltage (Fig.1). The evacuation system has consist of two stages that have RP and TMP after sampling cone and skimmer cone, respectively. The glow discharge in the RP stage could avoid by increasing the length of insulated pumping hose to 1.8m at accelerating voltage 5kV.

Results

ICP-HRMS spectrum was measured by magnetic field scanning from m/z 1 to 85 including elements of Li, Be, Al, Cr, Fe and Ni; each concentration 100ng/ml in nitric acid (1mol/l), under the condition of resolution 4,000 (Fig.2). In the expanded mass spectra are able to show the good separation of element ion peaks and artifact ion species peaks. For example, the partial range mass spectra are showed in figure 3(a) - (c), and elemental compositions of all peaks are assigned. And figure 4 shows the expanded mass spectrum at m/z 56, 10ppb Fe and ArO, under higher resolution condition R=10,000.

Conclusions

Masses and isotope abundances of element and artifact ion species produced in ICP interface could be determined by using HRMS, we found that they are multi-atomic ion complex consist of Ar, O, N and H. Especially, it is necessary to identify 2nd and 3rd abundant isotope such as \(^{16}\)N, \(^{17}\)O, \(^{18}\)O, contribution for the analysis of trace level of elements. The results of this study suggest that the high resolution, high sensitivity ICP-HRMS is very effective means to obtain reliable qualitative and quantitative results.

High Resolution ICP-MS Investigation of molecular species In difficult matrices.
A Walsh, N Bradshaw, R C Hutton, J E Cantle. VG Elemental, Winsford, Cheshire,

Introduction

The use of the argon inductively coupled plasma as an ion source has become widely accepted in inorganic and elemental mass spectrometry. Approximately five hundred systems are now in use worldwide. Conventional ICP-MS instruments couple the atmospheric ICP to a quadrupole mass spectrometer via an optimised supersonic beam interface.

The ICP is well suited to use as an elemental ion source. The relatively high first ionization potential of argon (15.7eV) gives greater than 90% ionization for over 70% of elements within the plasma, however the levels of doubly charged ions are minimized. The ions are sampled from a region at approximately 8000K, thus ensuring high levels of dissociation and ionization even for refractory materials.

The spectrum produced from the ICP is simple, consisting of mainly isotopic peaks. However matrix specific interferences can limit the determination of some elements at trace and ultratrace levels due to spectral overlaps, when measured with the quadrupole instrument. These matrix related peaks occur mainly at lower mass and are predominantly singly charged two and three atom species. The formation processes for these species are not well understood and the normal method of overcoming particular problems has been to reduce the level of the problematic matrix element. For example it is received wisdom that the use of sulphuric and hydrochloric acid based digestion should be avoided and replaced by nitric acid, to reduce the occurrence of such interfering species.

We have investigated the formation of molecular species in two common matrices, sulphuric and hydrochloric acids. The behaviour of molecular species with matrix concentration has been determined. Data has been obtained showing how the use of a high resolution mass analyser in place of the quadrupole allows the analysis of interfered elements in the so called difficult matrices. The high resolution mass analyser also allows the identification and separation of molecular species appearing at nominally the same mass in the spectrum.

Instrumentation

The investigation was undertaken using the VG PlasmaTrace high resolution ICP-MS. This instrument couples the ICP to the double focusing magnetic sector mass spectrometer via a novel plasma sampling interface (pat pending) that extracts ions from the ICP and accelerates them to the high energies required by a double focusing mass spectrometer of this type. Instrument resolution can be quickly varied by means of remotely controlled variable slits at the object and image points of the spectrometer.

The very low background noise of the instrument (typically 0.1 Hz) allowed confirmation of species formation even at very low equivalent concentrations. In the acid interference investigation the instrument resolution was set to 3400 to allow for separation of the potential molecular species formed at nominally the same mass to be monitored. Resolution used during the quantitation of known levels of trace elements in both hydrochloric acid and brine solutions was varied during the analysis to resolve expected interference species.

Sample introduction was by conventional pneumatic nebulization using a corrosion resistant cross flow nebulizer. A peristaltic pump was used to introduce solution to the nebulizer to overcome any problems with sample viscosity changes. A platinum sampling cone was also used in this work as the conventional nickel cone was rapidly eroded by high acid concentrations.
Experimental

1. Acid Matrices

The masses of a number of known and potential interferences were monitored for a series of solutions of different concentrations of sulphuric and hydrochloric acid. Indium at 115 amu was used as an internal standard to monitor instrument stability and to correct for any potential suppression of instrument response with higher acid concentrations. Peak integrals were determined for all ions detected.

2. Quantitative Analysis of chloride matrices

Standard solutions of 0.05N HCl and 10 g/l of NaCl of known elemental concentration were analyzed. Resolution was selected so to allow the separation of predicted spectral interferences from the isotopes of interest. Three external standards of 10, 50 and 100ng/ml were used.

Conclusion

The VG PlasmaTrace has been designed as a variable resolution instrument to allow the analyst to achieve the best possible detection limits by optimising resolution to resolve isotopic and molecular peaks only when present in the spectrum and to use the low resolution highest sensitivity mode for isotopic peaks with no interference.

We are investigating the development of an automated pre-analysis routine to determine the sample matrix and the use of a simple expert system to predict the isotopes likely to be interfered by molecular species derived from the matrix constituent elements. The instrument would then be automatically configured to measure the user selected elements of interest at the resolution required for the particular matrix. To maintain total flexibility the user would have the capability of overriding this procedure.

Such a system requires that a rule set be produced to predict the likely interferences for any matrix. The underlying purpose of this work was to begin to attempt to identify that rule set.

The data shows that as might be expected the intensity of the molecular peaks does increase with matrix concentration. The trend appears to be linear. A number of the monitored masses showed no evidence of the formation of proposed species even at relatively high acid concentrations, whilst all the species that were detected occurred even at the 1% acid level. This allows the conclusion that, within the detection capability of the instrument and in these matrices, molecular formation is not triggered by the density of constituent elements being introduced into the plasma. Further studies are required to confirm this at matrix concentrations below those studied.

Two, three and four atom species have been positively identified by accurate mass assignment at medium and high resolution. Given the high thermal temperature (8000K) of the ICP together with the sample residence time within the plasma, it is unlikely that any molecular species would survive introduction into the ICP, to be sampled by the supersonic beam system. The supersonic expansion that then occurs means that the adiabatic motion of particles within the ion source that is formed is rapidly and efficiently transformed into isentropic motion along the beam axis. Therefore the collision frequency rapidly tends to zero. It is unlikely that three (and four) body collisions could occur in this region. It is proposed that reactions on the surfaces of the interface must be of major importance in the formation of molecular ions.

We have been unable yet to correlate the species formed with any predictive model, further work is required with a much larger set of matrices to attempt to identify this important model to allow both a simple predictive procedure to be used and also to allow the further development of the sampling interface to minimize the formation of molecular species.
Fast Atom Bombardment Mass Spectrometry of Iron-Sulfur Cubane Clusters

The cubane cluster \([\text{Fe}_4\text{S}_4]\), is one of the most widely distributed electron transfer sites in biology. Synthetic analogs have been investigated by an intensive body of structural, spectroscopic and magnetic studies for the last two decades\(^1\). However, no systematic study exists to determine either the suitability of FAB-MS, or the proper conditions necessary, for the characterization of these complexes. In the present work, both positive and negative ion FAB-MS has been used to characterize a series of iron-sulfur cluster dianions \([\text{Fe}_4\text{S}_4\text{X}_4]^2-\) with different cations: (a) \((\text{A})_2\text{Fe}_4\text{S}_4\text{Br}_4\), \(\text{A}=\text{Bu}_4\text{N}, \text{Pr}_4\text{N}, \text{Et}_4\text{N}; \) (b) \((\text{A})_2\text{Fe}_4\text{S}_4\text{Cl}_4\), \(\text{A}=\text{PPN}, \text{Ph}_4\text{P}, \text{Bu}_4\text{N}, \text{Me}_4\text{N}; \) (c) \((\text{A})_2\text{Fe}_4\text{S}_4(\text{SEt})_4\), \(\text{A}=\text{Ph}_4\text{R} \) \(\text{Ph}_4\text{As}; \) (d) \((\text{A})_2\text{Fe}_4\text{S}_4(\text{SPh})_4\), \(\text{A}=\text{Ph}_4\text{P}, \text{Bu}_4\text{N}; \) and (e) \((\text{Ph}_4\text{P})_2\text{Fe}_4\text{S}_4(\text{SPh})_2\text{Cl}_2\), where \(\text{Ph}=\text{Phenyl}, \) and \(\text{PPN}=(\text{Ph}_3\text{P})_2\text{N}.\)

Both 3-nitrobenzyl alcohol (NBA) and 2-nitrophenyl octyl ether (NPOE) are suitable matrices for the FAB-MS studies of complexes (a) and (b). Combining the structurally informative positive- and negative-ion spectra of \((\text{Et}_4\text{N})_2\text{Fe}_4\text{S}_4\text{Br}_4\) (Fig. 1 and Fig. 2), a molecular weight determination of iron-sulfur cluster complexes has been successfully achieved. Most of the complexes of (a) and (b) give similar mass spectral features to those shown for \((\text{Et}_4\text{N})_2\text{Fe}_4\text{S}_4\text{Br}_4\).

The positive ion FAB-MS studies of (c) and (d) give very limited information related to the molecular formula, however negative-ion measurements of all clusters using the matrix NPOE, provide the unique features of molecular ion and rich cluster fragment ions analogous to those found in the systems (a) and (b). Interestingly, if NBA is used as a matrix, a terminal ligand substitution reaction between NBA and \((\text{A})_2\text{Fe}_4\text{S}_4(\text{SEt})_4\) occurs, as shown in Fig. 3.

A mixed ligand cluster \((\text{Ph}_4\text{P})_2\text{Fe}_4\text{S}_4(\text{SPh})_2\text{Cl}_2\) was chosen to test the usefulness of FAB-MS to identify the disproportionation species of a ligand exchange equilibrium system shown in eq 1-3. FAB analysis (shown in Fig. 4) confirm these different species in solution except for \([\text{Fe}_4\text{S}_4(\text{SPh})_4]^2-\), which suggests the presence of the equilibria of eq 1 and eq 2 are predominant rather than those of eq 3.

\[
\begin{align*}
2[\text{Fe}_4\text{S}_4(\text{SPh})_2\text{Cl}]^2- & \underset{\text{eq } 1}{\longrightarrow} [\text{Fe}_4\text{S}_4(\text{SPh})\text{Cl}_3]^2- + [\text{Fe}_4\text{S}_4(\text{SPh})_3\text{Cl}]^2- \\
[\text{Fe}_4\text{S}_4(\text{SPh})_3\text{Cl}]^2- & \underset{\text{eq } 2}{\longrightarrow} [\text{Fe}_4\text{S}_4(\text{SPh})_2\text{Cl}_2]^2- + [\text{Fe}_4\text{S}_4\text{Cl}_4]^2- \\
2[\text{Fe}_4\text{S}_4(\text{SPh})_2\text{Cl}]^2- & \underset{\text{eq } 3}{\longrightarrow} [\text{Fe}_4\text{S}_4\text{Cl}_4]^2- + [\text{Fe}_4\text{S}_4(\text{SPh})_4]^2-
\end{align*}
\]

The results demonstrate that FAB-MS can be employed as a valid and convenient method for molecular weight determination and structural elucidation of iron-sulfur cubane clusters, as well as identification of intermediates of ligand substitution and disproportionation of mixed ligand cluster in the solution. The choice of matrix however is critical.

A considerable interest has been focused on the preparation and screening of transition metal complexes for use as possible chemotherapeutic agents since the first study reported in late sixties that the flat platinum (II) complex cisplatin shown successful evidence to against cancers. The mechanistic studies have also shown that the transition metals in these complexes provide a key rule in binding of the complexes to DNA. Recently, studies also shown the interactions between some square planar and planar orthometallated palladium (II) complexes and DNA. The most interesting activity towards DNA of the orthometallated complexes was exhibited by (N,N,2C')-2(6'-methoxyphenyl)-palladium (II)-chloride. The binding of this complex to DNA was reversed by the addition of NaCN, which suggested that ionization of Pd-Cl bond in the aqueous reaction medium was necessary for its binding to DNA.

It is suggested [1] that o-thiocresol derivatives of orthometallated Pd(II) complexes can act as a monitor in the event of a radical-based Pd-C homolysis. The abstractable benzylic C-H bond will quench the radical, forming a thio-metallacycle. To study the formation of thio-metallacycle, a series of thiocresol-Pd(II) complexes were prepared. The structures of these derivatives are listed as follows. Mass spectral analysis of these complexes was performed using fast atom bombardment (FAB) mass spectrometry which has proven to be a versatile ionization method for the analysis of inorganic, organometallic and coordination compounds [2].

FAB mass spectra were obtained from a Kratos MS-80 double focusing mass spectrometer operating at an accelerating voltage of 4 kV. A fast atom saddle-field gun (Iontech FAB-11NF) is mounted on a standard Kratos FAB source. The xenon atom beam was generated with a kinetic energy of ca. 6 kV.

It is noticed that these complexes do not generate FAB mass spectra under normal operation conditions using conventional liquid matrices such as glycerol, thioglycerol and 3-nitrobenzyl alcohol (NBA). Instead of introducing a new liquid matrix which may increase the solubility of metal complexes, it was found that a key point for obtaining FAB mass spectra of these complexes is the pretreatment of samples. The pretreatment of samples was very simple: firstly, add approximately 20 μg of sample into 10 μl of methanol, stir it to form a colloid and remove the colloid onto a FAB probe tip; then place 1 μl of NBA matrix on the tip before methanol was totally evaporated, stir it again and wait approximately 5 minutes to perform mass spectral analysis.

FAB mass spectra of some thiocresol-Pd(II) complexes are shown in Fig. 1. The molecular ion cluster was observed as a major peak at high mass region. The other major peak at high mass region corresponds to a fragment formed by the cleavage of Pd-S bond. Compare to the orthometallated Pd (II)-Cl complexes which generate a fragment resulted from Pd-Cl bond cleavage as the highest mass, the Pd-S bond seems to be stronger than the Pd-Cl bond. It is because the Pd-Cl bond was enhanced by the formation of a thio-metallacycle.

Interestingly, the predominant ions observed at molecular ion region in FAB mass spectra of these complexes correspond to M⁺, rather than the protonated [M+H]+. However, the protonated molecular ion was still observed, but its intensity is lower than that of molecular ion. It is clearly shown in Fig. 2 that a peak at m/z 524 corresponds to the molecular ion with most abundant Pd isotope (a.m. 106, natural abundance 27.3%). Since Pd doesn't have an isotope with a.m. 107, the intensity of peak at m/z 525 should only be about 24% of that of m/z 524 (contributed from 13C isotope). A relative intense peak observed at m/z 525 would indicate that there still undergoes a protonation process, even though it is only a minor
process. A plausible explanation for this observation is that these complexes do not have a stable protonation site. The formation of thio-metallicycle prevented the heterocatom sulphur from being a protonation site. On the other hand, the oxygen atom, if any, in the distal R group were not a suitable protonation site either. This would agree with our recent study [3] that a certain group of compounds do not generate protonated \( [M-H]^+ \) as predominant ions under FAB conditions.

Investigation of Multiply Charged Binuclear Metal Complexes Capable of Small Molecule Activation: Alex Reiter, Kristin Bowman Mertes, Tamboue E. Deffo, and Todd D. Williams; University of Kansas, Lawrence, KS 66045.

Introduction

We have synthesized asymmetric macrocycles capable of coordinating two different metals (Co, Cu, Mn, Ni, and Zn) and symmetric macrocycles for small molecule activation, e.g., CO2 and O2. The best method of characterizing these compounds has been mass spectrometry. FAB and B/E linked experiments were used to confirm the structure and to try to determine the location of the metals in the asymmetric macrocycle. FAB was used to characterize the interaction between the macrocycle and CO2 or O2.

Macrocycles used in the study

Experimental

Mass spectra were obtained on a VG ZAB-HS mass spectrometer equipped with an 11/250 data system. Fast-atom bombardment experiments were performed using a Xenon gun operated at 8 keV energy and 0.8 mA emission. Non-mixed and single metal samples were dissolved in CH2Cl2 and added to NBA as the matrix. The mixed-metal sample were dissolved in either CH2Cl2 or DMF and stearic acid was added in 1:1 molar ratio. The mixture was then added to NBA as the matrix. A narrow sample range, 12 μg-17 μg on the probe, was required for molecular ion detection. B/E scans were performed with precursor ions attenuated to 30% with He in the first field free region gas cell. Collision spectra were recorded in multichannel analyzer mode (MCA) under data system control. The scan range was 700-5 amu acquired at 15 sec/dec and 3 scans were obtained. The collision energy was 8 keV. The deconvolution were done by minimizing the absolute deviation of the isotope cluster.

Results and Discussion

Using NBA as a FAB matrix, the binuclear complexes with a single metal type produced a molecular ion corresponding to a singly charged species, even though the complex is formally a 2+ or 3+ compound. The molecular ion cluster is composed of a series of ions, which can be explained by various combinations of simultaneous loss of protons and metal reduction. The mixed metal complexes in NBA showed no ions related to the macrocycle (Figure 1), while in glycerol or magic bullet only the free ligand is observed. Various additives were tried in an attempt to get a molecular ion. Stearic acid and other long chain fatty acids (Figure 2), were successful in obtaining a molecular ion peak.

Stearic Acid Effect on Mixed-Metal Complexes

![Stearic Acid Effect on Mixed-Metal Complexes](image-url)
B/E linked experiments were used to try to determine the location of the metal in the asymmetric macrocycles. Initial results of CAD on the non-mixed metal and the single metal asymmetric complexes indicated the technique would not give conclusive evidence for the location of the metal centers. The problems with the method were low daughter ion resolution and possible ambiguities in assigning fragments (Figure 4). So, deconvolution of the molecular ions obtained by FAB from the mononuclear complexes was done in an effort to determine relative proton counts. Information obtained from these experiments was used to determine which half of the molecule the metal prefers.

The manganese macrocycles have shown ability to bind and activate both oxygen and carbon dioxide. Interaction between CO$_2$ and Cl-sym-Mn$_2$ was confirmed by leaking CO$_2$ into the source (Figures 5 and 6). The results of the experiment suggests that the CO$_2$ was replacing the bridging acetate in the Cl-sym-Mn$_2$ complex. The binding of CO$_2$ was also confirmed by UV-VIS and electrochemical methods. The Cl-sym-Mn$_2$ complex spectra has an ion corresponding to a bridging oxygen. The (Mn-O-Mn) structure was verified by its IR band as described by Wieghardt$^1$. We are now interested in determining whether the other oxygenated complexes observed in other FAB spectra of the different metals are mass spectral induced as suggested by Miller$^2$ or oxygenated complexes.

The National Institute of Health for its support of this work (GM 37577). Mr. Bob Drake of the University of Kansas Mass Spectroscopy Lab for his help in obtaining some of the mass spectra.

Introduction

The historical widespread use of lead (Pb) in paint, gasoline and automobile batteries has distributed Pb throughout the environment. Subsequently, sub-clinical Pb poisoning has become a significant health problem. Studies have shown that Pb may have adverse long term effects on cognitive and motor function at blood concentrations that are significantly below the level that gives rise to clinical symptoms. We have developed a stable isotope dilution GC-MS method for determining Pb in urine and blood using lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), as a chelating agent. Precision and accuracy of isotope ratio measurements at the 10 ng level was determined; memory effect was evaluated and the isotope dilution GC-MS method was validated by determining Pb in urine and whole blood standards.

Experimental

Lead nitrate (70.94 atom% $^{209}$Pb, Oak Ridge National Laboratory) used as an internal standard for isotope dilution was dissolved in deionized water with the addition of a few drops of concentrated HNO$_3$. Dilute solutions of the internal standard were prepared from the stock solution. The internal standard solution was calibrated by reverse isotope dilution GC-MS using a natural Pb primary standard.

One mL of the reconstituted urine sample and 200 nL of the whole blood samples were taken and mixed separately with a known weight of standardized Pb solution, in an amount which yielded an optimum isotope ratio in the mixture. The blood samples after mixing with Pb were treated with 400 μL of 25% HNO$_3$, vortexed, allowed to stand for 10 minutes and the supernates were taken for digestion using HNO$_3$ + H$_2$O$_2$. Urine samples were also digested using HNO$_3$ + H$_2$O$_2$ mixture. The Pb(FDEDTC)$_2$ chelate was formed at pH 3 in an acetate buffer using a 20 mM solution of Li(FDEDTC) and extracted into methylene chloride for GC-MS analysis.

A Finnigan MAT-8230 mass spectrometer with a 10 m DB-1 fused silica capillary column was used for isotope ratio measurements. The Pb isotope ratios were measured in duplicate by injecting 1 μL of the chelate solution and monitoring the isotopic cluster corresponding to the fragment ion (M-L)$^+$ formed by the loss of one ligand. Selected ion monitoring with voltage peak switching was used for data acquisition and isotope ratios were determined by integrating the chromatographic peak areas.

Results and Discussion

The $^{70}$ eV EI mass spectrum of Pb(FDEDTC)$_2$ showed that the fragment ion Pb(FDEDTC)$^+$ was of highest intensity. This most abundant isotopic group at nominal m/z 464 was used throughout these experiments to achieve the highest possible sensitivity. This ion group consisted of nominal m/z values 460, 462, 463 and 464, corresponding respectively to $^{209}$Pb, $^{208}$Pb, $^{207}$Pb and $^{206}$Pb.

The precision of the determination of isotope ratios was evaluated by performing replicate measurements of chelated natural Pb using 10 ng Pb for injection on three different days. The values for the overall precision of major isotope ratios m/z 462/464 and 463/464 were about 3%. There was a memory effect that would affect results when measuring samples with isotope ratios that differ by a
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

a memory effect that would affect results when measuring samples with isotope ratios that differ by a factor greater than 10 (Figure 1). This problem can however be minimized by optimum addition of the internal standard solution. No significant memory effect was observed during the sequential analyses of four synthetic mixtures containing 10 to 40 atom% of \(^{206}\)Pb (Figure 2). The isotope dilution GC-MS method was validated by the quantitation of Pb in the NIST freeze dried urine reference material SRM-2670 and bi-level whole blood toxicology controls from Ciba Corning. Pb concentrations were calculated using all the isotope ratios m/z 460/462, 460/463 and 460/464. The results are shown in the Table 1. There is good agreement among the determined and expected values. The signal-to-noise ratio observed in the reconstructed ion chromatogram indicates a potential limit-of-detection of 0.1 \(\mu g/L\) provided extreme care is taken to minimize contamination from reagents, laboratory and analyst.

Conclusion

Stable isotope dilution GC-MS using Li(FDEDTC) as a chelating agent is a sensitive method for Pb determination in urine and whole blood. The memory effect observed can be minimized by optimum addition of the internal standard solution.

Introduction

Growing interest in the use of stable enriched isotopes for studying the bioavailability of trace metals and the easy accessibility of organic mass spectrometers to clinical and biomedical laboratories encouraged us to develop gas chromatography-mass spectrometry (GC-MS) for the determination of trace metals in biological samples. Historically, the main problem preventing the widespread applicability of GC-MS methods to trace metals analysis has been the lack of suitable chelating agents. GC-MS requires volatile chelates which do not show memory or carry-over in the sequential analyses of samples with different isotope ratios at nanogram levels. We have successfully used N,N'-ethylenebis(trifluoroacetyl)acetoneimine, H$_2$(enTFA), as a chelating agent for copper (Cu). It is an essential trace element for several enzyme systems and the two well characterized Cu related diseases are Menke’s Syndrome (due to Cu deficiency) and Wilson’s disease (due to Cu excess).

Experimental

The $^{65}$Cu-enriched copper oxide (99.61 atom % $^{65}$Cu, Oak Ridge National Laboratory) used as an internal standard for isotope dilution was dissolved in 0.5 M HNO$_3$ with heating. Dilute solutions of the internal standard were prepared from the stock solution. The internal standard solution was calibrated by reverse isotope dilution GC-MS using the natural Cu primary standard and preparing the Cu chelate.

One mL of the reconstituted urine or serum sample was mixed with a known weight of standardized $^{65}$Cu solution. Urine samples were digested using concentrated HNO$_3$ and 50% H$_2$O$_2$ while serum samples were first deproteinized with concentrated HNO$_3$ followed by the same digestion. The digested biological extract was dissolved in 0.5 mL of deionized water and 2 mL of ethanol was added. The pH of the solution was adjusted to be greater than 11.5 and the chelating agent was added. The Cu(enTFA)$_2$ chelate was prepared by using a 50 mM solution of H$_2$(enTFA) in CH$_2$Cl$_2$. The reaction mixture was then extracted with 1 mL of CH$_2$Cl$_2$ followed by the addition of 2 mL of deionized water to induce phase separation.

Cu isotope ratios were measured in duplicate, by injecting 1 $\mu$L of the chelate solution and monitoring the group of ions corresponding to the molecular ion. The sample was injected on column, a 10 m DB-1 capillary column. Data were obtained in the selected ion monitoring mode using a Finnigan MAT-8230 GC-MS system operated in the electron ionization mode.

A rigorous evaluation of memory effect was performed by sequentially analyzing solutions of natural Cu and enriched $^{65}$Cu for isotope ratios m/z 395/393 corresponding to $^{65}$Cu/$^{64}$Cu, which differed by a factor of 60. The isotope dilution GC-MS method was validated by determining Cu in NIST urine and serum reference materials.

Results and Discussion

No appreciable carry-over or memory effect was observed for the analyses of two Cu samples with isotope ratios differing by a factor of 60 (Figure. 1). GC-MS method for Cu isotope ratio measurements was also validated by comparing the GC-MS results on four synthetic mixtures with those independently determined by inductively coupled plasma mass spectrometry (ICP-MS). The isotope ratios m/z 395/393 obtained by GC-MS and calculated from ICP-MS data for the four synthetic mixtures agreed within 1%.
Table 1 shows the results on the measurement of Cu in NIST freeze dried urine reference material SRM 2670 and human serum 909. Good agreement of the values determined by isotope dilution GC-MS with the certified NIST values indicated the validity of the present method for the determination of Cu in biological materials.

Conclusion

The results of this work demonstrate that isotope dilution GC-MS using H₂(enTFA₂) as a chelating agent can be used for determining Cu in urine. Results obtained are shown to be accurate and precise. No significant memory effect is seen in the determination of altered isotope ratios. This absence of memory effect not only allows accurate quantitation, but also shows that the technique can be used for isotope ratio measurements in metabolic and bioavailability studies.

Introduction

Cadmium (Cd) widely used in industrial processes is a cumulative toxin with a biological half-life in the whole body exceeding 10 years. Cd accumulates mainly in the kidney. In this paper, we report the development of a stable isotope dilution gas chromatography-mass spectrometry (GC-MS) method using enriched $^{106}$Cd as an internal standard and lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), as a chelating agent for determining Cd in urine. The use of isotope dilution technique provides the advantage of freedom from matrix effects; and, precision and accuracy of the analyses are not affected by incomplete recovery. Precision and accuracy of isotope ratio measurements at 10 ng level were evaluated; memory effect was investigated and the isotope dilution GC-MS method was validated by determining Cd in NIST urine reference material.

Experimental

The $^{106}$Cd-enriched cadmium oxide (79 atom% $^{106}$Cd, Oak Ridge National Laboratory) used as an internal standard for isotope dilution was dissolved in 2% HNO$_3$. Dilute solutions were prepared from this stock solution on a weight basis for isotope dilution experiments. The internal standard was calibrated by reverse isotope dilution GC-MS using the natural Cd primary standard.

One mL of the urine reference material was mixed separately with a known weight of standardized $^{106}$Cd internal standard solution. Urine samples were digested using HNO$_3$ + H$_2$O$_2$ mixture. The residue after digestion was dissolved in 2 mL of deionized water and undigested lipids were extracted prior to metal-chelate formation. A 20 mM solution of Li (FDEDTC) in deionized water was used to form Cd(FDEDTC)$_2$ chelate at pH 3 in an acetate buffer. The chelate was extracted with CH$_2$Cl$_2$ for GC-MS analysis.

Cd isotope ratios were measured in duplicate, by injecting 1 μL of the chelate solution and monitoring the isotopic cluster corresponding to the molecular ion. The sample was injected, on column, into a 10 m DB-1 bonded-phase fused silica capillary column. Data were obtained in the selected ion monitoring mode using a Finnigan MAT-8230 GC-MS system operated in the electron ionization mode and quantitation was achieved using the chromatographic peak area.

Results and Discussion

The 70 eV El mass spectrum of Cd(FDEDTC)$_2$ showed two groups of ions, molecular ion Cd(FDEDTC)$_2$$^+$ and fragment ion Cd(FDEDTC)$^+$ occurring at nominal m/z of 628 and 370, respectively. The most abundant isotopic group corresponding to the molecular ion was used throughout these experiments to achieve high sensitivity. This group consisted of nominal m/z 618, 620, 622, 623, 624, 625, 626 and 628, corresponding respectively to $^{106}$Cd, $^{108}$Cd, $^{110}$Cd, $^{111}$Cd, $^{112}$Cd, $^{113}$Cd, $^{114}$Cd and $^{116}$Cd.
The precision of the determination of isotope ratios was evaluated by injecting 1 µL of chelate solution containing about 10 ng of Cd. Replicate determinations were made on different days. Table 1 shows the results of precision evaluation. Overall precision values of 1 to 3% were obtained for the different isotope ratios, except for the m/z 618/626 and 620/626 ratios which gave a precision of 6 to 7% due to the low natural abundances of $^{105}$Cd (1.25 atom%) and $^{108}$Cd (0.89 atom%).

Memory effect was investigated by analyzing two synthetic mixtures differing in m/z 618/626 ratio by a factor of 10. A small memory effect was observed which can be minimized by optimum addition of the internal standard using a good experimental design.

The accuracy of the isotope dilution GC-MS method was validated by the quantitation of Cd in NIST freeze dried urine SRM-2670. Good agreement between the NIST certified values and experimentally determined results was obtained as shown in Table 2. This work has led to further studies with ICP-MS and TIMS for a definitive measure of the relative precision and accuracy of this isotope dilution chelation method.

**Conclusions**

Stable isotope dilution-gas chromatography-mass spectrometry using Li(FDIDTC) as a chelating agent can be used for Cd determination in urine at the 10 µg/L level with a high degree of precision and accuracy. There is a small memory effect which can be minimized by optimum addition of the internal standard solution.

AN ENTROPY BASED DECONVOLUTION METHOD FOR OBTAINING PARENT MASSES WITH MIXTURES OF MULTIPLY-CHARGED IONS IN ESI-MS. Bruce Reinhold and Vernon Reinhold, Harvard School of Public Health, 665 Huntington Avenue, Boston, MA 02115.

Electrospray ionization of many protein and peptide samples produce mixtures of different molecular ions, each with a range of charge states. With glycoprotein samples, this can be attributed to differing glycotypes and glycoforms, (and other post-translational modifications during biosynthesis), which are extremely difficult to resolve chromatographically. The mass spectra of such materials can generate patterns of considerable complexity, making it a formidable challenge to extract parent masses.

This report describes an algorithm for the extraction of parent masses from ESI spectra consisting of mixtures of multiply-charged ions. The algorithm is based on the relative (level-2) entropy as a pattern recognition procedure. Entropy approaches have been used in a number of other applications such as clustering in image processing in astrophysical studies. Application of this algorithm to typical ESI-MS spectra has resulted in marked improvement of peak detection vs artifacts, a feature most valuable with mixtures of considerable complexity.

Some numerical band resolution enhancement techniques (Fourier deconvolution, Fourier differentiation) are illustrated in their application to poorly resolved peaks. These techniques amplify the midrange Fourier components relative to the low frequency components. This narrows peaks and thereby reduces artifacts due to 'accidental' overlap. The techniques also introduce a high frequency cutoff to reduce noise. These issues are illustrated with synthetic spectra (computer generated) and selected ESI spectra of glycopeptides.
An example of a typical complex ESI mass spectrum. The baseline does not exist and many of the peaks overlap.

Processing in Fourier Space

The idea is to increase the weight of the high frequencies and the importance of the high frequencies is the high frequency content of the data.

Spectral Deconvolution

Spectrum
Applications of an Improved Technique for the Transformation of the Electrospray Spectra of Proteins on to a True Molecular Mass Scale.

INTRODUCTION
In the form initially produced by the spectrometer, the electrospray spectra of protein mixtures are complex, each protein in the mixture being represented by a series of multiply charged ions. These ions occur with mass to charge ratio (m) given by:

\[ m = \frac{M+nH}{n} \]

where \( M \) is the molecular mass of the protein
and \( n \) is the number of charges on an ion, a series of consecutive integers.

A 15kDa protein typically produces about 10 peaks with a range of \( n \) from 10-20. Larger proteins, eg. albumins (~ 66,000) often have 20 or more peaks in the series.

To aid interpretation some means is needed for simplifying electrospray spectra, so that each component in a mixture of proteins is represented as a single peak on a true molecular mass scale. Previous methods (ref) suffer from increased baseline noise and tend to produce artefacts. The object of this paper is to describe a method of reliably transforming electrospray data which preserves resolution, directly gives the molecular mass, improves the signal to noise ratio, and above all is less prone to the generation of artefacts.

METHOD
The electrospray spectra of proteins are normally acquired by operating the data system as a multichannel analyser. Typically, several data channels are used to record each dalton along the mass/charge (m/z) ratio axis.

To transform the data into a true molecular mass spectrum, the multiply charged series are first identified and hence the number of charges associated with each peak can be assigned. Data system algorithms for carrying out this procedure, either automatically or interactively are based on the equation shown above. Once the number of charges on each peak has been assigned, every channel on the m/z axis is assigned a charge value. Each channel in the m/z spectrum is then transformed to a molecular mass scale using \( M=n(m-H) \), and the resulting data summed.

RESULTS
The data shown in Figure 1 was obtained from a mixture of normal human haemoglobin (alpha globin = 15126.4; beta globin = 15867.2) and horse heart myoglobin (16951.5). Figure 1(a) shows part of the original electrospray spectrum of the mixture with peaks from the 3 major components (A,C,D) plus a minor component (B). The data after peak detection is shown in Figure 1(b). Figure 1(c) shows the data after transformation. Note that minor Na & K adduct peaks associated with the alpha and beta globin peaks (A and B) are faithfully reproduced. Also note that even though the 15\(^+\) ion from normal beta globin (C15) is only partially resolved from the 16\(^+\) ion from myoglobin (D16), there are no significant artefacts in the transformed data.

To illustrate the more general applicability of the transformation technique to multiply charged ion series from bio-polymers, Figure 2(a) shows the negative ion spectrum of a 14 base oligonucleotide (calculated mass 4261.9) analysed in neutral solution. Note the dramatic way in which the relative intensities of the sodium adducts change with charge state. Figure 2(b) shows the data transformed onto a true molecular mass scale.

Fig. 1. (a) Part of the electrospray spectrum from a mixture of normal human haemoglobin and myoglobin, (b) after peak detection and (c) after transformation.

Fig. 2. (a) The negative ion electrospray spectrum of a 14 base oligonucleotide and (b) the data after transformation into a mass spectrum.
HIGH MOLECULAR WEIGHT FOURIER-TRANSFORM MASS SPECTROMETRY

Fourier-transform mass spectrometry (FTMS) has exciting attributes for the analysis of large molecules: ultrahigh resolution, high mass-measuring accuracy, nondestructive ion detection, simultaneous ion detection over a wide m/z range, and extensive capabilities for tandem mass spectrometry (MS/MS, MS"). Combined with electrospray ionization (ESI), which generates multiply charged ions, the mass range of FTMS has been extended to biomolecules as large as bovine albumin (MW 66,267). While spectra containing multiply charged ions of many masses present a difficult problem for charge state assignment on non-FT instruments, necessary for determination of m from m/z values, the resolving power demonstrated by FTMS allows unequivocal charge state assignment by simply counting the number of $^{13}$C isotope peaks within a single m/z unit, Figure 1 (1,2).

The atmospheric pressure ESI source has been coupled to FTMS using 5 stages of differential pumping, maintaining the analyzer at 10^-9 torr, and 3 rf-only quadrupoles. Sensitivity is enhanced by thermally cooling the ions prior to mass analysis, using long ion storage times (>1,000 s) or by using pulsed gas admission to the cell coincident with ion admission thus reducing the required cooling period to 100-200 s. Resolving powers in excess of 60,000 using broadband detection (all ions m/z >400 are simultaneously detected in 1.7 s) have been obtained for single scan spectra of cytochrome c isomers (MW 12,230-12,360), Figures 1 and 2, and for equine myoglobin (MW 16,950) with femtomole sensitivity. The average measured isotopic distribution for the 14+ - 17+ charge states of Figure 3 are denoted as circles superimposed on the theoretical isotopic distribution (Figure 4). Poor reproducibility of the isotopic abundances causes difficulty in matching these against calculated isotope distributions, which is necessary for identifying the most abundant isotope and for determining the isotopically-averaged MW.

ESI-FTMS has been demonstrated to be a valuable analytical tool in the structural characterization of large biomolecules. Mass measuring errors of less than 0.003% were achieved with an external m/z calibration, while an internal calibration using overlapping isotopic peaks of different charge gave mass measuring errors of less than 0.001%. Spectra of bovine ubiquitin (MW 8,565) have identified a low abundance impurity not previously resolved with quadrupole instruments, and MS/MS spectra using nozzle/skimmer dissociation and CAD confirm the charge state assignments for fragment ions reported from low resolution quadrupole spectra. Further MS" advantages can be gained by using the Hadamard transform [3] and remeasurement [4] techniques unique to FTMS.

Electrospray Ionization on a Magnetic Sector Instrument with High Performance Array Detector

*Peter Dobberstein, Ulrich Giessmann, and Ernst Schroeder, Finnigan MAT GmbH, Barkhausenstr. 2, W-2800 Bremen 14, Germany

Data from a newly designed ESI source for magnetic sector instruments are presented. The source has 2 stages of differential pumping between the spray and the beam focusing region, keeping the pressure in the analyzer region below 10^{-7} Torr.

Gramicidin S was found to be an ideal substance for sensitivity measurements. The detection limit for full spectra at resolution 1,000 was determined by continuous infusion of 200 fmol/µl in MeOH/water at 1µl/min.

With the normal detector (slit + sem) a detection limit of 25 fmol was achieved. With the PATRIC™ array detector this was improved to 0.5 fmol (Fig. 1).

For the measurement of bovine insulin at a resolution of 8,000 (10% valley) signal averaging was applied and about 30 pmol have been consumed. With CsJ added as reference compound the accurate masses of the 4+ isotope cluster could be determined within 10 ppm (Fig. 2).
A full spectrum of myoglobin was acquired from less than 1 pmol using the normal detector (Fig. 3).

With the BIOMASS deconvolution algorithm the spectrum of multiply charged ions was transformed into a "molecular weight spectrum". The known molecular weight of myoglobin is found within ± 1 da (Fig. 4).

An example of a glycoprotein is ovalbumin (chicken egg). It generates relatively broad peaks, indicating the presence of at least 2 different components (Fig. 5).

Conclusion
ESI on a magnetic MS with array detector was demonstrated to have very high sensitivity and resolving power.
Electrospray ionization has expanded the role of mass spectrometry in the area of biochemistry through better determination of the molecular weights of peptides and small proteins. The greatly increased mass accuracy, relative to conventional methods such as gel electrophoresis, enables accurate determination of protein modifications. With careful measurement, average mass accuracies for proteins of 0.01% are being obtained with quadrupole and magnetic sector instruments. However, there are a number of protein modifications that result in small changes in mass that cannot be determined with 0.01% accuracy. For example, point modifications such as substitution of Asn for Leu, Glu for Lys, Asp for Asn, Glu for Gin, or a carboxy terminal OH for NH$_2$ all represent ca. a 1 u shift in mass. A 1 u difference in mass at MW 10,000 requires that mass measurement be better than 0.005%.

We have consistently obtained mass accuracies better than 0.003% (Table) for reasonably pure proteins to ca. 17,000 MW with an electrospray source interfaced to a ZAB-E double focusing magnetic sector instrument. For synthetic peptides between 5,000 and 10,000 u better than 0.002% mass accuracy has been consistently achieved. Accurate mass data were obtained by acquiring spectra of the peptide or protein with an internal reference mass standard, although preliminary work indicates good accuracies can be achieved running the sample and reference consecutively under identical conditions. The operating conditions for obtaining data were magnet scanning from 2,000 to 500 u at 20 s/dec using a resolution of between 1,200 and 2,000 (10% valley) and either PEG or PTMEG as an internal mass reference. From 5 to 25 scans of continuum time data were acquired into a single averaged file and the data were processed off-line on a VG OPUS workstation.

Consistent accurate mass data requires considerable manual intervention in either eliminating improperly centroided peaks or applying manipulations such as drawing baselines and peak smoothing. The difficulty in obtaining high accuracy is apparent when one realizes that for a 10,000 MW polymer, the +10 charge state molecular ion isotope cluster has a mass width of ca. 1 u and must be measured to 0.01 u to achieve 10 ppm accuracy. Because the isotope spread is ca. 1 u, resolution cannot be used to eliminate interferences (Figure 1). Figures 1 and 2 show the effect of resolution vs. mass. At MW ca. 5,000, 1,000 resolution gives the minimum peak width, whereas at MW 10,000, 2,000 resolution (10% valley) is necessary to achieve the minimum peak width of the isotope cluster. Interferences that cannot be removed with resolution will distort the mass measurement, but they can usually be identified by observing the peak symmetry and width.

Another factor that reduces mass accuracy is improper centroiding due to insufficient ion signal to adequately define the peak. This problem is most prevalent when sample limited or with samples that fail to give adequate signal by electrospray ionization. Sometimes good results can be achieved by 'eyeballing the centroid'.

It must be noted that there are many structural possibilities in proteins and modified proteins that will produce a 1 u mass shift. Thus, while increased mass accuracy adds confidence, used alone it can only eliminate possibilities that fall outside the mass accuracy window.

Introduction

Electrospray ionisation is now regarded as an extremely powerful technique for the formation of intact ions from complex, high molecular weight species in solution. This technique is now coupled to a CONCEPT mass spectrometer and routinely shows the benefits of high resolution, high sensitivity mass spectrometry.

Interfacing

The electrospray source is mounted on a modified source housing door. The instrument operates at an accelerating potential of 4 kV with no requirement for discharge suppression on the additional two stage pumping system. All spectra shown here were recorded by spraying a 50:50 methanol:water mixture solution of samples at a concentration of 10 pm M via a tapered stainless steel needle of 0.12 mm I/D. A flow rate of 2.4 µl min \(^{-1}\) was used. The source housing pressure is \(10^{-6}\) to \(10^{\text{torr}}\) during normal operation.

Example: Bovine Albumin

The number of charges acquired in electrospray for a given molecular weight is affected by a number of factors such as sample chemistry and spraying conditions. If the number of charges is very high, the peaks due to adjacent charge states are very close in mass and therefore less well resolved.

Bovine albumin (M.Wt. 66,500) with 50 charges (m/z 1330.5) and 51 charges (m/z 1304.4) gives peaks only 26 amu apart. On the other hand, bovine albumin with 30 charges (m/z 2217.5) and 31 charges (m/z 2145.9) gives peaks over 71 amu apart. These lower charge, higher m/z ions can be confidently recorded with good sensitivity as this data shows.

The benefit of electrospray on high mass range sector mass spectrometers is illustrated again in the spectrum of bovine albumin dimer at a molecular weight of 133,000. This shows very highly charged ions which extend to over m/z 3000.
Resolution and Mass Accuracy

One advantage of sector instruments is high resolution for lower molecular weight compounds - i.e. individual isotopes may be resolved. The spacing of these isotope peaks allows the number of charges to be determined by inspection rather than by calculation. This is useful in direct mixture analysis.

Resolution is also important for mass assignment since poorly resolved multiplets will result in incorrect assignments. Molecular ion peaks at high molecular weight are already broad due to natural isotopic abundance so that a resolving power of 2,000 to 3,000, which can be achieved on a magnetic sector instrument with very little loss in sensitivity, is sufficient to reproduce the overall isotopic profile with relatively little broadening. Thus the use of such resolving power offers considerable benefits for routine electrospray. Table 1 shows that mass measurement precision is improved with an increase in resolving power. The authors are currently working on data processing techniques to maximise the accuracy of these measurements.

Higher Mass Samples

Additional full scan experiments suggest that a similar precision of mass measurement may be attained at higher molecular weights. Figure 4 shows part of the electrospray spectrum, also recorded using a CONCEPT I H instrument at a resolving power of 1000, of horse radish peroxidase, a glycoprotein that has a sugar content of approximately 20%. Mass measurement of the two most abundant components recorded in this scan, using the data from the 19*, 20*, 21* and 22* states in each case, gives molecular weight values of 42,343.2 ± 2.2 and 43,164.8 ± 3.2. These measurements correspond to a precision of ±0.005% and ±0.007% respectively (Table 2). These results are very promising, especially considering the improvements that might be expected at higher resolving power.

ELECTROSPRAY ON A MAGNETIC SECTOR MASS SPECTROMETER

Fisons Plc., VG Analytical, Floats Road, Wythenshawe, Manchester, M23 9LE, England.

Electrospray ionisation, by virtue of its propensity to generate multiply charged ions, has been used with quadrupole and ion trap mass spectrometers to analyse large biomolecules with molecular weights up to 100K Dalton.

An electrospray ion source has been designed for the AutoSpec double focusing high performance magnetic sector mass spectrometer (Fig 1). It incorporates two differentially pumped intermediate regions between the atmospheric pressure chamber and high vacuum. The intermediate regions employ a novel ion optical arrangement designed to optimise ion transmission whilst removing most of the neutral species. Ion acceleration subsequently takes place at high vacuum (typically $1 \times 10^{-5}$ mBar) in the source housing of the mass spectrometer, where ion/neutral collisions are sufficiently infrequent to allow good transmission of large, multiply charged ions (Figs 2 and 3). Fig 4 illustrates the transformation of raw electrospray mass spectra onto a molecular mass scale.

High resolution analyses can be carried out with ease on a high performance instrument such as the AutoSpec, and Fig 5 shows the quintuply charged ion envelope from bovine insulin (average MW 5733.6). This spectrum was obtained at a resolving power of 7000 (10% valley definition).

Fig 6 shows a comparison between high and low energy collision regimes for structural elucidation of a small peptide, methionine enkephalinamide (MW 572). Most of the observed product ions can be readily interpreted in terms of the structure of this peptide. The ion at m/z 498 in the B/E linked scan is characteristic of decompositions induced by high energy collisions.

**FIGURE 1**

**FIGURE 2**
Recent developments in electrospray ionization have prompted widespread interest among mass spectrometrists studying large molecules. Most of these investigators use, and will continue to use, liquid secondary ion mass spectrometry (SIMS) ionization in their work. In many laboratories the same mass spectrometer will be used for both electrospray and liquid SIMS necessitating reconfiguration of the instrument when changing between the two ionization methods. Faced with this prospect, we decided to implement electrospray ionization on our triple quadrupole instrument (Nermag R30-10) so that we could easily switch between liquid SIMS and electrospray modes. The triple quadrupole instrument was previously modified to incorporate a cesium ion gun in which the cesium ion beam was coaxial with the sample probe and perpendicular to the quadrupole axis. To implement electrospray ionization, we chose the recently published design of Chowdhury, Katta, and Chait [1] which employs a heated metal capillary for desolvation.

**Experimental**

A diagram of the ion source is shown in Figure 1. The components are as follows: A. Hamilton 1705RN syringe with a Hamilton 80426 needle (25 gauge) driven by a Harvard Apparatus Model 11 syringe pump. The high voltage required to generate the spray is applied to the syringe needle. A Teflon insulating cap is placed over the syringe plunger handle to prevent discharge through the syringe plunger to the pump; B. Stainless steel counterelectrode disc insulated from the stainless steel capillary with Kel-F bushing; C. Upchurch Scientific P-640 Kel-F adapter, 1/4-28 thread to 10-32 Fingertight chromatography fitting sealed to flange with Teflon O-ring; D. 20 cm. x 0.062” o.d. 0.25 mm. i.d. 316 stainless steel tubing; not shown is heater wire (0.020” nichrome) in fiberglass sleeving wrapped on the capillary and an iron-constantan thermocouple to monitor capillary temperature; E. Kel-F bushing to align capillary end with skimmer. The bushing is mounted in a stainless steel plate mounted on two threaded standoffs; F. Skimmer cone with 0.5 mm. orifice (Vestec VT 1020A) located 3 mm. from end of capillary; G. Hemispherical electrode (radius 0.375”; center of radius at entrance of first ion source lens) which serves as the repeller for liquid SIMS operation. The skimmer cone and hemispherical electrode are electrically connected to the ion source repeller voltage supply (0-40 volts). H. Teflon washer (0.030”) which insulates the skimmer mounting plate from the housing. The mounting plate is attached with six 2-56 nylon screws; I. Standard lenses of the Nermag R30-10 FAB ion source; J. First quadrupole mass analyzer; K. Cesium ion gun (Antek) mounted to FAB ion source block; L. Nermag FAB probe (shown retracted from ion source); M. Upchurch scientific F100 Kel-F Fingertight chromatography fitting used with 18 gauge copper wire in 1/16” o.d. Teflon tubing to provide electrical feedthroughs for heater and thermocouple wires (one shown of four); N. Conflat type flanges 2.75” o.d. mounted with Viton O-ring in place of copper gasket to maintain constant spacing; O. Conflat type flanges, 4.5” o.d. mounted with Viton O-ring; P. Pumping port connected via butterfly valve to cold finger and mechanical pumps.

For electrospray analysis the samples were dissolved in 47:47:6 (v/v/v) water/methanol/acetic acid and delivered to the needle at a rate of 0.5-1.0 μL/min. Typical operating voltages were: needle, 4.4 kV; capillary and counterelectrode plate, 250 V; and skimmer/repeller, 30 V. The capillary was maintained at a temperature of 90-100°C.

For liquid SIMS analysis the samples were applied in 5% acetic acid or 0.1% trifluoroacetic acid to a film of thioglycerol onto the end of a gold plated 2 mm. dia stainless steel probe tip. Cesium ions (7 kV energy) were used to desorb sample ions.

**Results**

The combination ion source gave comparable performance in liquid SIMS mode to the standard Nermag FAB ion source indicating that the hemispherical repeller was an adequate
substitute for the curved metal strip repeller on the standard FAB ion source. Some results of sample analysis in electrospray mode are shown in figures 2 and 3. Figure 2 shows results obtained for equine myoglobin; the measured molecular weight \((16,944 \pm 5)\) was within 0.037% of the calculated molecular weight \((16,950.5)\). The accuracy of these measurements is limited by the acquisition of nominal mass data and could likely be improved by acquisition of "profile" data and measurement of mass to charge ratios to tenths of a unit. Figure 3 shows data obtained on bovine serum albumin, the largest protein examined with this ion source. The measured molecular weight \((66,541 \pm 39)\) was within 0.4% of the calculated mass \((66,267)\), similar to results reported previously [1,2].

Conclusion

A combination electrospray-liquid SIMS ion source has been constructed which allows use of both modes of ionization without the need for physical reconfiguration of the instrument. The electrospray data obtained on samples of bovine insulin (mol. wt. 5,733.6; error 0.034%), equine myoglobin (mol. wt. 16,950.5, error 0.037%) and bovine serum albumin (mol. wt. 66,267; error 0.4%) are comparable to previously published data. The detection limit for bovine insulin was less than 8.32 fmol of material for a full scan. The electrospray source also performed satisfactorily on a second tandem quadrupole instrument which required a longer desolvation capillary indicating that the design should be adaptable to a variety of instruments.

ANALYSIS OF MIXTURES OF CLOSELY RELATED FORMS OF BOVINE TRYPsin BY ELECTROSpray IONIZATION MASS SPECTROMETRY. USE OF CHARGE STATE DISTRIBUTIONS TO RESOLVE IONS OF THE DIFFERENT FORMS. S.K. Chowdhury and B.T. Chait, The Rockefeller University, New York, N.Y. 10021

Electrospray ionization (ESI) mass spectrometry has been utilized for the analysis of a commercial sample of bovine trypsin (Sigma T8642). Commercial active bovine trypsin normally contains a mixture of three different forms of the enzyme, namely β-, α-, and ψ-trypsin (1). β-trypsin is a single chain enzyme, resulting from the cleavage of the Lys(6) - Ile(7) bond of trypsinogen with the release of the hexapeptide, VDDDDK. The calculated MM of bovine β-trypsin is 23293.3 u. α-trypsin originates from the additional hydrolysis at Lys(131) and, therefore, has a MM 18 u higher than the β-form. ψ-trypsin refers to a form with an additional split at Lys(176) and its MM is 18 u higher than the α-enzyme (Scheme I). Peak broadening caused by the natural isotopic abundance of atoms in the protein molecules results in overlap of the ion peaks from the different trypsin forms. Therefore, accurate determination of the molecular masses of these trypsins in a mixture is not straightforward, particularly when one component is present in small amount relative to the others. Even when various forms are present in nearly equal amounts, a resolution of approximately 1300 would be required to resolve ions from the different forms, a resolution higher than is frequently used with quadrupole mass analyzers coupled to an ESI source. We describe here a method whereby the closely related forms of trypsin in a mixture can be resolved in the ESI mass spectrum according to the different number of charges acquired by the different forms, allowing the accurate determination of their masses.

The electrospray ionization mass spectrum of bovine trypsinogen and bovine trypsin are shown in Fig. 1 and 2 respectively obtained with the help of an ESI mass spectrometer constructed at the authors’ laboratory (2). A single ion intensity distribution of charged states is observed in the mass spectrum of trypsin (Fig. 2). One distribution centers around the 18+ ion and the other around the 14+ ion. 18+ and 14+ represent ions with 18 and 14 protons respectively attached to the trypsin molecule. The calculation of molecular mass (MM) from the observed m/z values of ions designated as 20+ to 12+ indicates the presence of three different proteins (Table 1). The MM obtained from the 12+ to 15+ ions is 23295.7 ± 1.8, that from the 17+ to 20+ ions is 23324.9 ± 2.3, and that from the 16+ ion is 23309.6 u. Ions with intermediate charge states (15+, 16+, and 17+) may have unresolved contributions from the proteins producing the two flanking ion distributions. The multiple resolved ion components observed with the 12+ to 15+ ions arise from the attachment(s) of sulfuric acid and/or phosphoric acid molecule(s) to the protein ions (3). These acids are formed in the acidic spray solution from the sulfate/phosphate impurities present in the protein sample.

The observed MM of 23295.7 u closely agrees to that calculated for β-trypsin, the value 23249.4 corresponds to ψ-trypsin, and the intermediate value, 23309.6 u appears to be in agreement with the calculated MM of α-trypsin. It is expected that ions arising from α-trypsin will have higher charge states than those arising from β-trypsin because it has an additional free NH₂-group (from the internal cleavage) and because its less constrained structure allows it to acquire and hold on to a higher number of charges (4). Similarly, it is expected that ions arising from ψ-trypsin will acquire a higher number of charges than both α and β-trypsin. The observed electrospray ionization charge state distributions of the bovine trypsin isofoms (Fig 2) confirm these expectations. The results described above are of practical importance because the different trypsin forms produce ions with different charge state distributions and therefore, yield ions in different regions of the mass spectrum. Thus, an accurate determination of the molecular masses of the three closely related different trypsin forms that differ in MM by only 18 u is obtained. We predict that this method for analyzing closely related forms of proteins will be generally applicable to other cases where the different forms adopt different higher order structures.

ELECTROSPRAY IONIZATION MASS SPECTROMETRY OF SYNTHETIC PEPTIDES AND PROTEINS. COMPARISON WITH $^{252}\text{Cf}$ PLASMA DESORPTION MASS SPECTROMETRY.

The Rockefeller University, New York, NY 10021.

Synthetic peptides and proteins are becoming of considerable use in diverse areas of biological science, immunology and medicine. We have shown previously (1) that $^{252}\text{Cf}$ plasma desorption mass spectrometry (POMS) is a powerful analytical tool for the analysis of synthetic peptides and proteins. Here we report the use of electrospray ionization (ESI) mass spectrometry for the analysis of such compounds. The study is based on the detailed analysis of more than 300 synthetic peptides and proteins in the authors' laboratory.

The ESI mass spectrometer used for the study has been described previously (2). Because the sequence of the target peptide is known, the determination of the molecular weight (MW) provides a rapid verification of the primary structure of the peptide. Disagreement between the observed and the calculated MW indicates a possible modification of the peptide and provides clues regarding the nature of the modification. Another important use of the technique is the rapid assessment of the homogeneity of the target peptide. We find that ESI mass spectrometry provides an enormously useful complementary tool to the more commonly employed HPLC analysis. Fig. 1 shows an electrospray ionization mass spectrum of Asn$^{12}$ transforming growth factor-α. In addition to the ions corresponding to the correct MW, we also observe a by-product 58.2u higher than the target compound. High resolution HPLC analysis of the above protein produced a single, symmetric peak (Fig. 1a). Another example is given in Fig. 1b which shows an ESI mass spectrum of endothelin. The spectrum shows peaks corresponding to a peptide 41.8u higher than the calculated MW of endothelin. One probable cause for this mass discrepancy could be acetylation.

We also make a detailed comparative evaluation of ESI with $^{252}\text{Cf}$ PDMS for the analysis of synthetic peptides and proteins. Factors such as mass accuracy, speed, sensitivity, resolution, ability to handle mixtures, universality, and ease of interpretation are compared (Table 1). Each of the techniques was found to have particular merits and drawbacks. Fig. 2a shows an ESI spectrum of an analog of mast cell degranulating peptide which was difficult to interpret. On the other hand, $^{252}\text{Cf}$ PDMS spectrum of the same peptide (Fig. 2b) was much easier to interpret. Therefore, PDMS can be used to analyze mixtures of synthetic peptides and proteins.

The intensity of the peptide and protein ions in the mass spectra is strongly dependent on the stability of the spray, which in turn, depends on the purity of the analyte. Presence of strong acids such as HCl, H$_2$SO$_4$, TFA etc. above 1% and/or salt concentration above 10mM perturb the stability of the spray and reduce the quality of the spectra. We use ESI routinely to analyze synthetic peptides and proteins because of its higher speed and use PDMS where ESI spectra are difficult to interpret and/or obtain.

References.

2. HOMOGENEITY OF FINAL PRODUCT

Frequently, HPLC analysis yields a single peak from mixtures of closely related final products.

Fig. 1a

In addition to the target compound, a by-product is detected with a MM 58.2 u higher than the expected MM.

INTRODUCTION

Electrospray ionization (ESI) mass spectrometry and matrix assisted laser desorption time-of-flight mass spectrometry (LD-MS) have shown great promise in the analysis of large biomolecules with molecular weight greater than 5000 amu. While FAB mapping of peptides is effective, particularly in the range below 5000 amu, we were interested in using ESI to analyze proteins and protein fragment mixtures above this mass range. Two ESI sample introduction techniques were used to examine clostripain digests of Ribonuclease A: Direct Infusion and LC/ESI. We have also used LD-MS for the construction of SEQUENCE-ORDERED peptide maps using clostripain digests of modified ribonuclease A.

EXPERIMENTAL

Clostripain digests were performed in 10 mM Tris/Cl, 1 mM CaCl$_2$, 2.5 mM DTT, pH 7.5, with Clostripetidase B (Promega) at an enzyme:substrate ratio of 1:100 (w/w). Approximately 1.36 mg of reduced pyridylethyl RNase A in 680 µL of the above buffer and 13.6 µL of activated enzyme solution were mixed. Aliquots were removed at 0, 1, 2, 4, 8, 16, 32, 51, 107, 151 minutes and at 23 hours.

The electrospray analyses were performed on a Finnigan MAT TSQ70 mass spectrometer fitted with a Finnigan electrospray source. All spectra were obtained in the positive ion mode using Q3. Deconvolution of the resulting spectra was done on a DECStation 2100 using the Finnigan BioMass Deconvolution program.

Direct Infusion was done using a drying gas temperature of 60°C and a solution flow rate of 2.25 µl/min. The digest aliquots were dissolved in 57.5% methanol/37.5% water/5% acetic acid to give a final concentration of 10 pmol/µl. The run times were 5 minutes with a total sample consumption of 125 pmols.

LC/ESI utilized a nitrogen drying gas temperature of 80°C and a nitrogen sheath gas pressure of 45 psi. Isopropanol was used as the sheath liquid with a flow rate of 2.25 µl/min.

LC was performed on a reverse phase Sherisorb OSD2 C$_{18}$ microcapillary column (250 µm ID x 21 cm) with a 20 cm transfer line (50 µm ID) connecting the column and the TSQ70. Two HPLC pumps were used with a splitter that gave a split ratio of 45:1 at a flow rate of 2 µl/min through the column. The mobile phase was acetonitrile/water/0.1% TFA. Total run time was 40 minutes using a linear gradient from 3-90% acetonitrile over 30 minutes and holding at 90% acetonitrile for an additional 10 minutes.

The digest aliquots were dissolved in water and 40 pmols were injected onto the column using a Rheodyne 8125 injection valve with a 5 µl loop. The mass spectrometer was used as the detector for the LC separations.

RESULTS

The Direct Infusion ESI deconvoluted spectrum of the 1 minute clostripain digest is shown in Figure 1. The deconvoluted spectrum of the 1 minute clostripain digest with LC/ESI, Figure 2, is averaged over the LC run after the injection peak elutes.

Peak detection is not as efficient using Direct Infusion for the analysis of low concentration components in a complex protein digest. The ratios of the peak intensities for both methods show the same relative trends. The largest peak for the 1 minute digest spectra for both methods is the molecular ion of the reactant protein (m/z 14531.5).

Using selected ion chromatograms to isolate the elution time of each fragment for the LC/ESI spectrum allowed identification of each peak present in the digest. In all, 15 out of 15 peptide fragments were found using LC/ESI while only 10 out of 15 were found by Direct Infusion.

Comparison of the LC/ESI spectra for the 1 minute clostripain digest with LD data shows differing peak intensity ratios than those obtained with either ESI method. The mass accuracy of the LC/ESI data is equivalent to that obtained with LD-MS (Table 1). For LD/MS 13 out of 15 possible peptides were identified.
CONCLUSIONS

LC/ESI, in contrast to Direct Infusion, is the method of choice in analyzing concentration components in complex mixtures. Not all fragment peaks were identified using Direct Infusion ESI. Both LD-MS and LC/ESI MS give better results for fragment peak detection and subsequent digest analysis. The mass accuracy for both LD-MS and LC/ESI MS was, in general, 0.02% or better.

COMPARISON OF LD-MS AND LC/ESI FRAGMENT ION MOLECULAR WEIGHT
Formation of charged droplets in electrospray

P. Juhasz
Central Research Institute for Physics
of the Hungarian Academy of Sciences
1525. Budapest, 114. POB 49, Hungary

Flow patterns which can be observed in nature have to satisfy the equations of hydrodynamics and, in addition, must be stable with respect to small perturbations. If this statement were not true, probably, electrospray would not exist at all. Instead of spraying, arbitrarily long thin liquid jets could be drawn from the high voltage capillary, and these liquid satisfy the hydrodynamic balance conditions which can be compressed in the form:

\[ \frac{2 \rho \rho_0^2}{\pi^3 R^3} - \frac{\varepsilon_0 V_0^2}{R \ln^2 R} + \gamma = 0 \]  

where \( R, Q, \rho, V_0, \) and \( \gamma \) are the radius of the jet, the flow rate, the density of the liquid, the capillary voltage, and the surface tension, respectively.

However, there are small perturbations, with respect to which liquid jets are unstable, which grow in amplitude until the jet will disrupt into droplets. The disintegration process will be dominated by the fastest growing unstable mode also called 'the most dangerous unstable mode' [1]. Spatial distribution of the small perturbations are described in terms of their Fourier components (modes) characterized by the wave number, \( k \). The temporal evolution of the modes is given by multiplicative factors of the form: \( \exp[-i \omega(k)t] \) where \( \omega \) is the complex frequency. Whenever the imaginary part of the frequency is positive, that mode will grow exponentially in time. The most dangerous mode represents the maximum of the (positive) imaginary part of the frequency as a function of the wave number. Dispersion equation for an electrified liquid jet has the form [2]:

\[ \omega^2 = \frac{\gamma}{\rho R^3} \left[ (k^2 - 1) - \frac{\varepsilon_0 V_0^2}{\gamma R \ln^2 R} \frac{x K_1(x)}{K_0(x)} \right] \frac{x I_3(x)}{I_2(x)} \]  

where \( x = kR \) and \( I_0, I_1, K_0, K_1 \) are modified Bessel functions in the standard notation.

In this model the size of droplets into which unstable electrified jets disrupt is determined by the wavenumber of the most rapidly growing unstable mode characterized by the wave number \( k' \). This wavenumber can be found where the imaginary part of the frequency is maximal (and positive). The most probable volume of droplets is approximated by a cylindrical volume of the radius \( R \) and of the length \( 2\pi/k' \). Thus, the most probable droplet radius:

\[ \langle \tau \rangle = R \left( \frac{3\pi}{2k'^2 R} \right)^{1/3} \]  

The general numerical procedure is the following: determine the jet radius at a given flow rate and capillary voltage from Eq. 1. Calculate the dispersion equation with the known radius and find the maximum of \( \text{Im}(\omega) \) as a function of \( k \) from the Eq. 2.

ESI/MS OF PROTEINS: WHY MORE CHARGES THAN EXPECTED?

Electrospray mass spectra for peptides and proteins consist of multiply charged molecular ions each representing a charge state or m/z. A review of ESIMS analysis of peptides and proteins indicates that 80% of peptides and proteins analyzed in the positive ion mode have charge states equal to or less than the number of basic groups belonging to the expected "basic amino acid" residues Arg, Lys, His and the α-NH₂ group of the N-terminal residue. However, the other 20% of peptides and proteins were indicated to have unexpected charge states in excess of the "conventional" basic groups (Arg, Lys, His, & α-NH₂) present in the polymer. The extra proton acceptor sites on these peptides and proteins that appear to function in the ESI process have not been clearly defined. A question that arises is: Are there other amino acid residues with a side chain groups that may act similarly to the groups offered by the more conventional basic amino acid residues (Arg, Lys, His, & α-NH₂) present in the polymer? Amino acid proton affinity measurement studies involving the unimolecular decomposition of FAB-MS generated protonated amino acid dimers place glutamine high in the list with the basic residues. ESIMS studies on some glutamine containing proteins showing extra charge states such as human growth hormone (hGH) has led to the suggestion that glutamine (Q) residues may be involved.

In order to test the possible role of glutamine as a proton acceptor in the ESI process, we focused on a simple glutamine containing peptide case that was brought to our attention by the study of Lee et al. on the LC/ESIMS on a tryptic digest of biosynthetic bovine growth hormone (bGH) and our work on the LC/ESIMS on a tryptic digest of biosynthetic human growth hormone (hGH). Human GH and bGH are proteins that have amino acid sequences that are 70% identical. In both studies the last tryptic peptide to elute from C18 RP-HPLC columns was a very hydrophobic peptide identified as the respective T9 peptides of both species of recombinant GH. Interestingly, the bovine GH T9 gave an "unexpected" +3 charge state for its sequence while human T9 gave only the expected +2 charge state upon LC/ESIMS analysis. The T9 peptides from the two species differ in only three out of eighteen amino acid positions. The difference in the observed charge states for these two closely related peptides suggested that minor sequence differences may influence the charge state of a peptide ion produced by the ESI process.

Our strategy was to use a synthetic peptide analog approach in an attempt to map determinants for the extra charge state observed in the ESI/MS analysis of the bGH T9 peptide that showed the extra charge state previously seen.

We synthesized derivatives of the bGH T9 peptide using micro-methodology suitable for subsequent ESIMS analysis and noted which derivatives gave "unexpected" or "extra" charge states.

ESIMS analysis of several synthetic peptide derivatives shown in Table 1 led to the conclusion that the first glutamine in the structure was a proton acceptor. Figure 1 shows the ESIMS mass spectra for four "critical substitution" derivatives residue. Note that only the top structure containing two glutamines and the bottom structure having only the first glutamine in place show (M+3H) ions, the "extra" or "unexpected" charge state species.

We conclude with the following points:

1. The first glutamine (Q) of the bGH T9 peptide is "unique". Of the two glutamines present, the first alone acted as a proton acceptor. This indicates that glutaminyl residues are unequal in demonstrating this property. This result suggests that the microenvironment around the proton acceptor glutamine is important when the peptide is subjected to the ESI process.

256
2. It is of utmost interest to note that prolactin (PRL), a protein hormone homologous to growth hormone (GH), which belongs to the GH-PRL family (these protein hormones are thought to be derived from a common ancestral gene) has a GH T9 homologous region. Comparison of the amino acid sequences of the T9 homologous regions for growth hormones and prolactins from several different species indicated that there are Arg (R) substitutions in most of the prolactins for the amino acid position corresponding to the unique glutamine proton acceptor in the homologous GH’s. Furthermore, within the prolactin family the mouse PRL has a glutamine substitution in this basic residue site.

3. This comparative sequence information coupled with our study has led us to the realization and the hypothesis that “unique” glutaminy1 residues detectable by ESIMS analysis may function as proton acceptors and mimic the more conventional basic residues (R, K, & H) in biologically functioning native proteins.

4. Protein chemists should consider glutamine as a “conservative” substitution for a basic amino acid in “some cases”. ESIMS analysis of synthetic variants of the glutamine containing peptide regions in question should aid in the identification of these “unique” proton acceptor glutamines.

A Comparison of In Source Fragmentation of Peptides vs. CID Products as Observed During Electrospray Ionization Mass Spectrometry
D.B. Kassel, J. Tamura and B.D. Musselman Glaxo, Inc. RTP, NC 27770

The design and implementation of electrospray ionization (ESI) on magnetic sector mass spectrometers has been well documented. The principal advantage sector mass spectrometers offer are improved resolution and mass assignments for both "normal" and collision induced dissociation (CID) modes of analysis. The ability to obtain high resolution product ions derived from the collision of multiply charged precursor ions would enable product ion charge states and sequence determinations to be made much more reliably.

We have generated the product ion spectra for several peptides and small proteins at sufficient resolving power to identify product ion charge states based on the spacing of isotope peaks for doubly, triply and quadruply charged precursors. The implementation of ESI on a high performance JEOL SX102 magnetic sector mass spectrometer has also enabled us to acquire CID spectra of these compounds in two modes; (a) at low energy (via capillary/skimmer induced dissociation) and (b) at high energy (via constant B/E linked scanning techniques. The ability to effect fragmentation in both these regions has contributed greatly to the reliable interpretation of CID spectra. The CID generated via capillary/skimmer induced dissociation and at high energy (in the first field free region following the ion source) enabled complete sequence identifications to be made for bradykinin and renin substrate, which, under normal ESI operating conditions, produced exclusively the doubly and triply charged states, respectively. The in-source fragmentation of renin produced a series of a, b, and y ions, giving partial sequence information from positions 6-14 in the molecule. Only with the aid of collision induced dissociation at high energy was it possible to generate product ions which allowed for isomeric amino acids to be differentiated (e.g., leucine and isoleucine) and N-terminal sequence specific ions which helped elucidate the primary sequence of the molecule.

The ability to obtain useful sequence information when handling larger molecular weight peptides, though, is limited. We investigated the ability to fragment glucagon "in-source." Under normal ESI conditions (i.e., a capillary/skimmer 1 potential difference = 30V), glucagon exists primarily as the stable 3+ charged ion. Increasing the potential difference between capillary and skimmer 1 to 100V resulted only in a shift in the most abundant charge state (i.e., the 2+ ion). However, the ability to obtain B/E linked scan high energy CID data on the stable 3+ charge state for glucagon proved much more valuable. In the analysis of this peptide at high energy, a wealth of 2+ charge state product ions were observed. The charge state of these product ions were determined by operating the sector mass spectrometer at a nominal resolution of 1500, sufficient to partially resolve the isotope peaks of the respective product ions.

It is clear that alone, neither capillary/skimmer induced dissociation or high energy CID spectra contained sufficient product ion information to permit the complete sequence determination of these peptides. However, the combination of the two sets of data, do appear to provide sufficient sequence information to readily deduce primary sequences of low to medium molecular weight peptides.

The usefulness of this methodology was thus extended to the characterization of larger biomolecules. Therefore, we investigated the utility of generating sequence information by both capillary/skimmer induced dissociation and high energy CID for a model protein, amylin (MW=3920). The ESI mass spectrum of this protein is shown in Figure 1. The resolution of the mass spectrometer was set to 4000 in order to resolve sufficiently the spacing of isotope peaks and establish a charge state for the major ion in the spectrum. Capillary/skimmer induced dissociation did not produce any significant fragmentation. The spectrum generated at a capillary/skimmer
potential difference of 100V resulted only in a charged stripped mass spectrum, producing the 3+ charged state ion almost exclusively. The B/E linked scan high energy spectrum, on the other hand, provided a significant amount of structurally useful sequence information (as shown in Figure 2). The charge state of these product ions was obtained by operating at a resolution sufficient to partially resolve the isotope peaks. Interestingly, the major ions produced in this product ion analysis were of the type b3+ and y3+. We are currently investigating the use of other collision gases which might be used to produce more high energy-like fragments.

Electrospray Mass Spectrum of Amylin

Sample Purification within A Mass Spectrometer: Enhancing The Quality of Protein Mass Spectra by Ion Kinetic Energy Filtering

*Rong Feng and Yasuo Konishi, National Research Council of Canada, Biotechnology Research Institute, 6100 Royalmount Avenue, Montreal, Quebec H4P 2R2, Canada

The presence of some non-protein substances, especially some polar polymers, in a protein solution has often been a nuisance to the electrospray or ionspray (pneumatically assisted electrospray) analysis, as they produce their own spectra with high sensitivities and wide mass distributions that sometimes overshadow or overlap the weak protein signals. These interfering background signals not only complicate the data analysis, but also compromise the accuracy of protein mass measurement by overlapping the protein peaks. In some cases these contaminants still remain even after a sample has gone through HPLC or dialysis purification. Additional sample clean-ups may not be warranted, as the small amount of the remaining contaminants is usually harmless to the ordinary biochemical research. We report here a new method for the removal of the concomitant non-protein ions within a quadrupole mass spectrometer without additional sample purification.

Ion kinetic energy profile analysis (using the Sciex API III MS) has revealed that non-protein ions, such as polymer ions due to adducts formation, in general have less kinetic energy than the heavier protein ions. As shown in Fig. 1, the retarding potential required to stop papain ions (23,422 Da, 14+ - 19+) is a few higher than the one needed to stop polypropylglycol ions (200 - 2,400 Da, 1+ - 2+). This kinetic energy difference may have resulted from the electrospraying and the atmospheric pressure sampling processes. First, the heavy protein ions may have gained more momentum (thus more kinetic energy) than the light non-protein ions during the supersonic free-jet expansion in the atmosphere/vacuum interface region. Second, the multi-charged protein ions may have retained more kinetic energy than the usually single- or double-charged polymer ions during their voltage-driven migration in the atmosphere. Third, during the supersonic expansion between the electrically biased sampling orifice and quadrupole guidance lenses, the multi-charged protein ions may have been accelerated more than the less-charged polymer ions. The observed effect is probably due to the combination of all three factors.

Taking advantage of this kinetic energy difference, these polymeric contaminant ions can be prevented from entering the quadrupole mass analyzer by putting on it a bias voltage (Fig. 2). The maximum bias voltage that can be applied without severely affecting the protein ions depends on the protein mass and charge state. Usually, the higher the protein mass, the higher the bias voltage it tolerates, and the more complete the contaminant removal. The clean protein ions from such kinetic energy filtering not only produce much cleaner mass spectra, but also increase spectral resolution due to the reduction of the background signals and the slowing down of the protein ions. In some dramatic cases, the sample analyses were not possible without kinetic energy filtering. For example, in a sample of chemically modified cathepsin B (28,762 Da) the protein signals were invisible in the mass spectrum, because they were completely buried under the signals from an unknown polymer (Fig. 3a). However, electrically biasing the quadrupole mass analyzer essentially removed all the interfering polymer ions and revealed the protein signals (Fig. 3b).

Since peptides and small proteins usually have less kinetic energies than large proteins, the former can also be selectively removed to enhance the spectra of the latter, whose ion signals sometimes are much weaker than those of the former. For example, the signals of the degradation fragments (13.4, 23.6 and 47.3 kDa) (Fig. 4a) of anti-(α1-acid glycoprotein) have been removed from the spectrum of this 150 kDa IgG class antibody (Fig. 4b).
The above studies demonstrate that (1) concomitant non-protein ions have less kinetic energy than protein ions, and (2) this kinetic energy difference can be used to clean up protein mass spectra, and (3) the method is readily applicable on commercial instruments.
Thermally Induced Dissociation of Large Ions from Electrospray Ionization. Alan L. Rockwood, Mark Busman, Harold R. Udseth and Richard D. Smith. Pacific Northwest Laboratories, Richland, WA 99352

Introduction:
Using a heated metal capillary inlet for the sampling of the plume from an electrospray source, we have been able to achieve controlled desolvation and fragmentation by the careful control of capillary heating. The fragmentation processes yield fragment ions similar to those observed by dissociation in the interface and by low energy CID in triple quadrupole experiments.

Experimental:
The thermally induced dissociation (TID) studies were performed on a TAGA 6000E triple quadrupole mass spectrometer. The inlet region has been modified to afford differential pumping between the capillary inlet and the skimmer entrance into the "Q0" region of the mass spectrometer. The electrospray apparatus used a coaxial arrangement with analyte flowing through the center of the apparatus, while being surrounded by a sheath flow of methanol. A small flow of air around the liquid helps stabilize the electrospray current. The heated capillary was constructed of stainless steel (10 cm long, 0.0625" o.d., 0.020" i.d.). The capillary is attached to the TAGA front end by a specially constructed flange. The capillary is resistively heated (50A DC power supply, HP Model 6259B). A schematic of the interface is shown in Figure 1.

Results:
Figures 2a and 2b show spectra for melittin. Figure 2a corresponds to moderate heating (25 W, 200 C, "warm"). Figure 2b corresponds to strong heating (50 W, 350 C, "hot"). The "warm" spectrum was acquired with no potentials applied between the capillary and the skimmer for the stimulation of collisional desolvation in the interface. Effective desolvation has been done by application of heat. The "hot" spectrum was, again, acquired with no capillary-skimmer bias. The extensive fragmentation was achieved by the application of heat through the capillary. The progressive attenuation of the parent ion peaks for a variety of molecules, along with the corresponding appearance of fragment ions, has been observed upon application of stronger heating. At the highest degree of heating the spectra show the collapse of the current into an atmospheric pressure

Figure 1
Figure 2a: melittin: warm capillary (−200°C)

Figure 2b: melittin: hot capillary (−350°C)

unresolved envelope of decomposition products. The additive effect of thermal and collisional activation of ions in the interface region has also been observed. Similar degrees of fragmentation can be obtained by various combinations of thermal and collisional heating.

Conclusions:
Ions can be thermally dissociated. The amount of activation energy deposited is probably independent of the ion’s charge state (as opposed to methods for collisional heating in the interface). The role of coulombic forces in the dissociation of multiply charged ions becomes evident, since ions are activated to similar “temperatures” regardless of charge state. The TID technique provides a convenient method for producing fragment ions for further dissociation in a tandem instrument, and provides a basis for kinetic studies.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Protein Structural Effects on Electrospray Ionization Mass Spectra and Tandem Mass Spectra

Joseph A. Loo, Karen J. Light, Rachel R. Ogorzalek Loo, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
P.O. Box 999, Richland, WA 99352

Mass spectrometry (MS) and tandem mass spectrometry (MS/MS) are important tools for primary structure determination. Electrospray ionization (ESI) is an efficient method for producing multiply charged ions of large peptides and proteins, especially important for instruments of limited m/z. Tandem mass spectrometry can be applied to multiply charged ions to obtain further structural information. Preliminary evidence indicates that fragmentation processes occur primarily from regions remote to the likely charge sites. Comparison of the MS/MS spectra of different charge states of a protein can provide further insight into the fragmentation processes of multiply charged ions.

In addition to the charge state, higher order (secondary, tertiary, quarternary) structure of the protein has an effect on the ESI-MS and (possibly) MS/MS spectra. Changes in the ESI mass spectra (e.g., a bimodal charge distribution) have been observed by changing the solution pH, the organic solvent composition, or by the addition of other denaturants for polypeptides such as ubiquitin (M_r 8564), lysozyme (M_r 14306), and myoglobin (M_r 16950). Such changes in the proteins' solution environment are known to induce conformational changes, i.e., effect three-dimensional structure. Cleavage of disulfide bonds with reducing agents such as 1,3-dithiothreitol also changes the three-dimensional structure of a protein. More charges are typically observed in the resulting ESI mass spectrum and differences are observed in the collisionally activated dissociation (CAD) mass spectrum. Reduction of disulfide bonds arguably allows a compact, globular form to stretch to a more extended conformation, resulting in a shift in the charge state distribution to higher charge. Regions formerly enclosed by Cys-Cys bonds can be probed by CAD. Our results clearly suggest that conformation state can be monitored by ESI-MS, and also suggests the role of tandem MS for further probing of higher order structure.

Analysis of polypeptides and proteins by ESI-MS has generally been performed in the positive ionization mode. The more basic amino acid residues (arginine, lysine, histidine, and the amino-terminus) have dissociation constants such that proteins in acidic solutions (pH < 3) will generally be more positively (protonated) charged. We have observed an approximate correlation between the maximum positive charge observed in polypeptide ESI mass spectra and the number of basic residues, although we (and others) have also observed a poorer correlation for disulfide-rich proteins (due to cysteine-cysteine linkages). Not surprising, most polypeptides in unbuffered aqueous solutions do not afford an equivalent extent of multiple charging in the negative ionization mode. Acidic residues such as glutamic acid and aspartic acid in proteins have pK_a's typically around 5 or less.

Multiply charged anionic molecular ions can be produced in basic pH aqueous solutions by ESI. Horse heart myoglobin (M_r 16950.7) in 1% NH_4OH (pH 10-10.5) yields an electrospray ionization mass spectrum with a bell-shaped multiple charge distribution to approximately the (M-19H)^19- charge state. Molecular weight determination from the same method of calculation routinely used for positive ions but modified for proton loss rather than proton addition, yielded an M_r value of 16949.7 ± 1.2. Also observed in the mass spectrum are ions corresponding to the heme cofactor attached to the polypeptide chain. Even though the heme group is non-covalently bound to the peptide in solution, under certain conditions, species for the heme-peptide are observed in ESI mass spectra. Horse myoglobin has 13 Glu and 7 Asp residues, closely corresponding to the maximum negative charge observed.
Figure 1 is a negative ion ESI mass spectrum for an aspartic proteinase found in gastric juice, pepsin (porcine, M_r 33.6 kDa). Pepsin does not afford a positive ion ESI mass spectrum with our limited m/z range quadrupole instrumentation, while limited success for pepsin has been reported for other ionization/desorption methods such as CI-252 plasma desorption and matrix-assisted laser desorption. Porcine pepsin has only 2 Arg, 1 Lys, and 1 His residues, not nearly enough basic residues for production of multiply (positively) charged ions below m/z 2000. However, 29 Asp and 13 Glu acidic amino acid residues allows multiple charging in the negative ionization mode to the (M-42H)^{42-} charge state with the protein in an aqueous 1% NH₄OH solution. A variety of peptides and proteins up to M_r 66 kDa (serum albumin) and, in addition, small polysaccharides, have been successfully analyzed by negative ion ESI-MS. We are currently exploring the utility of MS/MS of multiply charged negative ions for structural analysis.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC05-76RLO 1830.
Electrospray ionization (ESI) has been employed as an ion source for gas phase ion-ion reaction studies carried out in the high pressure inlet to a quadrupole mass spectrometer. Previously, ion-ion reaction studies were limited to small species relevant to plasma, flame, and atmospheric chemistry. Because ESI efficiently transfers ions from solutions of non-volatile species into the gas phase, the size range of ions available for reaction studies is dramatically extended. In these investigations, multiple ionization sources are used in an arrangement merging unipolar streams of positive and negative ions at near atmospheric pressure. One or both of the reactants are highly charged macroions which undergo partial neutralization or charge inversion to yield charged products.

ESI-generated protein ions, \((M+nH)^{n+}\), react with negatively charges species generated by a discharge, resulting in a shift of the cation charge state distribution to lower charge (higher \(m/z\)), due to proton transfer. The ion intensity maximum in the ESI charge state distribution of horse heart myoglobin (\(M_r 16951\)) shifted from \((M+19H)^{19+}\) to \((M+14H)^{14+}\) after reaction. For horse heart cytochrome c (\(M_r 12,360\)) (Figure 1) the maximum shifted from the 15+ to the 13+ charge state. Some loss in overall ion current is observed after reaction; at least part of that loss arises from our mass spectrometer's lower sensitivity at higher \(m/z\). A relatively greater loss was observed in the myoglobin partial neutralization (total ion current from all charge states reduced by about a factor of 20) than in that for cytochrome c (reduced by a factor of 3). In these ion-ion reactions, attenuation of the high charge states is commonly observed; enhancement of the lower charge states is also observed. In some systems, e.g., myoglobin, the observation of low charge state enhancement is dependent on the capillary-skimmer bias, in part because the ion-ion reaction products show increased solvation and adduct formation. Studies employing dual ESI sources to react \((M+nH)^{n+}\) cations with \((M'-mH)^{m-}\) anions have displayed qualitatively similar behavior, also shifting the charge distributions to lower charge states. The combination of negative ESI source and positive discharge has been investigated, as well. Negative ESI of oligodeoxyadenylic acid, \(p(dA)_9\), yields primarily dianions, with lesser amounts of \((M-H)^-\) and \((M-3H)^-\). Operation of the positive discharge reduces the intensities of the \((M-3H)^-\), \((M-2H)^-\), and \((M-3H+Na)^2-\) ions, while increasing the intensity of \((M-H)^-\).

Collisionally activated dissociation (CAD) of electrospray generated ions occurs efficiently in our instrument at elevated capillary-skimmer biases. However, under the same conditions but with the discharge source operating fragmentation is reduced. This reduction has been observed for \((M+nH)^{n+}\) ions in combination with negative discharge operation and for \((M'-mH)^{m-}\) ions with positive discharge operation, consistent with a partial neutralization reaction occurring in the inlet. CAD occurs in the capillary outlet-skimmer region of the instrument preferentially for higher charge states because of their higher translational energies. If the partial neutralization reaction occurs in the inlet, the number of highly charged ions most likely to fragment is therefore reduced prior to reaching the outlet-skimmer region, resulting in less fragmentation.

Evidence of novel charge inversion from ion-ion reactions has been obtained in dual ESI source experiments. Protonated adenosine 5'-monophosphate (AMP) and fluorescein molecules \((M+H)^+\) are observed as products in the reaction of highly charged macroions \((M+nH)^{n+}\) with species generated in the negative electrospray ionization of AMP or fluorescein. The \((M+H)^+\) products most likely arise from charge inversion of \((M-H)^-\) anions. Protonated fluorescein was observed as a product of reaction with multiply protonated myoglobin (Figure 2) and cytochrome c, and to a smaller extent with melittin, but not with the less highly charged serine and bradykinin ions, or with positively charged species of lower proton affinity from an air discharge. Production of protonated AMP was also only observed for reactions with highly protonated reactants.
In addition to possible analytical applications, these techniques hold promise for future investigations of proton transfer and reactivity with gas phase macrolons.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830. This research has been supported internally by the Molecular Sciences Research Center and the Environmental and Molecular Sciences Laboratory at Pacific Northwest Laboratory.
Simultaneous Determination of the Acid and Lactone Forms of Three HMG CoA Reductase Inhibitors in Plasma by Ionspray Mass Spectrometry.
E. Dank, D. Wang-Iverson, J. Pursley, E. Ivashkiv, M. Jemal and A. I. Cohen
Bristol-Myers Squibb Pharmaceutical Research Institute New Brunswick, New Jersey 08903

Pravastatin, lovastatin and simvastatin are three compounds which inhibit the rate-limiting step of cholesterol synthesis, HMG CoA reductase, and have proven efficacious in the treatment of hypercholesterolemia. Pravastatin is administered as the active acid, while lovastatin and simvastatin are administered as lactones and hydrolyzed in vivo to their active forms. The analyses based on GC/MS methods (2-4), despite their high sensitivity, are usually time-consuming, require derivatization and don't permit analysis of acid and lactone forms simultaneously. The HPLC method (1) has insufficient sensitivity and selectivity. We developed a simple, fast and selective assay for simultaneous determination of the acid and lactone form of each of these compounds in plasma/serum by LC/MS using pneumatically assisted electrospray (ionspray) as the MS technique. Use of HPLC eliminated the need for derivatization and sample vaporization for injection as required for GC based methods. In addition it reduced the possibility of acid-lactone interconversion.

Plasma/serum samples spiked with the internal standards were extracted on C2 solid phase cartridges using acetonitrile as eluent and dry extracts were dissolved in loading mobile phase. Plasma samples were stored frozen at -20°C until analysis. The separations were carried out by reversed-phase gradient chromatography on a microbore column DELTABOND C8, 100x2 mm, 5 μm particle size, in the system acetonitrile-water, containing 5 mM of ammonium acetate. Gradient conditions were slightly different for three pairs of analytes: for lovastatin, acetonitrile increased from 30% to 80% in 5 min; for simvastatin, from the initial 32.5% to 80% in 4.5 min and for pravastatin, from 15% to 83% in 5.5 min. The column was maintained at 60°C, flow rate 0.3 mL/min with split of 1:6. All compounds eluted within six minutes and the total analysis time was about nine minutes. The mass spectrometer was operated in the positive ion mode at a low orifice voltage, 45 V, and ammoniated molecular ions were monitored. The system was linear from 5 ng/mL to 1000 ng/mL. The quantifiable limit was about 2 ng/mL for the lactone and 5 ng/mL for the acid forms of all analyzed compounds. Internal standards used are shown in the table:

The biotransformation of xenobiotics may result in the formation of electrophilic metabolites that react with nucleophilic sites in macromolecules. Electrophilic attack of DNA is believed to be an initiation step in a process that may ultimately result in carcinogenesis or mutagenesis, while the analogous reaction of proteins may result in idiosyncratic reactions and cytotoxicity. Hemoglobin has been found to be a particularly useful protein for monitoring tissue exposure to electrophiles because of its availability and its long biological lifetime, which permits determination of cumulative doses. Studies with intrinsically reactive or metabolically activated adducting agents have shown a proportionality between specific adducts of hemoglobin and of DNA. In contrast to DNA, adducted hemoglobin is not generally repaired over the lifetime of the protein. Thus, the monitoring of hemoglobin adducts appears to represent a convenient and sensitive method for assessing tissue exposure to potentially harmful electrophilic metabolites. The characterization of the molecular structure of these adducts may represent a generally useful approach for studying metabolic pathways of xenobiotics. We report here the evaluation of electrospray mass spectrometry (ESI MS) for the rapid and sensitive detection and molecular weight characterization of human hemoglobin adducts of electrophilic metabolites of xenobiotics, using N-acetyl-p-benzoquinone imine (NAPQI) and p-benzoquinone (BZQ) as model electrophiles. Evidence has previously been presented that NAPQI and BZQ are in vivo metabolites of acetaminophen (APAP), and BZQ is an in vivo metabolite of benzene.

EXPERIMENTAL: Human hemoglobin was reacted in vitro with BZQ or NAPQI in whole blood, erythrocytes suspended in phosphate buffered saline (PBS), or free hemoglobin in PBS. Erythrocytes were washed successively with reduced glutathione (5 mM) in PBS and PBS before being lysed in ice cold water. Globin was isolated by addition of hemoglobin to hydrochloric acid/acetone (1/99, v/v), washed successively with acetone and diethyl ether, and stored frozen at -20°C after air drying. The globin was chromatographed using gradient elution reversed-phase HPLC (Vydac C18, 330 Å, 4.6 mm i.d. x 25 cm) and a water/acetonitrile mobile phase containing 0.1% TFA. Chromatographic fractions were lyophilized and dissolved in methanol/water containing 2% acetic acid at concentrations ranging from 5-100 pmole/μL. ESI MS were recorded on a Hewlett-Packard Model 5988A mass spectrometer equipped with an Analytica of Branford, Inc. ESI source. RESULTS AND DISCUSSION: Comparison of the UV absorbance of unadducted versus adducted globin chains at 214 nm and 303 nm indicated reaction of the α- and δ-chains, but no detectable reaction of the β-chain (e.g., Figure 1). An adduct of a component that eluted prior to the major β-chain (pref) was also observed. Plots of the UV absorbance ratio (303 nm/214 nm) of the globin chains indicated a nonlinear increase in the extent of reaction of globin with increasing concentrations of electrophile. Whole blood, erythrocytes suspended in PBS and free hemoglobin reacted in a similar manner, except for quantitative differences in the extent of adduction. The ESI mass spectra of all of the globin chains had a bimodal distribution of ions under the ESI conditions used, irrespective of whether the chains were adducted by BZQ or NAPQI (e.g., Figure 2). The distribution of ions appeared to be slightly different for the adducted β-chains than for the unadducted β-chain. The molecular weights of the globin chains were determined with a precision of ±0.04% or better, and the average molecular weights of the α-, β- and δ-chains were in agreement with the known sequence of these chains. The average molecular weights of the BZQ and NAPQI adducted β-chain were 108 Da and 149 Da higher, respectively, than the unadducted chain. These results are consistent with the formation of hydroquinone and 4-hydroxyacetanilide adducts following reaction with BZQ and NAPQI, respectively. The pref component had an
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

average molecular weight that was 305 Da higher than that of the β-chain, suggesting that this was a glutathionyl adduct of the β-chain (theoretical mass 306 Da higher than unadducted chain). The average molecular weight of the BZQ adduct of the preβ component was 107 Da higher than the preβ component, which is likely a 2,5-dicysteinyl hydroquinone adduct based on previous studies of the reaction of BZQ with glutathione.9 The results of these studies clearly demonstrate the utility of ESI MS for the detection and molecular weight characterization of hemoglobin adducts of electrophilic metabolites of xenobiotics.

Electrospray ionization-mass spectrometry (ESI-MS) is rapidly becoming a practical biochemical tool for peptide and protein analysis. Production of multiply charged molecular ions allows conventional mass spectrometers of limited m/z range to analyze proteins with relative molecular mass (M_r) greater than 100 kDa with precisions of better than 0.005%. The utility of ESI is further enhanced by the increased efficiency of multiply charged ions for collisionally activated dissociation (CAD), often yielding multiply charged product ions that can be correlated to the amino acid sequence. Dissociation of the multiply charged ions can be induced either in the atmospheric pressure/vacuum interface (nozzle-skimmer region) or in the collision quadrupole cell of the triple quadrupole mass spectrometer. Human hemoglobin (Hb, ~62 kDa) consists of 2 a chains (15.1 kDa, 141 residues) and 2 non-a chains associated with a prosthetic heme group. Hemoglobin variants, of which over 400 are known, are characterized by amino acid substitutions in the globin polypeptide chain. We have investigated ESI-CAD-MS of eight intact 3-globin variant polypeptides as a tool for potential rapid analysis of these amino acid substitutions. The approximate location of the modification can be deduced from comparison of the CAD mass spectra and the observance of mass shifts of the fragment ions containing the substituted amino acid. Also, the effects of these amino acid substitutions on the CAD mass spectra was investigated. The effect of residues such as proline on collisional dissociation data for multiply charged parent ions has been previously noted by our laboratory. The fragmentations observed for these Hb 3-globin variants are dominated by cleavage on the NH2-terminus side of proline residues present in the polypeptide chain. One major site of fragmentation of the Hb 3 chain variants is the NH2-terminus of the proline at residue 51. Complementary ions are observed from this fragmentation process as highly charged (+8 to +13) b_{50} and y_{66} fragment ions. These complementary fragment ions are not observed for the Willamette variant as it has a substitution at residue 51 of an arginine for the proline, and therefore does not fragment at that site. Other variants studied with amino acid substitutions covering various molecular regions showed no differences in the CAD mass spectra. The majority of the dissociation products observed are assigned as fragment ions of relatively low charge state (+1 to +4) based on comparison of the MS/MS and interface dissociation spectra of the variants. Extensive fragmentations at the COOH-terminus of the polypeptide chain are observed as singly, doubly, and triply charged "y_n" fragment ions. A series of doubly charged "b_n" fragment ions from the NH2-terminus in addition to a singly charged b_4 fragment ion from cleavage of the -CO-N- backbone bonds are present in the dissociation mass spectra. The majority of the other fragment ions observed are centered around proline residues.

The recent application of the Electrospray ionization (ESI) technique to the field of proteins has allowed many laboratories to determine the molecular weights (MW) of proteins on instruments of limited mass range \((1,2)\). Recently we have acquired an electrospray ion source from the Vestec Corp. for our Vestec 201A LC/MS instrument and applied the ESI technique to the determination of the MW of bovine and porcine recombinant somatotropins (rbST and rpST) and some of their analogs at position 99 \((3)\). In this work we determined the centroids of the various clusters manually and calculated the number of charges, the MWs and the average MWs off-line. This method is long, tedious, prone to human errors and consumes a lot of the sample under investigation.

Since then we have computerized the data processing step so that the data acquired on the Teknivent Vector 1 system are transferred to the Harris\textsuperscript{7} dual CPU computer and processed. Two methods of calculating the average MWs have been developed in our labs: one using the centroid determination \((4)\) and the other one using a deconvolution algorithm as described in the literature \((5)\). In general the accuracy of the data is similar to the manual method, although the deconvolution method seems to give more accurate results in most cases. Several facilities have been incorporated in these programs: smoothing of noisy scans, manual picking of the clusters of a series if necessary, deletion of certain peaks that are due to noise, subtraction of the peaks that have been interpreted, etc. In the deconvolution method the abundances belonging to a given cluster series are summed and displayed on the mass scale of the protein. Thus the peak areas reflect the abundances of the proteins present as well as of impurities and adducts formed. The average MWs of the peaks, even small ones, can be easily determined by positioning the cursor at the center of a given peak displayed on a CRT screen.

We have expanded this research to other proteins of interest to our research community. Thus we have analyzed several homologs of recombinant bovine somatotropin (rbST) in which an additional amino acid has been inserted and in which one or more amino acids have been changed. Insertion of a serine between the threonine at position 98 and the aspartic acid at position 99 of rbST-99D yielded a partial sequence of -98Thr-99Ser-100Asp-101Ser-. The theoretical average MW of this protein is 21,900. The found values were 21,901.3 and 21,900.5. When the aspartic acid in the previous sequence was replaced by serine, the following partial sequence -98Thr-99Ser-100Ser-101Ser- was the result. The theoretical average MW for this protein is 21,872.0 and the found values are 21,874.3 and 21,871.5.

The mixtures of natural growth hormones from the pituitary glands of cows pigs and humans have also been analyzed by this technique. The ESI mass spectrum of the pituitary bovine

274
somatotropin (pbST) is shown in Fig.1. From this it is apparent that two major proteins are present in this mixture. The average MWs of these two proteins were determined as 21,812.5 and 21,425.0. Thus the higher MW protein corresponds to bovine somatotropin (theory 21,812.0) while the lower MW corresponds to bovine somatotropin which has lost 4 amino acids from the amino terminus (bST-AFPA). A similar analysis has allowed us to assign the other peaks to sulfate/phosphate adducts or losses of amino acids from the amino terminus or a combination of both.

DEGLYCOSYLATION OF INTACT PROTEINS WITH SUBSEQUENT ANALYSIS BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY.

Mass spectral analysis of glycoproteins can identify or confirm the structures of both polypeptide and oligosaccharide portions of these important molecules. However, heterogeneity present in the carbohydrates may decrease the sensitivity of analysis of intact glycoproteins by electrospray ionization mass spectrometry or may prevent detection altogether. Previous work on identification of proteins following deglycosylation has been done at the peptide level. Removal of the oligosaccharides therefore facilitates mass spectrometric detection of glycoproteins. Subsequent measurement of the polypeptide mass provides answers questions to regarding the fidelity of expression of recombinant proteins, and the presence of backbone clips or processing. In this work, chemical and enzymatic methods for removing N-linked and O-linked carbohydrates were compared. Ribonuclease B was used as the primary standard for deglycosylation with hydrofluoric acid (HF), trifluoromethanesulfonic acid (TFMSA), endo H, and PNGase F.

Few glycoproteins yield interpretable mass spectra without deglycosylation. One exception is ribonuclease B (Mr 14,900-15,550) where the two major and three minor glycoforms give distinct masses for each (Figure 1). Deglycosylation of this protein was accomplished by enzymatic methods (Endo H and PNGase F) and acid cleavages (HF and TFMSA). The product of cleavages by endo H, HF and TFMSA retain one N-acetylglucosamine residue attached to the asparagine. Starting material in these cases containing both glycosylated (ribonuclease B) and non-glycosylated (ribonuclease A) forms of the protein. The products observed from chemical deglycosylation gave a broad cluster of peaks in the region of protein with a single GlcNAc attached. PNGase F digestion was successful at the 20 picomole level and endo H was successful at the 10 picomole level (Figure 2). The products were introduced into the mass spectrometer using HPLC for best signal to noise and peak width.

The mass spectrum of the intact bovine fetuin, which contains three N-linked and four O-linked oligosaccharides, was not interpretable without prior knowledge. However, sequential removal of the sialic acid residues, N-linked and most O-linked oligosaccharides using neuraminidase, PNGase F and O-glycanase produced a mass spectrum where the protein mass could be determined.

Methods for isolating and desalting the protein cores varied depending on the hydrophobicity of the product. Reversed-phase HPLC was preferred if solubility allowed, and best results were obtained by capillary LC/MS. Alternatively, many deglycosylated proteins are very hydrophobic (eg. DNase), and poorly soluble in aqueous/acetonitrile solutions. Salts and surfactants were removed by precipitation of DNase and it was dissolved in 100% DMSO for electrospray ionization mass spectrometry (Figure 3). The protein remained intact during this procedure as shown by the intact mass.

In summary, removal of the N-linked and O-linked oligosaccharides allowed masses of the amino acid portion of the glycoproteins to be determined with good accuracy. Limitations to the method include the lack of a universal enzyme for the removal of O-linked oligosaccharides, and poor solubility of many deglycosylated proteins.

Figure 1. Ribonuclease B contains five molecular species at Mr 14,899, 15.061, 15.224, 15.366, and 15.548 kDa. Each glycoform differs from the next homolog by a mannose residue (+162 Da).

Figure 2. Digestion of ribonuclease B with endo H produced protein masses corresponding to a single GlcNAc residue (B, 13.885 kDa). PNGase F digestion gave similar results. (data not shown) and Deglycosylations were carried out using 10 picomoles (endo H) or 20 picomoles (PNGase F) of starting glycoprotein, and the solutions were desalted and introduced into the mass spectrometer by capillary LC/MS.

Figure 3. The electrospray ionization mass spectrum of recombinant DNase following digestion with PNGase F. The precipitated protein was ionized from 100% DMSO. The peak top is shifted to a mass slightly higher than theoretical (as shown by the lines) due to residual salts.
Electrospray Analysis Of Ribonuclease B: Observation Of Glycoforms

Bovine pancreatic ribonuclease B (RNase B) is a 124 amino acid glycoprotein of 13,700 protein mass with a single N-linked glycosylation site containing a series of structurally defined high-mannose oligosaccharides. The commercial availability of RNase B as well as the structural simplicity of its oligosaccharides makes the glycoprotein a convenient and common choice for the development of carbohydrate analytical techniques. We have attempted to validate the utility of electrospray MS for the characterization of oligosaccharide structures on an intact glycoprotein using RNase B as a model.

Electrospray MS analyses were performed by continuous infusion of 100 ng/μL solutions of RNase in 5% acetic acid in 20:80 methanol:water into a Vestec Model E200 Electrospray interface. Each spectrum is the average of three 10 second scans, corresponding to the consumption of 17.5 pmol during the analysis. Electrospray MS analysis of "pure" RNase B (Fig. 1), obtained from Sigma, indicated the presence of a complex mixture dominated by multiply-charged ions (labeled A) from the non-glycosylated form RNase A. Also observed were multiply-charged ions (labeled B) which were assigned to RNase B. The "pure" RNase B sample was then purified by Sigma to generate a second RNase B, "ultrapure" B. ESPMS analysis of "ultrapure" RNase B (Fig. 2) demonstrated the absence of RNase A and the presence of multiply-charged ions indicative of a mixture of nine components. The difference in mass between the two major components, 1 and 4, was 162 amu, which corresponds to one mannose unit. The masses observed for 1 and 4 were consistent with oligosaccharide components Man₅GlcNAc₂ and Man₅GlcNAc₂, respectively, on RNase. The mass differences between components 4 and 7 (160 amu), 7 and 8 (166 amu), and 8 and 9 (160 amu) suggested the presence of additional mannose units. Components 2 and 5 were identified as acetate adducts to species 1 and 4, respectively.

To further characterize the glycoforms of RNase B, "pure" and "ultrapure" RNase B were analyzed by reverse phase HPLC, CZE, and SDS-PAGE. HPLC and SDS-PAGE analyses indicated the presence of 2 components (RNase A and RNase B) in the "pure" sample and one component (RNase B) in the "ultrapure" sample. In the CZE analyses, 3 components (RNase A, Man₅RNase B and Man₅RNase B) were observed in the "pure" sample and 2 components (Man₅RNase B and Man₅RNase B) in the "ultrapure" sample.

To validate the ESPMS results, "ultrapure" RNase B was subjected to classical sugar analysis. N-linked oligosaccharides were released from RNase B by treatment with anhydrous hydrazine. After purification by paper chromatography, the oligosaccharides were labeled by reduction with ²H-borohydride and subjected to gel permeation chromatography on Biogel P4 (Fig. 3). The major oligosaccharides eluted at 9.0 and 9.9 glucose units, characteristic of Man₅GlcNAc₂ and Man₅GlcNAc₂ species, respectively. These sugars coeluted with standard oligosaccharides, and both yielded the Man₅GlcNAc₂ species (5.5 glucose units) upon treatment with Jack Bean alpha-mannosidase, indicating that they both contain the beta-linked mannose core, Man(bet1-4)GlcNAc(bet1-4)GlcNAc(bet1-4)GlcNAc-OH and 4 or 5 outer alpha-linked mannose residues.

SELECTIVE DETECTION OF GLYCOPEPTIDES IN PROTEIN DIGESTS BY ELECTROSPRAY LC MS/MS

*Michael J. Huddleston, Mark F Bean, John R Barr, and Steven A. Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

Locating glycosylated peptides in an HPLC map of a protein digest is a frequently encountered task in protein analysis. As mass spectrometry is called on to confirm structure and map post-translational modifications of increasingly larger proteins, techniques that rely on changes in HPLC pattern after removal of the carbohydrates to identify potential glycopeptides become less reliable. Furthermore, the characteristic multiple-peak signature of a glycopeptide arising from heterogeneity in the carbohydrate may be obscured by coeluting peptides that are often present in significantly higher concentration than any of the individual glycoforms. Clearly, more selective detection methods are required. Toward this end we have investigated the utility of constant neutral-loss and parent-ion scans on a triple quadrupole mass analyzer during electrospray MS and LC-MS.

MODEL STUDIES ON OLIGOSACCHARIDES AND ISOLATED GLYCOPEPTIDES: A pure oligosaccharide, Man$_4$GlcNac, as well as glycopeptides derived glycopeptides containing high-mannose or complex oligosaccharides were used as model compounds to study the use of different scan modes for glycopeptide-specific detection and to optimize the ESMS system parameters for sensitivity.

NEUTRAL-LOSS SCAN MODE: The neutral-loss scan was less informative than the parent-scan mode. Since the mass of a neutral loss is affected by the charge state of the parent ion, this type of MS/MS experiment is, in general, less useful in ESMs.

PARENT-SCAN MODE: These experiments provided useful information. The carbohydrate-related fragments are lost preferentially from the protonated ion species. Therefore the parent-scan data has the appearance of the normal ESMs data yielding predominantly MW information, but it is selectively obtained for glycopeptides. Most importantly, the information is obtained regardless of charge state.

The following oxonium fragment ions were evaluated in parent scan mode: m/z 147 (Fuc), m/z 163 (Hex), m/z 204 (HexNac), m/z 232 (NeuAc) and m/z 366 (HexHexNac). The m/z 163 and m/z 204 gave useful data with the pure oligosaccharide and the oligomannose glycopeptide, and m/z 204 and m/z 366 gave useful data for the complex glycopeptide. Generation of the m/z 204 HexNac fragment appears to be general for any carbohydrate or glycopeptide containing HexNac in the inner core. Like peptide immonium-ions, this fragment arises from that population of molecules that is extensively fragmented upon collisional activation. At present we are not sure if the 204 is arising selectively from one of the two inner core HexNac’s. Because the m/z 204 is generic to all of the common glycopeptide structural types it was chosen for the LC-MS/MS experiments.

LC/MS/MS OF PROTEIN DIGESTS FOR LOCATING GLYCOPEPTIDES: Parent scanning of m/z 204 (HO-HexNac$^+$) has been used to locate glycopeptides in the LC-MS/MS data of three glycoproteins. (1) CD4, the receptor for the HIV-virus: two sites of glycosylation; (2) gp120, the 85 kDa surface glycoprotein of the HIV-virus: 24 potential sites of glycosylation; and (3) soluble complement receptor, a 250 kDa glycoprotein containing 25 potential sites of glycosylation (Fig. 1). The mass spectra from scans at which the TIC of the parent ion scan shows a response were examined to see if the response was due to glycopeptide. In most cases the spectra (for example, see Fig. 2) contained series of molecular weight-related signals separated by the mass increments of hexose, sialic acid, deoxyhexose, etc. Multiple signals for the same glycopeptide are observed because the carbohydrate moieties are often heterogeneous, but this heterogeneity does not affect the retention behavior on RP-HPLC to a great extent. Parent ion scanning for m/z 204 occasionally detected peptides that could fragment to yield an abundant m/z 204 (typically as a y$_n$ or b$_n$ fragment).

SUMMARY: LC/MS/MS VS. LC/MS FOR LOCATING GLYCOPEPTIDES IN COMPLEX MIXTURES

* LC/MS/MS in parent scan mode enables glycopeptides to be located rapidly in complex digests.
* Interference from co-eluting peptides which can obscure the presence of the glycopeptides is eliminated.
* The same carbohydrate compositional information obtainable from the normal MS scans is available from the parent ion scan data.
* Parents of m/z 204 (HexNac) in LC/MS/MS mode should permit equally facile identification of O-linked as well as N-linked carbohydrates.
* Other parent scan modes (such as parents of NeuAc and Hexose) are useful for distinguishing complex from oligomannose carbohydrates.

In contrast to peak pair searching and "diagonal" analysis of LC/MS data, parent scanning enables glycopeptides lacking heterogeneity to be identified.
Figure 1. (top) Total ion current trace for the LC-ESMS analysis of a tryptic digest of soluble complement receptor. (bottom) Parent-ion scan profile of m/z 204 acquired during an LC-ESMS/MS analysis of the above sample. Separation was carried out on a 1mm C-18 column with a TFA/CH$_3$CN/H$_2$O gradient at a flow rate of 40 µl/min.

CHEMICAL MODIFICATION OF GLYCOPEPTIDES AND PEPTIDES FOR ENHANCING MULTIPLE CHARGING IN ESI-MS.

Zamas Lam, Bruce B. Reinhold and Vernon N. Reinhold

Harvard University School of Public Health, Boston, MA 02115.

Molecular weight determination of high mass peptides by electrospray ionization is one of the most important recent developments in mass spectrometry. It has been shown that the main sites of protonation are the amino group on arginine, lysine, ornithine and histidine residues. For peptides or small proteins with a sufficient number of basic residues, the observed multiple charge states can be used for direct analysis. For tryptic glycopeptides or peptides lacking basic residues their mass/charge ratio may fall outside the mass range of the instrument and their detectability is severely limited.

This presentation describes two procedures for enhancing multiple charging of these peptides by quantitative i) amidation of acidic residues to afford amino group bearing sites, ii) vinylpyridine etheration of cysteine residue. The advantages of increasing the number of charge states on peptides and glycopeptides are threefold:

i) brings the mass/charge ratio within the mass range of the triple quadrupole,
ii) increases the ionization efficiency,
iii) improves the detection of glycoforms in a complex mixture.

These advantages can be best illustrated if we consider the three tryptic glycopeptides derived from bovine fetuin, BF T55-85 (peptide base mass 3402.79), BF T126-141 (peptide base mass 1755.08) and BF T142-169 (peptide base mass 3017.39). They are all glycosylated with various glycoforms of complex-type structures with base mass between 892 to 3300. Therefore in their native form their mass/charge ratio is above the mass range of the triple quadrupole and cannot be effectively analysed by ESI.

After amidation or etheration, these glycopeptides will carry more residues for protonation to bring their mass/charge ratio down to the triple quadrupole mass range. Another added advantage of this procedure is that multiple charging improves the detection of glycoforms in a complex mixtures. This is illustrated with the synthetic ESI spectra of native and amidated BF T126-141. The native glycopeptide (maximum of 3 charge states) after deconvolution gives a lot of erroneous signals while the amidated glycopeptide (maximum of 6 charge states) provides a much better analysis of the spectrum.

Cys-Cys residues are reduced in the normal manner (TRIS buffer, guanidine HCl and dithiothreitol) follow by treatment with 4-vinylpyridine (VP) to afford the thio-ether. The carboxyl groups are quantitatively amidated with N,N-dimethylethlyenediamine (DMED) or with the more reactive 3,3'-diamino-N-methylidipropylamine (DAMDPA), which convert
carboxyl groups to amino group bearing sites. Small peptides are directly amidated as their methyl ester in hexafluoroisopropanol, while larger protein are amidated via a carbodiimide reaction in hexafluoroacetone. The DMED reaction is stoichiometric, while only one of the free amine in DAMDPA is involved in the condensation reaction. Both VP and DMED derivatives carry one charge site, while DAMDPA derivatives carry two possible sites for protonation.

The FAB spectra of the amidated peptides showed very prominent doubly charge molecular ions (sometime the base peak), while the ESI spectra of the derivatized peptides showed more multiple charging than the native material. We have applied these procedures to a variety of peptides and proteins, and find them very straightforward and can be easily incorporated as a standard step prior to ESI analysis.
ELECTROCHEMISTRY AND TANDEM MASS SPECTROMETRY: A DYNAMIC COMBINATION FOR STUDYING BIOLOGICAL REDOX REACTIONS

Kevin J. Volk, Edward Kerns, Mike S. Lee, and Ira E. Rosenberg
Bristol-Myers Squibb Co., Wallingford, CT 06492

The development of methods to provide information concerning the activity, mechanism of action, and metabolism of various drug candidates is an important aspect of the pharmaceutical drug discovery process. Therefore, techniques which can give insights into the mechanism and structural factors which might influence metabolite formation are significant tools. Electrochemical methods have been used successfully to investigate the redox chemistry of biologically significant molecules as well as synthetic compounds with biological activity (1-4). This is based on the fact that both electrochemical and biological redox (oxidation or reduction) reactions involve heterogeneous electron-transfer processes. As a result, electrochemistry in combination with mass spectrometry (EC/MS) is well suited to provide insight into redox and related chemical reactivity of compounds of biological interest.

In these studies, an electrode is poised at a suitable potential and is used to simulate the redox enzyme. The products of the electrochemical reaction are analyzed by mass spectrometry (Figure 1). Although the unique selectivity associated with enzymes cannot as yet be precisely duplicated using this method, in analogy to the active site of an enzyme, the substrate molecule must be properly oriented before an electron transfer reaction can occur at the electrode surface. Buspirone, an anxiolytic drug, was chosen as a model compound due to the extensive data available about its in-vivo routes of metabolism (5).

Figure 2 illustrates the mass chromatograms of the [M + H]^+ ions of buspirone and four oxidation products observed by mass spectrometry using a thermospray interface. Daughter MS/MS spectra were acquired for each of these products and the spectra revealed possible structures for these compounds. Figure 3 illustrates the daughter MS/MS spectrum of an electrochemically generated oxidation product of buspirone. Based on the product profile, two separate oxidation pathways were proposed to account for products identified by MS/MS. Figure 4 shows a comparison of the electrochemically generated products with those metabolites formed in-vivo. These results indicate that EC/MS/MS can be used to provide information concerning metabolism and degradation processes of drug candidates. The formation of these species via electrochemical oxidation of buspirone and detection by mass spectrometry is significant since the same metabolites are formed in-vivo.

Microdialysis sampling combined on-line with electrospray mass spectrometry

Current protocols for rapid structure elucidation of trace compounds in complex mixtures, which are based on tandem mass spectrometry (MS/MS) and LC/MS/MS, are currently in use in our laboratory. For example, drug metabolites in physiological fluids are currently screened using the parent and neutral loss MS/MS modes, followed by obtaining detailed structural information by daughter MS/MS and LC/MS/MS. In this manner, endogenous and xenobiotic compounds are commonly identified by mass spectrometry at concentrations below 1 microgram/mL in physiological fluids. As part of an ongoing improvement of methods, studies were performed to enhance present trace mixture analysis procedures and instruments to obtain chemical information directly from biological systems.

Microdialysis sampling (1-4) readily interfaces with certain types of mass spectrometers. It provides a method for sampling living animals which causes minimal disruption, permits analysis in real time and may reduce degradation of analytes. We previously described an integrated microdialysis/MS/MS system using the thermospray interface and a series of sampling valves (5). In the present study the use of the electrospray interface has improved the performance of the system.

The system used in these studies is shown in the following figure. A CMA/10 microdialysis probe from Carnegie Medicin was connected directly to the ionspray interface of a Sciex API III tandem quadrupole mass spectrometer. The quantitative capabilities of the system were studied using selected reaction monitoring, in which Q1 was set to selectively pass the (M+H)+ ion of a model compound gepirone and Q3 was set to selectively pass the m/z 122 collision induced fragment ion of gepirone. In this way the MS/MS served to selectively detect gepirone in the presence of a complex matrix without time-consuming chromatographic separation. The capability of the system for MS/MS screening and structure elucidation was performed by dialyzing solutions of gepirone or a plasma sample containing gepirone and metabolites while collecting daughter, parent and neutral loss MS/MS spectra.

The effect of dialysis flowrate on the response of the system was studied by changing the dialysis flowrate from 2 to 20 microliters/min. It was found that the response increased in direct proportion to decreases in the flowrate. This result reflects the fact that with reduced flowrates the dialysis efficiency increases and causes increased concentration of analyte in the dialysate. Electrospray, being a concentration sensitive ionization device, produces greater ion yield as the concentration of the analyte increases. Thus, microdialysis with low flowrates is an ideal match for electrospray ionization. A flowrate of 10 microliters/min was used for the remainder of the studies, for comparability to previous studies. However, these results indicate that at least 10 times greater sensitivity may be achieved at a flowrate of 1 microliter/min.

The detection limit of the system was studied by dialyzing successively lower concentrations of gepirone. A detection limit of about 100 ng/mL was observed.

The limit of identification, the lowest concentration at which a useful MS/MS spectrum could be obtained for structure elucidation, was found by dialysis of successively lower concentrations of gepirone. At a concentration of 200 ng/mL a useful daughter MS/MS spectrum was obtained which contained all of the characteristic daughter ions of gepirone.

The capability of the system for MS/MS structure elucidation was studied by dialyzing a plasma sample in vitro. Using a series of parent and neutral loss MS/MS screens, two
metabolites and gepirone were observed in the plasma. A daughter MS/MS analysis of the metabolite at m/z 376 indicated that this metabolite was hydroxylated on the dione moiety. The pyrimidinyl piperazine metabolite was also readily observed.

An integrated microdialysis/MS/MS system offers advantages over traditional strategies of biological sample analysis. The sample is obtained with a minimum of disruption and degradation. The sample is directly analyzed by the mass spectrometer with immediate production of data each 2 seconds, while in most applications of microdialysis samples are collected for 10-30 minutes and analyzed off-line after sample storage and preparation. Valuable structural information may be obtained from mass spectra using this system. Use of an electrospray interface with the system permits sensitive detection of analytes and low energy ionization for labile molecules. Future applications of this apparatus may include: drug metabolite screening directly from living awake animals, analysis of drugs, metabolites and endogenous compounds in tissues, investigative pharmacokinetics, and monitoring of in-vitro biochemical reactions. The system may be applied to broader experimental strategies involving the simultaneous monitoring of physiological data and chemical events in a living system.

References
Electrospray MS has generated a great deal of interest due to its suitability for the analysis of high molecular weight and thermally-labile compounds. For many compounds, electrospray has been shown to be a gentle ionization technique, providing spectra similar to those from FAB/MS. Electrospray has the additional advantage of generating multiply-charged ions, allowing mass spectrometric analysis of compounds not normally within the mass range of the instrument.

Our interest has been to combine electrospray with small-scale separation techniques designed for the analysis of low levels of analyte. Two such techniques are capillary zone electrophoresis (CZE) and nanoscale capillary LC (75 μ i.d. packed columns) (nCLC), which are characterized by submicroliter per minute flow rates, small injection volumes, and high separation efficiencies. These characteristics make these separation techniques ideal for on-line coupling with mass spectrometry.

Because of the sub-microliter per minute flow rates associated with these techniques, a make-up flow is required for the generation of a stable ESI spray. This supplemental flow is provided coaxially with a modified Vestec ESI probe. Coaxial arrangement of the analytical column and a sheath flow (to provide sufficient flow for generation of the spray) does not compromise chromatographic resolution and permits the independent optimization of sheath flow and analytical mobile phase.

CZE and nCLC have been successfully coupled to ESI/MS and have been applied to a wide variety of mixtures. Separation of synthetic mixtures of peptides, proteins, tryptic digests, and bile acids can be readily achieved using either CZE or nCLC, but the higher loading capacity of the nCLC column proves distinctly advantageous where mass spectrometric sensitivities are limiting. On the other hand, CZE peak widths are narrower, detection limits are lower, and analysis times are shorter.

Separations of closely-related cytochrome C's and myoglobin were achieved by CZE/ESI at the femtomole level, while nCLC separations have been performed on tryptic digests of ACTH and cytochrome C, and bile acids. Mixtures of neuropeptides, angiotensins, and chemotactic peptides could be separated by both techniques. Separations have been achieved on as little as 2 pmoles per component by CZE/ESI/MS and 12 pmoles by nCLC/ESI/MS.
SUBTRACTIVE METABOLIC PROFILING BY CAPILLARY LC-ES-MS IN THE METHODICAL SCREENING FOR SIGNAL AND EFFECOTOR MOLECULES THAT PLAY A ROLE IN FIREBLIGHT DISEASE.

G.J. Feistner
Beckman Research Institute of the City of Hope, Duarte, CA 91010

Fireblight is one of the longest known and most feared plant diseases and is especially destructive to pear and apple. The name is derived from the typical firetorched appearance of the late, necrotic stage of this disease. Toxins of low molecular mass excreted by the causative bacterium, Erwinia amylovora, have long been suspected to contribute to fireblight necrosis because crude extracts from infected tissue or culture filtrates can cause necrosis in cell cultures, shoots, or intact host plants. Previous research by this investigator tentatively identified dihydro-phenylalanine (DHP) as a potential fireblight toxin [Phytochemistry 27, 3417-3422 (1988)]. However, these studies relied on only a few E. amylovora strains and subsequent investigations have revealed that DHP is not constitutively produced by all virulent isolates of E. amylovora. Other, yet unidentified toxins or inhibitors of the hypersensitive reaction (HR) may also contribute to the development of fireblight. Because of its high speed, high sensitivity, high specificity and resolution, low chemical background, ‘soft ionization’, and its feasibility to directly interface with LC [thereby avoiding a drying step that is deleterious for DHP (G. Feistner, 35th ASMS Conference, Denver, 1987)], electrospray (ES) mass spectrometry is extensively employed in our screening for novel bioactive compounds. Here, I report on the identification and partial characterization of siderophore-like compounds from wildtype E. amylovora 1430. Based on their abilities to bind ferric ion, four siderophores have been tentatively identified. Figs. 1a and 1b show the ES spectra of one of them, MW 587, before and after mixing with ferric citrate. The other ligands have molecular masses of 601, 619, and 800. Interestingly, the spectra of the ferric complexes not only show the binding of one ([MW + Fe3+ -2H+]++; e.g., m/z 641, 655, 673), but also of 2 ferric ions ([MW +2Fe3+ -4H+]2++; e.g., m/z 347.5, 354.5). Mass chromatography suggested that the same ligands also can bind aluminum as [MW + Al3+ -2H+]++. The latter was confirmed in experiments in which the siderophore was mixed with AlCl3. Fig. 1c shows the ES spectrum of the ligand with MW 601 after mixing. Moreover, when this mixture was further treated with ferric citrate, the aluminum was not replaced but a mixed ferric/aluminum complex ([601 +Fe3+ +Al3+ - 4H+]2++; m/z 340; Fig. 1d) was formed. MS/MS studies indicate that the ligands are composed of three monomers. To my knowledge, siderophores with such...
characteristics have not yet been described. We may thus have encountered the non-catechol, non-hydroxamate-type siderophores previously identified by Leong and Neilands based on a growth factor assay [Arch. Biochem. Biophys. 218, 351-359 (1982)]. Metabolic profiling by capillary LC-ES-MS was used to demonstrate that the production of the siderophore-like compounds increased under iron-deficiency stress but that their production was minimal and unresponsive to iron-deficiency stress in an avirulent, single site transposon mutant. Fig. 2 gives examples of the mass chromatograms obtained (still subject to improvement) and shows that by using this methodology many more compounds can be identified than would ever be possible with UV detection (bottom panel). The dynamic range is approximately 10^3 which appears to be adequate for the detection of the loss of a biosynthetic capacity or of a coarse regulatory mechanisms thereof. In general, siderophores enable pathogens to grow in the iron-deficient environment of a host tissue and, through binding of free ferric ions, inhibit the production of hydroxyl radicals that are produced by the host plant during the HR in an attempt to kill the pathogen. The observed siderophore-like compounds may thus have a direct bearing on the development of fireblight disease, which is a strong incentive for us to fully elucidate their structures.
Electrospray ionization-mass spectrometry (ES-MS) has gained most of its recent attention because of the ability to produce multiply charged ions from very large biomolecules making them amenable to analysis by most modern mass spectrometers. However, ES-MS is equally well suited for compounds of low or moderate molecular weight that are difficult to volatilize intact by other methods. Moreover, the early work of Fenn and co-workers (1,2) and recent reports by Kedarle and co-workers (3,4) attest to the applicability of ES-MS to the study of the gas-phase chemistry of multiply solvated or coordinated metal ions. The utility of ES-MS for the analysis of metals in solution derives in part from the facility with which the metal ions are solvated by or form complexes with the ES solvent or other reagents added to the solvent. Solvation and complexation can be a hindrance, however, in the analytical application of ES-MS to the analysis of metals in solution, especially solutions of metals in water.

The data presented here demonstrate that many of the problems in the ES-MS analysis of metals can be overcome by complexing the metals with crown ethers and/or extracting the metals from water into an organic phase using crown ethers. This procedure, in addition to transferring the metals to a solvent more amenable to the spraying process, concentrating the metals by reduction in solvent volume (thereby lowering detection limits), and providing the possibility of preferential metal complexation/extraction, usually results in the observation of a single metal-ligand complex of the same charge as the metal in solution when using the appropriate crown ether for the metal(s) of interest.

The data described in this paper were acquired on an ES/ion trap mass spectrometer combination that has been described previously (5). All reagents were obtained from commercial suppliers and used without further purification and all solvents used were HPLC grade. Methanol/water soluble metal salts were used to prepare standard solutions of the metals in water and methanol. Standard solutions of the crown ethers were prepared in toluene.

One of the major problems faced in the analytical application of ES-MS to metal analysis is the formation of metal-solvent adduct ions. These adducts complicate the spectra and spread the analyte signal out over several ionic species thereby raising detection limits. This problem is less severe for singly charged species such as the alkali metals, but for multiply charged species the problem can be quite pronounced. Another problem in the analysis of metals is the loss of charge state information. That is, the charge state of the metal in solution is not always preserved in the gas-phase. As Kedarle and co-workers (3,4) have pointed out, charge reduction of a particular metal ion depends on the relative ionization energies of the metal ions and ES solvents employed. The ES mass spectrum of UO$_2^{2+}$ demonstrates this phenomenon. In this spectrum (not shown), UO$_2^+$ and other singly charged species are observed rather than UO$_2^{2+}$, which is the ionic species in solution.

The first of these problems, and possibly the second, can be largely overcome by complexing the metals in solution with a crown ether such as 12-crown-4 or dibenzo-18-crown-6 (see Figure 1). For example, the ES spectrum of Na$^+$ sprayed from methanol (Figure 2) is complicated by the presence of adduct ions containing both water and methanol. The ES spectrum in Figure 3, obtained from the same solution after addition of the complexing agent dibenzo-18-crown-6, contains only one peak, which corresponds to the Na-crown complex. It should be pointed out that the affinity of dibenzo-18-crown-6 for other metals ions, for example Ba$^{2+}$ and Ca$^{2+}$, is much less than for Na$^+$. Also, for these two particular multiply charged metal ions, 2:1 and 3:1 crown:metal complexes are observed in the ES spectrum rather than the 1:1 complex. However, formation of a 1:1 complex for most metals is probably possible since a large number of crown ethers have been synthesized that are selective for specific metal ions or sets of metal ions.

The selective nature of crowns for particular metal ions can be used to selectively extract metal ions from aqueous solutions into an organic solvent for analysis by ES-MS. The spectrum in Figure 4 was obtained from the toluene extract of a water/HNO$_3$ solution containing each of the alkali metals using 12-crown-4 as the complexing agent. The peaks indicative of several of the metals present in the water solution, namely peaks from the Li-, Na-, and K-crown complexes, are observed. It should be pointed out that no signal from the metal ions could be observed when spraying the water/HNO$_3$ solution. The spectrum obtained from the extract is complicated by the presence of H$_2$O$^+$, H$_2$O$_2^-$, and MeOH$^+$-crown complexes. However, this problem might be alleviated by adjustment of solution pH. More importantly, the Ca- and Mg-complexes are not observed since the affinity of 12-crown-4 for these ions is very low. Other crowns could be used to selectively extract these metal ions versus the other alkali metals in the mixture.

We have also begun to investigate the MS/MS behavior of the metal-crown complexes. Initial results indicate that certain of the 1:1 metal-crown complexes dissociate by loss of the neutral crown with the charge remaining with the metal. Results for complexes where the crown:metal ratio was greater than 1:1 show successive losses of the neutral crowns from the metal. Based on these results, it appears that MS/MS spectra of a series of metal-crown complexes using a single crown and/or a single metal with several different crowns might be used to determine the relative gas-phase affinities of selected metals and selected crowns. Also, the data from the MS/MS spectra might be used to determine successive metal ion-crown bond energies.

ISP (Ionspray) is a version of ESP (Electrospray) in which droplets are created by both a high electric field and pneumatic nebulization. Both have recently been regarded as powerful soft ionization techniques for characterization of very high molecular weight biopolymers and many polar, thermally labile compounds. In this study, it is found that polyphosphonic acids especially with polyamine backbones are very suitable for such ionization techniques.

ISP/MS

Four compounds of X-(PO₃H₂)x, Structures I-IV, were used for this study. None yielded TSP spectra (positive nor negative). Static FAB* showed distinct MH⁺ and MₓMH⁺ in the (+) and M⁻H⁻, MₓM⁻H⁻ in the (-) modes for I and II but none for III and IV when X is a polyamine. Ionspray showed very distinct molecular ion information in both modes for I, II and IV. Only negative spectra are useful for III. In general, the negative spectra are overall more sensitive. 1 ng of I by flow injection mode gave a structurally recognizable spectrum in the (-) mode as shown in Fig. 1.

MS/MS

Daughter scans of either the MH⁺ or (M-H)⁻ of each compound yielded many different product ions by CID, as shown in Figs. 2 and 3.

From these experiments, Ionspray offers high ionization efficiency for this type of small and yet very polar compounds. Unambiguous molecular ion information are attainable through simple sample introduction. MS/MS experiments provide additional qualitative information through the product ions.

Thermospray Interface Line Ammonolysis of Diethylamine Derivative of p-Phenylene Diisocyanate and Diethylene Glycol/Adipic Acid Polyester During LC/MS Analysis

A. R. Taylor and M. J. DeKrey
Conoco Inc., POB 1267, Ponca City, OK 74603

G. A. Sherwood
Dupont Chemicals, Wilmington, DE 19880-0262

We have observed that ammonolysis of diethylamine derivatized phenyl isocyanate(A), dipropylamine derivatized phenyl isocyanate(B), and diethylamine derivatized p-phenylene diisocyanate(C) occurs in the thermospray interface line. Evidence for this ammonolysis reaction was obtained by the isolation and collection of compound C with the thermospray interface at ambient, 200, 250, 300, and 350 °C.

The data also suggests diethylamine(dipropylamine) liberated during the ammonolysis becomes available for adduct formation.

Hydrolysis of diethylene glycol/adipic acid polyester was observed in the mass spectra resulting from thermospray LC/MS. LC/MS/MS analysis was also performed on the polyester sample.

The thermospray mass spectra observed for compounds A, B, C, and a polyester were more complex than expected. Ions were observed that only could be explained as coming from multiple compounds based on protonated/ammoniated pairs (see Figures 1 & 2).

Compound C was separated by LC and collected from the thermospray interface line at ambient, 200, 250, 300, and 350 °C into a Reactiva® cooled with ice water. Only one LC peak representing compound C was found from the ambient temperature collection, whereas at 300 °C there were at least four new compounds formed. The mass spectra corresponding to these newly formed compounds suggests products of an ammonolysis reaction (see Figure 1). The mass spectra were very complex because each LC peak contained several ammonolysis product compounds as well as possible adduct ions of the various compounds (see Figure 2).

Figure 1. Ammonolysis Scheme and Thermospray Ions
The relative amounts of the major compounds (detected by UV) obtained by collecting compound C at various temperatures are shown in Table 1.

Analogous to the ammonolysis effect, hydrolysis was also observed in the thermospray interface line for a diethylene glycol/adipic acid polyester. Some of the LC peaks were found to contain a series of ammoniated ions associated with small oligomers of the polyester. The presence of these ions can best be explained as hydrolysis products formed during passage of the polyester through the Interface line. The thermospray mass spectrum of the polyester gave several ions including protonated, ammoniated ion pairs which can be assigned structures of various polyester oligomers (see Figure 3).

LC/MS/MS experiments on ions at 772, 666, 556, 450, and 234 daltons yielded fragmentation ions expected for the diethylene glycol/adipic acid polyester:
Overview: Thermospray mass spectrometry (TSMS) combined with high-performance liquid chromatography (HPLC) can analyze for steroids without the need for derivatization (1). Because TSMS can be used with polar solvents and electrolytes, an electrochemical (EC) cell can be conveniently attached (2). During the HPLC/TSMS analysis of the steroid oxymetholone, concern developed with respect to the ease of oxidation of this compound and its possible metabolic fate. The electrochemical oxidation of oxymetholone was investigated by a combined EC/TSMS technique referred to as solution electrochemistry mass spectrometry (SECYMS).

Experimental: A Vestec Thermospray controller and source was attached to a Finnigan 4500 quadrupole mass spectrometer. A Coulochem 5100A potentiostat and model 5020 coulometric guard cell were interfaced to the mass spectrometer. The liquid carrier for direct injections consisted of 50/50 methanol (MeOH)/water with 0.1 M ammonium formate. The mobile phase for HPLC was comprised of 85/15 MeOH/water with 0.1% acetic acid. Nominal concentrations of steroids diluted in MeOH or acetonitrile (ACN) were 0.02 mg/ml with 100 μL injections. HPLC with an ultraviolet (UV) detector was set at 280 nm. Figure 1 shows the block diagram for direct injections and HPLC analyses.

Results and Discussion: The TSMS of oxymetholone produces an [M + H]+ ion at m/z 333 with no fragmentation. Similarly, d2-testosterone gave an ion at m/z 291. Because of chemical modification of oxymetholone diluted in methanol (3), steroids were diluted in ACN. Oxymetholone was analyzed by the SECYMS method via direct injection over a range of 0.0 to 0.8 V vs. SHE (Figure 2). At a potential of approximately +0.6 V, the oxymetholone oxidized to a compound with an ion at m/z 319. Figure 3 demonstrates the changes before and after oxidation for oxymetholone. A similar investigation of d2-testosterone gave no indication of oxidation.

An EC/HPLC/UV/TSMS experiment was performed to observe the retention time of the compound produced in the SECYMS experiment. On injection followed by oxidation, the chromatographic peak of oxymetholone (6.7 min) diminished and a new chromatographic peak at approximately 3.6 min was observed (Figure 4) with an ion at m/z 319.

Conclusions: The SECYMS experiment clearly demonstrates the ease of oxidation of oxymetholone compared to the similar steroid d2-testosterone. In comparing these two molecules (Figure 5), a major difference is the vinyl alcohol group attached to the 2-position of oxymetholone. It is speculated that this vinyl alcohol substituent is being affected during electrochemical oxidation. This is substantiated by comparison of the chromatographic peaks in Figure 4. Note that the oxymetholone has a broadened peak compared to the compound eluting at 3.6 min. It has been reported that the intramolecular hydrogen bonding of the vinyl alcohol group results in oxymetholone adsorbing to various surfaces such as alumina (4). With oxidation of the vinyl alcohol group, this "stickiness" disappears for the compound eluting at 3.6 min. The compound represented by the ion at m/z 319 may be the result of a carbonyl replacing the =CHOH substituent in oxymetholone. It was also observed that the compound eluting at 3.6 min did not produce a detectable UV signal at 280 nm.

This study suggests that oxymetholone, unlike the majority of other steroids, may be readily altered by in vivo processes that can result in the oxidation of oxymetholone to form metabolites with little of the parent oxymetholone remaining. Future work will involve a comparison of compounds isolated from biological systems to those observed in this study.

Figure 5
INTRODUCTION: Oligomycins A, B and C are of biochemical interest mainly because of their use as ATP-ase inhibitors. These oligomycins were first isolated in 1954 from a strain of *Streptomyces diastatochromogenes*. The structures of oligomycins have been determined by a variety of techniques including X-ray crystallography as well as spectroscopic and chemical correlations. Oligomycins are neutral macrolide antibiotics containing a 26-membered α,β-unsaturated lactone with a conjugated diene, fused to a bicyclic spiroketal. The EIMS of these compounds and their derivatives have been reported.

We have investigated the use of negative ion thermospray (NTSP) LC/MS for the qualitative analysis of oligomycins. To study the fragmentation behavior of the compounds under thermospray MS conditions, we have used the commercially available oligomycins (A,B,C), as well as a recently described new compound F28249o, as models. The structures of oligomycins are shown in Scheme 1.

EXPERIMENTAL: LC/MS was performed on the Finnigan MAT TSP-46 single quadrupole mass spectrometer with a Finnigan thermospray interface. The thermospray spectra were obtained in the negative ion mode using the thermospray interface operated at a jet temperature of 230 °C, Finnigan sapphire vaporizer (temperature range 70 to 100 °C), a repeller setting of 1KV and the discharge ionization electrode at 1 KV, mass range 150-900 amu, 1.5 sec/scan rate.

The HPLC system consisted of a Waters 600-MS solvent delivery system and WISP 710B autosampler with 990-MS photodiode array detector. The oligomycins were separated on a Waters C-18 Nova-Pak column(5μ, 150mm x 3.9mm ID). The mobile phase was 75% methanol in water and/or 0.1M ammonium acetate (pH=6.5) buffer at a flow rate of 1.2 ml/min. The detection was by UV absorbance at 225 nm.

RESULTS & DISCUSSION: Thermospray MS has been classified, as a soft ionization technique primarily yielding molecular weight information. This information is not sufficient for structure determination of unknown or even suspected known compounds. However, by controlling the TSP-MS parameters such as vaporizer temperature, buffer ionization, repeller voltage and the mode of ionization (positive ion or negative ion), it is possible to obtain molecular weight plus structural information for the determination of structures of unknown compounds. The objective of the present study was to extend the analytical capabilities of the LC/TSP-MS technique with a single quadrupole instrument.

Negative ion TSP-MS: Oligomycins showed better sensitivity in the negative ion mode than in the positive ion mode under LC/TSP-MS conditions. Negative ion TSP spectra showed electron capture molecular ions [M-], [M-H]-, [M-H2O]-, and abundant thermally induced fragment ions. The genesis of fragment ions is due to three types of fragmentations: retro-aldol, ester cleavage and retro Diels Alder. These ions are diagnostic for the characterization of oligomycins (Scheme 1).

The [M-H2O]- ion (F1) is more abundant than the M-. in A,B, & F28249o, while the M-. ion is dominant in oligomycin-C. Retro-aldol (RA) fragment ions (F2) at m/z 574, 588, 574, and 590 are dominant in the NTSP-MS of oligomycins A, B,C & F28249o respectively. The mass shift of RA ions is the indication of structural modifications in the top portion of the molecule. Similarly, the ions observed at m/z 214(F4) and 196 (F5) in A, B and F28249o, indicate the presence of an OH group at C-12. The ion at m/z 296(F12) observed in NTSP-MS of oligomycin-F28249o, indicates the presence of an OH group at C-21. NTSP-MS of oligomycin-B showed a diagnostic ion at m/z 281(F10). NTSP-MS of oligomycins
showed the formation of adduct ions [M+CH3COOH]-, and [Fragment ion F4 +CH3COOH]-, under ammonium acetate buffer ionization conditions.

**Mixture analysis of Oligomycins.** A standard mixture of oligomycins-A, B, C & F28249ω (2 g/L) was prepared and 50 μL injected for HPLC/UV (225nm) and LCMS analysis. The compounds were well resolved with 75%MeOH in ammonium acetate buffer. The elution order of the compounds is F28249ω (7.5min), oligomycin- B(8.94min), A(15.14min) and C(24.55min). The crude extract of F28249 was also analyzed using LC/NTSP-MS under similar conditions. This sample showed four peaks, the major compound (88%) is F28249ω, whereas the other three minor compounds ω2(M-. 792 ), ω3(M-. 820), & ω4(M-. 790) are unknown. Based on the LCMS and UV data the structure of F28249ω has been proposed as shown in Scheme 1 (F28249ω: R1= H2, R2= H, R3= OH).

**CONCLUSIONS:** We have successfully demonstrated here, that the combined LC/UV and LC/TSP-MS are powerful tools for the direct analysis of fermentation products for detection and identification, as well as structure determination of unknown oligomycins. The present work is another example where negative ion is superior to the positive ion TSP-MS.

**REFERENCES:**
A mixture of eight selected azo and quinone dyes was analyzed using a Hewlett-Packard thermospray (TS) ion source. The selected dyes are shown in Table I. Azo and quinone dyes are used for textile dyeing and are commonly found in waste water, soils and waste materials in and near textile processing and manufacturing. Most azo dyes cannot be analyzed by gas chromatography-mass spectrometry because of their thermal lability. Recent methods for analysis of the selected set of dyes, provided a method which used a 2.1 mm LC column using a 0.4 mL/min flow rate coupled to a down stream "Tee" with 0.8 mL/min ammonium acetate buffer for post column addition. The post column addition requires additional plumbing and an additional HPLC pump to execute the method. Similar chromatographic separations of the selected dyes may be obtained by the use of either a 4.6 or a 2.1 mm column incorporating the buffer in the precolumn configuration.

The Thermospray signal response has a strong dependency on both the buffer concentration and more importantly, the TS ion source pressure. Given the buffer to be held at a constant concentration, the ion source pressure becomes the important factor. Maintaining the pressure in the TS ion source can be accomplished by increasing the LC flow rate or by throttling the TS ion source pump out valve when flow rates under 1.0 mL/min are required for chromatographic separation. The throttling technique may be used for flow rates down to 0.2 mL/min.

The ion source used with the dyes was a standard HP ion source incorporating a fragmentor electrode which enhanced the sensitivity up to a factor of 20 when optimized near 55 volts. The ion source is shown in Figure 1.

TABLE I

| DISPERSE BLUE 3 | DISPERSE ORANGE 3 |
| DISPERSE YELLOW 5 | DISPERSE BLUE 14 |
| DISPERSE RED 1 | SOLVENT RED 23 |
| DISPERSE BROWN 1 | DISPERSE RED 13 |

The fragmentor electrode provides increased sensitivity for all dyes in this analysis. By increasing the voltage from 55 to 200 volts, the dyes were fragmented in to smaller ion fragments. The fragmentation appears to be due to the acceleration of electrons and ions in the TS source near the ion exit cone.

Figure 2 shows the chromatogram of the eight dyes with many impurities, homologues and isomers of the dye set. The LC conditions were: A = 0.05 M NH4OAc and B = MeOH. Linear gradient from 50% B to 90% in 13 min. on a 4.6 x 120 mm C-18 3um column without post column addition. Flow rate was 1.0 mL/min.

In the past decade, the first reports of the acquired Immunodeficiency syndrome (AIDS) surfaced, the human Immunodeficiency virus (HIV) was discovered to be the causative agent, and 3'-azido-2',3'-di-deoxythymidine (AZT) was approved as an AIDS-static agent. A large percentage of the compounds which have been shown to display activity against HIV in vitro are 2',3'-dideoxynucleosides [2] or 2',3'-dehydro-2',3'-dideoxynucleosides [3]. In addition, C-Nucleosides have been shown to possess a variety of biological activity, most importantly as potential anti-tumor and anti-AIDS agents (e.g., showdomycin [4]).

In pursuit of new routes to such compounds, (i.e., 2' or 3' modifications) one should include the possibility of utilizing the corresponding 2' or 3'-keto derivatives. Though these keto nucleosides have been available since the 1960's, little has been reported on their use in the synthesis of nucleoside analogues. This is largely because keto nucleosides are perceived to be unstable, especially under basic conditions. Similarly, little effort has been reported on synthesis of nucleosides via the corresponding oxyglycals. We have recently discovered conditions which allow palladium(0) catalysts to undergo oxidative-addition with 2,3,4,6-tetrabenzylglycosyl methanesulfonate (mesylate), followed by rapid beta-hydride elimination. This method offers a two-step, one-pot route to the synthesis of (perbenzyl)oxyglycals.

In pursuit of new routes to such substituted sugar analogues, a substantial amount of oxyglycal, 3, was required. Benzylatlon of methyl glucoside affords 2 [5]. After hydrolysis [5] and generation of the mesylate [6], oxidative-addition of palladium, followed by beta-hydride elimination affords 3. In general, NMR spectra of these compounds are complex and not always definitive, therefore we have sought additional means of analysis. In addition, the mesylate is relatively unstable, therefore, a practical method of following the progress of these reactions is required. Thermospray LC/MS has proven ideal in this regard. In this study we report on the LC/MS/MS analysis of oxyglycals produced via the palladium catalyzed reaction shown in Figure 1.

![Diagram of reactions used to produce tetrabenzyl oxyglucal from alpha-methyl glucoside](image)

A VG Trio 3 triple quadrupole (with a hexapole collision cell) mass spectrometer was used in this study. All compounds were stable and separable under HPLC conditions using a Waters 600 MS HPLC system with a 25 cm x 4.6 mm reverse phase C18 column. In order to minimize the time of exposure of these compounds to water, 100 percent acetonitrile was used as the mobile phase (0.7 mL/min) and the electrolyte solution for thermospray, 0.1 M ammonium acetate (adjusted to pH 5 with acetic acid), was added post-column (using an ISCO 2350 HPLC pump; 0.5 mL/min) prior to introduction to the mass spectrometer. In all cases, a molecular ion of the type [M + NH₄]⁺ was observed as the base peak in the thermospray mass spectrum. Once observed, the molecular ion was mass selected in quadrupole one, collisionally activated in the hexapole collision cell using xenon gas at 1 x 10⁻⁵ mBar analyzer pressure (normal operation pressure ca. 3 x 10⁻⁸ mBar) and 5 eV collision energy.

The MS/MS spectra of the glucose analogues contain virtually the same fragment ions. In the MS/MS spectrum of methyl (perbenzyl) glucoside, a fragment ion at m/z 523 is observed and is assigned as loss of ammonia and methanol leading to the formation of an oxyglucal cation species which goes on to lose benzyl alcohol forming a fragment ion at m/z 415. This fragment ion, as well as all others that follow are common to all MS/MS spectra shown in Figure 2. In the MS/MS spectrum of (perbenzyl) glucose, fragment ions at m/z 540 and 523 are observed and assigned to loss of
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

water and loss of ammonia, respectively, again leading to the formation of an oxyglucal cation species. It is not surprising, therefore, that the \([M + \text{NH}_4]^+\) molecular ion of (perbenzyl) oxyglucal would lose ammonia and benzyl alcohol to form the fragment ion at m/z 415. This result suggests that each ion goes through its most stable gas phase configuration, that of the oxyglucal, prior to eliminating benzyl alcohol.

In order to be of use in nucleoside synthesis, the reactions were performed on ribose. In general, the tribenzyl ribose and tribenzyl ribul produced abundant molecular ions of the type \([M + \text{NH}_4]^+\) (see Figure 3). Thermospray MS/MS of these compounds produced spectra which contained (as above) structurally significant fragment ions corresponding to the known structure of each molecule. For example, in the MS/MS spectrum of (perbenzyl) ribose fragments ions at m/z 420, 403, and 295 are observed corresponding to loss of water, then loss of ammonia followed by loss of benzyl alcohol, respectively. Fragment ions at m/z 181 and 193 are formed via ring cleavage reactions. It is interesting to note that an ion at m/z 193 is not observed in the MS/MS spectrum for (perbenzyl) ribul. It is possible that the double bond in the ring prevents this product ion from forming.

Figure 2. Thermospray MS/MS spectra of perbenzyl... a) oxyglucal; b) methyl glucoside; c) oxyribul; d) ribose.

Recently, Danishefsky reported on a method for the stereoselective epoxidation of glycals using dimethyldioxirane [8]. Danishefsky further reported that the epoxides formed underwent clean ring opening at the anomeric carbon when using \(\text{O}-\text{nucleophiles}\) [7]. In future experiments, it is hoped that through epoxidation of perbenzyl ribose using the technique reported by Danishefsky, an easier route will be discovered towards the formation of 2'-ketonucleosides.

Many species of higher fungi produce specially adapted propagules called sclerotia as a means of surviving harsh climates or nutrient-poor conditions (2). These relatively large resting bodies can survive for several months to several years in the soil, despite exposure to insects that consume fungi. Our studies have shown that sclerotia produced by Aspergillus species frequently contain antinsectan metabolites, some of which deter feeding by fungivorous insects (2,3).

In this paper, the results of thermospray mass spectrometric analysis of a chloroform extract from a non-aflatoxigenic strain of Aspergillus flavus are presented. The characterization of metabolites from these extracts originally involved collection of chromatographic fractions followed by further purification and analysis using NMR and mass spectrometry. Of ten compounds isolated from a chloroform extract of A. flavus sclerotia using HPLC, four were shown to have potent antifeedant activity against fungivorous insects which encounter sclerotia in nature. Three of these had not been previously reported (2,3).

A VG Trio 3 triple quadrupole mass spectrometer was used in this study. All compounds were stable under HPLC conditions using a Waters 600-MS HPLC system with a 25 cm x 4.6 mm reverse phase C18 column. Since the mobile phase consisted of 70:30 methanol:water, the 0.1 M ammonium acetate electrolyte solution (adjusted to pH 5 with acetic acid) necessary for thermospray ionization was added post-column. This provided a relatively simple means of assuring significant and stable levels of ionizing reagent for ion production. The column flow rate was 0.7 mL/min. The electrolyte solution for thermospray was added post-column (after the UV detector) using an ISCO 2350 HPLC pump at a flow rate of 0.5 mL/min prior to introduction to the mass spectrometer. In all cases, a molecular ion of the type [M + H]+ was observed, however, the [M + NH4]+ molecular ion was the base peak of the mass spectrum, In most cases. A VG 11-250 J data system coupled to a DEC PDP 11/53 was used to acquire data. The UV output was collected simultaneously with the total ion chromatogram (Figure 1). A 10- to 15-second delay occurred between the UV and TIC peak onsets.

Figure 1 Total ion current chromatogram and UV trace (215 nm) from the thermospray analysis of the chloroform extract from the sclerotia of Aspergillus flavus

Several compounds have been previously isolated and characterized from the chloroform extract of the sclerotia of Aspergillus flavus (see structures 1-6 in Figure 2). In the experiments reported here, four UV active chromatographic peaks of significant abundance were observed (see Figure 1). The first peak was characterized as having molecular ions at m/z 455 and 472 corresponding to [M + H]+ and [M + NH4]+ respectively (see Figure 2a). Characteristic of most thermospray spectra, fragment ions in general were of low abundance or not observed. One fragment ion observed was at m/z 440 corresponding to loss of methyl from the protonated molecular ion or loss of methane and ammonia from the ammoniated molecular ion.

Peak two was characterized by the molecular ions at m/z 438 and 455 ([M + H]+ and [M + NH4]+), respectively; Figure 2b). Fragment ions at m/z 420 and 403 were observed and assigned as consecutive loss of water and OH from the protonated molecular ion.

Peak three had previously been separated into two components (3 & 4) using a 25 cm x 10 mm; semi-preparative column at 2 mL/min. The structures of compounds 3 and 4 are shown in Figure 2c. The complex nature of the molecular ion region is characteristic of the mixture present in the peak (see Figure 3 for mass chromatogram overlay of these two compounds). For example, the ions at m/z 418 and 435 are assigned as the [M + H]+ and [M + NH4]+ molecular ions, respectively, of compound 3. Fragment ions are observed at m/z 400 and 383 corresponding to loss of water and of water and OH, respectively. The ions at 422 and 439 are assigned as the [M + 2H]+ and [M + NH4]+ molecular ions, respectively, of compound 4; a fragment ion at m/z 404 is observed as loss of water from the protonated molecular ion.

Peak three had previously been separated into two components (3 & 4) using a 25 cm x 10 mm; semi-preparative column at 2 mL/min. The structures of compounds 3 and 4 are shown in Figure 2c. The complex nature of the molecular ion region is characteristic of the mixture present in the peak (see Figure 3 for mass chromatogram overlay of these two compounds). For example, the ions at m/z 418 and 435 are assigned as the [M + H]+ and [M + NH4]+ molecular ions, respectively, of compound 3. Fragment ions are observed at m/z 400 and 383 corresponding to loss of water and of water and OH, respectively. The ions at 422 and 439 are assigned as the [M + 2H]+ and [M + NH4]+ molecular ions, respectively, of compound 4; a fragment ion at m/z 404 is observed as loss of water from the protonated molecular ion.
Figure 2. Thermospray mass spectra from the four major UV active chromatographic peaks observed.

The fourth peak, much like peak three, is a mixture of two compounds. In this case, the compounds are isomers of molecular weight 421 (see Figure 2d). The molecular ions at m/z 422 and 439 are observed, with fragment ions at m/z 404 and 386 assigned to two consecutive losses of water from the protonated molecular ion. A molecular ion of the type \([M + NH_3 + NH_4]^+\) is also observed at m/z 456. The reason for reconvolution of the last two chromatographic peaks is at this time unknown.

This technique will provide for a more streamlined approach toward the surveying of sclerotial extracts for unique bioactive metabolites. It is clear that improvements in both chromatographic resolution and ion sensitivity will be necessary to make this technique analytically useful. In the case where co-eluting compounds of different mass are observed, MS/MS experiments will be performed to enhance the structurally significant fragment ions observed.

INVESTIGATION OF EIGHT HETEROCYCLIC AMINES AND TWO OF THEIR N-OXIDATION PRODUCTS BY THERMOSPRAY MASS SPECTROMETRY (TSMS)

INTRODUCTION

The formation of mutagenic polycyclic aromatic hydrocarbons (PAHs) during the cooking process of foods, primarily meat products, was reported by Lijinsky and Shubik in 1964 (1). The development of the Ames assay in 1975 made it possible to test food products for mutagenic activity, then isolate new mutagenic compounds formed in these products. Several years later, Sugimura and co-workers (2) reported that the mutagenic activity of cooked fish and beef products could not be accounted for by PAHs alone. This resulted in the discovery of the aromatic heterocyclic amines as the group of compounds responsible for this additional mutagenic activity (3). Some of these heterocyclic amines have been found to be suspected carcinogens (4). These findings substantiate the need to develop sensitive analytical techniques to detect these compounds in various cooked meat products at the ppb level. Yamaizumi et al. (5) have reported the use of high-performance liquid chromatography/thermospray mass spectrometry (HPLC/TSMS) for the analysis of two of these compounds. We now report the analysis of eight of these heterocyclic amines by HPLC/TSMS plus the synthesis and analysis of two of their N-oxide derivatives.

EXPERIMENTAL

HPLC/TSMS system: The eight heterocyclic amines and two of their N-oxidation products were resolved using a SynChropak SCD-100 column (Synchrom, Inc., Lafayette, IN). The silica base packing was 5 microns (particle size) with 100 angstrom average pore size. The mobile phase was 0.05 M ammonium acetate in water adjusted to a pH of 5.2 with acetic acid/acetonitrile (75/25, v/v). An Isco (Lincoln, NE) model LC-5000 syringe pump was used at a flow rate of 1 ml/min connected to a Rheodyne 7125 injector fitted with a 20 μl loop. TSMS analysis was performed using a Delsi Nermag (Houston, TX) R1010C quadrupole mass spectrometer equipped with a Delsi/Nermag TS source and a Vestec (Houston, TX) TS interface and controller. The TS source was operated in the positive ion, "discharge off" and "filament off" mode. Typically, the TS source block was set to 160°C and the control temperature was set at 132°C.

NMR: 1H NMR spectra of IQ, MeIQx and their N-oxidation products were carried out at 500 MHz on a Bruker AM500 spectrometer. The chemical shifts are reported in ppm by assigning the DMSO resonance to 2.49 ppm. Spectral parameters are first order measurements.

Synthesis of N-oxides: The synthesis of the N-oxidation products were accomplished using the method of Chaudhuri et al. (6) for the preparation of antihistamine N-oxides, using the m-chloroperoxybenzoic acid method.
RESULTS AND DISCUSSION

We analyzed a series of eight heterocyclic amines by thermoSDrav mass spectrometry (TSMS). For each compound the [M+H]+ ion was the base peak. We also used TSMS to analyze the two synthesized N-oxidation products of IQ and MeIQx. As shown in Figure 1, the [M+H]+ ion for MeIQx was observed at m/z 214 as the base peak. The N-oxidation product of MeIQx had an [M+H]+ ion at m/z 230 (see Figure 2). The TS mass spectrum for IQ included the [M+H]+ ion at m/z 199 as the base peak, while for the IQ N-oxidation product the TS mass spectrum exhibited an [M+H]+ ion at m/z 215.

The NMR results confirmed the site of this oxidation as that of the N-6 location on the quinoline moiety. The oxidation product of MeIQx also resulted in a confirmed site of oxidation at the N-6 location on the quinoline moiety.

An investigation of the utility of the HPLC/TSMS method for the analysis of these chemicals as well as for compound identification of in vitro and in vivo metabolites is in progress. These mutagenic aminoimidazo azaarenes will be assayed in samples derived from both cooked meat products and cigarette smoke condensate using the HPLC/TSMS method.

REFERENCES

We have carried out a careful study of the ionization efficiency in ionspary (pneumatically assisted electrospray) mass spectrometry [1]. Not only ion currents arriving at the detector of the mass spectrometer were measured, but also the current leaving the electrospray/ionspray device in the atmospheric pressure ion source. Spray currents and ion currents are conveniently measured as a function of sample concentration by flow injection with a large sample loop (50 µL) which delivers a broad sample plug at a low flow rate (5 µL/min) into the electrospray/ionspray device. The measured currents can be backgound subtracted to obtain "true" sample spray currents and ion signals.

We have found that the base spray current of a "pure" HPLC quality solvent is apparently due to salts present as impurities. In a particular solvent, the steady state concentration of salts arriving at the sprayer is the result of the equilibrium between adsorption and desorption from components in the liquid handling system. When a strongly solvating solvent (100% methanol) is injected into a stream of solvent having a lower polarity (95% acetonitrile + 5% methanol), sodium salts are released from the walls of the liquid handling system and produce anomalous spray currents (Figure 1) and anomalous sodium adduct ion signals of neutral components in the liquid phase or the gas phase in the atmospheric pressure ion source. When a less polar solvent mixture (95% acetonitrile + 5% methanol) is injected into a stream of a strongly solvating solvent (100% methanol) a temporary decrease of the spray current (and XNa+ ion signals) followed by a short peak is observed (Figure 2). A true "blank" solvent injection and reliable sample injections can be performed only if the solvent stream and the solvent used for the sample solution are identical and preferably taken from the same container.

Sample adsorption problems are usually associated with chromatographic columns. Adsorption phenomena can also interfere with flow injection experiments. We found for example that 8-hydroxyquinoline glucuronide is strongly adsorbed and slowly desorbed when injected as a solution in 95% acetonitrile + 5% methanol. The addition of acetic acid to a final concentration of 10^-4 M alleviates the adsorption problem. The wall of the fused silica transfer line between the injector and the ionspary nebulizer appears to be the major adsorption site.

The mass spectrometer used is a NERMAG R3010 triple quadrupole equipped with a home made atmospheric pressure ion source and ionspray LC/MS interface

INTRODUCTION:
The combination of capillary electrophoresis (CE) and ion-spray mass-spectrometry provides a highly efficient technique with very selective detection. We previously reported this coupling via a liquid-junction interface. We now describe several design modifications which improve its analytical ruggedness and overall performance. Gel capillary electrophoresis represents another field of growing interest. We have challenged the liquid-junction ion-spray interface to also achieve gel CE/MS coupling.

EXPERIMENTAL:
Capillary electrophoresis was performed on an in-house constructed CE unit, and a Beckman P/ACE 2000. We coupled it to a TGA 6000E (upgraded to an API III) triple-quadrupole mass-spectrometer equipped with an API source. The interfacing was performed by means of a liquid-Junction (1). The improved version is presented on fig. 1. Free-zone CE separations were performed in 75 µm i.d. untreated fused-silica capillaries. Gel CE separations were accomplished in gel-filled capillaries from ABI (Micro-Gel 100 50 µm i.d. x 40 cm) and Beckman (Experimental formulation 75 µm i.d. x 55 cm). The inlet buffer was used as provided by the gel manufacturer (ABI: 75 mM Phosphate, 10% MeOH; Beckman: 100 mM Tris-Borate, 7M Urea) while the make-up buffer was 25%ACN, 5% Formic Acid for positive ion detection and 20%MeOH, 0.1% Triethylamine for negative ion detection.

RESULTS & DISCUSSION:
By using short columns and high electrical fields (1000 V/cm), one is able to achieve “fast” separations. We analysed a mixture of eight sulfonylureas (environmentally important herbicides) in less than 6 minutes in the 20 pmol range in the full scan mode (fig. 2). We have also been able to accomplish on-line CE/MS/MS analysis providing helpful assessment of the structure of two isobaric analytes since one of them doesn’t yield the benzylic cleavage.

Our first attempt to couple gel CE with mass spectrometry showed some promising aspects. However, the low sample capacity of these columns required operation of the mass spectrometer in the Selected Ion Monitoring (SIM) mode. Fig. 3 shows a gel-CE/SIM-MS analysis of a sample of polyacrylic acid. The most abundant ions in the sample (doubly-charged anions) were determined by infusion experiments of the sample diluted in the make-up buffer and then monitored by SIM during gel-CE/MS analysis. In spite of the low electrophoretic resolution, one can establish part of the given polymeric distribution of this sample.

CONCLUSION:
We were able to realize full-scan CE/MS analysis of a mixture containing eight sulfonylureas (herbicides) in less than 6 minutes. On-line CE/MS/MS provided sufficient information to characterize two isobaric sulfonylureas. We have accomplished the coupling of gel capillary electrophoresis with mass spectrometry and thus demonstrated the feasibility of this approach.

Research Triangle Park, NC 27709

Introduction
Electrospray MS has the capability to efficiently generate ions from a wide variety of compounds down to the low pg level. While the sensitivity obtained with electrospray MS is excellent, structural information is often non-existent. Usually only [M+H]+ and/or adduct ions and multiply charged ions are detected due to the gentle nature of ionization. Often the more costly combination of ES with MS/MS is employed to gather structural information on compounds of interest.

This paper reports on the use of collisional activation (CA) in the transport region of an electrospray single quadrupole MS as a way to obtain structural information for some environmentally and biologically significant compounds. Collisonal activation in the transport region can occur between the end of the capillary and the first skimmer (skimmer 1) by controlling the potential differences between these two points to accelerate ions in the high pressure supersonic expansion region. The ability to generate interpretable CAD spectra in the transport region of the electrospray interface could have significant ramifications in environmental and biological monitoring.

Experimental
The electrospray source (Analytica of Branford, Branford, CT) was interfaced to a Finnigan MAT 4500 Quadrupole MS (San Jose, CA). The ES design was similar to that reported previously [1]. The samples (10 pg-100 mg dissolved in 50% methanol in water) were introduced into the ES source through a 75 um i.d. tube at a flow rate of 2 uL/min using a syringe pump (ISCO Inc., Lincoln, NE) by means of a low pressure injection valve with a 5 uL loop (Analytica of Branford). The electrospray needle was held between +2.9 and 3.4 KV. A nitrogen drying gas heated to 185-190°C was introduced against the needle flow at a rate of 0.2-0.3 L/min. Positive ions formed from in the spray migrated down the 13.4 cm (0.5 mm i.d.) glass capillary which was positioned about 1.7-1.5 cm from the needle exit. Each end of the glass capillary was coated with a conductive metal to enable control of the electrical potential. The entrance of the capillary was grounded, but the exit voltage could be varied from 0-400 V to control collision energy. Ions migrated from the capillary through the 1.2 mm i.d. skimmer 1 typically set at 24 V (positioned 4.0 mm beyond the capillary exit) through skimmer 2 set at 17 V, then through a set of 3 lenses set at -21, 4.4 and -58 V respectively and finally into the quadrupole mass analyzer. The quadrupole was scanned from 10-500 daltons in four seconds. Pressure in the system ranged from atmospheric at the needle exit to 0.9 torr at skimmer 1 and 6 x 10^-6 torr in the quadrupole analyzer.

Results and Discussion
To determine the extent collision energy varied with the potential difference on the capillary and skimmer, internal energy distribution (P(E)) and average internal energy (Eaverage) of ions can be measured in the electrospray transport region in a similar fashion that has been reported for high and low energy collision in sector, quadrupole and ion trap MS/MS instruments [2,3]. Tetraethyl silane was used to estimate P(E) for various capillary-skimmer 1 potential differences shown in Figure 1A. The maximum internal energy (Emax) after a single collision was calculated and used as a reference in comparing the observed Emax values from the P(E) curve in Figure 2A. Emax of an ion after a single collision is given by energy for the center of mass (Ecom) plus the energy for the lowest energy fragmentation process (Eo). These observations (Figure 1A) support that (1) Emax can be used to estimate maximum internal energy, (2) that the width of the P(E) curve increases when increasing the potential difference between the capillary and skimmer, and most importantly, (3) the internal energy is proportional to the potential difference between the capillary and skimmer (Figure 1B).

The electrospray MS analysis of several pesticides and antibiotics demonstrates the capability of the system to generate interpretable CAD spectra as well as the capability to vary collision energy. For example, propoxur, a carbamate pesticide, exhibited an [M+H]+ ion at a capillary-skimmer potential difference of 25 V (Figure 2A). At a capillary-skimmer potential difference of 85 V fragments resulting from the loss of C3Hg, C3Hg and CONCH3, followed by loss of water are detected (Figure 2B). Potential differences above 140 V volts result in the formation of low mass fragment ions (e.g., m/z 314).
Furthermore, the CAD spectra for propoxur resulted in better than 70% daughter ion current yield compared to the non-CAD spectra. The major daughter ions for 10 pg of propoxur could be detected under full scan CAD conditions.

**Conclusions**

By varying the capillary-skimmer potential differences, $E_{\text{average}}$ from near 0 eV to greater than 7 eV can be selected (in a matter of seconds) for solving problems in structural elucidation and/or improved specificity. Furthermore, the operation at potential differences in the 0-200 V range did not change peak shape, instrument resolution, and resulted minimal loss in ion transmission.

The electrospraying of aqueous solutions containing strong electrolytes such as trifluoroacetic acid (TFA), has, in the past proven difficult because of the high solution conductivities and similarly high surface tensions prevent the formation of a stable spray, as the applied voltages necessary to electrospray these type of solutions often produce a corona discharge in the surrounding air, and has consequently resulted in poor spray characteristics, ion current instability, and loss of sensitivity, which in electrospray LC-MS studies which often use these type of solutions, analysis has been made difficult.

Improvements have been developed for a conventional electrospray source allowing the spraying of high aqueous content solutions with improved stability and enhanced sensitivity allowing the on line analysis of peptides and proteins providing both sequence and molecular weight information.

The improved stability has been affected with the use of a multilayered needle device which delivers a concentric liquid sheath and a focusing gas around a central analyte flow. The desired properties for a good sheath liquid are that it be miscible with water and other mobile phase solvents, that it has a boiling point above that of water, to prevent premature evaporation of the solvent, and that its surface tension is low relative to water, to aid in droplet formation. In positive ion electrospray it has been found that 2-methoxyethanol provides the best performance, not only in improved stability but also enhances the observed ion signal. Isopropanol has found the most utility as a sheath liquid in the negative ion mode. These two solvents also possess electrical conductivities that are slightly higher than other potential sheath liquids such as butanol and methanol, although the implication of this property to improved spray stability is not fully understood.

Sensitivity enhancements have been obtained by the addition of a tube lens in the viscous gas flow region situated between the capillary exit and the skimmer orifice in the electrospray source. The tube lens focuses ions in an expanding jet and shapes and intensifies the ion beam through the gas disturbance and into the skimmer orifice. The lens also causes the ion beam divergence angle after the skimmer to be narrower than on a system operating without the tube lens. The lens shapes the electric fields so that more ions are forced down the jet centerline, thus increasing the fraction of ions captured by the subsequent lens system and the mass analyser and has increased the observed ion signal by up to a factor of five.

The effects of the combination of the sheath liquids and the tube lens are shown in figure 1. This showing the respective improvements in signal with choice of sheath liquid and the benefits afforded by the tube lens.

Figure 2. shows the stability observed in an electrospray LC-MS analysis of a Lactoglobulin A tryptic digest before and after implementation of the 2-methoxyethanol sheath and the tube lens.

TUNABLE COHERENT VACUUM ULTRAVIOLET PHOTOIONIZATION OF ALIPHATIC COMPOUNDS

S.E. Van Bramer and M.V. Johnston, University of Delaware, Department of Chemistry and Biochemistry, Newark, DE, 19716

INTRODUCTION: Coherent VUV photoionization has become a very useful technique for soft, universal ionization. Until now, work with coherent VUV photoionization has been limited to 118.2 nm radiation which is easily produced by frequency tripling the third harmonic of a Nd:YAG laser. By using rare gas mixtures for third harmonic generation it is possible to efficiently produce coherent VUV radiation from 118 to 130 nm. The generation and use of this radiation is discussed.

EXPERIMENTAL: Coherent VUV radiation is produced by frequency tripling UV radiation in rare gas mixtures. For third harmonic generation of 118 nm radiation the third harmonic of a Nd:YAG laser (355 nm) is focused in a phase matched mixture of xenon and argon. At other wavelengths the output of a Nd:YAG pumped dye laser is mixed with residual 1064 nm radiation in a KD*P crystal to produce tunable UV radiation from 360 to 390 nm. This radiation is then focused in a mixture of either xenon or krypton phase matched with argon.

RESULTS: The argon is used to compensate for the negative dispersion of the krypton or xenon. For third harmonic generation to occur under focused conditions the generating medium must be negatively dispersive. Regions of negative dispersion occur to the high energy side of atomic transitions. The amount of negative dispersion can be optimized either by adjusting the rare gas pressure or by compensating with a second, positively dispersive, gas. By using a second gas it is possible to increase the partial pressure, and the efficiency, of the third harmonic medium while maintaining the optimum dispersion conditions.

Although the efficiency of third harmonic generation is increased by using a positively dispersive gas to optimize the dispersion, the wavelength region of efficient conversion is substantially decreased. This is shown below in the wavelength scans for pure Kr (10 torr) and for a mixture of 25% Kr in Ar at 350 torr. Because coherent VUV generation is usually used for scanning experiments the narrow wavelength region of the mixture is unacceptable. However, for VUV photoionization experiments it is not necessary to scan wavelength so it is possible to take advantage of this increase in efficiency.

318
An interesting trend is seen in the Table above. As the wavelength increases the optimum mixing ratio decreases. This can be understood in terms of the negative dispersion per atom, which increases as the atomic transition (123.58 nm for Kr and 129.6 nm for Xe) is approached. As a result, a higher relative amount of argon is required to compensate for the increasing negative dispersion. By adjusting the relative amount of Ar it is possible to select a rare gas mixture which is most efficient at a selected VUV photoionization wavelength.

SOFT IONIZATION: The ability to select a photoionization wavelength makes it possible to control fragmentation. The wavelength dependence of fragmentation was studied for a number of functional groups which typically show little or no molecular ion. \( n \)-Alkanes, alkenes, ketones, carboxylic acids, ethers, amines, and aldehydes all form predominant molecular ions at low photoionization energies. The results for octanal, which fragments extensively above 9.6 eV, are shown below. A number of interesting fragments are seen at higher energies, including the metastable loss of \( \text{H}_2\text{O} \) (m/z 110), the McLafferty ion (m/z 84), and two \([\text{M-}2\text{nC}_{2n}\text{H}_{4n}]^+\) (m/z 72 and 100) fragments. As the photoionization energy is reduced the relative abundance of these fragments changes, indicating the K vs E dependence for each fragment. Finally, a change of only 0.7 eV eliminates almost all fragmentation. This strong wavelength dependence of fragmentation indicates that Tunable VUV photoionization will be very useful in experiments which require soft, universal ionization.

SINGLE PHOTON IONIZATION OF NEUTRALS PRODUCED BY ULTRAVIOLET LASER DESORPTION

C.D. Mowry and M.V. Johnston, University of Delaware, Department of Chemistry and Biochemistry, Newark, DE 19716

INTRODUCTION: A linear time-of-flight mass spectrometer allowing photoionization of ultraviolet laser desorbed neutrals is described. Single photon ionization is achieved using coherent vacuum ultraviolet radiation at 118 nm. Laser desorption (LD) and photoionization (PI) are both performed in the source region of the mass spectrometer. LD/PI provides qualitative information on the internal and kinetic energies of laser desorbed neutral molecules. Initial results involving nicotinic acid and a nicotinic acid:octyl amine solution are presented.

EXPERIMENTAL: An excimer laser (248 nm) is used for desorption. The laser beam is focused to 150 x 100 μm on the desorption probe at an angle 48° from the flight tube axis. Samples are deposited in μl quantities and air dried. The probe can be rotated 360° to access fresh sample surface, and vacuum is maintained during probe removal and insertion. Vacuum ultraviolet (VUV) radiation generated by frequency tripling the third harmonic of a Nd:YAG laser is used to ionize neutral desorption products. An off-axis optical alignment allows the 118 nm radiation to be focused a few mm from the probe surface along the flight tube axis, whereas residual 355 nm radiation is directed several mm below the plane of the flight tube. Primary desorption ions are rejected using a pulsed voltage applied to the backing plate of the source region. A delay generator controls the timing of the voltage pulse and also the delay between LD and PI lasers. The MCP detector signal is collected using a digital oscilloscope.

RESULTS: The LD spectrum of nicotinic acid in Figure 1 shows the molecular and fragment ions produced. LD/PI also produces molecular and fragment ions for nicotinic acid. The presence of a metastable tail in LD/PI for m/z 105 suggests this ion is produced by unimolecular dissociation of M* after photoionization. The gas phase mass spectrum of nicotinic acid does not contain any fragment ions, indicating that 10.5 eV alone is not energetic enough to cause fragmentation at 100°C. These observations imply that the desorbed neutrals have high internal energy.

LD and LD/PI spectra of a 5:1 molar solution of nicotinic acid:octyl amine is shown in Figure 2. Laser desorption of this sample shows only MH* for octyl amine and no fragment ions attributable to octyl amine. A fragment ion at m/z 30 is the only predominant ion observed from octyl amine in the LD/PI spectrum. The spectrum is similar to 70 eV mass spectra of octyl amine. Gas phase laser desorption products of octyl amine at room temperature creates metastable fragments but also an abundant parent ion. Laser desorbed octyl amine neutrals therefore also have a high internal energy.

Ion peak widths in LD/PI mass spectra are as narrow as those of gas phase spectra obtained in this instrument. This indicates a small distribution of kinetic energies for the desorbed neutrals. Broader peaks would be expected in LD/PI if the kinetic energy distribution was large. The small kinetic energy distribution in LD/PI suggests two possibilities: 1) the kinetic energy distribution of desorbed neutrals is different than that of desorbed ions 2) the broadening of peaks in LD is due to some factor other than kinetic energy.

LD/PI should be useful for gaining information about mechanisms, characteristics, and energetics of laser desorption. The capacity exists currently for tunable VUV radiation from 9.6 to 10.5 eV, which should permit selective ionization of desorbed neutrals. The variable delay between LD and PI events will allow investigation into the kinetic energy distribution of desorbed neutrals under various conditions.
Aryltriphénylphosphonium Halides as "Molecular Thermometers" in Matrix Assisted Laser Desorption

J. Claereboudt¹, M. Claeys¹, R. Gijbels² and A. Vertes²,
Departments of Pharmacy¹ and Chemistry², University of Antwerp (UIA)
Universiteitsplein 1, B-2610 Wilrijk, Belgium

Matrix assisted laser desorption (MALD) exhibits unique capabilities in the volatilization of large organic molecules. Proteins with molecular masses exceeding 200 kDa were transferred intact into the gas phase utilizing this method [1]. Our aim was to investigate the mechanism of volatilization with special emphasis on the temperatures experienced by the guest molecules embedded in the matrix.

Triphenylphosphonium salts are known as thermally labile molecules. Moreover, their fragmentation pathways (simple cleavage versus rearrangement) reveal their internal energy distributions [2,3]. Therefore, we used them as "molecular thermometers" to probe both the temperature experienced by the guest molecules and their internal energies.

Laser desorption mass spectra of four different phosphonium salts in neat form and in nicotinic acid matrix (one of the best matrices in MALD) were measured using frequency quadrupled Nd-YAG laser for excitation. Glycerol and ammonium chloride matrices were also tried with benzyltriphenylphosphonium chloride (Table 1). All four phosphonium salts exhibit three characteristic reaction channels: intact cation formation, thermal decomposition and major fragmentation of the intact cation. These three possibilities are demonstrated for 1-naphthylmethyl-triphenylphosphonium chloride in Figure 1. The mentioned pathways have been studied and confirmed separately by electron impact, fast atom bombardment and laser desorption mass spectrometry [2,3].

The intensity ratio of thermal decomposition products to intact cation, \( \frac{I(m/z=401)+I(m/z=402)}{I(m/z=403)} \), is considered to be a direct measure of the thermal load on the phosphonium salt during the laser desorption process. The ratio of the fragmented cation intensity to the intact cation intensity, \( \frac{I(m/z=141)}{I(m/z=403)} \), is thought to be related to the internal energy of the desorbed cation. The change of these ratios as a consequence of nicotinic acid matrix addition to 1-naphthylmethyl-triphenylphosphonium chloride is displayed in Figure 2.

UV laser desorption time of flight mass spectra of the other neat aryl-triphenylphosphonium chlorides and the corresponding matrix assisted spectra also revealed dramatic differences in thermal processes and in fragmentation patterns. The lack of thermal degradation and clear indications of significantly lower internal energies were observed in the matrix assisted case in accordance with the predictions of our cool plume [4] and homogeneous bottleneck model [5].

Similar measurements with glycerol and ammonium chloride matrices showed similar, though greatly reduced "cooling" effect of these substances. Their reduced efficiency is also feasible in the framework of the cool plume model [4] with respect to the higher volatilization temperature and/or to the lower UV absorption of these materials.

**K+IDS ANALYSIS OF SEVERAL ORGANIC SALTS AND A COMPARISON OF THE RESULTS TO OTHER DESORPTION/IONIZATION METHODS**

D.L. Hensley and D. Bombick

Department of Chemistry, Wright State University, Dayton, OH 45435

The desorption/ionization method used here, potassium ionization of desorbed species (K+IDS), has worked well for a number of compound classes. The experimental procedure is simple and requires no modification to the mass spectrometer. A number of desorption/ionization (DI) methods have been used to analyze organic salts. We have chosen to target select penicillins and dyes due to their thermal instability and interest within the mass spectrometry community. By comparing these results to those obtained using other DI methods we can assess the utility of the K+IDS method in analyzing these compounds.

K+IDS is a technique that can be used to analyze thermally labile compounds at a much lower cost than alternative DI methods. K+IDS can be used with any mass spectrometer fitted with a direct insertion probe inlet. The probe used in this method is inexpensive and simple in construction. A solution containing the analyte is deposited on the probe and allowed to dry. The probe tip consists of a ceramic doped with an alkali salt (in this case potassium sulfate). Once inside the ion volume of the mass spectrometer the probe is rapidly heated to a temperature sufficient to emit potassium ions from the alkali ceramic.

The mechanism of K+IDS involves the interaction between potassium ions (thermionic emission) and desorbed species arising from the surface of the thermionic material. The desorbed species are either intact molecules and/or thermal decomposition products of the analyte. Under certain conditions the desorbed species may leave the surface as ions (i.e., surface ionization). The distribution of these products depend upon the heating rate of the alkali ceramic. Simply, K+IDS is a potassium ion chemical ionization method coupled with rapid heating.

Figure 1 shows the K+IDS spectrum of penicillin G procaine salt. This spectrum contains ample structural information and the molecular weight of the salt. (The ion at m/z 609 is the potassiated adduct of the intact salt). In cases where the cation is an alkali metal (e.g., penicillin G potassium salt) poor spectra are obtained. By adding ammonium chloride to the sample prior to deposition on the K+IDS probe, the spectra begin to resemble the results obtained from analytes which contain an organic cation.

Figure 2 shows a K+IDS spectrum of methylene blue obtained using a rapid heating rate. The most abundant ion (m/z 284) is the intact cation. The other ions present are believed to be intact cations of impurities present in the sample (e.g., m/z 270 and 256). This is not surprising from literature accounts of the types of impurities found in this dye.

For this spectrum the observed ion intensities parallel the reported purity for this sample (85%). As with other K+IDS analyses performed in our laboratory, quantitation of a mixture is best done using a rapid heating rate as possible. This minimizes the probability of decomposition products being formed which would complicate quantitation.

The use of an alkali ceramic material for the emission of potassium ions creates the possibility of utilizing the K+IDS method for the off-line analysis of thin layer chromatograms. Methylene blue was chosen to demonstrate this approach since it was known to contain two other contaminant cations at m/z 256 and 270. These cations are structurally the same except with differing methyl constituents. Thin layer chromatography on a 250 ng spot of methylene blue sample produced three well-defined spots. The silica containing each analyte was collected from the plate and a slurry was made which was deposited directly onto the thermionic probe tip. The silica containing the analyte proved to adhere well to the alkali ceramic material of the probe tip. The results of the three analyses are listed in the following table.

The most abundant ion in each spot is the cation for that analyte. Small amounts of the other cations are observed in each spectra due to poor chromatography and/or memory effects. It is clear that the use of the K+IDS technique is applicable to thin layer chromatographic analysis and has certain advantages over other DI methods which have been used in a similar fashion. In DI methods using a beam (e.g., SIMS), ions are only generated when analyte is exposed to the beam.
The amount of analyte exposed may be only a small fraction of the total sample. If this is the case, sensitivity may be a problem. In addition, K+IDS is a technique which can be rapidly performed therefore reducing analysis time.

In summary, this technique provides similar information as many other DI methods. The major advantages of K+IDS over other methods are cost savings and simplicity. The results presented here suggest the following conclusions.

1. Spectra are similar to other DI methods and are influenced by the heating rate employed.
2. Appropriate additives to the sample can influence spectral features.
3. Salts of organic dyes generate spectra lacking alkali ion adducts. Although this is the case a fast heating rate is still required.
4. Molecular weight information and structural information can be generated in this approach.
5. The use of the K+IDS technique for off-line TLC analysis is useful and provides advantages over other DI methods.

ON-LINE SINGLE PARTICLE ANALYSIS
BY LASER DESORPTION MASS SPECTROMETRY

McKeown, P.J., Johnston, M.V.
Department of Chemistry and Biochemistry
University of Delaware
Newark, De 19716

Murphy, D.P.
Aeronomy Lab, NOAA
Boulder, Co 80303

Introduction  Mass spectra of both organic and inorganic particles in the 3-10 \( \mu \)m range have been obtained by single-step, laser desorption/ionization. This method offers a few distinct advantages over other current methods. Complete mass spectra are obtained for each particle in an on-line mode. Also, sample integrity is maintained in two important ways. First, sample contamination and/or decomposition is reduced since particle/surface interactions are virtually eliminated. Second, the loss of volatile components is reduced since the particles spend less than a millisecond under vacuum conditions before ionization.

Experimental  Particles of known size and composition were generated and directed into the source region of a linear time-of-flight mass spectrometer through a differentially pumped nozzle assembly. The system is outlined in figure 1.

Particle detection in the source region of the mass spectrometer was accomplished by monitoring scattered radiation from a He-Ne laser. The He-Ne crossed the source region perpendicular to the flight region and was focused to a 100 \( \mu \)m spot. The scatter was collected by a fiber optic, detected by a photomultiplier, amplified and sent to a discriminator. The output of the discriminator was used to trigger an excimer laser for particle desorption/ionization. Ions were detected using a microchannel plate detector. The output was digitized with an oscilloscope or first logarithmically amplified.

Results  Figure two shows a mass spectrum of one 9 \( \mu \)m mixed salt particle. The particle was composed of NaCl, KCl and (NH₄)₂SO₄. The initial salt solution was prepared in a 4 : 1.5 : 2 molarity ratio, respectively. The laser was operated at 193 nm and at a pulse energy 50 MW/cm². The spectrum is dominated by K⁺, Na⁺, and NH₄⁺ yet contains a large number of cluster ions similar to those seen in LAMMA experiments. The largest peak in the spectrum is K⁺, however KCl in the salt solution was the least concentrated. This result may be due to the relatively low ionization potential for potassium or the result of particle concentrations differing from that of the original salt solution. The threshold for particle desorption was found to be approximately 25 MW/cm². Mixed salt particles of 6 and 9.5 \( \mu \)m were studied under the same experimental conditions. This difference represents a factor of 4 change in mass. However no significant change in ion current was observed, indicating incomplete desorption of the particle. Particles of less than 3 \( \mu \)m diameter could not be accommodated with the current optical configuration due to the lack of a baffle system preventing stray light from reaching the photomultiplier.

Figure three demonstrates the potential application of the logarithmic amplifier. The top spectrum is an expanded region of a salt particle spectrum. Weak features in the spectrum can be lost due to the limited dynamic range. The second spectrum was obtained from the same particle. The ion current was logarithmically amplified and then converted back to a linear form. The extended dynamic range is clearly demonstrated.

Two ion trajectory programs, SIMION and SIMTOF, were used to model single particle laser desorption. Two source region configurations were used for experimental and modelling work. The drawout voltage was varied from 2300 V to 0 V. Particle to particle variations in flight times for both configurations could be explained and predicted based upon the position of the particle in the excimer beam upon desorption. The peak widths were explained using an ion formation region slightly larger than the particle (10-20 \( \mu \)m) and an ion temperature between 1,000 and 10,000 K.

Reduction of pyritic sulfur and mineral matter in coal is important in controlling emission of sulfur gases and particulate matter during coal combustion. Coal cleaning techniques such as agglomeration are being investigated to selectively remove pyrite and mineral matter while maintaining the original BTU content of the coal. Following changes in the surface composition of the coal with treatment is important for understanding the mechanisms of the cleaning techniques. Proper control of the coal surface properties will improve the effectiveness of agglomeration in producing premium quality clean coal. Our studies involved monitoring changes in the near surface elemental composition with various agglomeration procedures, and correlating these changes with those observed by bulk techniques.

The Laser Microprobe Mass Analyzer has previously been used as a tool for mapping coal macerals. Changes in elemental surface composition can also be determined. Coal from Illinois #6, Pittsburgh #8, and Upper Freeport #3 seams was analyzed using the Leybold Heraeus LAMMA-1000, which has been described elsewhere. Samples were prepared by mounting the coal powder on double-sided sticky tape supported by zinc foil. The 250x microscope was used to select areas on the surface of individual coal particles. Fifty spectra were collected and averaged from each individual particle. A total of 10 particles were analyzed from each sample. This procedure was developed in order to compensate for the inhomogeneity of the coal surface and the variations in instrumental factors. The relative amounts of the following elements were semi-quantitatively determined: Li, Na, Mg, Al, Si, S, K, Ca, Ti, and Fe. The results were presented in terms of percent total ionization for the 10 elements. While the percent total ionization does not represent absolute concentrations, trends in concentration following physical and chemical treatment can be followed. Changes in the percent total ionization will be proportional to changes in the concentrations of the elements.

Coal cleaning through agglomeration consists of a preliminary grinding step during which the coal is ground in water with additives. Results of agglomeration of Pittsburgh #8 wet ground without additives were obtained in order to establish a base set of data. Feed, product and refuse samples from agglomeration were examined to determine the elemental composition. After successful agglomeration cleaning the concentration of pyrite should increase in the refuse. The elemental distributions for the 3 fractions from agglomeration for wet ground Pittsburgh #8 coal are shown in Figure 1. These samples showed for iron and sulfur a decrease in the percent total ionization from the feed to product and an increase from feed to refuse. Mg, Li, and Si also increased in the refuse. Na, Al, Ca, and Ti increased in concentration in the product and decreased in the refuse.

The addition of tall oil during grinding was studied in order to determine its effect on the elemental distributions of the 3 agglomeration fractions. Pittsburgh #8 coal wet ground with 200 ppm tall oil added showed similar behavior compared to the coal wet ground without additives. The iron and sulfur decreased in % total ionization in the product, and increased in the refuse. The addition of tall oil had no significant effect on the elemental composition of Pittsburgh #8 coal.
Agglomeration treatments were conducted using various hydrocarbon to coal ratios. It was postulated that addition of hydrocarbons during grinding will aid in the removal of pyrite. Illinois #6 wet ground base coal with no additives during grinding was first analyzed by LAMMA. Illinois #6 coal with a pentane to coal ratio of 1:5 was then analyzed to determine the effect of grinding additives on the surface elemental composition. The results for the % total ionization of the 10 elements for these 2 samples are shown in Figure 2. The addition of pentane had little effect on the elemental composition, with most elements showing little or no change in % total ionization. The iron and sulfur showed small increases in % total ionization for the pentane ground coal compared to the wet ground coal without additives. Na and K showed small decreases in % total ionization, which leads to speculation that the removal of these highly soluble cations from the surface of mineral matter may expose more pyrite resulting in increases in sulfur and iron surface concentration.

LAMMA analysis can be a useful technique in evaluating the success of physical and chemical treatments of coal. These results have been successfully correlated with bulk analysis data.

NECESSITY OF JET-COOling OF LASER-DESORBED MOLECULES IN THE MPI-ION-SOURCE OF A TOF MASS SPECTROMETER

F.J. Mayer, A. Holle, R. Frey, Bruker-Franzen Analytik GmbH, Fahrenheitstr.4, D-2800 Bremen 33, Germany

Laser desorption of neutral molecules followed by supersonic jet cooling and multiphoton ionization has become a well-known technique to examine labile, non-volatile molecules; many results have been published (see references in [1]). An interesting alternative to this ion source for a time-of-flight mass spectrometer is the laser desorption of neutrals with subsequent multiphoton ionization, located as close as possible to the place of desorption (i.e. without using a jet) [2]. The latter technique should at least be more sensitive, but up to now, results are reported only for small or stable compounds.

The Bruker TOF-1 time-of-flight mass spectrometer has been used to perform comparative measurements of laser desorption of neutrals without (ND) and with (ND-jet) subsequent cooling by a supersonic jet followed by resonance-enhanced multiphoton ionization (MPI). Neutral species were desorbed by means of a CO2 laser pulse (10.6 μm, 10 μs) and postionized by a UV laser pulse (270 nm, 8 ns). The ions are accelerated into a TOF mass spectrometer and detected with a dual microchannelplate detector.

The measurements have been performed for a series of 5 peptides with increasing number of amino acids labeled below as P1-P5: Tryptophan, GLY-PHE, GLY-LEU-TYR, Leucine-Enkephaline and Pentagastrin. Figure 1 gives as an example the results for Pentagastrin. (a) gives the spectrum for ND-MPI (b) gives the spectrum for ND-jet-MPI and (c) for ND-jet-EI i.e. electron impact ionization (EI) is used instead of multiphoton ionization (MPI).

For ND-jet-MPI the molecular ion is clearly observed for P1-P5 as a peak which has about the highest intensity. The power of the IR-laser was kept for all spectra at a constant high value of about 10^9 W/cm². The intensity of the ionization laser was also kept at a constant medium value of 10^7 W/cm² to produce not only molecular ions, but also some significant fragments. As wavelength 270 nm was chosen. For ND-MPI, the molecular ions are observed only for P1-P3. For P4, higher mass fragments can be seen (432 u and 449 u), and for P5, only small fragments are observed. In each case, especially for P4 and P5, we tried very carefully to obtain as much molecular ion signal as possible. The power of the desorption laser was reduced to the desorption threshold. When proceeding to higher mass peptides, we observed that the threshold power was increasing, i.e. more energy is needed for P5 to be desorbed than for P1. For ND-jet-EI, similar results as for ND-jet-MPI can be obtained, as shown in Fig. 1c. For more results with ND-jet-EI see [3].

Thus, the jet cooling is inherently needed, if peptides containing 4 and more amino acids are to be examined using neutral desorption (10 μs IR-pulses) and postionization. As can be seen from the EI experiments, the jet cooling is the important step, because even with the hard EI-ionization molecular ions are observed for P5. We conclude that the neutrals taking up some amounts of initial energy during desorption are able to survive as intact molecules as long as they are neutral. But after ionization they im-
mediately fragment due to the lower fragmentation thresholds of the ions. If, however, the internal temperatures of the molecule are cooled down after desorption (and before ionization) they have a chance to survive the ionization process as intact molecules no matter whether they are ionized by MPI or by EI. With the same argumentation an effect so far not understood can be explained: With ND-jet-MPI, molecular ions of labile samples with masses above 3000 are not observed as yet. Those high masses are heated even higher in the desorption step and the jet is no longer able to cool them to sufficiently low temperatures. Thus, they are fragmentized after ionization for the same reasons as lower mass peptides when no jet cooling is applied.

Introduction
Matrix-assisted laser desorption time of flight mass spectrometry (LDTOFMS) has rapidly become one of the forefront techniques for the mass spectrometric analysis of large biomolecules. Alterations of the original technique /1/ by Beavis and Chait has enabled the highly accurate molecular weight determinations of large proteins while maintaining pmol to sub-pmol sensitivity /2/. Added benefits of the Beavis and Chait technique are an immunity to large concentrations of contaminants, selective ionization of protein analytes and the ability to readily analyze complex mixtures. These benefits make LDTOFMS the mass spectrometric technique of choice for the direct analysis of naturally occurring protein mixtures, as demonstrated on the analysis of human and bovine milk /3/. We have analyzed several protein mixtures obtained directly from the biological source, including human milk whey and direct extracts of plant membrane proteins /16/. This communication presents the direct analysis, and partial identification, of human salivary proteins.

Experimental
Approximately 1 ml of human saliva was obtained and diluted by a factor of 10 with 0.1% aqueous TFA. To 1 microliter of the diluted saliva, 1 microliter of matrix solution (saturated sinapinic acid in 30:70, acetonitrile:0.1% aqueous TFA) was added. The combined 2 microliters was allowed to air dry on an insertion probe. Mass spectrometry was performed on a Vestec Model 2000 laser desorption time of flight mass spectrometer operating at 30 kV accelerating potential. The mass spectrum shown was obtained through the signal averaging of 100 laser shots (Nd:YAG laser operating at 355 nm). To obtain reasonable ion signal throughout the entire mass region investigated, a variation in laser power density at the sample was needed, i.e. a higher laser power density for the mass range > 16,000 Da. Two factors could contribute to this: a) the component analytes being in solution in varying concentrations, and, b) a lower detection efficiency for the higher mass ions. Unfortunately, when going to a higher laser power density to observe the larger ions, resolution of the lower mass ions was sacrificed. Mass calibration was performed prior to and following the analysis of saliva using apomyoglobin (horse heart MW = 16,950.7 Da). Molecular weight determination error, using an external calibrant, was estimated to be ±0.05%. Molecular weights of salivary proteins were calculated from established sequences using PROCOMP /4/.

Fig. 1 Matrix-assisted laser desorption time of flight mass spectrum of human saliva.
Results and Discussion

Fig. 1 shows the mass spectrum obtained from human saliva. Over 30 of the ion peaks were determined to represent component protein analytes i.e. their m/z values could not be justified by multiply charged values of other peaks or values derived from matrix adducts. Table I shows 14 salivary proteins identified using molecular weights calculated from known sequences. All assignments agree within 0.1% of the calculated masses with the exceptions of Protein C and amylase (for which no sequence data could be found). Molecular weights for salivary proteins PRP-IB6 and PRP-IB9 were calculated from their known sequences /15/, yet neither were observed in this saliva sample. In that only ~17% of the population secrete these proteins /15/ this is not surprising, however, PRP-IB6 has been observed in saliva samples obtained from other subjects /16/.

Conclusion

Demonstrated is the ability of matrix-assisted laser desorption time of flight mass spectrometry to yield useful molecular weight data on complex naturally occurring protein mixtures, with no prior separation. This, coupled with the inherent sensitivity of the technique, suggest the possible use of LDTOFMS as a means of monitoring bodily proteins at quantity levels which are not taxing to the subject.

Sample preparation in desorption ionization techniques such as FAB, SIMS, PDMS, etc. employ the use of various matrices that play a role in the desorption and ionization of analyte molecules. Similar to other desorption techniques the matrix plays a key role in matrix assisted laser desorption (MALD). The interactions between matrix and analyte can be understood by considering our current view of the MALD process. The steps include: 1) photon absorption to produce an ensemble of excited state matrix molecules (S); 2) internal conversion of some S, species results in heating of a localized region; 3) the rapid heating causes ejection of "cluster species" from the surface, e.g. [(S)n—S] or [(S)n(A)m—S], where A represents analyte molecules; 4) the enhanced acidity of S, (relative to S0) results in proton transfer to yield [(S)n(A)m—AH+—S] or [(S)n—S] or intact analyte molecular ions [A+H]+.

The temporal profiles of mass selected ions produced by MALD is a direct measure of the time for formation of ions plus the resident time of the ions in the source. The time requirement for ion formation is governed by the mechanism of the ionization process. Figure 1 shows the temporal profile for the [M+H]+ ion of sinapic acid. The peak is bimodal composed of a sharp peak and a tailing distribution that extends beyond 50 usec. The ratios of ions in the two portions of the profile (short time for arrival vs. long time for arrival) varies from approximately 1:1 to 1:10. Although we have not made measurements of the KE distribution of the two components contained in the profile, preliminary measurements show that component A ions have higher kinetic energies than...
component B ions. Our interpretation of the arrival time distribution corresponds to ions formed directly (either [M+H]+ or small clusters) where the time scale for evaporation is short with respect to the ion source residence time (approximately 1 usec). Component B, on the other hand, arises from the ejection of "large" cluster species. These large cluster species also evaporate, but the time required for evaporation is longer because the number of solvent molecules is "large". We are now performing experiments using accelerating voltage metastable ion scans in an effort to determine the distribution of cluster size. For example, accelerating voltage metastable ion scans will allow us to identify the parent ion(s) of a particular daughter ion;

\[ [M+H]^+ S, \rightarrow [M+H]^+ S_{n+1} + aS. \]

The overall shape of the temporal profile is dependent upon a number of experimental parameters, e.g., laser power density, ion source focussing "ion draw-out potential", matrix to analyte ratio, liquid matrix vs solid matrix, etc., but under these circumstances we continue to observe a bimodal peak that contains components A & B.

Sample preparation in desorption ionization techniques such as FAB, SIMS, PDMS, etc. employ the use of various matrices that play a role in the desorption and ionization of analyte molecules. Similar to other desorption techniques the matrix plays a key role in matrix assisted laser desorption (MALD). The interactions between matrix and analyte can be understood by considering our current view of the MALD process. The steps include: 1) photon absorption to produce an ensemble of excited state matrix molecules \((S)\); 2) internal conversion of some \(S\) species results in heating of a localized region; 3) the rapid heating causes ejection of "cluster species" from the surface, e.g. \([(S)(n)\rightarrow S]\) or \([(S)(n)\rightarrow (A)(n)\rightarrow S]\), where \(A\) represents analyte molecules; 4) the enhanced acidity of \(S\) (relative to \(S\)) results in proton transfer to yield \([(S)(n)\rightarrow (A)(m)\rightarrow AH^+\rightarrow S]\); 5) evaporation of the cluster yields solvated adducts, \([(S)(n)\rightarrow AH^+]\) and \([(S)(n)\rightarrow S]\) or intact analyte molecular ions \([A+H]^+\).

The key component of the matrix assisted laser desorption mechanism that we have proposed is the enhanced acidity of the absorbing matrix in the excited state. With this in mind consider the resonance structures of sinapic acid shown in figure 1. Upon photon absorption the acidity of the phenolic proton is believed to be increased by delocalization of the lone pair of electrons on the adjacent oxygen through resonance effects. Organic solute interactions that shift the equilibrium toward the right (figure 1), may be useful in enhancing the population of acidic hydrogens available for proton transfer in the excited state. The hydrogen bonding interactions shown in figure 2 may shift the equilibrium of the species represented in figure 1 by stabilizing the charged...
carboxylate group of the Sinapic acid.

INTRODUCTION
Since its introduction in 1987, matrix-assisted laser desorption mass spectrometry (LD-MS) has
become increasingly popular in the field of biochemistry. A wide variety of matrices and wavelengths have
been investigated with the intention of reducing the matrix induced chemical noise and increasing the
applicability of the method to different classes of molecules. The most widely used matrices to date are
nicotinic acid (266 nm, Nd-YAG laser) and sinapinic acid (266 nm, dye laser; 337 nm, N₂-laser; 355 nm Nd-
YAG laser) and its homologues. Time-of-flight mass spectrometers are easy to build and the focus has
been on N₂-lasers, which are inexpensive and thus reduce the overall cost of an instrument.

Of interest to biochemists is the composition of multimers, such as enzymes, verification of
hybridization, identification of ligands and detection of chemical modifications. Even though LD ionization
is a so called soft technique, only very few examples of enzymes surviving the ionization process as intact
multimers (e.g. streptavidin) have been reported. Karas et al. showed the influence of the alcohol content
on the dissociation of multimers into subunits. Nicotinic acid is a water soluble compound, which allows
for a less denaturing environment, whereas sinapinic acid is not soluble in pure water. This is possibly
the reason why no multimers have been reported so far in conjunction with the sinapinic acid matrix.

PROTEINS INVESTIGATED
Alcohol dehydrogenases (ADH) catalyze the oxidation of alcohols. Yeast ADH exists as two
isozymes that differ in 23 amino acids. Each isozyme is reported to consist of 4 identical subunits. Horse
liver ADH is a dimer of two different subunits. Comparing the two enzymes shows an inhomologous primary
structure. Even so, the tertiary structures are very similar and all main enzymatic mechanisms are common
to both proteins. On the other hand, the structural deviations affect the subunit interaction and it is
expected that the quaternary structure of the two proteins will be different.

Avidin is a glycoprotein composed of 4 essentially identical polypeptide chains. It forms a very
strong complex with d-biotin, a fact that has been widely exploited for the design of affinity columns. The
binding constant is in the order of 10⁻¹⁵ M and the biotin binding ability occurs between pH values of 2 to
13, and at guanidine hydrochloride concentrations of up to 3M, reflecting the stability of the complex.
Binding of biotin by single subunits was observed with a binding constant of 10⁻⁷ M.

RESULTS AND DISCUSSION
The two forms of ADH investigated have very similar tertiary structure with the exception mentioned
above, but are expected to differ in their quaternary geometry. Indeed y-ADH shows an increased signal
for the dimer, whereas with h-ADH, only the monomer can be detected.

The average molecular weight thus determined for y-ADH is 36'915 (σ₁₈ = 37) for the monomer and
73'540 (σ₁₈ = 195) for the dimer. These values are high by 140 - 160 u for the monomer but well within
the margin of error for the dimer. The deviation for the monomer possibly reflects the presence of zinc
ions.

Verification of the dimeric form of y-ADH was done with gel filtration. Treatment of y-ADH with
denaturing agents (3M guanidine hydrochloride or NH₄HCO₃) dissociates the dimer predominantly into
monomeric subunits, thus proving that the dimeric form seen with LD-MS is not covalently linked.
Electrospray spectra of untreated y-ADH support this finding.

The avidin/biotin system was chosen as a model compound for the investigation of ligand-protein
binding, because it has a very strong affinity for biotin, even under what is normally considered denaturing
conditions. However, no evidence of multimers and biotin binding was detected.

EXPERIMENTAL CONDITIONS
The laser desorption time-of-flight mass spectrometer used has a 50 cm flight tube and is operated
at an accelerating voltage of 20kV. A N₂-laser yields an adjustable power density of around 10⁶ W/cm².
Data acquisition is done with a LeCroy 9450 digital oscilloscope. ADH was dissolved in water at a concentration of approx. 10 pmol/μl, sinapinic acid in 50% EtOH or 70% ACN.

Gel filtration was performed on a Sephadex G25 column (1.4x29.0 cm) at a flow rate of 0.9 ml/min with 1% NH₄HCO₃ at pH 8. The sample concentrations were 10 pmol/μl, 700 μl were loaded. y-ADH was denatured in 3M guanidine hydrochloride.

CONCLUSION

The sinapinic acid/337 nm combination can be used to determine multimeric protein structures under certain conditions, although it appears to be less generally applicable relative to the nicotinic acid/266 nm experiment.

In the case of y-ADH, the hydrophobic forces holding the subunits together were sufficiently strong to prevent dissociation under the conditions used for sample preparation. This was not the case for avidin/biotin binding, which showed only monomeric avidin on LD-MS analysis.

Current and future studies are aimed at elucidating the critical parameters of the y-ADH system to better understand conditions necessary for the observation of multimeric protein complexes.

Two-Step Laser Desorption / Multiphoton Ionization Mass Spectrometry: Applications and Mechanisms

C. R. Maechling, R. Zenobi, L. J. Kovalenko, S. J. Clemett, R. N. Zare
Department of Chemistry, Stanford University, Stanford, CA 94305-5080

The capacity of laser desorption to volatilize intact neutral molecules combined with the high sensitivity and molecular selectivity of resonance-enhanced multiphoton ionization (REMPI) make two-step laser mass spectrometry (L\textsuperscript{2}MS) a powerful technique for the organic analysis of unique cosmochemical and geochemical samples. The utility of L\textsuperscript{2}MS has been demonstrated by the in situ analysis of polyaromatic hydrocarbons (PAHs) in both carbonaceous [1] and ordinary [2] chondrites, and our recent modifications to reduce the desorption laser spot size from 1 mm to 40 \(\mu\)m has allowed us to expand this technique to extra-terrestrial bodies of limited size and fine spatial heterogeneity. We have recently used L\textsuperscript{2}MS to analyze the acid (HF-HCl) insoluble residues of the interiors of the carbonaceous chondrites Murray and Murchison, the unequilibrated ordinary chondrites Bishunpur and Semarkona, and the ordinary chondrites Saratov and Barwell. These residues, consisting of particles no larger than 200 \(\mu\)m in diameter, were individually mounted onto a sample platter for analysis.

In the L\textsuperscript{2}MS technique, the output of a pulsed CO\textsubscript{2} laser (10.6 \(\mu\)m) is focussed through a microscope objective onto the sample producing the rapid desorption of neutral molecules; the effective desorption region is a spot 40 \(\mu\)m in diameter. After a 19\(\mu\)s time delay, the frequency-quadrupled output of a pulsed Nd:YAG laser (266 nm) selectively ionizes the PAHs in the mixture of desorbing species by 1+1 REMPI. The ions are mass analyzed in a reflectron time-of-flight (TOF) mass spectrometer and detected by a microchannel plate.

Consistent with previous bulk chemical analyses, large PAH concentrations are found in the unequilibrated chondrites and undetectable amounts are found in the more equilibrated, thermally processed chondrites [3]. The acid residue of Bishunpur has the strongest signal (figure 1), followed by Semarkona, Murchison, Murray, and Saratov. The incremental spacings of 14 amu indicate the successive alkylated PAH skeletons. No detectable signal is observed from Harwell, which is consistent with its type-6 petrographic classification. This sample also serves as a reference for contamination introduced during sample preparation. Although great care was taken to ensure that we did not introduce contamination in our lab, the indigeneity of the organic material remains speculative, as the histories of the meteorites on Earth are not well documented.

In an effort to further classify the organic material, we have noted trends in the ratios of a set of PAHs in the meteorites. The ratios compare nicely between the Murchison and Murray samples and between the Bishunpur and Semarkona samples, while showing distinct differences between the carbonaceous and unequilibrated chondrites samples; reassuringly, these ratios differ from the other meteorite residues.

We also present an investigation of the laser induced desorption process. To better understand this process we are conducting experiments to quantitate the flow of energy from the laser heated substrate into the adsorbate molecules. Various coverages of naphthalene on a quartz substrate have been studied in the collision-free environment of an ultrahigh vacuum (UHV) chamber. Again, desorption is induced with a CO\textsubscript{2} laser.
(10.6 μm) and the molecules are ionized with the Nd:YAG laser (266 nm); however, the mass analyzer on the UHV apparatus is a linear TOF system. The energy transfer is described by the correlation of three experiments: 1) the time-dependence of the surface temperature, 2) the kinetic energy, and 3) the internal energy distributions of the desorbed molecules. We have successfully modelled the temperature evolution of the quartz surface using a numerical simulation program whose results agree to within 10% of experimental measurements [4]. We have also measured velocity distributions of submonolayer coverages of naphthalene; a Maxwell-Boltzmann fit to these distributions indicates a translational temperature of 224 K [5]. The last of these measurements is currently in progress.

**Figure 1:** Mass spectrum of the Bishunpur acid-insoluble residue. The labelled masses match those of bare PAH skeletons, except the peak at mass 152 which has been verified as a fragment of mass 178. The spectrum is a 15-shot average.
THE DESIGN AND PERFORMANCE OF A LASER DESORPTION -
LASER IONIZATION - TIME-OF-FLIGHT SPECTROMETER:
HOW TO DO IT YOURSELF.

University of California, Davis, CA 95616

Laser Desorption - Laser Photoionization - Time-of-Flight Mass Spectrometry (LD-LP-TOFMS) is aptly suited to environmental analyses due to the characteristics which have given it wide application from the study of small molecules to the characterization of biopolymers. The laser desorption step due to its insensitivity to salts and essentially instantaneous volatilization of the sample is an effective means to directly analyze soot or fly ash samples for polycyclic aromatic hydrocarbons (PAHs) and their chlorinated analogs eliminating laborious and costly extraction methods. Photoionization allows one by careful choice of wavelength to selectively ionize the PAHs from the complex matrix of the soot particles. The time-of-flight spectrometer with its yet undetermined upper molecular weight limit and superior resolving capability when equipped with a nozzle expansion and reflectron is the mass analyzer of choice for this pulsed source experiment. Since commercial instruments of this type were not readily available and funds were limited at project inception, we chose to design and build the instrument ourselves.

We designed and built a LD-LP-TOFMS outfitted to operate in linear or reflectron mode with the option of sample introduction / seeding via supersonic expansion. The SIMION software package was used to model the electrostatic field and trajectories of ions in the source and flight tube, both to sort out working designs for the construction phase and source parameters for focusing the ion beam while bringing the instrument on line. To date we have used the instrument in linear mode only with single step UV desorption / ionization and applied it to the characterization of our PAH standards. Several spots obtained from incineration experiments were analyzed to demonstrate the potential to obtain selective ionization of components by varying the ionizing wavelength. The 266 nm (frequency - quadrupled output of the Nd:YAG ) light was passed trough a Raman shifter which generated Stokes (299 nm) and anti-Stokes (239 nm) shifted UV wavelengths for Photoionization . Figures 1 and 2 show spectra obtained from a trichloroethylene (TCE) flame soot using 266 nm and 299 nm. We obtained our first spectrum combining CO2 laser desorption with 266 nm ionization from a soot produced in a benzene/methane flame.

In the course of our experiments we learned a great deal about the critical effects of probe design on the signal observed. Probe orientation as well as the nature of the sample / probe interface were explored. Other investigators have also encountered probe effects and come up with some unique solutions i.e. a prism probe or a porous substrate on the probe surface to eliminate spatial effects on the initial ion packet distribution and shot to shot desorption yield variances. Figure 3 shows a photodesorption / ionization spectrum of pyrene resulting from penetration of the evanescent wave beyond the prism boundary.

Evaluation of Factors Contributing to the Accuracy and Reliability of the Mass Assignments In Matrix Assisted Laser Desorption Mass Spectrometry

P. Juhasz, J. E. Biller, C. E. Costello, I. A. Papayannopoulos, and K. Biemann
Department of Chemistry, MIT, Cambridge, MA 02139

EXPERIMENTAL

Matrix assisted LASER desorption experiments were run on a time-of-flight mass spectrometer model VT2000 manufactured by VESTEC Corp. The more important operational parameters were:
- Wavelength: 355 nm
- Accelerating voltage: in most cases 30 kV
- Matrix: sinapinic acid
- Amount of analyte: ca. 1 pmol

Method of sample preparation is described in Ref. 1. Data are processed on a MicroVAX 3600 computer. Data processing software for the VAX station which makes use of the large storage space and high CPU speed has been developed in our laboratory. Generally, 5-20 individual spectra (called runs) were taken from a single sample preparation and stored in a single data file. Runs contained averages from a number of laser shots (typically 50). Each run could be smoothed, calibrated, and displayed on the screen or plotted on a graphics printer.

COMPARISON OF INTERNAL AND EXTERNAL CALIBRATION

Whenever internal calibration is possible it is superior to external calibration. However, internal calibration is not always possible, especially if the molecular weight of the calibration compound is far from that of the unknown compound. This often the case with samples in the 100 kDa range where no calibration compound of known mass is available presently. External calibration is a good alternative in these cases.

Table 1. compares external and internal calibrations at different accelerating voltages. The mass of cytochrome C was determined calibrated to porcine insulin externally and as well as internally, too. The resolution is also included in the table measured at the (M+ H)⁺ peak of insulin, as an indicator of the quality of the spectra. It is remarkable that the accuracy is one order of magnitude better with internal calibration whereas improvement in reproducibility is less significant (that is, the decrease of σ). Accuracy and reproducibility of the mass assignment seems to be independent of the accelerating voltage in the range of 20-30 kV.

EFFECT OF AVERAGING

Originally, the aim of averaging a number of LD mass spectra was to reduce signal-to-noise ratio for the high mass molecular ions. However, a systematic study reveals that not only the S/N ratio but also the accuracy and reproducibility of the mass measurements improves impressively with averaging the individual spectra as shown in Table 2. Note that both proteins can be ionized very easily and give a strong signal even for single laser shots. It is somewhat unexpected that averaging single shot spectra also increases the resolution. Taking 20-50 shot averages seems optimal from the point of view of
accuracy, reliability, and sample consumption as well.

**TABLE 2** Measurement of Cytochrome C (MW 12,359.1); calibration to porcine insulin. "Determined at the (M+ H)⁺ peak of insulin.

**COMPARISON OF THE EXPERIMENTAL AND THEORETICAL PEAK SHAPE**

Comparison of the theoretical isotope distribution with the experimental peak shape can partly explain the uncertainties in mass accuracy. We compared the isotope distribution and the measured peak shape of the molecular ion of porcine insulin. The resolution was high enough to see low mass adducts or loss of small fragments. It turned out that in this case peak broadening in the mass spectrometer is due rather to energy spread of the ions than to adduct formation or fragmentation. This finding, however, may not hold for larger molecular ions.

**REFERENCES**

While matrix assisted laser desorption mass spectrometry is capable of ionizing biomolecules in excess of 200,000 daltons, the low mass resolution of the time-of-flight mass analyzers employed limits the obtainable mass measurement accuracy. This is compounded by the preponderance of adduct species at higher mass which further degrade the apparent mass spectral resolution and cause a significant uncertainty in determining ion peak centroids. While mass resolutions of 300-500 (fwhm) can be estimated for low mass proteins such as bovine insulin (mw=5733.5), it becomes almost impossible to accurately determine instrumental resolutions at higher mass. This is due to the natural broadening of the isotopic peak distribution at higher mass and the increase in the various ion species surrounding the molecular ion peak ([M+H]+H)\(^+\) at higher mass. Despite the problem with estimating mass resolution at \(m/z\) > 10,000, some degradation in experimental mass resolution seemed to be occurring at higher masses. This could be due to the presence of additional unresolved ion species not observed at lower mass which can cause an apparent loss of mass resolution or it could be the result of a physical effect which actually degrades instrumental mass resolution. The latter may be associated with the mechanism of very large ion detection as discussed by Spengler et. al.\(^1\). In order to determine the actual experimental mass resolution at higher masses, a computer program was developed to calculate the expected theoretical isotopic mass distributions for a given empirical formula and output a simulated peak profile for any given mass resolution. The program was written in FORTRAN and utilizes a variation on the algorithm described by Yergey\(^2\), optimized to run on an AT-clone personal computer. The output can be directly compared to experimental data by importing the output into our mass spectrometer’s data analysis program (Spectra Calc, Galactic Industries). Output for various ion structures can also be summed to produce a theoretical mass spectrum at a given mass resolution which can then be compared to experimental data.

Low mass peptides and proteins (<6,000 daltons) were run experimentally by matrix assisted laser desorption (sinapinic acid matrix; 337 nm laser wavelength) in order to identify the ion species produced. Most of the major ion species are easily mass resolved in this molecular weight range. In addition, two data processing techniques were employed to improve the apparent mass resolution of the data. Initially, spectral deconvolution of the spectra was employed but resulted in only minor improvement for lower mass species. Spectral deconvolution is a widely used technique, particularly in optical spectrometry, which can remove various line-broadening components of spectra. At higher masses, significant resolution improvement can be seen. Indeed, preliminary results suggest that this type of data processing can also improve mass accuracy determinations. The mass accuracy for horse heart cytochrome C (mw=12360.1) calibrated with myoglobin (mw=16951.5) improved from 0.01% to 0.005% when deconvolution was applied prior to time-to-mass conversion. For lower mass ions, maximum likelihood calculations provided significantly improved spectral resolution. The maximum likelihood method (Spectrum Square Associates) is a statistical process which finds the most likely spectral representation given a peak shape (gaussian) and estimated peak-width (fwhm). The results of this approach for the B chain of bovine insulin (mw=5349.95) are shown in Figure 1. It can be seen that the matrix addition peak actually corresponds to more than one ion species produced. These results are clearly observed, even in the raw experimental data (Figure 2) and are not an artifact of any of the spectral data processing techniques. The identified ion species observed for low mass proteins and peptides are summarized in Table I.

Using this information and the observed tendency of larger proteins to add multiple matrix species, theoretical peak profiles were constructed at various mass resolutions and fitted to the experimental data in an iterative approach. Using the peaks and relative intensities shown in Table 2, a best-fit theoretical mass spectrum for myoglobin was constructed based upon a resolution of 225 (fwhm) and is shown in Figure 3. The experimental and difference spectra are also shown. This compares to an experimentally measured resolution of 300 (fwhm) for bovine insulin. Based upon these results it appears that some of the resolution loss at higher mass is due to something other than additional ion species. The postulated acid (acetic and sulfurlc) adduct ions are consistent with species observed for lower mass proteins although they are not always observed for lower mass proteins and are never observed as multiple adds at low mass. Still, there existence is possible, given the known tendency for multiple matrix adds to...
(with significantly higher relative intensities than observed for lower mass proteins) in higher molecular weight proteins. Some ion species in addition to the known matrix adducts must be present in order to account for the observed experimental ion distributions. Future experiments include substituting trichloroacetic acid in the sample preparation for acetic acid to look for a mass shift in the adducts formed and chemical means to precipitate sulfate will be tried in an attempt to verify the sulfuric acid adduct.

Electron and Ion Conversion From Large Molecular Ions Incident on Various Surfaces

J. Martens, W. Ens, and K. G. Standing, Physics Dept., University of Manitoba, Winnipeg, Canada R3T 2N2

Introduction: Detection of small ions in time-of-flight (TOF) mass spectrometry normally requires the ejection of electrons from a surface, followed by electron multiplication, then current measurement or pulse counting. Electron conversion is a convenient mechanism for ion detection in TOF measurements because the electrons have a high velocity compared to the ions, so they produce little time dispersion. However, the efficiency of electron production depends on the velocity of the incident ion; it drops to a very low value below a “threshold” velocity $\approx 10^6$ cm/s [1]. Thus, detection of large ions by this process is difficult without application of very large accelerating voltages to the incident ions.

Evidence has been accumulating that detection of large molecules is accomplished mainly by secondary ion emission, rather than electron emission [2,3]. In order to investigate this question and to determine the properties of various surfaces as secondary electron or ion emitters, we have constructed a tandem TOF system where large molecular ions produced by matrix-assisted laser desorption are used as primary ions.

Experimental: A schematic diagram of the apparatus is shown in Figure 1. A wide range of molecular and cluster ions were produced by matrix-assisted laser desorption using sinapinic acid as a matrix. After mass selection in one TOF tube, they were incident on various surfaces. The ions produced at these surfaces were accelerated and mass analyzed in a second TOF tube. Positive laser desorbed projectiles of 13 keV or 15 keV were used. Normally, the potential of the investigated surface was $V_g = -5$ kV or $-8$ kV, (i.e. negative ion spectra were observed), but some spectra of positive ions were also taken using $V_g = +5$ kV. The resolution in the secondary spectra is limited by the time spread of the primary ions, which becomes larger for higher molecular weight projectiles.

Electron Conversion and Large Molecules: Our results confirm earlier findings that for large molecules incident on surfaces, ion conversion dominates electron conversion. For 23 keV insulin molecular ions incident on a CsI surface, only a small shoulder due to electrons is observed on the H$^-$ peak. This shoulder disappears when a magnetic field is applied. For molecular ions of trypsin, the magnetic field has no discernible effect on the secondary spectrum. In these measurements, a two grid system was used to prevent ions that originate at the grid from striking the target.

Secondary Ion Spectra: Detailed analysis is still in progress but the following observations can be made:

a) For incident projectiles of molecular weight greater than $\approx 5000$ u, the secondary spectra between m/z 10 and 80 are remarkably similar, independent of surface (see Fig. 2). The dominant ion in this range is at m/z 25, presumably CpH$^-$.

b) The H$^-$ ion falls off in intensity with respect to the larger ions as the projectile mass is increased. However, a signal from H$^-$ is observable for projectiles at least up to the monomer of albumin, and possibly for its dimer at mass 132 000 u.

c) Although an 18 keV insulin ion moves relatively slowly (about the speed of a 3 eV proton), it can cause the ejection of small intact molecular ions (Tyr-Gly) from surfaces.

The Mechanism of Ion Conversion: The similarity of the secondary ion spectra from insulin bombardment of different surfaces (above) suggests that the ions are produced by surface-induced dissociation. This interpretation is supported by the difference from the spectra obtained with a light projectile like benzopyrene (276 u), where desorption is the main process (Fig. 3).

Further evidence for surface-induced dissociation was obtained for positive secondary ion spectra from a CsI coated surface. As the mass of the projectile increases, the abundance of the Cs$^+$ ion desorbed from the surface decreases relative to the ions below m/z 100 (Fig. 3). For projectiles above mass $\approx 10 000$ u, no Cs$^+$ signal was observed. Since the relative H$^+$ yields also drops with increasing projectile mass, it may be partly accounted for by desorption from the surface.

Conclusion: For molecular ions above 10 000 u incident on a surface at $\approx 20$ keV, electron conversion is insignificant compared to ion conversion. The secondary H$^+$ yield also decreases with projectile mass, but H$^-$ ions are still observed for projectiles up to at least 66 000 u.

The distribution of secondary ions is sensitive to the nature of the surface for primary ions larger than insulin, suggesting that surface-induced dissociation is the main process of ion conversion.

The dominant negative secondary ion is at m/z 25 while the positive distribution peaks at about m/z 60.

This report discusses research directed towards optimizing and understanding laser desorption (LD) of neutral molecules. A variety of compounds were desorbed at the four harmonic wavelengths of a Nd:Yag laser (1064, 532, 355, and 266 nm). The jet entrained neutrals were post-ionized with 255 nm Multiphoton Ionization (MUPI) and mass analyzed with a RETOF MS. In principle, the advantage of separating the LD step from the ionization step is that each step can be independently optimized to yield improvements in system performance while allowing greater flexibility in both ionization and desorption conditions. In addition MUPI mass spectra are relatively easy to interpret since post-ionization of desorbed neutrals leads to the formation of pure molecular ions without adduct ion formation [1]. Finally separation of desorption and ionization allows direct probing of the significance of resonant sample absorption for efficient LD by investigating the neutral sample desorption efficiency as a function of desorbing wavelength and sample absorption.

In the first study the effect of sample absorption at the desorbing wavelength was investigated. Lower LD threshold energies were observed under resonant LD conditions, as shown in Table 1. The results also showed that resonant LD efficiently produced abundant neutral molecular species from all compounds studied [2]. Under non-resonant LD conditions no intact neutral molecules could be detected for the thermally labile compounds and these results suggested that substrate heating does not lead to desorption of intact molecules from thermally labile compounds.

* All values given in this table are observation thresholds.
* Numbers in parentheses are methanolic solution absorptivities in L/mol·cm.
* Pentacene values measured in benzene.
* Underlined thresholds were measured using focused LD conditions.
° (Fe') indicates that appearance of the molecular ion signal was observed to coincide with the observation of post-ionized substrate specific Fe neutrals.
* N.S. indicates no signal from post-ionized neutrals was observed.
In the second study 266 nm resonant LD of a number of peptides up to a mass of 2000 da was performed. Variations in the ionizing laser power and wavelength strongly indicated that formation of neutral sequence specific fragments occurs during the LD process. Both N-terminal fragments ($A'$, $C'$) and C-terminal fragments ($X_n$, $Y_n$, $Z_n$) were observed. As expected for neutral fragments formed during LD, only MUPI ionizable chromophore containing fragments were observed. These fragments can be useful in determining the amino acid sequence of peptides, as shown for Substance P in Figure 1.

![Fig. 1: 266 nm Laser Desorption of Substance P. The desorbed neutrals were ionized at a wavelength of 255 nm.](image)

In the third study absorbing matrices were added to assist the desorption of thermally labile compounds at non-resonant wavelengths. Beside the metal matrices Pt, Au and Ag, other absorbing matrices like Pentacene and Graphite could be used to enhance desorption of neutral molecules from non-absorbing compounds. Efficient laser desorption of thermally labile intact neutral molecules is only achieved by direct coupling of the desorbing laser energy into the sample bulk via absorption by the sample itself or by a dispersed absorbing matrix.

Recombinant human macrophage colony stimulating factor (rhM-CSF) is a hematopoietic growth factor that induces proliferation of cells of the monocyte/macrophage lineage. The CHO-expressed protein is a homodimer consisting of two 223 amino acid disulfide linked subunits which result from processing of a 553 amino acid precursor. In addition to extensive N- and C-terminal processing, each monomer is modified via the addition of two sites of N-linked glycosylation and several sites of O-linked glycosylation. Based on extensive mass spectrometric characterization of the monomeric subunits, the major species of native rhM-CSF have chemical molecular masses of 64-66 kD. Nonreducing SDS-PAGE yields an apparent molecular mass of 90 kD. This large discrepancy is due to the fact that migration in the SDS-PAGE system is based upon the physical properties of the protein. In addition, SDS-PAGE may be insensitive to small changes in mass due to the action of proteolytic or glycolytic enzymes.

The recent commercialization of LD-TOF offers an alternative to SDS-PAGE for the characterization of molecules produced by recombinant technologies. LD-TOF measures the chemical mass of the molecule and thus is unaffected by the physical/hydrodynamic properties of the protein. In addition, with reported mass accuracy of 0.1%, shifts in molecular mass may be assessed and assigned to specific modifications. Based on these features we have developed a strategy (Scheme I) which can provide structural information during the early stages of cell culture or purification. This method involves chemical or enzymatic manipulation of the molecule interspersed with molecular mass analysis. As an example, rhM-CSF was analyzed in its native state and after various manipulations. Analysis of native rhM-CSF by LD-TOF results in a broad peaks in the 64-66kD range due to the various sites of glycosylation within the dimer. Reduction and alkylation of rhM-CSF to produce monomeric rhM-CSF also yields a broad peak. This peak broadening may be a result of the contribution of the number of different carbohydrate forms of rhM-CSF. Removal of the C-terminus of dimeric rhM-CSF reduces the mass, however, the peak is still broad due in part to the remaining N-linked carbohydrate in the N-domain. Reduction and alkylation of this species yields monomeric N-domain and results in a slightly sharper peak in which at least two species are partially resolved. Finally, removal of the N-linked carbohydrate from this sample results in one very sharp peak and another partially resolved peak shifted up in molecular mass. The shift in mass may correspond to the presence of a single site of O-linked glycosylation. A comparison of these LD-TOF spectra with the same species run in nonreducing and reducing SDS-PAGE gels illustrates some of the advantages of LD-TOF MS. Based on these results as well as the increasing number of literature references, it is apparent that LD-TOF is a powerful addition to the analytical tools employed for the characterization of recombinant proteins (Scheme II). A few of the potential applications of LD-TOF mass spectrometry in the field of biotechnology include; accurate molecular mass determination of intact proteins, evaluation of posttranslational processing events or posttranslational modifications, assessment of protein heterogeneity due to proteolysis or incomplete processing, disulfide bond analysis, assessment and monitoring of protein integrity following certain process or purification steps, rapid characterization of a protein isolated from cell culture media without the need for extensive purification and the study of receptor/ligand interactions or receptor/ligand complexes from chemical cross-linking experiments.

In order to process LD-TOF data obtained in different laboratories a general PC based peak detection and processing software package has been developed. The program incorporates a set of flexible commands, employs mouse operation and can process laser desorption and electrospray ionization mass spectra. It contains a series of algorithms which effectively address several characteristic features of LD-TOF spectra including; broad, unresolved peaks, poor signal-to-noise and peak shapes and irregular baselines.

Mass Measurement Accuracy in
Matrix Assisted Laser Desorption Mass Spectrometry

J. S. Cottrell, K. K. Mock, M. P. Stevenson,
Finnigan MAT Ltd., Hemel Hempstead, Herts, UK

Matrix Assisted Laser Desorption Mass Spectrometry provides a rapid and sensitive means of obtaining molecular weight information from biologically important molecules such as proteins and carbohydrates. In most cases, mass analysis has been by Time-of-Flight (TOF) which provides excellent sensitivity and mass range but only limited mass resolution.

Factors which cause loss of resolution by peak broadening are less of a concern than those which cause a mass measurement error by shifting the peak centroid. Resolution is useful in mixture analysis, but this requirement can often be circumvented by prior use of chromatography. A working resolution of 500 to 1000 would probably suffice in most cases.

The greatest source of peak broadening and mass measurement error in Matrix Assisted LD is undoubtedly adduct formation [1].

The most prominent adduct observed in protein spectra is between the sample and the preferred matrix degradation product. In the case of sinapinic acid, this adduct gives rise to a satellite peak at (M+206). If this main adduct peak cannot be resolved from the sample peak then a substantial mass measurement error is introduced. The relative intensity of the adduct peaks tend to increase with mass so that, even if the main adduct peak cannot be resolved, the use of an internal calibrant which is sufficiently similar to the unknown as to exhibit a similar level of adduct formation will provide a partial correction.

It has been widely reported that increasing the laser power much over the threshold for ion production causes a dramatic broadening of the peakshape. This broadening is asymmetric, being mainly on the high mass side, so that the result is a mass deviation in addition to a reduction in resolution. It is likely that the several factors are responsible for the observed phenomena. We suspect that the main contribution comes from an increased degree of adduct formation, particularly the addition of one or more alkali metal atoms.

Other contributions to peak broadening and shifting are much less important than adduct formation. Ion - neutral collisions close to the sample surface are a possible cause of tailing on the high mass side of a peak. Significant levels of metastables have been observed using a reflectron mass analyser [2]. On linear instruments, the effect of metastable decay is limited to peak broadening caused by the release of kinetic energy during fragmentation.

Published data on measured energy spreads indicate that initial kinetic energies are low, in the region of 2 eV [3]. Even allowing for this to rise with increasing irradiance, it seems unlikely to be a significant contributor to the observed peak width.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The mass measurement accuracy which can be achieved without an internal standard is especially important. Many additional sources of error influence external calibration. Sample to sample variations in the length of the flight path, the energy of the ions, and the inherent precision of the timing electronics will appear as deviations in measured mass.

By careful attention to instrument design, it is realistic to expect a mass measurement accuracy of 0.1% without the use of an internal standard. Under favourable conditions, internal calibration can give an accuracy approaching 0.01%.

Examples for recent progress in matrix-assisted laser desorption/ionization (LDI) will be described in the following, for the ultraviolet (UV) range (A) and the infrared (IR) range (B):

(A) A series of experiments has revealed that 2,5-Dihydroxybenzoic acid (DHB) represents a matrix compound with excellent performance at wavelengths of 337 nm (nitrogen laser) and 355 nm (tripled Nd-YAG wavelength). Part of the advantages observed for DHB is based on a pronounced crystallization, if small volumes (0.1-1 μl) of solutions containing matrix and analyte are dried slowly. LDI from large crystal needles protruding towards the insight of the preparation shows high shot-to-shot reproducibility and allows for at least several hundreds of successive shots on the same spot at threshold irradiance without deterioration of the macromolecule ion signal. This indicates a very low (some tens of nm) ablation depth and an extremely low (in the attomol range) amount of analyte consumed for a mass spectrum. Further advantages of a DHB-matrix are lack of/low intensity adduct ion formation and a relatively clean and non-intense matrix background (below 300 Dalton). DHB can be used both for proteins, native and derivatized oligosaccharides, as well as for more complex glycoconjugates as glycosphingolipids; it can be applied over a wide range of protein concentrations (10⁻⁵ to 10⁻³ M), thus a sensitivity in the low fmol range (total sample amount loaded) is easily attainable. Furthermore DHB also exhibits a high tolerance for even high concentration impurities and biochemical reagents, such as inorganic salts, buffers and detergents, including SDS (sodium dodecysulfate). Figure 1 shows a matrix UVLDI mass spectrum of a hemoglobin sample containing 10% SDS, taken at 337 nm and accumulated from 20 single laser shots.

For a systematic investigation large (mm-size) crystals have been grown from saturated DHB solutions containing low concentration of proteins. Protein molecules are homogeneously distributed within the matrix host crystals as can be controlled by LDI from both crystal surface and its inside, the crystals even show the diffraction pattern of an undisturbed DHB single crystal in preliminary X-ray crystallography experiments. This intimate mixture of matrix and analyte molecules (but not of low molecular weight impurities) is therefore regarded to be the reason for the superior performance of these crystals, but also of that of crystal needles in regular preparations in LDI.

Until now matrix-LDI mass spectra have generally shown low mass resolution. Best results (mass res. of ≤ 500 FWHM) have surprisingly been obtained with linear TOF instruments using high initial ion acceleration. In the meantime it has been shown that peak broadening due to adduct ion formation, time spreads induced by secondary ions instead of electrons in the detection process and possibly metastable fragmentation of macromolecular ions may explain the observed large peak widths. Improved reflector-type TOF mass spectrometers have recently been installed proving that mass resolutions of more than 2000 are accessible also for matrix-LDI conditions of peptides and small proteins. Registered peak widths of less than
7 ns close to the pulse width of the laser indicate that there are no principal limits for the attainable mass resolution as supposed by delayed ion formation in the gas phase. Figure 2 shows a mass spectrum of porcine cytochrome C, measured with a reflectron TOF of 1.7 m equivalent drift path. The observed peak width of 10 Dalton (see extension) is close to the envelope of the isotopic distribution. A lower intensity peak due to the loss of water is also observed. This high mass resolution capability may become important for an improvement in mass determination accuracy, because peak components formed by cationized analyte molecules and adduct ion species can be sorted out; it will also increase the ability to determine chemical heterogeneity of compounds.

(B) The current experience for matrix-assisted Infrared LDI indicates that most of the features are comparable to those observed in the UV range. Experiments were performed with pulsed Er-YAG (2.94 μm), Er-YSGG (2.79 μm) and with a CO₂ laser (10.6 μm). Preparation requirements, accessible mass range and tolerance of even high concentration impurities are similar, a pronounced influence of the laser wavelength/matrix absorption properties is also observed. Differences appear in a smaller shot-to-shot reproducibility (except for liquid matrices) and a higher amount of ablated material. Furthermore, a tendency for the formation of more highly charged molecular ions becomes apparent, strongly pronounced for some matrix compounds. Advantages are a considerably larger number of usable matrices covering very different classes of organic compounds, as well as the availability of several liquid matrices (glycerol, triethanolamine and lactic acid). Most promising are initial results proving that Tris-buffer and especially water (by freezing down aqueous protein solution) are working as a matrix in IR-LDI. Figure 3 and 4 show spectra of cytochrome C and lysozyme taken from a dried protein solution in Tris-buffer and a small volume of a frozen aqueous protein solution respectively.

Laser Desorption (LD) and Plasma Desorption (PD) Mass Spectrometry have been used as off-line detectors for various forms of chromatography and electrophoresis. We routinely characterize isolates from column, thin layer and high-performance liquid chromatography. We have also developed simple approaches for collecting fractions from both supercritical fluid chromatography and capillary zone electrophoresis. Finally, we have developed initial methods for recovering proteins from SDS-polyacrylamide gel electrophoresis.

A reverse-phase HPLC chromatogram of an Olestra sample, prepared by reacting sucrose with a mixture of C\(_2\), C\(_4\), C\(_6\) and C\(_8\) fatty acids, is given in Fig. 1 (top). A total of 2 mg of sample was injected and seven fractions were collected as indicated. Excellent-quality mass spectra were obtained on all of the fractions, including fractions 3, 5 and 7. The spectrum of fraction 7 is given in Fig. 1 (bottom). It was obtained by PDMS analysis of about 1 µg of total mass. Given that about 10 major components were detected, it is clear that acceptable quality PD mass spectra can be obtained on about 100 ng of non-polar, high mass molecules. These materials would be difficult to analyze with on-line methods such as flow-FAB and electrospray ionization.

The experimental arrangement that we are currently exploring for SFC/PDMS is given in Fig. 2 (top). Analytes are detected using a non-destructive in-line UV cell. After detection, analytes which are normally vented to atmosphere are simply intercepted with a PDMS sample foil. The fraction of the eluant that sticks to the surface is then available for MS analysis. SFC peak widths are typically broad enough that it is easy to collect fractions even when they elute adjacent to one another in the chromatogram. Fig. 2 (middle) shows a supercritical fluid chromatogram of a commercial nonionic surfactant mixture. Eight fractions were collected from a single injection of this mixture. The PD mass spectrum of a representative fraction, indicated with an arrow, is given in Fig. 2 (bottom). Excellent-quality spectra were obtained with only a few minutes of sample integration time. Off-line PDMS detection limits for nonionic surfactants are presently about 5 ng (injected onto the SFC). We are currently attempting to develop SFC collection methods that are compatible with the use of flame ionization detectors.

The approach used to collect fractions from CZE employs a porous glass joint near the cathodic end of the separation column (1,2). We have previously demonstrated sub-picomolar PDMS detection limits for small synthetic peptides collected from CZE(2). Initial results obtained using matrix-assisted laser desorption mass spectrometry are also very encouraging. The LD mass spectrum of 1.5 pmol of a bovine trypsinogen isolate (a total of 3 pmols of analyte was initially injected onto the column) is given in Fig. 3. Even larger proteins such as bovine serum albumin have been successfully collected and analyzed by LDMS.

We are currently using electroelution to facilitate the recovery of large proteins from SDS-PAGE. Protein recoveries, determined in separate quantitative HPLC experiments, are in the range of 30 – 40%. A LD mass spectrum of carboxymethylated lactalbumin, electroeluted from an SDS-polyacrylamide gel after electrophoresis, is given in Fig. 4. The signal-to-noise ratio is fairly weak, possibly because SDS quenches LDMS response(3). In the example shown, we simply used a hydrophilic membrane to retain the protein, while SDS and other low-molecular-weight impurities were washed through. Overall sensitivity will hopefully increase as improved methods for SDS removal are developed.

Fig. 2 Experimental arrangement for offline SFC/PDMS (top); chromatogram of a commercial nonionic mixture (middle); PD mass spectrum of the indicated component (bottom).

Fig. 3 LD mass spectrum of 1.5 pmols of bovine trypsinogen isolated from CZE.

Fig. 4 LD mass spectrum of carboxymethylated lactalbumin electroeluted from an SDS-polyacrylamide gel.
CO$_2$ laser desorption of organometallic complexes in the source cell of an FTMS-2000 dual cell FT-ICR (Extrel, Madison, WI) gives dramatically different product ions in the two cells of the instrument. In the source region we observe the parent ion and low energy fragments ions. In the analyzer region the bare metal ion is the base peak. (Figure 1) The intensity of the ions in the analyzer region are 10-50 times greater than the ion in the source region. The partitioning of the laser desorption products is not observed to depend on the trapping voltages or the voltage on the conductance limit. Even with 10 V on the conductance limit we still observe the atomic metal ion in the analyzer region. This phenomenon is observed for both neutral complexes such as Re$_4$H$_4$(CO)$_{12}$ and ionic complexes such as [Bu$_4$N]$^+$Pd[dmit]$^-$. The partitioning of the products does appear to depend on the laser focus and energy. When the beam focus was changed the intensity in the analyzer region was significantly reduced and in some cases the metal ion was not observed. The dependance of the partitioning of the product ions on laser focus and power is still under investigation.

Re$^*$ (IP = 7.76 eV) in the analyzer region reacts by charge transfer with NO (IP = 9.26 eV) added through a pulse valve. This reaction is not observed to go to completion but it indicates that at least some of the Re$^*$ in the analyzer region is in an excited state (Re$^*$a$^3$D = 9.47 eV). The reaction is slow with an apparent rate constant on the order of 2x 10$^{-11}$ molecules cm$^3$ s$^{-1}$. Re$^*$ reacts with aromatic molecules by dissociative addition. Benzene reacts with Re$^*$ by successive dehydrogenation steps;

$$\text{Re}^* + C_6H_6 = \text{ReC}_6H_4^+ + H_2$$
ReC₆H₄⁺ + C₆H₆ = Re(C₆H₄)₂⁺ + H₂
Re(C₆H₄)₂⁺ + C₆H₆ = Re(C₆H₄)₃⁺ + H₂

Also observed were Re(C₆H₄)(C₆H₆)⁺ and Re(C₆H₄)₂(C₆H₆)⁺ and at long reaction time these clusters became dominant. Re⁺ also reacts to dehydrogenate toluene.

This partitioning phenomenon is a way to easily produce atomic metal ions of reactive metals or radioactive metals such as ⁹⁹Tc for ion molecule reaction studies.
AN ELECTROSTATIC ENERGY ANALYZER TIME-OF-FLIGHT INSTRUMENT FOR FUNDAMENTAL STUDIES OF MATRIX-ASSISTED-UV-LASER DESORPTION IONIZATION

L.J. Waller, T.L. Uhlenbrock, F.H. Strobel, and D.H. Russell
Department of Chemistry, Texas A&M University, College Station, Texas 77843

The E-TOF/R-TOF instrument is shown schematically in Figure 1. The ions are extracted and focussed by a three element lens SIMS source. MS-I consists of a Kratos MS-9 electrostatic energy analyzer. MS-II consists of a multi-element reflectron with an angle of 0°(co-linear). Time-of-flight spectra can be obtained by using a time-to-digital converter (LeCroy model 4208 TDC), a 350 MHz digital oscilloscope (LeCroy model 9450), or a transient recorder (LeCroy model TR882D 200 MHz digitizer). All of the TOF data acquisition modules are interfaced to an IBM-AT(286) computer by using a National Instruments GPIB mainframe card. Event sequencing for the various experiments is controlled by a EG&G Princeton Applied Research digital delay generator model 9650.

The laser systems consist of 1) a Laser Science Inc. cartridge type N, laser (model VSG 337 at a 1-20 Hz pulse rate) with a pulse duration of 3 ns that is used for ionization, and 2) a Questek Series 2000 Excimer Laser (200 mJ(Ar/F₂, 193 nm) 1-80 Hz pulse rate) with a pulse duration of 8-17 ns that is used for photodissociation.

The reflectron TOF to be used for the E-TOF/R-TOF consists of a total flight path of 3.6 meters and the reflection angle is approximately zero degrees. The advantages of a colinear reflectron are high transmission and high mass resolution in comparison to that obtained with larger (5°-20°) reflecting angles. The colinear arrangement is also convenient for positioning detectors to detect both neutrals and ions. For example, neutrals forms by metastable ion dissociation reactions, collision-induced dissociation (CID), or photodissociation in the region between MS-I and MS-II are detected by a microchannel plate detector (detector #2) positioned behind the reflectron. Ions are detected by the microchannel plate detector (detector #1) positioned at the entrance to the reflectron TOF.

A particular advantage of the ion-neutral correlation experiment is the m/z resolution of MS-II is not determined by the temporal characteristics of the ionization process. For example, unimolecular dissociation, collision-induced dissociation, or photodissociation of m,* (mass-selected by MS-I) produces a fragment ion (m,*) and a neutral (m,0), and the velocity of m,0 and m,* is the same as that of m,*.

Neutral fragment will not experience any force due to the reflectron and will strike detector #2 and produce a signal. m,* will be decelerated upon entering the reflectron, eventually reaching zero velocity, at which point its direction is reversed. m,* is then re-accelerated back to its initial velocity. Because the initial velocities of the fragment ions is independent of the m/z value, the time that an ion spends in the reflectron depends upon the rate of deceleration and re-acceleration. The rate of deceleration/re-acceleration is proportional to the m/z of m,*.

The ion-neutral correlation experiment can be performed in two ways. The first is to use the neutral signal as the start for the time-of-flight measurement and measure the arrival time for the ion. The second method uses the ion as the start event for the time-of-flight experiment while delaying the signal from the neutral detector. The two methods should give identical spectra. A special requirement if this experiment is the need for a low beam current density in order to eliminate (or minimize) the number of false correlations.

The standard mode of operation for time-of-flight instruments is to form ions by using a pulsed ionization source, pulsed laser (for multiphoton ionization or desorption), and, assuming the ions are formed with a narrow distribution of kinetic energies, the mass resolution of the time-of-flight measurement is limited by the temporal characteristics of the ionization pulse. This is the reason that the ionization pulse durations of 1-3 nanoseconds are required for high mass resolution measurements. The use of short ionization pulses presents a major obstacle to performing laser ionization/laser photodissociation tandem mass spectrometry experiments. For example, the efficiency of single photon photodissociation is quite low ranging from a few per cent to 0.1-0.5% for large molecules. If we assume
a photodissociation efficiency of 0.1%, then $10^6$ primary ions yields 10 fragment ions. Because the number of reaction channels available to the activated ion is quite large (say 10-15 structurally significant fragment ions are typical for relatively small peptides), it may be necessary to accumulate data from $10^6$-10$^7$ events in order to collect a statistically significant data set. If the repetition rate of the laser is 10kHz, a data set of $10^6$ events can be obtained in 100 seconds. However, as the ion yield or photodissociation efficiency decreases, as is observed for increasing molecular weight, the number of events required to collect a statistically significant data set also increases.

An alternative approach to performing measurements with a pulsed ion beam is to form large numbers of ions per ionization pulse and collect the data by using a transient recorder. This is a common mode of operation for matrix-assisted laser desorption where the yield of ions per laser pulse is high, e.g., 10-100 ions are formed for each laser pulse. The limitation of this experiment is the high rate of sample consumption and the inherent loss in sensitivity over single ion counting experiments. The sample consumption rate does not effect acquisition of normal mass spectral data but this does pose a problem for signal-averaging. In addition, because the efficiency of the activation/dissociation process is low the transient recorder mode is less sensitive than TDC.

A complicating factor associated with laser desorption ionization, and especially matrix-assisted laser desorption, is the temporal evolution of ions following laser excitation. The laser pulse width is approximately 3 ns but the arrival-time distribution for the [M+H]$^+$ ions are bimodal. One portion of the arrival-time distribution extends to 50-70 us. This result complicates tandem mass spectrometry experiments with an instrument such as shown in Figure 1 in two ways: (i) the start signal for the time-of-flight experiment is not sufficiently defined to give acceptable mass resolution, and (ii) to achieve reasonable mass resolution it is necessary to pulse the ion beam entering MS-II such that a small slice of the arrival distribution is selected. Although such an experiment achieves the desired result, the sensitivity is reduced because a substantial portion of the ions produced are not analyzed.

Figure 1. Schematic diagram of the pulsed ion source/pulsed laser E-TOF/reflection TOF.
MEASUREMENT OF INITIAL TRANSLATIONAL ENERGIES OF PEPTIDE IONS IN LASER DESORPTION/IONIZATION MASS SPECTROMETRY

Y. Pan and R. J. Cotter, Middle Atlantic Mass Spectrometry Facility, Johns Hopkins School of Medicine, Baltimore MD 21205

Initial translational energy distributions of [Arg]-vasopressin and lysozyme molecular ions generated by matrix-assisted UV laser desorption/ionization were measured using a delayed ion extraction linear time-of-flight mass spectrometer. Energy distributions of the nicotinic acid matrix ions, with or without the presence of peptide, were also measured. These were compared with the energy distribution of gramicidin ions using IR laser desorption.

The principles of determining ion translational energy distribution using the delayed ion extraction TOF method have been derived in a previous study by Spengler and Cotter. A Q-switched frequency quadrupled Nd:YAG laser (Continuum YG660, Santa Clara, CA) was used for the UV laser experiments. A CO₂ pulsed laser (Tachisto 215A, Needham, MA) was used for the IR laser experiments. Ions were desorbed for a silver metal surface.

In a delayed ion extraction TOF experiment, ions formed during the short laser pulses (t=0) are extracted into the ion acceleration region at a later time (t=t₀). During the time t₀ ions drift in the field free region at their initial desorption velocities. The velocity components at direction normal to the desorption surface can be calculated as a function of t₀’s and the location of the probe. The ion velocities then can be directly inverted to the translational energies of the ions. The ion population at a particular delay time was measured from the ion signal intensity in the mass spectrum. The experimental method used here can be considered as a more direct way of measuring initial translational energies of ions. In contrast to ion retarding potential techniques or peakwidth analysis, the ion energies are determined independently of ion acceleration.

The initial translational energy distributions of both [Arg]-vasopressin (Figure 1) and lysozyme molecular ions (Figure 2) desorbing from the matrix mixture by UV laser irradiation markedly deviate from normal distribution. From the measurements shown in Figures 1 and 2, the molecular ions of vasopressin (m/z 1085) have typical translational energies of about 2 eV with 8 eV (FWHM) energy spread, the molecular ions of lysozyme (m/z 14300) have typical translational energies of 5-8 eV with 15 eV energy spread. The unsymmetrical ion populations at the high energy side is in contrast to the measured initial translational energy distribution of gramicidin molecular ions by IR laser irradiation as shown in Figure 3. The high energy ion population therefore may be attributed to the effect of the matrix ions and neutral molecules as a result of a collective desorption, of which the peptide ions may receive high translational energies by moving with small particles of high velocities. This become more evident as the speed distributions of both peptide and matrix ions were examined. Two laser irradiances were used for lysozyme energy measurements. No significant differences in measured translational energy distributions were observed as the laser irradiance increases from the threshold to a much higher irradiance. Increase in laser irradiance only increases the total ion yields (in this case it increases by 4 times) but does not change the translational energy distribution (Figure 2). This observation is in consistent with other studies.

The translational energy distributions of the nicotinic acid matrix ions are also worth noticing. (Figure 4). The energy distribution of nicotinic acid ions from the vasopressin/matrix mixture is basically the same as that of the pure matrix with a maximum ion population at about 1 eV. However the energy distribution of nicotinic acid ions from the lysozyme/matrix mixture shifts much to the lower energy side with a
maximum ion population at less than 0.2 eV. This decrease in translational energy of the matrix ions may be a result of collisions of the small matrix ions with large peptide ions as they move as packets.

Figure 1. [Arg] vasopressin/nicotinic acid mixture by UV/LDI. 1 ul 10^-6 M peptide aqueous solution and 1 ul matrix solution were applied to the silver probe and air-dried. (Sample preparations were the same for all experiments). 150 single shot spectra were accumulated for each delay time. The distance from the probe surface to the center of the drawout window (defined as the “probe distance”) was 14.5 mm. Plotted is the measured ion density of the protonated peptide molecular ions (m/z 1085) against translational energy of the ions.

Figure 2. Lysozyme/nicotinic acid mixture by UV/LDI. 1 ul 10^-6 M peptide aqueous solution and 1 ul matrix solution were used. 200 single shot spectra were accumulated for each delay time. The probe distance was 2.5 mm. Plotted is the measured ion density of peptide molecular ions (m/z 14300) against translational energy of the ions from two experiments. Ion densities from the experiment using lower laser irradiance were scaled up to give a better comparison of the two experimental results.

Figure 3. Gramicidin by IR/LDI. 1 ul 10^-4 M peptide aqueous solution was used. The laser was operated at 1 Hz. 50 spectra were accumulated for each delay time. The probe distance was 15 mm. Plotted is the measured ion density of the protonated peptide molecular ions (m/z 1198) against translational energy of the ions.

Figure 4. Nicotinic acid by UV/LDI. 1.5 ul 10^-5 M nicotinic acid aqueous solution were used. The Q-switch was operated at 2 Hz. 50 spectra were accumulated for each delay time. The probe distance was 14.5 mm. Plotted is the ion density of the protonated nicotinic acid molecular ions (m/z 124) against translational energy of the ions from three experiments.

A UV Laser Desorption Mass Spectrometer for Routine Use in a Life Science Laboratory.

Matthias Mann, Ole Vorm and Peter Roepstorff
Department of Molecular Biology, Odense University, DK - 5230 Odense M, Denmark

Following Hillenkamp and Karas' revolutionary announcement of desorption of very large biopolymers using UV laser mass spectrometry (LD), several groups have started building UV-LD mass spectrometers. However, laser desorption mass spectrometry is still operationally complex, mainly owing to the difficulties in finding and reproducing correct measurement parameters and sample preparation conditions. Furthermore, systems used so far have usually been designed for and used in research environments.

Here we describe a UV LD mass spectrometer built with the following goals in mind: (a) ease of use, (b) high sample throughput, (c) low maintenance, and (d) sensitivity, resolution and mass accuracy as high as other published systems. We modified a Bio Ion 10 mass spectrometer originally used for plasma desorption mass spectrometry, which makes sample introduction both convenient and efficient. A low cost and virtually maintenance-free nitrogen laser was coupled via an optical bench to the apparatus. Laser intensity and the position of the laser spot on the target can be adjusted by elements on the optical bench.

A digital oscilloscope (LeCroy 9450) measures the output of a double channeltron with up to 400 megasamples/s and with a memory depth of 50000 samples. The data is transferred to a Macintosh II computer where it can be displayed and manipulated using a program written by us. That program, which also controls the laser, follows standard Macintosh conventions for the graphical user interface making it easy to use. All acquisition parameters are controlled from the computer screen limiting operator interaction with the instrument to sample introduction.

As table 1 shows, the apparatus is capable of excellent mass accuracy, approaching that of electrospray data. In our preliminary experience we find this accuracy to be typical of proteins for which an adequate signal - to - noise ratio can be obtained by LDMS. Results for the resolution (table 2) match published results.

We conclude that the hardware of our simple device is fully competitive with other systems while operation is made easier. In figure 2 one of our first applications of this instrument to the solution of problems in protein chemistry is shown. Further work will focus on improving the signal - to - noise ratio, developing software to automatically perform most of the acquisition process and on sample preparation to make LDMS results more reproducible.

Figure 1. LDMS can be used to rapidly check the correct expressing of recombinant AcylCoA Binding Protein (ACBP) in different host organisms. The top part of the left figure shows a spectrum of recombinant ACBP expressed in E. coli. The bottom part shows recombinant ACBP derivatized for binding studies. The expected mass difference of 104 Da is confirmed by LDMS.

Figure 2 (below). Rapid check of the homogeneity of recombinant ACBP. Comparison of its peak width those of Insulin and Myoglobin shows that this ACBP sample is heterogeneous (here probably due to partial oxidation of the two methionyl residues).
Matrix-assisted laser desorption (MALD) ionization provides a unique opportunity to probe fundamental processes involved in desorption ionization. For instance, there seems to be little doubt that the MALD process is initiated by resonant photon absorption (probably single photon, e.g., S\textsubscript{0} --- S\textsubscript{1}) by a molecule in a dense medium. Although MALD can be achieved by pumping higher lying electronic states of the matrix, there are probably very few advantages to using higher photon energies. In fact, there may be distinct disadvantages for use of higher photon energies. The rational for this view is based on our current view of the MALD process. Figure 1 presents a pictorial view of our proposed mechanism. The steps include: 1) photon absorption to produce an ensemble of S\textsubscript{1}; 2) internal conversion of some S\textsubscript{1} species results in heating of a localized region; 3) the rapid heating causes ejection of "cluster species" from the surface, e.g., [(S\textsubscript{1})\textsubscript{n} --- S\textsubscript{0}] or [(S\textsubscript{1})\textsubscript{n} (A\textsubscript{n}) --- S\textsubscript{0}], where A represents analyte molecules; 4) the enhanced acidity of S\textsubscript{1} (relative to S\textsubscript{0}) results in proton transfer to yield [(S\textsubscript{1})\textsubscript{n} (A\textsubscript{n}) --- AH\textsuperscript{+} --- S\textsubscript{0}]; 5) evaporation of the cluster yields solvated adducts, [(S\textsubscript{1})\textsubscript{n} --- AH\textsuperscript{+}] and [(S\textsubscript{1})\textsubscript{n} --- S\textsubscript{0}] or intact analyte molecular ions [A + H\textsuperscript{+}].

The proton transfer will be quenched if S\textsubscript{1} decays by radiative or non-radiative pathways, e.g., S\textsubscript{0} --- A. Coupling of electronic energy transfer can be eliminated by using matrices where the adiabatic transition energy (E\textsubscript{a}) for the matrix molecules is less than that for the analyte (Figure 2). In general, pumping of high energy transitions, S\textsubscript{1} --- S\textsubscript{2}, will be less effective for MALD because of electronic energy transfer and the coupling of these states to the triplet manifold. For example, the types of molecules that work best for

---

MALD, polar aromatics, the higher lying electronic states are more strongly coupled to the triplet manifold, this will be advantageous only if the acidity of the $T_1$ state is sufficient to promote the proton transfer reaction. Note: There are some cases where the acidity of the triplet is greater than the acidity of the singlet state.

---

HPLC-Frit-FAB-MS of Peptides Using Thioglycerol as Matrix

Larry Shampine, Daniel B. Kassel, and Robert J. Anderegg
Glaxo, Inc. Research Triangle Park, NC 27709

HPLC has been effectively coupled to mass spectrometry using several continuous-flow (CF)-FAB or LSIMS methods. CF-FAB has also been used in a flow-injection mode because of reports of lower matrix interference and decreased suppression of ion signals in mixtures as compared to static FAB. In most situations, a liquid matrix is added to the LC mobile phase or added co-axially post-column to improve the stability of the secondary ion beam. Glycerol is used almost exclusively for this purpose, although many other matrices (eg. thioglycerol, nitrobenzyl alcohol, etc.) are commonly employed for static FAB (1).

In a preliminary set of experiments, we observed that thioglycolrol rather than glycerol in the mobile phase during LC-MS decreased the matrix background and improved the ion signals from peptides. This study attempts to characterize the utility of thioglycerol in LC-frit-FAB-MS.

When glycerol is used for a matrix in either static or CF-FAB, a high background of clusters is evident. The regular pattern of ions m/z 645, 737, 829, etc correspond to clusters of (glycerol_n + H)^+. Although these ions are suppressed somewhat when sample elutes and can be further reduced by background subtraction, they still pose a potential interference if they coincide with the mass of the molecular ion or important fragment ions. The background from thioglycerol is substantially less, especially at higher mass (ie. > m/z 600).

Figure 1 shows a comparison between the absolute abundances of peptide ions when glycerol and thioglycerol were added as the matrix. The protonated molecular ion and a series of sequence-specific fragment ions were considered. Although the abundance of sequence-related fragment ions is roughly comparable in either glycerol or thioglycerol, the abundance of the protonated molecular ion is substantially higher in thioglycerol than in glycerol. This enhancement is 2 to 4-fold for the peptides tested and, together with the decreased background, leads to an even greater improvement in signal/noise. The effect seems to be exaggerated at higher molecular weight (> 2000).

The optimum conditions for LC-MS using glycerol as a matrix have been reported (2). Because of the lower viscosity and higher volatility of thioglycerol, one might expect optimum conditions to be somewhat different. Fig. 2 shows the sensitivity of peptide ions as a function of thioglycerol content (flow injection). Both the protonated molecular ion and selected fragment ions reached a maximum at about 2.5% thioglycerol. At lower percentages of thioglycerol, the ion signal was somewhat unstable and the peak shape was poor or split. The poor peak shape could be overcome to some extent by increasing the flow rate of the solution from 5 ul/min to 15 ul/min, but the ion source pressure was correspondingly higher.

Ion source temperature was varied from ambient to about 55 ° C. The optimum was 40-42 °, with a sharp drop in sensitivity above 50 °. This is somewhat lower than the optimum for glycerol (50-55 °), as would be expected based on the higher volatility of thioglycerol.

A possible concern of using thioglycerol as a mobile phase additive in LC-MS is that peptides containing disulfide bonds may be reduced by the thiol. To test this, an oxytocin metabolite containing a disulfide was analyzed by static FAB in glycerol both before and after 24 hr in a solution of acetonitrile:water:TFA:thioglycerol (2%). Some slight increase in the amount of reduction was apparent, but the predominant species was still the peptide with an intact disulfide bond. The acidity of the mobile phase used here and in most reversed-phase LC experiments undoubtedly helps to prevent more extensive reduction.
LC-MS using thioglycerol in the mobile phase produced the same improvement in peptide signal that was observed in flow injection. Peak shapes were slightly broader and reproducibility was somewhat poorer than when using glycerol in the mobile phase. Although the LC-MS results when using a 4.6 mm (i.d.) column with post-column stream-splitting showed the same improvement as did flow injection, when 1 mm columns or packed capillaries (350 μm, i.d.) were used, some degradation of the column performance seemed to occur in the presence of thioglycerol. The performance could be recovered by washing extensively with methanol. It is unclear at this time if the poorer performance resulted from some alteration of the interaction between the analyte and the stationary phase, or was simply a general increase in baseline caused by thioglycerol, but further study of this phenomenon is warranted.

Ion Abundance vs. Percent Thiglycerol in Mobile Phase
FACTORS AFFECTING BAND BROADENING IN LC-FABMS SYSTEMS USING PRECOLUMN ADDITION OF THE VISCIOUS MATRIX

Jean-Pierre Gagné, A. Carrier, and Michel J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7

In systems using continuous flow fast atom bombardment to interface liquid chromatography to mass spectrometry (LC-FABMS), the addition of a viscous matrix to the mobile phase is essential for the proper ionization of the analytes to occur. Although post-column addition of the matrix has been suggested, it is usually easier and more common to achieve analysis by pre-column mixing of the matrix to the mobile phase. In the latter case as the concentration of the matrix exceeds a few percent the overall chromatographic performance of the system is reduced as shown recently using compounds such as peptides, organic acids and phenolic compounds (1). The broadening resulting from pre-column addition can be examined by monitoring the changes in the normalized peak width (w₁/₂/tn). As shown in Figure 1 the increase in Gly content between 0-30% induces broadening (w₁/₂/tn). For p-hydroxybenzoic acid, the less retained compound, broadening can be as high as 67% at 30% Gly. For vanillic acid and met-enkephalin the increases in broadening are 37% and 28% respectively. This correlates well with the decrease in number of theoretical plates and loss in resolution observed with the increase in Gly content (1). In order to find the source of broadening examination of the variances associated with the system is necessary.

In multi-component systems such as LC-FABMS, induced broadening of the input signal can be described by the sum of individual variances associated with each component. The total variance, σ² = σ²(chr) + σ²(int) + σ²(ms), as shown in equation [1].

σ² = σ²(chr) + σ²(int) + σ²(ms)  [1]

The chromatographic variance (σ²(chr)) can be expressed as the sum of the variance occurring in the column (σ²(c)) and extra column broadening (σ²(ex)). Broadening occurring within the column results from kinetic (σ²(k')) and extra column broadening (σ²(ex)).

H = A exp(B/Gly) + C/Gly + Dm + T (1 + E + 1/k' + 1/Dm)² [2]

σ²(chr) = σ²(chr) + σ²(int) + σ²(ms)  [3]

Figure 2 shows typical Van Deemter plots obtained for met-enkephalin when Gly in the mobile phase was increased from 0-30%. The data indicate that as the concentration of Gly is increased, the C term steadily increases as shown by the increase in the slopes. No significant difference was observed in the C term for Gly values below 3% but as the value increased above 5% the slope steadily increased. Since the C term depends on k' and Dm, it is possible to identify the factors responsible for the loss in efficiency observed in the chromatographic system when the concentration of the matrix is increased.

σ²(chr) = σ²(chr) + σ²(int) + σ²(ms)  [4]

Figure 2 shows typical Van Deemter plots obtained for met-enkephalin when Gly in the mobile phase was increased from 0-30%. The data indicate that as the concentration of Gly is increased, the C term steadily increases as shown by the increase in the slopes. No significant difference was observed in the C term for Gly values below 3% but as the value increased above 5% the slope steadily increased. Since the C term depends on k' and Dm, it is possible to identify the factors responsible for the loss in efficiency observed in the chromatographic system when the concentration of the matrix is increased.

In LC-FABMS other variances are also likely to act as dispersion operators. The dispersion operators in the interface are the transfer capillary (0.075 x 1000mm) and the liquid droplet which forms on the probe tip. The total variance (σ²(ms)) associated with the interface is the sum of the variance of the interface and the contribution from the probe tip.
tube ($\sigma^2_d$) and the variance associated with the droplet ($\sigma^2_g$). The contribution of the transfer capillary tubing estimated from the Taylor-Golay relationship is less than 0.15 µL at 30% Gly and this dispersion can be lower for a smaller capillary. Thus the dispersion produced by the capillary is small. Volumetric dispersion also occurs at the end of the probe and it is relatively difficult to evaluate since there are many phenomena occurring in the droplet. These are mainly related to evaporation, mixing and diffusion. In order to estimate that dispersion the droplet can be assumed to act as a "connecting tube" and the variance associated with it can be obtained from the Taylor-Golay relation (3). Alternatively, the droplet can be considered as a mixing chamber in which case the variance associated with it can be obtained from equation [4]. Values for the variance ($\sigma^2_g$) can be obtained (Table 1) using each of these models. The data show that the laminar contribution is superior to the mixing effect. Furthermore, it can be observed that the effect of the addition of glycerol increases the value of the laminar contribution. The dispersion created by the droplet at the tip of the FAB probe is estimated between 0.63 and 1.47 µL when the concentration in glycerol is around 30%. These values appear as minimal since other broadening phenomena are occurring at the tip and it is known that the concentration of Gly on the tip can be as high as 90%. A dispersion of 1.47 µL appears reasonable under those circumstances and the main contribution to broadening of the interface is due to the formation of the liquid droplet which represents ≈35% of the total broadening measured ($1.47^2/2.5^2$). Thus, the measured dispersion implies that the interface can contribute significantly to the broadening of the chromatographic band especially for narrow bands such as those found with capillary columns. The signal can also be broadened by the mass spectrometer ($\sigma^2_{ms}$) if the scanning speed of the instrument is too slow. For compounds that elute in narrow bands, the cycle time should be of the order of 0.5-1 second to maintain chromatographic integrity and longer cycle times should be avoided.

SENSITIVITY ENHANCEMENT FOR STATIC AND CONTINUOUS FLOW FAB/MS ANALYSIS OF NUCLEOTIDES BY QUATERNARY AMINE SURFACTANTS

Steven M. Musser and James A. Kelley
Laboratory of Medicinal Chemistry, DTP, DCT, NCI, NIH, Bethesda, MD, 20892

Our laboratory is concerned with the in vitro and in vivo analysis of nucleoside analogs and their metabolites as part of the preclinical evaluation and development of these compounds as new anti-AIDS and antitumor agents. These drugs are usually activated by intracellular phosphorylation. Identification of phosphorylated metabolites is therefore important in determining the mechanism of action and assessing the effectiveness of these drugs. Nucleotide metabolites isolated from cells have proven to be difficult to analyze using mass spectrometry because of salt contamination, low sensitivity and chemical instability. Continuous flow fast atom bombardment (CF-FAB) has been shown to improve sensitivity for nucleotides when compared to static FAB (1), however, the sensitivity is not high enough for identification of nucleotide metabolites from biological matrices. SIMS experiments have demonstrated a dramatic increase in sensitivity for adenosine triphosphate when hexadecylpyridinium acetate was with the matrix (2). Therefore, in this study we have evaluated the utility of quaternary amine surfactants for CF-FAB analysis of nucleotides.

A 300-350 µl/min flow from a Spectra-Physics model 8800 ternary gradient HPLC pump was split prior to the injector to provide a flow rate of 4-5 µl/min. A 0.30 mm i.d. X 250 mm glass lined stainless steel capillary column was packed with 3 µm Nucleosil C18 and used for the separations. For CF-FAB experiments the following mobile phases were mixed to provide optimum elution of the various nucleotides: (A) 94 % H₂O:5 % glycerol:1 % ACN, containing 10 mM ammonium formate and 50 µM dodecyl trimethylammonium hydroxide (pH 8.2); (B) 45 % H₂O:5 % glycerol:50 % ACN, containing 100 mM ammonium formate and 50 µM dodecyl trimethylammonium hydroxide (pH 8.2). Mass spectra were obtained on a VG 7070E mass spectrometer (6 kV accelerating voltage) using xenon fast atoms for ionization. A mass range 1100 - 100 amu was scanned at a rate of 10 sec/dec for all experiments. For static FAB experiments, 1 µl aliquots of the nucleotides dissolved in H₂O were mixed with matrix on the probe tip. For CF-FAB experiments 2 µl injections of the nucleotide standards were made onto the µ-HPLC column. The eluent from the µ-HPLC column was directed into the ion source via a 1 m X 50 µm i.d. fused silica capillary. In CF-FAB experiments the probe tip was heated to 55 °C.

Use of the quaternary amine surfactant, dodecyl trimethylammonium hydroxide, along with µ-column HPLC-CF-FAB provides several advantages over CF-FAB and static FAB for nucleotide analysis:

1. The quaternary amine surfactant serves as a an ion pair reagent that facilitates nucleotide separation on reverse phase columns.
2. Use of a column removes the majority of salt interferences from the sample. This increases sensitivity and decreases FAB spectrum complexity.
3. The physical properties of the surfactant increase the "wetability" of the probe tip and decrease the probe tip and decrease the surface tension of the matrix film. This results in better flow stability and less noise.
4. Overall, using the proper surfactant provides a 10X increase in sensitivity over CF-FAB alone and a factor of 100X increase over static FAB analysis.

While some longer chain surfactants provided slightly better sensitivity, dodecyl trimethylammonium hydroxide resulted in better overall performance, particularly in terms of chromatographic separations.

Continuous Flow-Fab Mass Spectral Analysis of UDP-Sugars from Mammalian Cells

Mary F. Grubb and Steven M. Musser
National Cancer Institute, NIH, Bethesda, MD 20892

Interest in the analysis of UDP-sugars is attributed to their position in cells in the synthesis of a wide array of biochemical processes. The polarity and lack of volatility of these compounds make them ideal candidates for LC-MS.

Detection and identification of UDP-hexoses and UDP-hexosamines in extracts of mammalian cells (mouse leukemia, L1210) was accomplished by ion-pair microcolumn LC-frit FAB MS. The system comprised a 0.25 x 250 mm stainless steel glass lined capillary packed with 3 μm particles (C-18, Nucleosil) interfaced via a 1 m capillary to the FAB source. Mobile phase was split prior to the injection site such that flow into the source was 4-5 μl/min. Components of the mobile phase were 10 mM ammonium formate and 25 μM dodecyl trimethylammonium formate, pH 8.2, with 1% each acetonitrile and glycerol (A) or 100 mM ammonium formate and 25 μM dodecyl trimethylammonium formate, pH 8.2, with 50% acetonitrile and 1% glycerol (B). From 0-10 min, B was increased linearly from 0 to 15%. Under these conditions, UDP-glucose and UDP-xylose elute at 17.0 min, and UDP-N-acetylglucosamine at 20.5 min. The peaks overlap, but their maxima are resolved enough to allow for clean spectra.

Cell extracts were prepared from cultures grown in suspension by precipitating rinsed cells in a 60% methanol. Dried extract residue was filtered once, subjected to preparative HPLC, and the eluate refiltered prior to LC-MS analysis. The preparative LC step was necessary to isolate the UDP-sugar fraction from other nucleotides and salts which could interfere in the analysis and clog the microcolumn. Despite this precaution, there was evidence of salt suppression of ionization of cellular UDP-sugars.

A standard FAB spectrum of UDP-glucose shows a M-1 ion at 565 amu, as well as an ion for glucose-1-diphosphate (339 amu). UDP-N-acetylglucosamine yielded a M-1 ion at 606 amu and fragments at m/z 300 (N-acetylglucosamine-1-diphosphate) and m/z 300 (N-acetylglucosamine-1-phosphate). A mass spectrum of L1210 cell extract contained ions 565 and 606, but not the M-1 for UDP-xylose. In addition to the M-1 peak, a UDP-xylose standard spectrum had peaks for fragments xylose-1-diphosphate (309), xylose-1-diphosphate - H₂O (291), and xylose-1-phosphate - H₂O. All three UDP-sugars fragmented to UDP (m/z 403) and uracil (m/z 111).

The presence of UDP-glucose and UDP-N-acetylglucosamine in L1210 cells was confirmed by HPLC using a variable wavelength detector monitoring 262 nm.

Analysis of cloricromene acid levels in the rabbit plasma by continuous-flow fast atom bombardment (CF-FAB) mass spectrometry

S. Chen, L. Zangirolami, R. Mariot, P. Bellato, G. Menon and *P. Traldi
FIDIA Research Laboratories, 35031 Abano Terme, Italy and *CNR Mass Spectrometry Service, 35200 Padua, Italy

Cloricromene acid is a stable catabolite of cloricromene that inhibits the platelet aggregation (1-2), known to be formed through the hydrolysis of the ester bond within this coumarin derivative (Fig.1 and 2) in plasma (3). The measurement of the acid levels in plasma is essential for an understanding of disposition of cloricromene in vivo. We use CF-FAB to quantify the acid in the rabbit plasma after an intraduodenal administration of cloricromene. Work was done on a VG-ZAB-2F mass spectrometer with its standard ion source and CF-FAB probe with a one-meter-long 75 um capillary column using methanol:water:thioglycerol (70:27:3) as the mobile phase at a flow rate of 3-5 ul/min provided by a micropump. Calibration curve was prepared by combining various concentrations of the acid with constant amount of the internal standard (5 ng of cloricromene). Quantitative range for the acid is 1-25 ng plotted by the measurement of the peak area ratios (Fig.3). A summary of the procedures for analysis of the acid is shown in Fig.4. Fig.5 shows the decay curve of cloricromene acid in the plasma from 3 rabbits after the administration. For evaluation of the results obtained by CF-FAB method we also quantified the acid levels in the rabbit plasma by reverse phase high performance liquid chromatography combined with fluorescence detector by measurement of the peak area of the acid. The data obtained by the two methods present a good agreement.

Analysis of the molecular species of phospholipids from fish liver by continuous-flow fast atom bombardment (CF-FAB) mass spectrometry

S. Chen,* D. Favretto and P. Traldi

*FIDIA Research Laboratories, 35031 Abano Terme, Italy and CNR
Mass Spectrometry Service, 35200 Padua, Italy

Mass spectrometry has grown increasingly useful for characterizing phospholipids, and fast atom bombardment ionization is currently the most widely used mass spectrometric method for analysis of intact molecules of the species from biological samples because of its some advantages, such as capability of directly analyzing the species from crude extract. Despite its achievement, static FAB has several drawbacks. Ion suppression effect that often occurred with mixture analysis of the compounds hampered to obtain evidence for identification of the fatty acid composition in the species. We used CF-FAB to identify natural phospholipid species from biological sample. The total lipids were extracted from 50 mg liver tissue from an alive torta fish by the method of Bligh and Dyer, and then choline phospholipids were isolated from others on a silica acid column. CF-FAB was carried out on a VG ZAB-2F with its standard source, gun and CF-FAB probe with methanol:water:thioglycerol (70:25:5) for positive ion analysis and methanol:water:triethanolamine (70:28:2) for negative ion measurement as the mobile phase carried by a one-meter-long fused silica capillary column (100 um,i.d.) at a flow rate of 3-5 ul/min. Fig.1 shows the positive and negative ion spectra of choline phospholipids in the fish liver. The molecular species could be identified based on the abundant protonated ions (Fig.1a) and the fatty acid fragments (Fig.1b).

Fig.2 shows the negative ion spectrum of the other classes in the liver. They are mainly phosphatidylethanolamine, phosphatidylinositol and phosphatidylserine. Most of the fatty acid chains containing the classes could be observed from the mixture. Identified molecular species in the liver phospholipids are listed in Table 1. Fig. 3 shows the negative ion spectrum of a crude extract. The main species in the classes could be identified. We used static FAB to analyze the extracts as well. But the unsatisfactory results were obtained.

In summary, CF-FAB method is effective for analysis of phospholipid species because of its major advantage of less ion suppression effect that aids to improve the intensities of useful ions from a mixture. It is also suggested that identification of phospholipid species would become easy if the samples analyzed could undergo a simple isolation as mentioned above before CF-FAB measurement. Influence from the molecular weight overlapping (for example, an ion relates to the two species molecules) would be avoided. The present results also indicated that a high content of 22:6 fatty acid-containing molecular species within major classes of glycerophospholipid is present in this biological sample.

CONTINUOUS-FLOW LIQUID SECONDARY ION MASS SPECTROMETRY OF FLAVONOID CONJUGATES

Lloyd W. Sumner and Paul W. Geno, Department of Chemistry, Oklahoma State University, Stillwater, OK 74078-0447

Flavonoid conjugates encompass a large category of secondary plant metabolites. These compounds are predominantly isolated as O- or C-glycosidic conjugates from complex mixtures and serve a multitude of functions in plant tissues. Recently the isoflavonoid conjugate medicarpin-3'-O-glucoside-6'-O-malonate (MGM) has been shown to inhibit microbial infection in leguminous plant cells. Our primary interest lies in identification and characterization of flavonoid conjugates associated with alfalfa cell cultures.

Owing to the polarity and thermally labile nature of the glycosidic linkage, flavonoid conjugates are not amenable to normal electron impact ionization and GC/MS without extensive derivatization. Low intensity or nonexistent molecular ions of the nonderivatized components are observed in EI spectra. Molecular ion intensities are drastically increased when a "softer" ionization technique such as liquid secondary ion mass spectrometry (LSIMS) is used. Separation of mixtures of flavonoid conjugates can be performed by liquid chromatography. Our goal was to develop a comprehensive method for the separation and characterization of flavonoids. We anticipated that continuous-flow LSIMS (CF-LSIMS) would provide a uniquely beneficial online separation and analysis strategy that would overcome the obstacles previously encountered with GC/MS.

To establish the CF-LSIMS method on the VG ZAB2-SE, a series of flavonoid conjugates consisting of rutin, naringin, and esculin were used. Flow-injection CF-LSIMS was performed with a slightly modified VG continuous-flow probe. Total and selected ion chromatograms for three repetitive injections of rutin and a representative spectrum are given in FIG. 1. Detection limits were then determined for the standards utilizing normal LSIMS and then CF-LSIMS operating in a flow-injection mode. The minimum detectable quantities (MDQ) found for both techniques are presented in TABLE 1. It was found that the detection limits for the CF-LSIMS system were lower than the those of the LSIMS system, which was expected.

A microbore HPLC system was then used to separate and identify a mixture of the above standards. Resulting spectra were similar to that given in FIG. 1. Detection limits were then determined for the mixture through a microbore HPLC interface and the results are also reported in TABLE 1. The results presented elevated detection limits which were attributed to band spreading while on the column and dead volumes associated with the microbore HPLC system.

To remedy any possible dead volumes, preliminary investigation into packed fused silica capillary columns (PFSC) was performed. A UV trace for the separation utilizing a 31cm x 320μm I.D. PFSC is presented in FIG. 2. Spectra obtained were also similar to FIG. 1.

Tandem mass spectra were then acquired for the individual standards by normal LSIMS since future goals will focus on LC/CF-LSIMS tandem mass spectrometry. These spectra correspond to those found in the literature. Tandem mass spectrometry will be used to determine unknown flavonoid conjugates utilizing characteristic fragmentation patterns observed in standards conjugates.

DETECTION OF BENZO(A)PYRENE METABOLITES BY CONTINUOUS-FLOW FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Yohannes Teffera, David L. Smith, and William M. Baird,
Department of Medicinal Chemistry and Pharmacognosy, Purdue University,
West Lafayette, IN 47907

Benzo(a)pyrene (BP) is a common contaminant of the environment. BP has been shown to cause cancer in animals after metabolic activation. The majority of BP is metabolized to water-soluble conjugates of glucuronic acid, glutathione or sulfates. The detection of these conjugates is important since they represent the extent of exposure of the organism to the parent hydrocarbon. Recently, we have reported the development of a continuous-flow FABMS method for the detection of BP-sulfates in cell cultures. In this paper, we present the results of the application of a similar method for the detection of BP-glucuronides from cell media.

Media from BP-treated cell cultures of hamster embryo cells, mouse hepatoma cell line Hepa-1c1c7, and the human hepatoma cell line HepG2 were extracted with ethylacetate/water after adjustment of pH to 4.5. The ethylacetate portion was fractionated by reversed phase HPLC (1). Fractions corresponding to the retention time of authentic BP-glucuronide were analyzed by continuous-flow FABMS (1). On-line experiments were performed using a 1 mm ID microbore column.

A resolution of 10,000 was necessary to separate molecular anion from background signal. Although this caused attenuation of the signal by ten times, a detection limit of a picogram was achieved. Fractions from HPLC analysis of media from BP-treated and untreated Hepa-1c1c7 cells (Fig. 1a and d, upper) were analyzed by continuous-flow FABMS. Single ion recording of fractions from BP-treated Hepa-1c1c7 cells gave response (Fig. 1a, lower) while fractions from untreated cells gave no response (Fig. 1d, lower). The same results were observed for hamster embryo cells. No response was observed for BP-treated HepG2 cells. Calculations based on standard curve and recovery studies indicated that the concentration of BP-glucuronide in the media of BP-treated Hepa-1c1c7 and hamster embryo cells was 250 ng/ml and 90 ng/ml, respectively. These indicated that Hepa-1c1c7 cells and hamster embryo cells have converted 18 % and 25 % of the BP into BP-glucuronide, respectively. The minimum amount that could be quantitated by this method was 0.5 ng. This suggested that HepG2 cell culture, which showed no signal, have converted less than 0.05% of the BP into BP-glucuronide. When BP-treated cells were analyzed by on-line HPLCMS (under conditions different than used in off-line HPLC fractionation), two partially resolved peaks were observed (Fig. 2a and b). On-line LCMS analysis of untreated cells (Fig. 2c) and a mixture of authentic samples (Fig. 2d) indicated that these partially resolved peaks were isomeric phenolic glucuronides.

These results demonstrate that continuous-flow FABMS can be used to analyze BP-metabolites in cell cultures. The sensitivity and detection limit are with in the range at which biological studies are carried out. The method can also be used for the analyses of other hydrocarbons. The on-line experiments demonstrate a rapid and simple method of detection and identification of metabolites.

ICI Americas
1200 S. 47th St.
Richmond, CA 94804 USA

Cycloate is a selective, pre-plant incorporated, thiocarbamate herbicide used primarily in sugar beets. In a crop rotation study the metabolism of cycloate was studied in radish and spinach by flow FAB/MS, MS/MS, and microbore LC flow FAB/MS.

The CAD spectra of a series of suspected metabolites were obtained by flow FAB MS/MS on a Finnigan MAT TSQ 70. Good quality spectra were obtained at 5-50 ng injections. Methanol extracts of leaves from plants grown in cycloate treated soil were also examined by flow FAB MS/MS. Prior chromatographic data suggested that N-ethyl-N-cyclohexylamine and the N-malonylcysteine conjugate of cycloate were present in some of the samples. CAD spectra of the extracts confirmed the presence of only N-ethyl-N-cyclohexylamine. An extract was then partially purified by preparative TLC and the band that co-migrated with the N-malonylcysteine conjugate of cycloate was re-examined by flow FAB MS/MS. The resulting spectrum verified the presence of the conjugate.

Microbore LC flow FAB was done to identify unknown metabolites. This was accomplished with a 0.322 mm diameter C-18 microbore LC column (LC Packings) that was 130 mm in length. An unknown cycloate metabolite which had been partially purified by HPLC was chromatographed on the microbore LC column using .1/10/30/60 trifluoroacetic acid/glycerol/acetonitrile/water. The spectrum obtained (top Figure) is consistent with a malonyl derivative of a cycloate glycoside. Flow FAB MS/MS (bottom Figure) located the cyclohexyl ring as the site of cycloate hydroxylation.
Alkyl Sulfate and Sulfonate Analysis Using Negative Ion Continuous Flow FAB LC/MS on a Magnetic Sector Instrument
J. G. Nowlin, J. Gumulka, H. N. Diep, I. Dzidic
W. R. West, Shell Development Company, Houston, Texas 77083

Introduction:
A reliable analysis for alkyl sulfates and sulfonates capable of providing both qualitative and quantitative data has been of interest to the surfactant industry for some time. Within the last two years a reverse phase ion-paired liquid chromatographic separation of alkyl sulfates and sulfonates using conductivity detection was implemented at Shell’s Westhollow Research Center. The same LC method has recently been interfaced to Continuous Flow Fast Ion Bombardment on the VG TS 250 mass spectrometer to determine whether or not the negative ion CFFIB analysis of 5 μl (1%) of the HPLC affluent would produce adequate signals for identification of the sulfates and sulfonates.

Experimental:
Reference mixtures containing 5 to 50 ppm of alkyl sulfates and sulfonates were used for the LC-CFFIB evaluation. Three percent glycerol was added to the mobile phase and the LC system re-evaluated for chromatographic effects. The methanol/water gradient was modified to optimize the separation and to compensate for peak broadening caused by the addition of glycerol. The HPLC gradient HPLC program included:

A: 40% MeOH + 3% Glycerol + 10%(0.4g/L)NH₄Ac in H₂O
B: 80% MeOH + 3% Glycerol + 10%(0.4g/L)NH₄Ac in H₂O

Program
0 - 9 minutes: A=65% B=35%
10 - 15 minutes: A=55% B=45%
16 - 30 minutes: A:65% B=35%

The C₈ analytical column (Custom LC, 15cm x 4.6mm) used for the separation was maintained at 40°C to minimize back pressure caused by the addition of glycerol.

Fifty μl of the 5 to 50 ppm test samples was injected onto the C₈ column with a 0.5 ml/min flow rate. The flow was split 100:1 in such a way that the 1% or 5 μl was directed to the mass spectrometer and the larger portion of the flow was directed to the conductivity detector for additional monitoring of the separation.

The TS 250 FIB source was heated to 120°C for the flow FIB experiments. Under these conditions, the system produced a stable beam and was reliable and reproducible over several days of testing.

Sensitivity:
Sample concentrations delivered to the mass spectrometer ranged from 12.5 ng in the hexadecene sulfonate mixture to 0.5 ng of individual disulfonates in the alpha olefin blend. This series of experiments illustrates that the LC-FIB system is capable of detecting sulfates and sulfonates at concentration levels below 1 ppm.

Conclusion:
Existing analytical LC methods using gradient elution can be easily interfaced to CFFIB. The 1% of the total flow directed to the mass spectrometer produced adequate negative ion responses to allow identification of the alkyl sulfates and sulfonates. Even with the 100:1 split, these test samples overloaded the system. The most desirable peak shape and quality spectra were observed on the impurities not previously detected by LC alone. Sensitivity of the method was very satisfactory.
Acknowledgements:

We would like to express our appreciation to Vic Parr and Dave Wood (SAL, Manchester, UK) for their assistance in establishing the CFFIB analysis and for their support of the TS 250.

We would also like to acknowledge the support of the VG companies with special thanks to Rahil Amin, Scott Campbell, Dan Carlile, Ian Groove, Max Letcher and Roberto Raso.
ELECTROACCUMULATION OF SAMPLES FROM ELECTROPHORETIC GELS FOR MASS SPECTROMETRIC ANALYSIS

Yu Cao, Jian Yin, James O. Mullis, Kenneth L. Busch, and Lawrence A. Bottomley
School of Chemistry & Biochemistry
Georgia Institute of Technology, Atlanta, GA 30332

At the 1990 ASMS, we introduced a procedure that used mechanical disruption of an isolated area of a planar electrophoretic gel using either a mechanical rotor/stator or piezoelectric homogenizer. These homogenizers, used in combination with chemical degradation of the gel, created a microslurry of gel particles and sample molecules dispersed in an aqueous extraction solvent. A small amount of this suspension, ranging in volume between 50 and 1000 microliters was processed through a particulate filter and a concentration column. This processing allowed a sharp plug of fairly concentrated sample to be passed through a capillary transfer line to a flow FAB ionization source on the mass spectrometer. This device was successful in reaching the time goal and the extraction efficiency, and was demonstrated for samples such as small peptides, angiotensin, and vitamin B12.

A separate presentation at this meeting summarizes work that we have completed using direct laser desorption with matrix assistance for the determination of samples using a Fourier transform ion cyclotron resonance mass spectrometer. Some success is evident, but several other methods are more generally successful in preparing the sample. These include the “freeze-squeeze” method of releasing sample molecules from within agarose gels, and electroelution into small quantities of buffer solution deposited on the top of an aqueous gel. Recoveries for these methods have been determined to be high, ranging up to 80% for some samples. A few ng (a few pmoles) of sample applied to the electrophoretic gel was sufficient to generate useful mass spectra, and in some cases, collision-induced dissociation MS/MS spectra. The three sections of this presentation focus on electroelution onto nitrocellulose membranes and collection electrodes, electroaccumulation onto an optically transparent surface so that UV/vis or fluorescence spectroscopy might be used to monitor the accumulation of sample, and the release of samples from modified gels, especially low melting point agarose gels.

ELECTROELUTION: The initial device constructed for these experiments consists of two metal electrodes. A platinum circle or stainless steel tube is used to isolate the sample band on the electrophoretic gel. A metal wire electrode is placed in the center of the circle; it is on this wire that the sample accumulates. The potential applied to the metal wire electrode is opposite of the polarity of the sample molecule in the buffer solution used or added to the local area. The electrophoretic band can be moved rapidly to the central electrode under the influence of the applied potential, limited only by the ability of the gel itself to support the gradient. The relatively small area of the wire electrode means that only a small amount of sample can be accumulated onto the wire, although the spatial resolution on the surface can be very fine.

Another device used for electroaccumulation based on some modifications of standard technology. Two electrodes are used in conjunction with a small nitrocellulose membrane. The platinum wires are positioned in such a way that the sample band and the nitrocellulose are adjacent and within the potential gradient. Again the potential of the electrode is set to move the charged sample ions towards the nitrocellulose. Up to 50V can be applied to the system for short periods of time, using a nitrocellulose membrane with a pore size of 100 microns. Recovery time is presently in the range of 2 to 3 minutes. A standard extraction procedure is used to remove SDS and stain molecules (if present). This involves a Konigsberg acetone precipitation and occasionally a short centrifugation. The sample can be extracted from the nitrocellulose with methanol. The nitrocellulose must be chosen with care. Most commercial nitrocellulose membranes sold for the purposes of electrotransfer include 3% by weight of a wetting agent, which is a surfactant polymer. This fact is seldom explicitly noted on the specifications sheet. The surfactant gives a high quality FAB mass spectrum and swamps out signal from the sample.

ELECTROELUTION ONTO OPTICAL SURFACES: Electroelution accomplished on a rapid time scale has to be accompanied by some indicator that signals when the sample has been transferred or
accumulated to some predetermined level. Collection of the sample onto nitrocellulose generally proceeds to completion, and ample time is allowed for that situation to be reached. We have used a quartz plate coated with Indium doped tin oxide (ITO) to accomplish electroaccumulation of samples (Figure 1). The ITO coating creates a stable conductive coating on one side of the quartz plate. The ITO plate (a pale brown) can be analyzed during electroaccumulation by UV/vis spectroscopy since it is optically transparent in the range of 220 nm to 1000 nm. UV detection at 254 nm can be used as an indication of the amount of sample on the plate. We also plan to use a fluorescence detector. At present, Coomassie blue staining confirms that protein molecules do move rapidly to the quartz ITO plate. The ITO surface coating is known from independent work to be particularly good for binding of biomolecules through hydrogen bonding. A significant limitation in the present setup is that 5.5 V is the highest potential that can be applied to the sputter-coated plate without loss of the coating. The transfer process must therefore be performed under current controlled and potential controlled conditions (a standard potentiostat is used). The distance between the two electrodes has to be significantly reduced so that the sample recovery time is not excessively long.

**MODIFIED AGAROSE GELS:** Agarose gels can be processed with the "freeze squeeze" method in which the gel is frozen and pressure is then applied to produce a few microliters of solution containing the analyte molecules. Sample recoveries are excellent, but we also wanted to find alternative methods. Agarose gels are available in several modified forms. We performed some initial experiments on a low melting point (about 65°C) agarose gel available commercially. Figure 2 illustrates the sequence of events that releases sample molecules from within the gel within only a few seconds. The gel is cored with a large syringe that has been pre-loaded with a hot 5M KI solution, and for which the syringe has been preheated. The gel cores easily; the potassium iodide prevents resolidification of the gel within the few seconds it then takes to force the resultant solution through a low molecular weight cut off filter, or alternatively a C18 SEPPAK type cartridge. The gel solution passes through the column or cutoff filter, and the sample molecules are held as a plug on the syringe side of the filter or the syringe side of the C18 column. Reversing the flow through the filter passes a concentrated sample through the transfer line to the mass spectrometer, echoing the exact procedure that we described in our previous work.
The direct analysis of substances in liquid matrices by FAB-MS/LSIMS is a powerful addition to the "tool collection" of the mass spectrometrist. In particular, the ability to continuously flow a sample containing solution into the mass spectrometer source substantially increases the types of samples amenable to mass analysis. The main problems in interfacing the liquid and vacuum "phases" are matching the heat flow between the probe surface and the liquid phase to be analyzed prior to vaporization, the creation of a stable liquid phase on the surface of the probe and the requirement that the flow of liquid, as well as gas from a FAB gun, not overload the spectrometers vacuum pumps.

Development of such a device has been in progress in our laboratory in order to bring this capability to a number of quadrupole mass spectrometers, including the HP 598x series. For our HP5982, we have built and begun testing of a very small Continuous Flow-FAB/LSIMS probe which fits through the DIP inlet and utilized a Cesium-ion gun as the primary ion beam. The Cs-gun features a focusable and steerable beam and has the advantage of significantly reducing the gas load on the pumping system. This should also improve the sensitivity since lower source pressures and longer mean free paths should allow better ion collection compared to gas type FAB guns.

Development of such a probe faces severe design constraints: The most demanding aspect is the small size (0.120" dia x .35" long) that such a probe must be to fit this particular ionization source. Other significant problems include the restrictions on primary and secondary ion beam geometries and that of limited primary beam access to the probe tip. We have overcome these problems with a probe design that incorporates both a thermocouple and a nichrome heater within the limited volume available in addition to a fused silica capillary which delivers the solution to the FAB zone. The liquid can flow directly onto the analysis zone or a piece of absorbent material, used as a liquid support. The probe tip and overall experimental setup is shown schematically in Fig. 1.

This probe has thus far been tested on a HP5982 mass spectrometer upgraded with a High Energy Dynode (HED) detector (Phrasor Scientific) and a recently released Cesium Ion Gun (Phrasor Scientific). The probe was tested with a wide range of liquid flow rates (1-20 µL/min using 10% glycerol:water) and demonstrates good sensitivity and almost no memory effects. This is illustrated in Fig. 2 for repeated 0.2µL injections of a 5.4mM sample of dimethyl-dioctadecyl ammonium chloride (Aerosurf, 638 ng/injection) for operation in the selected ion mode ((M-C1)+-551 amu). The probe is also capable of providing high quality mass spectra. This is shown in Fig. 3 for the same Aerosurf solution at a flow rate of 1 µL/min while using the absorbent material. It is important to note that the high mass detection is significantly improved by the use of the HED detector. Work is currently in progress to increase the allowable flow rates and to operate the probe with a variety of solutions.

CONTINUOUS-FLOW FAST ATOM BOMBARDMENT ON AN EXTERNAL ION SOURCE FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETER

Clifford Watson, Gary Kruppa*, John Wronka, and Frank Laukien, Bruker Instruments, Inc., 19 Fortune Drive, Billerica, MA 01821, * Spectrospin AG, Industriestrasse 26, CH-8117 Fallanden, Switzerland

A continuous-flow (CF) probe interface for fast-atom bombardment (FAB) and secondary ion mass spectrometry (SIMS) has been developed for an external-ion-source Fourier transform ion cyclotron resonance (EIS-FTICR) mass spectrometer. The new interface provides quick and convenient sample introduction and reduces the chemical background associated with the use of a liquid matrix. Medium-resolution broadband, high-resolution heterodyne, and tandem mass spectrometry spectra were obtained on selected peptide samples. The CF-probe interface has also been used to interface a HPLC unit to an EIS-FTICR mass spectrometer.

Since its introduction by Barber, et al. (1) in 1981, fast-atom bombardment (FAB) has become a commonly used desorption ionization techniques for nonvolatile organic molecules. The key benefit of FAB has been the soft ionization nature of the technique that often produces an abundant (quasi-) molecular ion signal. In conventional or static FAB, the sample consists of an analyte dissolved in a suitable liquid matrix. The sample is introduced into the mass spectrometer on the tip of a direct insertion probe (DIP), and is bombarded by a beam of fast (8-10 keV) argon or xenon atoms. While static FAB is a very powerful method, it has some limitations: the analyte signal changes in intensity over time as the matrix evaporates or as the analyte on the target spot becomes depleted, and the liquid matrix produces an abundant background of low m/z ions.

A somewhat new variation of FAB, commonly called continuous flow FAB (CF-FAB) (2), resolves several of these problems and provides additional advantages. The continuous introduction of sample maintains a constant analyte/matrix concentration producing ion intensities that are more stable. This facilitates the optimization of the experimental conditions and provides for increased sensitivity (3). The CF technique provides flexibility in choice of the matrix and often water containing 5 to 10% of glycerol has been used. The lower glycerol concentration reduces the amount of low mass chemical noise (4). The CF-FAB technique also provides a simple interface for liquid chromatography (5).

A somewhat new variation of FAB, commonly called continuous flow FAB (CF-FAB) (2), resolves several of these problems and provides additional advantages. The continuous introduction of sample maintains a constant analyte/matrix concentration producing ion intensities that are more stable. This facilitates the optimization of the experimental conditions and provides for increased sensitivity (3). The CF technique provides flexibility in choice of the matrix and often water containing 5 to 10% of glycerol has been used. The lower glycerol concentration reduces the amount of low mass chemical noise (4). The CF-FAB technique also provides a simple interface for liquid chromatography (5).

The CF-probe interface, illustrated in Figure 1, consisted of a fused silica (0.120 to 0.050 mm i.d.) capillary mounted inside a temperature programmable insertion probe. The heated CF-probe containing the capillary inserts into the external ion source of a Spectrospin CMS-47X mass spectrometer through a standard vacuum port. Liquid samples are introduced directly into the external ion source via a microliter syringe pump. The EIS-FTICR mass spectrometer was equipped with two probe ports located on opposite sides of the external ion source vacuum chamber. Either an Ion Tech FAB gun (10 kV) or a Phrasor Scientific SIMS gun (15 kV) was mounted in the second port opposite the CF-probe. Ions produced in the external ion source were detected with a FTICR mass analyzer. Under CF-FAB conditions, the EIS pressure varied from 4 to 9 x 10^{-4} mbar. The pressure in the FT-ICR mass analyzer high-vacuum chamber was maintained between 5 x 10^{-10} to 3 x 10^{-9} mbar.

The CF-probe interface was used to couple a Bruker LC 21 solvent delivery system for gradient HPLC experiments. A standard reverse phase analytical C18 column 4.6 mm i.d. x 25 cm was used for the HPLC studies. The HPLC solvents were composed of water (94.9% H2O, 5% glycerol, 0.1% TFA) and acetonitrile (60% ACN, 34.9% H2O, 0.1% TFA). The HPLC was operated at a flow rate of 0.5 ml/min. and a split of 500:1 divided the flow between a standard 254 nm UV detector and the CF-probe.

For comparison, a static FAB spectrum obtained from analyzing a 1 μg sample of Gramicidin S in glycerol and a CF-FAB mass spectrum that was obtained on a 500 ng sample of Gramicidin S in a methanol/glycerol matrix are shown in Figure 2. The reduction of glycerol ions (m/z 185, 277, 369...) in the CF-FAB spectrum resulted from the decreased concentration of glycerol in the matrix. Even though more sample was consumed in the static FAB experiment, the measured CF-FAB signal-to-noise ratio of the protonated molecule at m/z 1141.7 was 25 times larger than for static FAB.

Analysis of higher mass ions (m/z > 2000) has been facilitated with the use of the CF-probe interface. A high resolution mass spectrum of melittin from honey bee venom (m/z 2848) in a NBA matrix is shown in Figure 3. The transient signal from melittin lasted over 1 s and a mass resolution of 19,000 (FWHH) was obtained at m/z 2848.
The CF-probe has been used as an interface between a standard HPLC system and an EIS-FTICR mass spectrometer. The 0.5 ml/min flow of effluent from the HPLC was divided between a standard UV detector and the CF-probe. About 2 μg of the total material injected on the column is deposited on the CF-probe tip during the HPLC run. The UV trace recorded for a mixture of the tripeptide, Gly-Leu-Tyr, and angiotensin II is shown in Figure 4. Mass spectra recorded at the maximum ion signal of each HPLC peak are also shown in Figure 4.

The ability to introduce liquid samples directly into an EIS-FTICR has many potential benefits, including stable long-lived signal intensities, a simple liquid chromatography interface, and rapid sample introduction with the potential of high throughput and automation. Coupled with an EIS-FTICR mass spectrometer, the CF-interface provides high mass resolution, high mass accuracy, and MS^n capabilities. Future experiments are planned to evaluate the CF-probe interface with microbore HPLC and capillary electrophoresis.

One of the objectives of our laboratory is to evaluate the utility of tandem mass spectrometry, interfaced with various sample introduction/ionization techniques, in elucidating drug metabolite structures without the use of radioisotopes. For the analysis of drug metabolites and polar drug conjugates, continuous flow-fast atom bombardment (CF-FAB) offers several operational advantages over static FAB. First, the interface allows for direct injection of aqueous samples without removing the FAB target for reloading, thereby avoiding the need to realign the target with the primary ion beam. Second, CF-FAB offers a quantitative comparison of sample injections. Third, because of the decrease in the intensity of matrix cluster ions, a higher relative sensitivity is achieved due to an improvement in the signal to background ratio.

A tandem quadrupole mass spectrometer (Finnigan MAT, TSQ-70) was initially fitted with a commercially available CF-FAB interface (Finnigan MAT, Bioprobe). This interface was difficult to use because it had three centers of alignment: the target, capillary inlet, and FAB gun. It also suffered from severe "memory" effects from previous injections.

A newly designed direct introduction type of CF-FAB probe¹ for a Finnigan TSQ-70 mass spectrometer, similar to that described by Caprioli et al.², was devised to eliminate the problems experienced with the commercial interface. The major design differences were that the inlet capillary line was threaded through a heated direct insertion probe and positioned to extend just beyond the end of a removable target. A filter pad was then used as a "wick", which was mounted to the source housing and positioned to make contact to the underside of the target.

The matrix for CF-FAB was composed of 10% glycerol in 50:50 water/methanol, adjusted to a pH of approximately 3.0 using 1 N HCl. Using a syringe pump (ISCO, model LC-2600), the matrix was delivered through the inlet capillary at approximately 10 μl/min, with an indicated pressure of 50 psi. The CF-FAB probe tip was heated to 30°C. Sample introduction was made manually using a 1 μl loop injector (Rheodyne, model 7410). FAB mass spectra were obtained using a saddle field-type discharge source (Ion Tech, Ltd., model FAB11NF) mounted at a right angle to the CF-FAB probe. Xenon was used as the primary ionizing beam at an energy of 8 keV and an indicated gun current of 0.2-0.3 mA.
The following performance characteristics for this probe were observed: 1) less than a ±10\% variation in the glycerol matrix ions (i.e., m/z 185) under normal operating flow; 2) upon repeated sample injections, less than a ±10\% variation in the reproducibility of peak areas with no significant deterioration in peak shape; 3) a 10-15 sec peak width at half height; 4) a significant reduction of memory effects between samples when compared to the commercial probe; and 5) improvement of the overall "sensitivity" by at least a factor of 10\(x\) greater than normally observed for static FAB.

An antiarrhythmic compound, ibutilide (U-70226, MW 384, C\(_{20}\)H\(_{36}\)N\(_2\)O\(_3\)S) was selected as a test compound. This drug represents a class of compounds of interest to our laboratory and the results obtained by CF-FAB could be readily compared to previous data obtained using static FAB. Approximately 500 ng of ibutilide yielded an MH\(^+\) 385 protonated molecular ion as the base peak under static FAB when scanning from 100 to 500 amu per sec. Using the CF-FAB probe, 50 ng of analyte yielded the same MH\(^+\) 385 protonated molecular ion along with structurally related ions at m/z 156, 214, 306, and 367 which were easily observed using the background subtraction features typically used for chromatographic separation.

In the MS/MS mode, CAD fragment ions were generated within the collision cell using argon as the target gas at a pressure of ca. 0.85-1.0 mtorr and applying a collision energy of -20 to -35 eV. A daughter spectrum of the MH\(^+\) 385 ion was obtained on 5 ng of ibutilide. Using SRM, m/z 385\(\rightarrow\)144, the lower limit of detection was approximately 50 pg.

Disadvantages associated with this technique are analogous to those associated with static FAB. For example, the well characterized effects of the matrix upon experimental results is still a consideration. In addition, CF-FAB has the constraints of very low flow rate which requires sample splitting for on-line HPLC operating at a flow rate of 0.5-2 ml/min. A better approach for isolating drug metabolites from biological samples, which would utilize the advantages of tandem mass spectrometry, may be off-line sample preparation prior to CF-FAB. Using a syringe pump, bypass valve, and manual injector, the LC system used in this study was configured to provide a convenient and rapid method for making loop injections of samples obtained from semi-preparative HPLC, solid phase extraction, or trapping techniques.

**ANALYSIS OF PHARMACEUTICAL DEGRADATION PRODUCTS BY GRADIENT MICRO HPLC / DYNAMIC LIQUID SECONDARY ION MASS SPECTROMETRY (L–SIMS)**

*Russell C. Spreen, Karin M. Kirkland; ICI Pharmaceuticals Group, A Business Unit of ICI Americas Inc., Wilmington, Delaware 19897, and Adrian R. Woolfitt; VG Analytical Ltd., Wythenshawe, Manchester, M23 9LE, UK.*

**Introduction:**
An important step in the development of pharmaceuticals is the characterization of degradants. When stressed by heat or light, pharmaceuticals partially degrade into new compounds which may influence product safety or efficacy. As part of the regulatory process, degradation products need to be identified and evaluated for toxicity. The characterization of trace amounts of pharmaceutical degradants can be complex due to the large excess of drug present in the sample. Furthermore, some degradants cannot be analyzed by traditional methods at the trace level due to instability or irreversible adsorption to glass. This study focuses on the application of gradient micro HPLC/dynamic L–SIMS for the rapid screening of crude degradants of the leukotriene antagonist compound LA–1 shown in Figure 1.

**Experimental:**
Degradation products were formed by extended exposure of compound LA–1 to concentrated HCl. In previous studies on related compounds this forced degradation method has facilitated the production of many naturally occurring degradants on a relatively short time scale (1–2 months).

Approximately 100 mgs of LA–1 was treated with 5 ml of concentrated HCl in a small petri dish, covered, and allowed to sit. Upon evaporation of the HCl solution to dryness, approximately 10 mgs of the resulting colored residue was removed and extracted with 3 mls of ethyl acetate. Compound LA–1 has low solubility in ethyl acetate and remained as a white precipitate. The partitioning of the colored degradants into the ethyl acetate could be visually observed. The ethyl acetate solution was decanted, taken to dryness under nitrogen, reconstituted in 100 ul of methanol, and concentrated to approximately 10–20 ul. Aliquots of this solution were then injected into the 60 nl fixed loop injector for micro HPLC/MS analysis. Conventional HPLC analysis of the colored solid residue fully dissolved in methanol showed that total degradants accounted for less than 1% of the total UV absorbance.

The hardware components of the micro HPLC/MS system are shown schematically in Figure 2. This system is somewhat unusual in that solvent gradients are formed at flow rates of a few microliters per minute without splitting. The solvent gradient is not linear; however, good day-to-day reproducibility was observed. UV detection was accomplished by using a conventional UV detector fitted with a specially manufactured capillary flow cell (LC Packings). This method was found to be more sensitive and easier to use than the on-column detection method.

Mass spectrometry was performed with a VG 70–VSEQ tandem hybrid mass spectrometer fitted with a screen/wick dynamic L–SIMS probe. A detailed drawing of the dynamic L–SIMS probe tip is shown in Figure 3. This probe design has provided stable long term (7 hour) performance with a variety of HPLC mobile phases. Good quality positive and negative full scan spectra were obtained for compound LA–1 at the 10 pmole level (6 ngs), and 1 pmole injections of LA–1 could be clearly observed in reconstructed ion profiles. The various micro HPLC and MS experimental parameters for the gradient experiments are summarized at the bottom of Figure 2.

**Results:**
The LA–1 degradant mixture was examined using gradient micro HPLC combined with both negative multiple ion monitoring (Figure 4) and full scan positive/negative ion switching mass spectrometry. In each of these experiments, the quantity of individual mixture components is conservatively estimated to be less than 10 ngs. The combined positive and negative ion data make tentative identifications possible (see Table 1). In some cases the fragmentation pattern is such that only generic identifications can be made. The major degradation pathways involve the formation of mono-, di- and tri-hydroxylated and hydroxy-keto degradants. The multiplicity of the various types of degradants is indicated by the number of peaks in the single ion profiles. The fine structure of the reconstructed ion profiles in Figure 4 is reproducible and can also be observed in the ion profiles derived from the full scan experiments. The portion of the chromatogram between 45 and 60 minutes is dominated by the hydroxy containing degradants. The sum of the various negative ion profiles for the hydroxy containing degradants is shown in Figure 4 and corresponds well with the UV absorbance trace.

**Conclusion:**
Micro HPLC/MS with positive/negative switching is a valuable technique for rapidly screening degradant mixtures for low level components. The direct (splitless) introduction of total microcolumn eluent into the mass spectrometer enables the full scan mass spectral analysis of degradants at the 1–10 pmole level. The screen/wick dynamic L–SIMS probe performs well with HPLC gradients, and very stable and reproducible results were obtained. The combination of positive and negative ion spectra facilitates the determination of molecular weight and structural features and is necessary to obtain maximum coverage of the chromatogram.

Illustration of Chromatographic Integrity.
Since its introduction, fast atom bombardment mass spectrometry (FABMS) has proven to be a powerful tool for the analysis of involatile and thermally labile compounds. The technique is simple to use and the generation of protonated ions of the type (M+H)+ allows for molecular mass determination for several classes of organic compounds. Many investigations concerning the basic processes involved in FAB have been conducted and several mechanisms have been forwarded to explain the features observed in the mass spectra. Of the mechanisms proposed, some invoke gas phase reactions while others are described in terms of solution phase processes. Solution phase processes in FAB ionization have been discussed in terms of preformed ions for ionic and zwitterionic compounds and fast atom beam-induced ionization for non-ionic species. Meanwhile, similarities in the ionic species generated in FAB and CI have been used as evidence of gas phase processes. In order to investigate the basic mechanisms involved in FAB ionization, systems in which anomalous (M-H)+ parent-molecular ions are produced have been extensively investigated in this laboratory. Cyclic acetals yield (M-H)+ ions and therefore offer an interesting system in which to compare the FAB results with that obtained in CI. In this work, a series of 2-phenyl-1,3-dioxolanes and several of their deuterated analogues have been systematically studied in FAB and CI and the mass spectra were compared in order to gain insight into the basic FAB ionization mechanism.

The (M+H)+ ion was observed to be the major peak in the molecular ion region of the CI mass spectra when NH₃, i-C₄H₁₀ and CH₄ were employed as reagent gases (Table 1 and Figure 1). It is interesting to note in the CI(CH₄) mass spectrum only, the presence of a significant ion at (M-H)+ which results from hydride abstraction from the neutral acetal species. CAD/MIKES experiments were performed to verify that the (M+H)+ ion was not the precursor of (M-H)+. Hence, in CI(CH₄) the (M+H)+ and (M-H)+ ion formation can be discussed in terms of competitive bimolecular gas phase reactions involving the neutral molecular acetals. In CI(NH₃, i-C₄H₁₀) experiments the (M+H)+ ion is predominantly formed by proton transfer and hydride abstraction is not a competitive process. This can be explained in terms of increasing hydride ion affinities (HIA) of the protonated reagent gas species: HIA for CH₅+, C₄H₉+, NH₄+ are 272, 231, 195 kcal/mol, respectively. From the CI(CH₄) mass spectra of the 2-d acetals it is observed that (M+H)+ is more intense than (M-D)+ which is assumed to be a consequence of the primary isotope effect where the fragmentation of the C-D bond is slower than that of the C-H bond.

From the FAB (magic bullet) mass spectra of the non-deuterated acetals (Table 1 and Figure 1) the (M+H)+ ion is observed to be dominant in the molecular ion region. For the 2-d acetals it is seen that the loss of D+ is strongly favored over H+ loss (Figure 1). This suggests that the (M+H)+ formation process in FAB is of a different energy to that in CI(CH₄). Interestingly, a (M+H)+ peak of significant intensity is also observed in the FAB mass spectra of the 2-d acetals which is again most likely a consequence of the primary isotope effect. Comparison of FAB results with CI requires a knowledge of the gas phase hydride ion affinity of the protonated magic bullet because in the gas phase model, the protonated matrix molecules are considered to act as the reactant gaseous species. The closest comparable HIA value to that of protonated magic bullet is for protonated methanol: HIA ((CH₃OH)H*) = 119 kcal/mol. Although the ((CH₃OH)H*) value may not be quantitatively accurate for HIA(protonated magic bullet), HIA(CH₅*) is over 150 kcal/mol.

In conclusion, the experimental evidence presented suggests that (M-H)+ ion formation in FAB is not the product of a gas phase process. One possible interpretation of the FAB results is that (M-H)+ and (M-H)+ ion formation occur in solution as competitive reactions. In Figure 2, the proposed gas phase and condensed phase potential energy diagrams for proton addition and hydride abstraction involving the cyclic acetals are displayed. In the gas phase, (M+H)+ formation is favored for CI(NH₃, i-C₄H₁₀) while competitive (M-H)+ formation was observed in CI(CH₄). For the solution phase process the activation energy barriers to the formation of (M+H)+ and (M-H)+ are known to be related to the solvation energies of the appropriate transition states for each reaction. If a three-charge-centre transition state is formed in the hydride abstraction reaction, this transition state would be better solvated than the proton transfer transition state, leading to a lower activation energy barrier for (M-H)+ formation with respect to (M+H)+ (Figure 2). Hence, this solution phase model explains the domination of (M-H)+ in the non-deuterated acetal FAB mass spectra which cannot be rationalized by bimolecular gas phase reactions, as indicated by the CI data.
The solution phase model presented in this study can also be used to explain the recent observation of the anomalous formation of both \((M-H)^+\) and \((M+Na)^+\) ions in the FAB mass spectra of some derivatized sugars containing ether groups\(^2\). In those systems, hydride abstraction by \(Na^+\) cannot compete with \(Na^+\) addition in solution while \((M-H)^+\) formation on reaction with the electrophilic matrix species in the condensed phase is predicted to be favored over simple protonation. Another interesting aspect of the application of the solution phase model to explain FAB ionization of cyclic acetals, is that the electrophilic matrix precursors to \((M-H)^+\) formation are not expected to be preformed in solution as both magic bullet and cyclic acetals are non-ionic. This suggests that the reactive electrophilic species are generated in solution from fast atom beam-induced ionization.

COMPARISON OF PROTON ADDITION AND HYDRIDE ABSTRACTION IN CYCLIC ACETALS IN GAS PHASE AND LIQUID PHASE

401

Studies of reduction occurring during the FAB or LSIMS process have come to the conclusion that the phenomenon is due to interaction of the bombardment beam with the sample and/or the matrix. In our laboratory, this problem becomes quite significant when FAB MS is used for structure elucidation and identification of impurities in drug substances. GAZT was identified as a metabolite of AZT. In the course of the analysis, a peak was noted at 418 Da in the FAB mass spectrum which was shown to be the glucuronide of 1'-amino-2'-deoxy-thymidine (reduced GAZT) by MS/MS techniques. At first, this was thought to be another metabolite of AZT but subsequent NMR analysis and HPLC retention time data showed that reduced GAZT was not present in the metabolite samples and was an artifact of the FAB process. GAZT was subsequently synthesized in the Wellcome Research Laboratories and the purified material was shown not to contain any of the reduced impurity by NMR and HPLC analysis but did so by FAB mass spectrometry. At this point, we began a study into the conditions and causes of reduction of GAZT.

The LSIMS spectrum of synthetic GAZT in glycerol shows the (M+H)+ ion at 444 Da for GAZT and an ion at 418 Da for the reduced product. Mass spectra of GAZT in 1-thioglycerol and DTT/DTE (magic bullet) exhibit both ions but the reduced product appears at a lower level in both matrices compared to glycerol. The LSIMS mass spectrum of AZT and glutathione in these three matrices also exhibit this phenomenon. Reduction is also observed in the FAB MS of AZT where ions are observed in the matrices at 268 Da and 242 Da for AZT and reduced AZT respectively. Glutathione exhibits a protonated molecular ion at 613 Da and a reduced product at 308 Da which is the result of cleavage of the disulfide bond to produce two identical tripeptides. The amount of reduction product appearing in LSIMS mass spectra is greatest for glycerol and least for DTT/DTE for all three compounds. This is the opposite of what is expected since DTT and DTE are better reducing agents than glycerol. These data suggest that a phenomenon other than chemical reduction by the matrix is involved in this phenomenon. Yazdanparast, et al., also showed that the fast atom beam during FAB was essential for the production of reduction products for oxytocin in dithiothreitol/dithioerythritol (DTT/DTE). They also reported that different amounts of reduction occurred for peptides in thioglycerol and glycerol but did not pursue this observation further. Other researchers have concluded that the incident fast atom beam (FAB) or ion beam (LSIMS) is responsible for the reduction which occurs, but the nature of the matrix also plays a role in the amount of reduction observed.

To investigate this further, mixed matrices using glycerol and thioglycerol were used to obtain LSIMS spectra of GAZT and glutathione. Matrix mixtures of 75/25, 50/50, and 25/75 glycerol to thioglycerol were used. In all cases but one, the ratios are the same and are equal to the ratios obtained for pure thioglycerol matrix. This

402
suggests that thioglycerol acts as an inhibitor to the production of reduced product. Recently, Kasakoff and Rye\textsuperscript{4} made the same observation for the FAB ionization of methylene blue in glycerol/thioglycerol mixed matrices. They conclude that the reduction observed in glycerol is due to free electrons produced by the bombardment beam and that thioglycerol is acting as an electron/radical scavenger which causes the reduction effect to be lowered in glycerol/thioglycerol mixtures. Kasakoff and Rye further suggest that for thioglycerol to exhibit the reduction products, another mechanism of reduction must be occurring. We have reached the same conclusion and support it as shown below.

Since reduction could also be due to chemical reduction involving the matrix, a hydrogenation catalyst, finely divided palladium on carbon, was added to the three matrices and mass spectra were obtained for GAZT and for glutathione. The data show that using the catalyst DTT/DTE produces a higher ratio of the reduced products for both compounds than does either thioglycerol or glycerol. Further, in the glycerol matrix, no GAZT or its reduction product could be observed while the signal for glutathione and its reduction product were quite weak, and no reduction in peak intensities was observed for the thioglycerol or DTT/DTE matrices. This is the order of matrices one would expect if the reduction were due to chemical interaction of a matrix and solute as discussed previously. Thus a second mechanism is present and it can be enhanced in the FAB/LSIMS process by introduction of a catalyst. However, this second mechanism is not involved in the glycerol matrix as shown by the lack of any enhancement of the reduction products by addition of a catalyst. To further prove that no reduction occurs in the glycerol matrix, glutathione was incubated at room temperature for five days with glycerol and glycerol plus Pd/C catalyst. HPLC analysis shows that the reduction observed in the glycerol matrix is not a result of the matrix alone resulting from a classical chemical reduction mechanism and that the reduction that is occurring is a result of the incident FAB/LSIMS beam. Using the information gathered from the experiments described above, we have developed experiments to determine the likelihood of reduction products occurring due to the FAB/LSIMS process rather than being components of the sample. Since the ratio of reduced to oxidized components is enhanced in glycerol compared to thioglycerol and DTT/DTE, analyzing the sample in more than one matrix and noting any differences in ratios should be a clue as to the origin of the reduction products. Further, addition of Pd/C to the DTT/DTE matrix should enhance those ions which are due reduction products of any other components in the sample. While this is not totally accurate in all cases, it does serve as aid in determining the source of impurity peaks observed in FAB/LSIMS mass spectra.

IDENTIFICATION AND CHARACTERIZATION OF AMINE CURED EPOXY PRODUCTS BY FAST ATOM BOMBARDMENT MS AND LIKED SCANS MS

James N. Kyranos, Arthur D. Little, Cambridge, Massachusetts, 02140,
Paul Vouros, Northeastern University, Boston, Massachusetts, 02115

The curing of epoxy resins with amines to create high performance composites is of considerable commercial interest. In order to understand the properties and behavior of these materials, a fundamental knowledge of their chemistry is required. The overall understanding of the bulk properties is facilitated by the identification and characterization of the many products which are formed during the polymerization process. However, since most commercially used epoxy resins are polyfunctional and they are most often cured with polyfunctional amines, the final product is very difficult to characterize. As a means of simplifying the problem a model epoxy, methoxyglycidyl ether of Bisphenol A (MGEBA) has been cured with simple amines. The products of these simple reactions have been used in identifying key polymerization processes.

Initial mass spectrometric studies of the products formed between MGEBA and aromatic amines, have provided a wealth of information on the relationship between fragmentation patterns and molecular structure. Although the data base obtained from the aromatic amines curing process was helpful in identifying and characterizing the products of MGEBA cured with cyanamide, there were additional products initially formed, as well as some very different fragmentations which occurred with the cyanamide cured products. Because of the relatively small molecular size of the aliphatic amine, the products which would initially be formed would be much less sterically hindered and could allow for other interesting reactions not favored by the aromatics.

The initial reaction products of MGEBA and cyanamide were isolated by preparative liquid chromatography and analyzed by fast atom bombardment (FAB) mass spectrometry. The relationship between fragmentation and molecular structure of the initial products helped in the identification of the products subsequently formed. Because of the inherent greater reactivity of this system, any additional information that could be accumulated would be helpful in structure characterization. Therefore, in addition to the normal full scan mass spectrum a linked scan of each molecular ion, as well as other selected ions were acquired so that the proposed fragmentations could be confirmed.

The full scan mass spectrum of a representative product from the curing reaction mixture of MGEBA and cyanamide is shown in Figure 1a. It is interesting to note that this isolated compound is a product of dicyanamide, rather than cyanamide. The dimerization of cyanamide is much more rapid than the curing process, thus suppressing the cyanamide/MGEBA reaction. In addition to a strong molecular ion peak, shown in Figure 1a, the other most intense ion is m/z 439. The familiar fragmentations, involving the tertiary carbon of MGEBA or the amine functionality, observed with the products of the curing of MGEBA and an aromatic amine were not as evident in this system. Instead, the ion of m/z 439 is very highly favored. The collisionally activated decomposition (CAD) spectrum of m/z 681 is shown in Figure 1b and confirms the relationship of m/z 439 to the protonated molecular ion. The proposed ion structure for this ion is given in Figure 2. The large intensity of the m/z ion is attributed to the proposed resonance stabilization. Similar fragmentations involving cyclization of fragment ions were also observed for the other reaction products of this system.

The results of these studies as well as those obtained for aromatic amine curing begin to establish a database which relates molecular structure to mass spectrometric fragmentation patterns. The development of such a multidimensional data base combined with MS/MS techniques will aid in the further identification and characterization of increasingly challenging mixtures which are commercially more important.

Figure 2  Proposed resonance stabilized structure of fragment ion m/z 439.
Polyyacetylenes and related synthetic polymers have been demonstrated to conduct electric current because of their extended series of conjugated double bonds (1). Potential applications of these polymers include use as organic semiconductors, components of electrolytic capacitors, or rechargeable batteries (2). In order to determine the factors that influence the conductivity of these polymers, accurate methods are needed to measure their chain length, molecular weight, and structure.

Field desorption (FD) mass spectrometry has been used to analyze oligomers and low molecular weight polymers such as poly(ethylenimine) (3). A newer technique than FD, fast atom bombardment (FAB) mass spectrometry has been applied to the analysis of a variety of compounds including biological polymers such as peptides and some synthetic oligomers and polymers (3). Compared to FD, FAB has the advantage of generating ions over a longer period of time, which facilitates collisional activation of selected precursor ions and then structural analysis of the product ions using tandem mass spectrometry. Recently, FAB mass spectrometry has been combined on-line with reversed phase HPLC in a system called continuous-flow FAB (CF-FAB) mass spectrometry (4). However, CF-FAB mass spectrometry has not previously been applied to the analysis of polyyacetylenes or other conductive polymers.

As part of our studies on the free-radical reactions of fluorinated alkynes and related compounds, we have been investigating the free-radical polymerization of 3,3,3-trifluoro-1-phenylpropyne to form a fluorinated polyyacetylene. We report here the synthesis and analysis of synthetic oligomers of 3,3,3-trifluoro-1-phenylpropyne (1) and its analog, 1-phenylpropyne (2) using gel permeation chromatography (GPC), FD mass spectrometry, CF-FAB LC/MS, and CF-FAB MS/MS.

The monomer, 3,3,3-trifluoro-1-phenylpropyne (1) was synthesized according to the method of Bumgardner and Bunch (5) and polymerized without solvent in a sealed vial at 90°C using benzoyl peroxide as a free radical initiator. The non-fluorinated analog, 1-phenylpropyne, was polymerized in a similar manner. Polymerizations were carried out with three different monomer/initiator ratios, 3:1, 10:1, and 20:1. Each crude reaction mixture was analyzed by GPC to determine the average molecular weight of the oligomers. Next, FD mass spectrometry and CF-FAB mass spectrometry and CF-FAB MS/MS were carried out on the crude reaction products to further characterize the oligomers.

Positive ion FD and CF-FAB mass spectra were obtained using a JEOL HX110HF double focusing mass spectrometer equipped with a DA5000 data system. The resolving power was set at 1000. Silicon emitters were used for FD, and a frit-FAB ion source at 45°C was used as the CF-FAB interface. B/E linked scans were carried out following collisional activation, and 5 to 8 scans were accumulated per analysis. The helium pressure in the collision cell in the first field-free region was adjusted so that the signal was attenuated 70%. LC/MS separations were carried out using an Applied Biosystems model 140A dual syringe pump, model 757 UV/VIS absorbance detector set at 450 nm, and Vydac C18 HPLC column (2.1 mm x 15 cm). The solvent system consisted of a 20 min gradient from 50:50:0.25 to 10:30:60:0.25 (v/v/v/w) water/methanol/ethyl acetate/3-nitrobenzylalcohol. The flow rate was 70 μl/min. The eluate from the HPLC column was split so that approximately 7 μl/min flowed to the mass spectrometer. Aliquots containing 20 μg of each reaction product mixture were injected onto the HPLC column per analysis. Because of the solvent split, approximately 2 μg of each mixture entered the CF-FAB interface.

The field desorption mass spectrum of oligomers of 3,3,3-trifluoro-1-phenylpropyne (monomer/initiator ratio of 10:1) is shown in Figure 1. Molecular ions of three series of oligomers were detected, one containing one hydrogen and one phenyl capping group (series A in Fig. 1), another containing two phenyl capping groups (series B), and a less abundant third series consisting of two hydrogen capping groups (series C). Both GPC and FD mass spectrometry provided similar average molecular weight information for the oligomeric mixtures and showed that a monomer/initiator ratio of 10:1 produced that highest average molecular weight. Ions within each series differed in mass by multiples of 170 mass units, with confirmed the molecular weight of the monomeric unit.
Figure 1. Positive ion FD mass spectrum of 2 µg of unpurified oligomers of 3,3,3-trifluoro-1-phenylpropyne synthesized using free radical polymerization with a monomer/initiator ratio of 10:1.

Because few sample ions of the unpurified reaction product mixture were detected using static FAB mass spectrometry, reversed phase HPLC was used to separate the oligomers in the mixture followed on-line by CF-FAB mass spectrometry. 3-Nitrobenzylalcohol in the mobile phase served as the FAB matrix. The reconstructed total ion chromatogram and selected ion chromatograms of the CF-FAB LC/MS analysis of oligomers of 3,3,3-trifluoro-1-phenylpropyne are shown in Figure 2. Like FD, CF-FAB mass spectrometry of these oligomers formed molecular ions without fragmentation. Therefore, CF-FAB MS/MS was used with collisional activation and B/E linked scanning to form structurally significant fragment ions. These analyses confirmed the presence of trifluoromethyl and phenyl substituents along the polyacetylene backbone. Ions corresponding to fragmentation of the polyacetylene backbone were also observed.

Figure 2. Reconstructed total ion chromatogram (TIC) and selected ion chromatograms for the CF-FAB LC/MS analysis of oligomers of 3,3,3-trifluoro-1-phenylpropyne (synthesized using a monomer/initiator ratio of 10:1).

We report here the first synthesis and characterization of oligomers of 3,3,3-trifluoro-1-phenylpropyne. In addition, the first CF-FAB LC/MS analyses of polyacetylenes are reported. CF-FAB LC/MS provided molecular weight and chain length information that was similar to FD analyses. However, CF-FAB LC/MS was also carried out, which provided additional structural information.

Mass Spectrometric Characterization of Conductive Polymers:

Mass spectrometry has become a viable technique for determining the molecular weight distribution and chemical structure of polymers with minimal sample preparation. Polyaniline\(^1\) and ring substituted\(^2\) polyanilines have been extensively investigated recently because of their moderately high electrical conductivity on doping with nonoxidizing Brønsted acids.

Attempts have been reported for the characterization of polyaniline and ring substituted polyanilines using field desorption (FD)\(^3\), laser desorption Fourier-Transform mass spectrometry (LD/FTMS)\(^4\) and secondary ion mass spectrometry (SIMS)\(^5\). Unfortunately, both LD/FTMS\(^4\) and FDMS\(^3\) provided little information on the chemical structure of these polymers. In SIMS, the highest mass detected in the negative ion spectrum contained only two monomer units; no direct information\(^5\) on the polymer chain structure was obtained from the positive ion spectrum.

In the present work, fast atom bombardment mass spectrometry is used to analyze poly(o-toluidine) (POT) of low molecular weight (m/z<5800) to evaluate its potential for the characterization of polymers of similar structure. Results show oligomer ions in the mass range of 400-2000 (Figure 1); only matrix ions are observed below m/z = 400. In the higher mass range (m/z 400-2000) ionic species detected are separated by the mass of a toluidine monomer (m/z = 105). An unexpected feature of the mass spectra is the observation of polymer series containing one oxygen atom per oligomer. This is further supported by MS/MS analysis of selected ions (Figure 2 and Scheme I). Several possible reasons for the presence of oxygen in the polymer will be presented.
CAD MASS SPECTRUM OF M/Z = 747

MS/MS ANALYSIS OF M/Z = 747

REFERENCES:
The use of filament winding techniques for the fabrication of laminate parts from carbon-fiber thermoplastic prepregs presents several problems for new high-performance resins which melt in the vicinity of 400°C. Small temperature excursions during processing may expose the resin to thermal degradation temperatures. In addition, oxygen present during processing may react with the hot resin. Consequently, it is important to know the effect of temperature and oxygen on the polymer in the vicinity of the process temperature.

10 to 20 mg samples of AS4/APC-2 carbon fiber/poly(aryl ether ether ketone) (PEEK) were isothermally heated for one hour at temperatures 35, 75, and 105°C above the recommended processing temperature (382°C) in nitrogen and 5 V% oxygen-in-nitrogen atmospheres. The latter was chosen to simulate the mildly oxidative environment likely during actual processing. Subsequently, vaporization/gas chromatography mass spectrometry (VapGC/MS) and evolved gas analysis mass spectrometry (EGAMS) were performed to determine the effect of sample treatment.

Sampling for Vap/GC analysis was performed by cryogenically trapping (Ref. 1) compounds desorbed from the prepreg during a 20 minute heat at 382°C. The chromatographic column was a Megabore DB-1 quartz capillary 30 m long by 0.54 mm ID. EGAMS was performed using 2 to 3 mg of sample crimped in gold solids probe sampling cups. The standard water-cooled solids probe of the ZAB mass spectrometer was heated from room temperature to 450°C at a rate of 10°C/min while mass spectra were continuously recorded.

Only minor differences were observed among the flame ionization chromatograms from samples treated at 417 and 457°C in the different atmospheres. No compounds were found in the mildly oxidized samples other than those present in the samples treated in pure nitrogen. There was a small decrease in the amount of material detected in chromatograms from samples treated in a mildly oxidative atmosphere compared to those treated in an inert atmosphere.

In contrast the flame ionization chromatograms from prepreg samples treated at 487°C for one hour were quite complex and difficult to compare. Additional compounds were formed in samples treated in the mildly oxidative atmosphere, and there was a greater quantity of products in the chromatogram from the mildly oxidized sample. Differences in the chromatograms were pinpointed by comparing the reconstructed ion currents of specific masses from the VapGC analyses. Masses 60 and 87 were very abundant in the reconstructed ion current plot from the sample treated in a mildly oxidative atmosphere. Differences in the EGAMS pyrolysis of the samples, mass spectra from the nitrogen treated sample were subtracted from mass spectra from the mildly oxidized sample at the equivalent probe temperature. A typical result is shown in Fig. 1. A positive mass peak indicates that the ion is more abundant in the mildly oxidized sample than in the sample treated in pure nitrogen, whereas a negative mass peak indicates the converse. Highlighted ions in the positive peak spectrum are not present in the sample treated in pure nitrogen.

Most of the ions seen in the pyrolysis of PEEK during EGAMS can be accounted for by simple cleavage of the polymer chain. Intra-chain cyclization about the ether portion of the chain to form furan compounds also may occur. The combinatorial tree below is coded as follows:

cient, indicating the presence of intrachain cyclized dibenzofuran in the major pyrolysis products.

Summary:
The presence of small amounts of oxygen has a marked effect upon degradation at 487°C, but less so at 457 and 417°C. The primary effect of oxygen at 487°C is to increase both the amount and the number of compounds produced during thermal treatment. EGAMS data indicate that at pyrolysis, samples treated in pure nitrogen and mildly oxidative atmospheres form many of the same products, except that they are more abundant in the oxygen treated sample. Several compounds such as D and DO are unique to the oxygen treated sample. This suggests that oxygen promotes the intra-chain cyclization process and the formation of lower molecular weight products.

ANALYSIS OF PHOSPHITE POLYMER STABILIZERS
BY LASER DESORPTION FT/ICR MASS SPECTROMETRY

Xinzhen Xiang, James Dahlgren, W. P. Enlow, and Alan G. Marshall

Depts. of Chemistry (X.X.; A.G.M.) and Biochemistry (A.G.M.), The Ohio State University, 120 W. 18th Avenue, Columbus, Ohio 43210; General Electric Company (J.D.; W.P.E.), Parkersburg Center, Fifth and Avery Streets, Parkersburg, WV 26102.

Phosphite additives are used extensively at ~0.1% level as antioxidants in the polyolefin industry, and are conventionally detected by extraction, liquid chromatography, and/or Fourier-transform infrared spectroscopy [1]. However, FT/IR analysis of the intact polymer may be precluded for polymers which themselves have strong infrared absorption, and extraction-based analysis may not necessarily give an accurate measure of the additive concentration in the original polymer. Although mass spectroscopy has been applied with uneven success to the direct analysis of various nonvolatile additives [2,3], detection and quantitation of phosphite antioxidants has proved to be particularly challenging, because such species tend to fragment far more readily than other additives [3]. In this work, we report successful production and detection of abundant molecular ions from Ultranox® 626 antioxidant [bis(2,4-di-t-butylphenyl) pentaerythritol diphosphite] and its corresponding phosphate oxidation product, XR-2504, and in addition the phosphite additive, Weston™ 618 (distearyl pentaerythritol diphosphite) by Nd:YAG laser desorption Fourier transform ion cyclotron resonance mass spectrometry (LD/FT/ICR/MS). In particular, molecular ion peaks were seen for Ultranox® 626 antioxidant in polyethylene terephthalate, polypropylene, and acrylonitrile butadiene styrene (ABS) at additive concentrations as low as 0.1%, when the probe was heated to about 200 °C prior to laser desorption. Heating evidently increases the free volume of the polymer to facilitate laser desorption/ionization of the additives. LD/FT/ICR/MS thus offers a sensitive and accurate means for detecting nonvolatile phosphite additives at commercially typical concentration in solid polymers.

Experimental

All samples reported in this work were provided by GE Specialty Chemicals. Additive samples were (~20 mg in 1 ml of methylene chloride) were added dropwise to the probe tip. Subsequent evaporation of the solvent left a uniform thin sample film on the probe tip. Polymer samples were prepared by hot pressing to form a thin film which was then affixed to the probe tip. FT/ICR mass spectra were obtained at 3.0 tesla with an Extrel FTMS-2000 instrument. Laser desorption was performed with a Continuum Model YG-660A Nd:YAG laser operated at 1.064 μm, at a power level of ~50 mJ in 10 ns. Since laser irradiation typically produces ~1000 fold excess of neutrals over ions, best results were obtained by ionizing the laser-desorbed neutrals by means of an electron beam (70 eV) passing through the ICR ion trap.

Results

LD/EI/FT/ICR mass spectra of the Ultranox® 626 additive and the Weston™ 618 additive are shown in Figures 1 and 2. By optimizing the laser power and excitation parameters, we were able to generate abundant molecular ions. Figure 3 shows a mass spectrum of a 1:1 mixture of the phosphate additive, Ultranox® 626, and its corresponding phosphate—note the comparable ion yields of the two species. Figure 4 shows the spectrum of Ultranox® 626 (0.1%) in polypropylene. Although no fragments from the polymer are seen (due to its high molecular weight and the low laser power in this experiment), the additive is clearly detected at 0.1% level. [Work supported by N.S.F. (CHE-8721498) and The Ohio State University.]

Stable fullerenes, C_{60} and C_{70}, were discovered in carbon cluster studies using photoionization and time-of-flight mass spectrometry (1,2). These fullerenes can be produced and extracted from graphite soots, as suggested by Kraetschmer, et al. (3). Fullerene molecules contain only carbons with non-planar sp2 hybridation and consist of twelve 5-membered rings with a differing number of 6-membered rings for each different fullerene. In the C_{60} molecule, the simplest form of fullerenes, every carbon of a 6-membered ring is shared with a 5-membered ring.

In this paper, we report the characterization of fullerenes by using various mass spectrometric techniques. The molecules are soluble in many organic solvents and sublimable above 300 °C. The onset temperatures for sublimation in MS vacuum were 300 and 360 °C, for C_{60} and C_{70}, respectively. With a desorption EI/CI probe, which can reach temperatures beyond 1000 °C, we also found higher fullerenes, most notably C_{90}.

Electron-impact ionization at 70-eV beam energy yields both singly-charged and doubly-charged molecular ions, indicating that the fullerene molecules are thermally and electronically stable. With high energy particle bombardment in plasma desorption, fullerenes also yield predominantly molecular ions (4). We also attempted to estimate first and second ionization potential by using a Finnigan TSQ-46B mass spectrometer. After calibrating with the known first IP of C_{60}, we estimate the first IP of C_{70} about 9 eV. The second IPs of C_{60} and C_{70} were estimated to be below 15 and 16 eV, respectively. In charge stripping experiments using oxygen as a collision gas, the second IP of C_{60} was measured to be 12.5 eV. When an inert gas, such as helium or argon, was used as a collision gas no charge stripping was observed (see Figure 1). Triply-charged ions were found in the collision-activation spectra of doubly-charged ions of fullerenes (Figure 2).

Chemical ionization (CI) using methane, isobutane and ammonia as reagent gases showed that the electron capture process is much more favorable than proton transfer and cation addition processes. In addition to increased sensitivity, electron capture yields much cleaner spectra than positive ion CI for fullerenes. The rather weak proton transfer spectra of fullerenes suggests that fullerenes are weak bases, at least in the vapor phase. Protonated molecules were observed in methane and isobutane CI, but not in ammonia CI. These results indicate that the proton affinities of fullerenes are between those of isobutane and ammonia.

Preliminary low resolution MS results indicate that unusual processes might also occur in negative ion MS. Negative CI using methane as a reagent gas showed (M + 14)-, (M + 16)- and (M + 30)- ions at m/z 734, 736 and 750, respectively. Using CD4 as a reagent gas, we see that these masses shifted to 736, 740 and 756, respectively (see Figure 3). These results suggest that (M + CH2)-, (M + CH4)- and (M + CH2 + CH4)- are present rather than (M + CH2)-, (M + O)- and (M + O + CH2)-. Confirmation of elemental composition of these ionic species by high resolution negative CI/MS is planned. When isobutane was used as a reagent gas, we observed (M + 58)- ion as well. Since C_{60} is a relatively large anion with high electron density, the reagent gas molecule might be able to attach to it, forming anion-molecule complexes.

Collision induced dissociation has been studied using a TSQ-46B tandem quadrupole mass spectrometer, which has collision energies limited to less than 30 eV. It was found that no dissociation was observed for cations and anions generated in the EI and positive/negative CI processes. However, with high collision energy in keV range using a tandem sector instrument, higher fullerenes, such as C_{70}, were found to dissociate into more stable lower fullerenes, such as C_{60} (Figure 4).

Analytical studies of transition metal oxide clusters are important due to the wide application of metal oxides, including use as catalysts and in microelectronic processes. Recently, mass spectrometric techniques have been applied in the study of gas phase clusters of molybdenum and tungsten oxides. Tandem mass spectrometry has been used in the structural characterization of heteropolyoxometalates. The objective of this study has been to examine various ionization techniques and instrumental configurations in studying the formation of metal oxide clusters. Particular attention has been paid to variations in cluster ion relative abundances using different techniques.

The highest number of clusters were observed in the chemical ionization spectrum for (MoO$_3$)$_n$, where $n=2$ to $12$, with a monotonic ion intensity decay after $n=3$. A closed ion source design required for the high pressure used in this ionization technique may have provided an optimum condition for the cluster formation. Another important factor is the fast heating rate which was applied to the direct exposure probe and provided a high oxide vapor concentration in the ion source.

The field desorption spectrum shows clusters from trimers to octamers for molybdenum oxide with a fast ion intensity decay after the hexamer. The absence of monomers and dimers with the presence of hexamers as the base peak in this spectrum suggest a special stability for trimers and hexamers. This ionization technique uses direct heating of the sample from an emitter in the presence of a high electric field which should provide the ionization potential necessary for a wide range of clusters. Several heating ramps were tested and the optimum rate was between 2 to 4 mA/min.

Field desorption mass spectrum of MoO$_3$ recorded on MS-1 of a JEOL HX110/HX110 tandem magnetic mass spectrometer which operated at an accelerating voltage of -10 kV, and a counter electrode voltage of +2.8 kV. The ion source temperature was 80°C. The spectrum is the sum of 6 scans in the profile mode with a 1.4 s scan time and a resolution of ±500. The oxides were loaded on benzotriflue activated carbon emitters from a methanol suspension by the dipping technique. The emitters were ramped to 30mA quickly followed by a ramp of 2 to 4 mA/min.
The most oxygen deficient cluster ions were observed using the SIMS ionization technique, where a 6 keV continuous neutral beam of xenon was used for sample desorption. The presence of these clusters suggests possible chemical reduction of the oxides. A very fast cluster ion decay after the trimer and the domination of reduced form of clusters for the tetramer are among other characteristic features of this ionization process. The probability for the presence of the reduced cluster increases with the cluster size. As the cluster mass increases, the ion signal for the oxygen deficient clusters becomes spread over an increasing mass range, effectively reducing the signal-to-noise ratio for any given peak in the cluster. Future comparison of these results to pulsed ionization beam experiments will provide a better understanding of ionization processes of this technique. The presence of oxygen adduct clusters is indicative of the oxyphilio nature of these transition metal oxides and several gas phase reactions with oxygen containing compounds have been demonstrated.

Laser desorption interfaced with time-of-flight instruments has been a popular and effective tool for cluster studies. An advantage of this technique is pulsed ionization which helps prolong the sample life-time and chemical state. The DLV mass spectrum of WO₃ at 355 nm shows cluster ions extending to hexamers. The base peak of the trimer and the presence of the oxygen rich ions are descriptive features of the spectrum. Polyoxometalates associate with cations in the solid state. Laser desorption studies of WO₃Na₄ were initiated in order to investigate formation of associated cation/anion clusters in the gas phase. The mass spectrum of this oxide shows similar clusters to WO₃, except for the abundant cluster series of [(WO₃)ₙNaO]⁺. This new cluster series dominates at higher cluster mass. The presence of WO₃Na⁺ ion suggests a chemical reduction which may be caused by the presence of the matrix. Future studies of transition metal oxides will investigate the interaction of different laser wavelengths and matrices.

Relative abundances of the cluster ions differ widely, depending on the technique used, and no "magic number" or special stability could be attributed to any of the cluster ions. The technique of chemical ionization using a quadrupole instrument appeared most effective in producing higher mass metal oxide clusters.

FOURIER TRANSFORM MASS SPECTROMETRY STUDIES OF TRANSITION METAL CLUSTER IONS PRODUCED BY FAST ATOM BOMBARDMENT

Carolyn J. Cassady
Department of Chemistry
Miami University
Oxford, OH 45056

Gas-phase transition metal cluster chemistry studies provide fundamental information which may be of use in surface, catalytic, and organometallic chemistries. Metal cluster ions are of particular interest, but are much more difficult to produce than atomic metal ions. The present work couples a universal cluster ion production method, fast atom bombardment (FAB), with a versatile method for studying gas-phase ion chemistry, Fourier transform ion cyclotron resonance mass spectrometry (FTMS). A variety of metal cluster ions can be studied by this technique.

The present study focuses on silver cluster ions. Silver clusters are important in photography, where photographic properties are dependent on the number of atoms in the cluster. Thus, the gas-phase chemistry of Agₙ⁺ may also exhibit size-related effects.

Silver cluster ions were produced by bombardment of silver foil, silver powder, silver oxide, and silver halides with a 10 kV xenon beam in an external FAB source. Electrostatic focusing was used to transfer the ions into the cell region of a Bruker CMS-47X FTMS. The reactivity of the mass-selected cluster ions was investigated with small molecules such as deuterium, oxygen, water, methanol, ethanol, methane, ethane, ethene, propene, benzene, and acetone.

One area of interest in the current study is the production of silver cluster ions. In the present experimental configuration, FAB on silver foil yields Agₓ⁺, x = 1-16. As is illustrated in Figure 1, Agₓ⁺ with odd x were seen in much higher abundances than ions with even x. These spectra are similar to those observed in FTMS studies of ions produced by laser desorption on silver oxide.(1) In contrast, xenon ion bombardment of silver foil in a magnetic sector instrument produces abundant even x clusters.(2) Thus, on the FTMS timescale the more stable odd x clusters (which have paired electrons) dominate.

The absolute ions intensities of Agₓ⁺, x = 1-5, may be greatly increased by applying HCl or H₂SO₄ to the Ag foil (Figure 2). The resulting spectra are similar to those obtained by FAB on silver oxide. In addition, silver halides produce Agₓ⁺ in high yields. The spectra also contain silver halide ions, as is illustrated in Figure 3 for AgCl. Silver halides proved to be the most convenient method for producing abundant small Agₓ⁺, therefore reactivity studies involved ions generated by FAB on silver bromide or silver chloride.

Ag⁺, Ag₃⁺, and Ag₆⁺ did not react with any of the small molecules involved in this study. This is not surprising since Ag⁺ is a stable 4s¹3d¹⁰ system, while the high abundances of Ag₃⁺ and Ag₆⁺ in the mass spectra indicate that these ions are also very stable. Ag₃⁺ is a closed shell system which is believed to have a triangular structure.(3) Previous studies have also found these ions to be unreactive with small alkanes, alkenes, and alcohols.(1)

In contrast to the odd x clusters, Ag₁⁺ was found to rapidly react with propene, acetone, and benzene to displace silver and produce AgL⁺ (L = reacting neutral). Slow reactions which could be quenched by argon were also observed with ethene and ethanol, while no reactions were observed with the other molecules involved in this study. The Ag⁺-Ag bond is weak, with a dissociation energy of 38 kcal/mol.(4) Thus, only species which have Ag⁺-L bonds that are stronger than 38 kcal/mole readily displace Ag from Agₓ⁺.

other fullerenes such as C\(_{2n}\), C\(_{g4}\), etc) can be produced\(^2\), numerous studies of the fullerenes are underway. While it was vaporization of graphite was due to a stable icosahedral structure, which became known as buckminsterfullerene or \"buckyball\". It was proposed that C\(_{60}\) might be responsible for spectral features in interstellar space known as the diffuse interstellar bands (DIB). With the recent introduction of a technique by which bulk quantities of C\(_{60}\) (and other fullerenes such as C\(_{2n}\), C\(_{g4}\), etc) can be produced\(^2\), numerous studies of the fullerenes are underway. While it has been established that C\(_{60}\) is not responsible for the DIB, it has been postulated recently that species such as C\(_{60}\)H\(^+\) may be important.\(^3\) Whether such species exist in the interstellar environment will depend on, among other factors, the proton affinity (PA) of the fullerenes. Recently, it has been reported that C\(_{60}\) can be protonated in the ion source of a mass spectrometer under conditions used for chemical ionization.\(^4\) This may have important implications for the existence of C\(_{60}\)H\(^+\) in the interstellar environment, as well as in the use of chemical ionization mass spectrometry for the analysis of fullerenes.

**EXPERIMENTAL**

The fullerenes used in this study were synthesized by a technique similar to that described by Krätschmer, et al.\(^2\) and separated by the technique described by Whetten and collaborators\(^2\). Chemical ionization mass spectra were recorded on a Finnigan TSQ-70 triple quadrupole mass spectrometer. The fullerenes were applied to a direct exposure probe as toluene solutions and desorbed by a current ramp. Various reagent gases were introduced into the source to form protonated and adduct ions. Proton affinities of the fullerenes were determined on an Extrel Fourier transform mass spectrometer. Reagent ions formed by electron ionization and ion-molecule reactions, and then isolated using SWIFT. Neutral fullerene ions were formed by volatilization from a heated probe. The proton affinities were determined by bracketing with various compounds of known proton affinity. Collision-induced dissociation mass spectra were obtained on the triple quadrupole instrument at voltages of 0-200 eV (lab energies). Xe was used as a collision gas under multiple collision conditions. Collision-induced dissociation mass spectra were also obtained on a ZAB-2PQ reverse geometry hybrid (BEGQ) mass spectrometer. Low energy collisions (0-500 eV) were carried out under multiple collision conditions in the quadrupoles with Xe as a collision gas. High energy CID spectra were obtained with MIKE scans, with 3-8 keV collisions using O\(_2\) as a target gas.

**RESULTS AND DISCUSSION**

Chemical ionization mass spectra of the fullerenes in the TSQ-70 showed that both C\(_{60}\)H\(^+\) and C\(_{70}\)H\(^+\) could be formed by protonation with reagent ions from isobutane (C\(_3\)H\(_7\)) and methane (CH\(_4\)). Adduct formation was far more extensive with isobutane reagent ions, suggesting that the proton affinities were similar. Despite the formation of \(\text{M+H}^+\) ions, considerable abundances of the radical cations of the fullerenes were observed, indicating that other types of reactions (charge transfer) occur in the CI source. Protonation was not observed with ammonia. Negative ion (electron attachment) were also obtained. C\(_{60}\) was found to have a higher electron capture cross section than C\(_{70}\), and negative ion CI is a more sensitive technique for the fullerenes. Negatively charged fullerene ions were observed out to C\(_{124}\). It was also found that reactions of C\(_{60}\) with oxygen could be observed with negative CI, with species such as C\(_{60}\)O\(^+\) (n=1-6) being detected. Similar reactions with fluorine (generated from SF\(_6\)) were also observed (C\(_{60}\)F\(_4\); n=1-2).

Proton transfer bracketing in the FTMS was used to determine the proton affinities of the fullerenes. The FTMS spectra of the proton transfer products of various reagent ions with the fullerenes showed an absence of charge transfer products, suggesting that the observation of the radical cation in the CI source is the result of reactions with species other than the major protonated reagents. The results of the proton transfer bracketing are shown in Table 1. The proton affinities of the fullerenes C\(_{60}\) and C\(_{70}\) are found to be between 204 and 207 kcal/mol. C\(_{70}\) is found to have a higher proton affinity than C\(_{60}\). The fact that proton transfer was observed between ammonia and the fullerenes in the FTMS and not in the high pressure CI source indicates that the fullerenes probably have a proton affinity nearly equal, but slightly higher than that of NH\(_3\) (multiple collisions or slow kinetic may affect the transfer process in the CI source).

Collision-induced dissociation mass spectra of the protonated fullerenes show an absence of significant fragments at energies of up to 200 eV. The primary fragmentation mechanism is the loss of H to form the radical cation. The CID spectra of fullerene adducts are dependent on the relative proton affinity of the adduct partner (A).
In general, fragmentation to lose AH*, A or AH (to form the radical fullerene ion) occurred. Significantly more fragmentation was observed with the radical cations of the fullerenes. Using Xe under multiple collision conditions (on the TSQ-70), C2 loss was observed in the 160-170 eV range (lab frame). At moderately higher energies (450 eV; Xe, multiple collisions) using the quadrupoles on the hybrid instrument, extensive fragmentation was observed (Figure 1). The enhanced abundances of certain carbon clusters (e.g. \(C_{11}, C_{15}, C_{19}, C_{30}\)) in the fragmentation spectrum corresponds well with the observation of similar "magic numbers" in studies of the formation of carbon clusters by laser vaporization. At high energy (4-8 keV; \(O_2\) target), similar results were obtained. In addition, charge stripping was observed with the singly charged fullerenes, and both stripping and reduction processes were observed in the multiply charged fullerenes.

*Y(N) indicates the proton transfer reaction did (did not) occur.

Figure 1. Low-energy collision-induced dissociation mass spectra of \(C_{60}^+\).

The physical and chemical properties of large carbon clusters, \( C_n \) (\( n > 40 \)), have been studied extensively over the past six years. The spherical nature of these clusters has been debated and inferred from both experimental and theoretical studies until the recent isolation and subsequent spectroscopic identification of the bulk fullerenes, \( C_{60} \) and \( C_{70} \). Although the \( n = 60 \) and 70 cluster ions are anomalously abundant ("magic numbers") in the mass spectrum, the other "magic numbers" have yet to be isolated. In a previous study\(^1\), the first ionization potentials (IPs) of \( C_n \) (\( n = 48 - 200 \)) were determined by charge-transfer bracketing of the carbon cluster cations, \( C_n^+ \), formed by the direct laser vaporization of graphite. The first IPs of the "magic number" clusters \( C_{50} \), \( C_{60} \) and \( C_{70} \) were determined to be approximately 0.5 eV higher than their neighboring clusters (e.g. \( C_{58} \), \( C_{62} \) etc.).

In this study, electron ionization (EI) of a mixture of \( C_{60} \) and \( C_{70} \) was used to generate the fullerene cations. In addition to the formation of singly-charged fullerenes, EI also generates a relatively high abundance of multiply-charged species (\( C_n^{x+} ; x = 2,3,4 \)). This allows the bracketing of the second and third IPs of the fullerenes by charge-transfer reactions in a Fourier transform ion cyclotron resonance mass spectrometer (FTMS). Following electron ionization, the \( C_n^{x+} \) of interest was mass-selected and then allowed to undergo radiative and collisional relaxation prior to the charge-transfer reaction period. The occurrence / non-occurrence of the charge-transfer reaction:

\[
C_n^{x+} + M \rightarrow C_n^{(x-1)+} + M^+
\]

was then determined as a function of the known IPs of neutral reactants, M. This technique allows the bracketing of the IPs of neutral or charged \( C_n \) species to within ± 0.1 eV to 0.2 eV depending upon the spacing of the neutral IPs (M) employed. An example of this procedure is illustrated in Figure 1 which shows the mass spectrum obtained following the isolation, thermalization and reaction of \( C_{60}^{2+} \) with fluorobenzene (IP = 9.20 eV). The observance of the charge-transfer reaction indicates that the IP(\( C_{60}^+ \)) or 2nd IP(\( C_{60}^+ \)) = 9.20 eV. The first, second and third IPs of \( C_{56} \), \( C_{60} \) and \( C_{70} \) were bracketed by this procedure to yield the following results:

<table>

The first IPs determined here are in agreement with the previous results using direct laser vaporization (DLV) of graphite as the \( C_n^+ \) source. This illustrates the similarity of the energetics/structures of \( C_n^+ \) formed by DLV of graphite and EI of gas-phase fullerenes. It was observed that \( C_{60}^+ \) reacted faster with m-toluidine (IP = 7.50 eV) than did \( C_{70}^+ \). This suggests that IP(\( C_{60}^+ \)) > IP(\( C_{70}^+ \)). To verify this, \( C_{60} \) and \( C_{70} \) were used as the neutral charge-transfer reagent in the reaction of \( C_{60}^+ \) and \( C_{70}^+ \) as shown in Figure 2. Charge transfer occurs in both
reactions but is clearly much faster from $C_{60}^+$ indicating that the IPs are nearly equivalent but $IP(C_{60}) > IP(C_{70})$.

The second IPs are only 1.5 - 2 eV higher than the first IPs which is consistent with their large abundance in the El spectrum, but are much lower in comparison to estimated second IPs of polycyclic aromatic hydrocarbons (e.g. 2nd IP(C$_{24}$H$_{12}$) = 13.3 eV). The trend in which the magic number clusters (C$_{60}$ and C$_{70}$) exhibit greater stability (higher IP) is also observed in the second IPs; 2nd IP(C$_{60}$) > 2nd IP(C$_{70}$) > 2nd IP(C$_{56}$). The third IPs are only ~2 eV higher than the corresponding second IPs which illustrates the high stability and electron delocalization / aromaticity of the fullerenes. The third IPs of C$_{56}$, C$_{60}$ and C$_{70}$ are indistinguishable, however, by the charge-transfer bracketing technique (11.2 ± 0.2 eV). In addition to charge transfer, several other interesting reactions occur for the triply-charged fullerenes including H$^+$ transfer,

$$C_n^{3+} + C_3H_8 \longrightarrow C_nH^2^+ + C_3H_7^+$

and O$^-$ transfer,

$$C_n^{3+} + CH_3NO_2 \longrightarrow C_nO^{2+} + CH_3NO^+.$$  

Figure 1. Reaction of $C_{60}^{2+}$ with $C_6H_5F$

FLOWING AFTERGLOW STUDIES OF BUCKMINSTERFULLERENE ANIONS

*Lee S. Sunderlin and Robert R. Squires
Department of Chemistry, Purdue University,
West Lafayette IN 47907

Buckminsterfullerene anions \( \text{C}_{60}^- \) and \( \text{C}_{70}^- \) have been formed by electron attachment in a flowing afterglow-triple quadrupole mass spectrometer. \( \approx 10^8 \) collisions with He in the flowing afterglow thermalize the ions, allowing room temperature reactions to be studied.

Both fullerides are unreactive with a variety of acids including \( \text{CF}_3\text{COOH} \), an extremely strong gas-phase acid (\( \Delta G_{\text{acid}} = 317 \text{ kcal/mol} \)). This indicates either that \( \text{C}_{60}^- \) and \( \text{C}_{70}^- \) are weak Bronsted bases, or that there is a substantial kinetic barrier to proton abstraction. Both explanations are consistent with the expected delocalization of the excess electron in these ions. The fullerides react slowly with \( \text{BF}_3 \), a very strong Lewis acid. This demonstrates that the fullerides are weak Lewis bases as well.

\( \text{C}_{60}^- \) and \( \text{C}_{70}^- \) react with \( \text{NO}_2 \) to form \( \text{C}_{60}\text{NO}_2^- \) and \( \text{C}_{70}\text{NO}_2^- \) with effective bimolecular rate constants of \( 1.2 \times 10^{-10} \) and \( 2.1 \times 10^{-10} \text{ cm}^3/\text{s} \), respectively. The rates correspond to reaction efficiencies of 19% and 33%. No further addition of \( \text{NO}_2 \) is seen, consistent with radical coupling of \( \text{NO}_2 \) and the fulleride anions. The rate constant is essentially independent of the argon buffer gas pressure over the range 0.1-0.5 Torr, suggesting that collisional stabilization of the adduct is saturated at these pressures.

\( \text{C}_{60}^- \) and \( \text{C}_{70}^- \) do not react with \( \text{NO} \) within the sensitivity of the experiment. Since \( \text{NO} \) is a doublet like \( \text{NO}_2 \), it is clear that radical character alone is insufficient to allow reaction. It is likely that high electron affinity leads to greater reactivity: \( \text{EA(NO)} = 0.03 \text{ eV} \), \( \text{EA(NO}_2) = 2.27 \text{ eV} \).

\( \text{NO}_2 \) does not extract an electron from \( \text{C}_{60}^- \) or \( \text{C}_{70}^- \), indicating that the vertical ionization energy of these molecules is greater than 2.27 eV. This is consistent with the work of Smalley et al. (Chem. Phys. Let. 1987, 139, 233), who estimate the electron affinity of \( \text{C}_{60}^- \) as 2.6-2.8 eV.

The reaction of \( \text{C}_{60}^- \) and \( \text{C}_{70}^- \) with \( \text{O}_2 \) shows a wide variety of products, but the majority of these are likely due to impurities. The reaction of \( \text{C}_{60}^- \) and \( \text{C}_{70}^- \) is at most very inefficient.
Figure 1. Mass spectra showing reactions of $C_{60}^-$ and $C_{70}^-$ with NO$_2$ at NO$_2$ flow rates (10$^{-3}$ STP cc/s) of (a) 0.8, (b) 9.4, and (c) 43.

Figure 2. Attenuation of $C_{60}^-$ and $C_{70}^-$ as a function of NO$_2$ flow rate. The reaction rates can be calculated from the slope of the decay curve.
IDEA:
A design is presented for a mass spectrometer based on the deflection of a pulsed ion beam with a time dependent electric field. By choosing the proper time dependence for the electric field, exact energy focussing can be obtained. This design is an alternative to a time of flight spectrometer. The design based on pulsed deflection would not require a bandwidth of the order of 100 MHz for the electronics, as required for a time of flight spectrometer. This could simplify the electronics. The spectrometer could deal with ions having an extremely broad distribution of initial energies.

The transverse displacement is

\[ y = \int_{t_d}^{t_l} \int_{t_d}^{d} \frac{e V(t')}{md} dt' dt \]

where

\[ td = \frac{L}{\sqrt{2eVa/m} + vo} \]

Choose a deflection voltage of the form

\[ V(t) = \frac{b}{t^2} \]

where \( b \) is a constant. Substituting back into the integral, one can simplify to

\[ y = \frac{eb}{md} \left( \frac{l}{L} + \ln \left[ \frac{L}{l+L} \right] \right) \]

Remarkably, the solution is completely independent of initial velocity. One can also solve for the exit angle

\[ \tan(\theta) = \frac{eb}{mdL} \left( \frac{l}{L} \right) \]

The required deflection voltages are of the same order as the acceleration voltage. The divergence of the deflection voltage as \( t \to 0 \) simply means that there is a lower mass limit to the deflected ions for a given voltage source.

SIMION calculations confirming the independence of deflection from initial energy are presented.

A deflection voltage of the form of a decaying exponential can be used to approximate a \( 1/t^2 \) voltage for a limited mass range. Such a voltage could easily be obtained from a discharging capacitor.
A heavy cluster primary ion beam source is being studied for desorbing large biomolecules from liquid matrices. The objectives of this research are threefold: increase desorbed secondary molecular ion yields, decrease chemical noise in FAB spectra and gain insight for contributing to existing theories that model desorption of macromolecules. The advantages of using heavy cluster primary beams in place of monatomic ion/atom or small molecular ion beams are several. Because clusters are multiply charged, impact energies up to 1 MeV or more are possible using only moderate acceleration voltages (up to 20 kV). At the same time, the impact energy per cluster particle is sufficiently low (1-3 eV) to prevent excessive radiation damage and subsequent ionization of damaged matrix material. Multiply charged heavy clusters are formed by electrohydrodynamic (EH) atomization of conductive aqueous methanol and glycerol mixtures in vacuum.

For this study, cluster beams were focused onto a JEOL HX100HF magnetic sector FAB stage. Negative ion spectra for a peptide of m/z = 2394 generated by cluster bombardment and a standard +6kV JEOL xenon gun are compared in Fig. 1 and Fig. 2. Clusters used in this study were formed at +15.3 kV potential from a 30% glycerol:70%water solution. Immediately apparent in the spectra comparison is the dramatic reduction in chemical noise as seen in the cluster spectra (Fig. 2), especially in the region of the doubly charged ion at m/z = 1197. Although the total ion yields are similar in this case, the signal-to-noise is vastly improved. Studies using other peptides show a similar reduction in the chemical noise background and, additionally, little or no fragmentation products, demonstrating the excellent potential of heavy cluster desorption for a "soft" particle-induced desorption technique exhibiting high signal-to-noise. In fact, using a FMRF-Amide-Like neuropeptide (m/z = 1243), the molecular ion was the major peak in the spectrum since the yield of low mass secondary matrix ions was greatly reduced compared to their predominant production using primary ion beams.

We conclude from these studies that, when using primary ion beams, chemical noise in FAB spectra is due to radiation damage in localized matrix regions with subsequent ejection of secondary matrix ions representative of the damage products. On the other hand, chemical noise using a primary heavy cluster beam is greatly reduced since the large cluster energy (MeV's) is distributed over a wide matrix impact area. Although sufficient to eject preformed ions, the low average impact energy per cluster particle (3 eV) minimizes both matrix damage and the desorption of damaged matrix ions. Presently, cluster beams generated by the EH method are accompanied by a small ion component in the beam. By reducing or eliminating this ion component in the cluster primary beam, achievement of even lower chemical noise and improved signal-to-noise in FAB spectra is predicted.

The use of mass spectrometry for structural elucidation of flavonoids has received considerable attention (1). The major fragmentation pathways and general rearrangement processes of these compounds can determine, in some cases, the type of flavonoids and establish the position of substituents on the molecular skeleton.

In particular, mass spectrometry of chalcone received considerable attention. The general fragmentation pattern and some intimate EI-induced decomposition mechanisms have been already discussed by us by ITMS measurements (2).

Still, in literature are present some discrepancies among some decomposition routes, as for example those leading to ions at m/z 130. Thus while Van de Sande et al. (3) sustained that such ion originates from a cyclic moiety and it is structured as a, Rouvier et al. (4) in an earlier investigation, based on substituted chalcones, proposed structure b (see figure 1). It is worth noting that structures a and b involve the presence of the two different phenyl groups of the original molecule. In the present study, in order to gain definitive information on both formation mechanism and structure of ions at m/z 130, we have investigated differently labelled (D, $^{13}$C, CH$_3$ and F) compounds 1-11 (see...
figure 2) by means of metastable ion studies (B$^2$/E linked scans and MIKES) by a double focus VG ZAB 2F instrument and collisional experiments performed on an ion trap device (Finnigan ITMS).

The non-enzymatic reaction between glucose and free amino groups of proteins is the first of a complex series of reactions (Maillard reaction) determining the formation of brown-yellow, fluorescent, insoluble products: the Advanced Glycation End Products (AGE). Their accumulation on long-lived proteins is considered one of the most important damage factors leading to diabetic complications (1).

Many efforts have been devoted by different groups to the identification of some of these products. These studies must necessarily pass through a degradation in well controlled conditions of the proteins, leading to the formation of low molecular weight species coming from the substructures originating from the interaction freeaminogroups-glucose and for these aim acid and enzymatic hydrolysis are currently employed. In this contest 2-(2-furoyl)-4(5)-(2-furanyl)-1H-imidazole (FFI)

was proposed as an AGE as it was identified among in vitro glycated and furtherly acid hydrolyzed albumin and polylysine (2,3).

Collisional spectroscopy was proved by us to be effective for an easy identification of FFI in different substrates (4) without any sample pretreatment or chromatographic separation with a detection limit in the ppb level. By such approach we proved the absence of FFI in in vivo glycated proteins (collagen of diabetic rats), demonstrating the unreliability of the alternative analytical procedures employed for FFI quantification (5). In particular RIA methods led to misleading results due to the poor specificity of the developed antibody reactive not against whole FFI, but against a substructure of FFI, i.e. the furoyl moiety.

Parent ion spectroscopy carried out on furoyl cation (m/z 95) accounted for the RIA results: in fact eight different furoyl containing compounds were easily evidenced and further identified by daughter ion spectroscopy performed on the related molecular ions (6). Such approach demonstrated the high specificity of collisional spectroscopy: the results that by RIA were ascribed to the presence of a single compound, by collisional experiments were proved to originate from eight structurally identified compounds, different from that invoked as real AGE marker.
In order to clarify the FFI origin (7) we performed enzymatic hydrolysis on in vitro and in vivo glycated proteins. In both cases FFI was not found, proving that it must be considered an artifact coming from acid hydrolysis (8, 9).

In the frame of a mechanistic study on AGE production, based on reaction between protected lysine and glucose, collision spectroscopy was successfully employed in the structural characterization of some reaction products, directly carried out in the reaction mixture (10).

EVIDENCES FOR GAS-PHASE, ION-MOLECULE REACTION AS RESPONSIBLE FOR CROWN ESTER BEHAVIOUR IN FAB CONDITIONS

Ornella Curcuruto and Pietro Traldi; CNR, Area di Ricerca, Corso Stati Uniti 4, I 35100 Padova, Italy
Gloriano Moneti; Centro di Spettrometria di Massa, Istituto Farmacologia, Viale Morgagni 65, I50100 Firenze, Italy

Fast atom bombardment (1) and liquid secondary ion mass spectrometry (2) have become ionization techniques currently employed, due to their use in mass spectrometric analysis of large and/or highly polar molecules (3). When the samples under study are neutral moieties, they usually undergo extensive protonation and/or cationization reactions which some Authors proposed to happen in the condensed phase while some others sustained to occur in the "selvedge" region, an high density gas just close to the matrix surface (4,5). However, the sequence of desorption/ionization phenomena can be dependent from the compounds under study (6).

In previous paper we described the El mass spectrometric behaviour of some crown esters (7) that show the formation of [M+H]+ and [M-H]+ ions. Such unusual behaviour was rationalized in terms of intrinsic basicity and intrinsic acidity of their M and M+- species respectively. For such reason we thought of interest to undertaken a study on FAB mass spectrometry of compounds 1-3 in different operative conditions in order to gain information on the FAB ionization mechanism.

Compounds 1-3 lead also in FAB conditions to [M+H]+ and [M-H]+ species in ratios very close to those observed in El conditions, together with abundant fragment ions. This behaviour can be justified by three different mechanisms:

i) Parallel protonation and hydride abstraction reactions occurring in condensed phase and further desorption of the preformed ions;

ii) FAB activation leading to unstable M+ species in the matrix, which reacts as in i) but in the condensed phase, thus giving rise to preformed ions [M+H]+ and [M-H]+;

iii) FAB activation firstly leading to the desorption of intact molecule and/or M+ ions, which in the "selvedge" region undergo gas-phase, ion-molecule reactions responsible for the [M+H]+ and [M-H]+ ions production.

In order to obtain data on the possible mechanism(s), a series of experiments was undertaken.

1: R = CH₂-CH
   CH₂-CH

2: R = (CH₂)₇

3: R = (CH₂)₈
The presence of matrix as well as its acidification do not lead to any variation in the $[M+H]^+/[M-H]^+$ ratio. These results lead to exclude hypothesis i) and ii), otherwise the formation of preformed ions in condensed phase should be easy detected. Metastable ion studies demonstrate that $[M-H]^+$ ions are not unimolecular decomposition products of $[M+H]^+$ ions.

Adding sodium or potassium chlorides in the glycerol solutions of 1-3 an easy formation of $[M+Na]^+$ and $[M+K]^+$ was observed together with general decrease of $[M+H]^+$ ions. Such data indicate that mechanism iii) seems to be the more reasonable one. The results here obtained support that in this case the FAB data must be rationalized in term of "gas-phase" explosion model.

MASS SPECTROMETRIC INVESTIGATION ON MONO-, DI- AND TRI-CARBOXYLIC DERIVATIVES OF PYRROLE

Silvia Catinella and Pietro Traldi; CNR, Area di Ricerca. Corso Stati Uniti 4, 135100 Padova, Italy
Carlo Costa, Antonella Bertazzo and Graziella Allegri. Dipartimento di Scienze Farmaceutiche, Via Marzolo 5, 135100 Padova, Italy

Pyrrole carboxylic acids have been found among the products of chemical degradation of melanins. The formation of these acids may be explained by the presence of carboxylated pyrrole units in the polymer structure or by assuming that carboxylated pyrrole units are linked through a carbonyl group to position 4 or 7 of indolequinone units (1). Since identification of these acids among the degradation products of melanins may give important structure indications, this study is aimed to their structure characterization by mass spectrometry (2,3). Until now, the mass spectrometric behaviour of pyrrole 2-carboxylic acid (compound 1) only has been described (4) and we will discuss it together with those of compounds 2-6.

The two pyrrole monocarboxylic acids (compounds 1 and 2) behave quite similarly leading to the same fragmentation pattern, also if clear differences are present in relative abundances of molecular and fragment ions. Deuterium labelling experiments proved that the primary H$_2$O loss implicate, for both 1 and 2 together with the carboxylic OH group, aminic hydrogen and H atom linked to carbon. The ratios M-D$_2$O/M-DHO are different for 1 and 2. Both primary COOH and CO$_2$ loss are also observed.

The pyrrole di-carboxylic acids (compounds 3-5) show an analogous decomposition pattern. Again the primary CO$_2$ loss is responsible for the base peak of all the isomers. It must necessarily lead for 5 to the M$^+$ of pyrrole 2-carboxylic acid, while for 4 to the formation of M$^+$ of pyrrole 3-carboxylic acid.

In the case of compound 3, two possibilities can be present: i.e the CO$_2$ loss could lead to the formation of pyrrole 2- and/or 3-carboxylic acids. The collisional spectrum of M-CO$_2$ ions of compound 3 results wholly superimposable to that of M$^+$ of compound 1 so proving that the CO$_2$ loss originates from the carboxylic moieties in position 3.
The primary H₂O loss is present for all the compounds, but for 3 and 4 the formation of anhydride species can be invoked, for compound 5 a fragment ion of the same structure already proposed for [M-H₂O]^+ of 1 and 2 must be considered. A clear difference exists among the CAD-MIKE spectra of compounds 3-5 in the relative abundance of [(M-H₂O)-OH]^+ ions. These species results more abundant for 3 and practically absent for 4. The [(M-H₂O)-OH]^+ ion is present also for 5, but its formation mechanism must be completely different from that proposed for 3.

Finally, for compound 6 the primary metastable supported fragmentation pathway is due to CO₂ loss, leading to ion at m/z 155, isomeric to M⁺ of compounds 3-5. Again, different structures of [M-CO₂]^+ ion can be proposed but simply looking at its further fragmentation processes, some information can be easily gained. In fact ion at m/z 155 further decomposes through CO₂ and H₂O losses, as observed for M⁺ of 3-5. But, in the present case, a new fragmentation route, consisting in the CH₂N⁻ loss, is present, suggesting that the structure of [M-CO₂]^+ ion for 6 is different from those of M⁺ of compounds 3, 4 and 5, i.e it must be that of M⁺ of pyrrole 2,4 dicarboxylic acid.

Pursuing our interest in the mass spectrometry of fluorine-containing compounds, we have compared the behaviors of barbituric acid (compound 1), 1,3-dimethyl barbituric acid (compound 2) and of some fluorinated derivatives (compounds 3-8). This investigation was carried out by electron impact (EI) ionization, as well as by both positive ion and negative ion fast atom bombardment (FAB) in order to gain information on the relative stability of protonated and deprotonated molecular species, together with extensive metastable ions study. All mass spectrometric measurements were performed on a VG ZAB 2F operating both in EI (70 eV, 200 uA, ion source temperature 130°C) and in FAB (3 keV Xenon atoms bombarding glycerol solutions of the samples) conditions. Metastable ions study was achieved by means of mass analyzed ion kinetic energy spectroscopy (MIKES).

Compounds 1 and 2 lead to a common fragmentation pattern. The values as obtained by MIKE spectra of M⁺ of 1 and 2 led us to propose molecular species in an open form originating from the cleavage of a ketoimidic bond with the formation of an \( \delta \) distonic ion:

\[
\begin{align*}
&\text{O} = \text{C} + \text{CR}^* + \text{F} + \text{C} \equiv \text{N} + \text{C} \equiv \text{N} + \text{H} \\
&\text{R}^* \quad \text{R}^* \quad \text{R}^* \quad \text{R}^*
\end{align*}
\]

From this distonic ion, arise all the fragment ions through the indicated cleavages in a position to the carbonyl groups and most of the fragment ions as well can be written in an open form corresponding to a \( \delta, \delta' \) or \( \delta '' \) distonic ion. In some cases, both complementary ions are detectable. However, a different behavior for 1 and 2 is well evidenced by cleavage 1 due to the presence of H rearrangements only for compound 2; this can be explained by the presence of the two N-methyl groups.
For compounds 3 and 4, molecular species can be proposed structured as the following distonic ion:

\[
\text{O}_2\text{C-C}_2\text{N}-\text{C}^+\text{N}^+\text{C}^+\text{CF}_2
\]

originating not from the already described cleavage of the chetoimidic bond, but from the rupture of F\text{2C-C} bond. The driving force of this alternative cleavage must be the electron withdrawing power of fluorine, as well as the particularly high stability of the -\text{CF}_2- radical. Also in this case, cleavages in \(R^2\) to the keto groups of the molecular species are responsible for the most of fragment ions; however, while for 1 and 2 complementary ions were often present, cleavages of the distonic ions in the case of 3 and 4 lead mainly to fluorine containing moieties. For compound 4, the occurrence of H rearrangement in fragmentation routes 2 and 4 can be related to the presence of N-methyl group. In the case of 5-fluoro, 5-alkyl derivatives 5-7, a common fragmentation pattern can be proposed. Most of cleavages, originating from molecular ion in distonic form, lead again to different distonic fragment ions:

\[
\text{O}_2\text{C-N}^+\text{C}^+\text{N}^+\text{C}^+\text{CF}^+\text{R}^2
\]

However, not all the fragmentation products of 6 and 7 can be rationalized via the common distonic ion proposed for the molecular species of 5-7. Hence we propose for 6 only, also an alternative rupture of HN-CO bond analogously to unfluorinated compounds 1 and 2. For compound 7 as well some fragment ions must reasonably come from an alternative rupture due to non equivalence of C\text{5-C}4 and C\text{5-C6} bonds. Hence another distonic ion can be invoked originating from ring opening between C\text{5} and C\text{6}. Finally, for compound 8, the 5-fluoro,5-phenyl derivative, the most of its fragmentation pattern can be justified by cleavage of C\text{5-C}0 bond, but the further decomposition processes are mainly due to the formation of highly stable phenyl containing ionic species.

As far as FAB measurements, compounds 1 and 2 under positive ion FAB conditions lead to protonated molecular species which are the base peak of the spectrum. Only three decomposition pathways involving ring cleavages are observed. Furthermore, a primary water loss, never detected in El, is present in both normal and MIKE spectra of MH+ species. The observed losses from MH+, lead us to propose as favoured protonation site the carbonyl oxygen. For FAB data, the intermediacy of a distonic cation can not easily be proposed.

Compounds 3 and 4 also show abundant MH+ ions and a particularly favoured water loss. The observed cleavages still indicate that also in FAB conditions the F\text{2C-C} bond is weaker than the H\text{2C-C} one. Compounds 5-7 still show the primary water loss and a particularly favoured primary F radical loss. The base peaks for both are due to FR\text{1-R}R\text{2C} loss. Compound 8 behaves quite similarly to 5-7, showing water, F, R\text{1-R}R\text{2C} losses.

Negative ion FAB spectra show for all compounds a base peak due to [M-H] \(-\) species, giving account for a particularly high stability of such ion. Further observed fragmentation is very poor: loss of CO is present for 1-8 while [(M-H) \(-\) (CONCO)]\(-\) particularly abundant for 5 and absent for 4 seems to indicate that for 1-3 and 5-8 proton abstraction originates from NH moieties. The lack of ring cleavages other than CO loss is to emphasize.
Electrohydrodynamic disintegration of liquids and ion formation in electrospray MS

U. Lüttgens and F.W. Rüllgen
Institute of Physical Chemistry, University of Bonn
Wegelerstr. 12, D-5300 Bonn 1, FRG

The ion formation in electrospray mass spectrometry (ES MS) is based on two steps: the electrohydrodynamic disintegration of liquid sample solutions into small charged droplets, and solvent evaporation from charged droplets leading to the formation of desolvated ions. Both steps are performed under atmospheric pressure conditions.

Electrohydrodynamic disintegration of liquids

The electrohydrodynamic disintegration of liquids is achieved by passing a solution through a capillary and applying a high voltage to the end of the capillary. We have investigated the electrohydrodynamic processes at the end of the capillary by optical microscopy and video recording for a number of solvents and solvent mixtures. The objective of this work is to elucidate the role of various parameters such as capillary potential, flow rate of the liquid, and physical properties of the liquid such as viscosity, surface tension and conductivity of the liquid on the disintegration processes and thereby on the formation of mass spectral ions.

The experiments revealed the occurrence of several distinctly different spray modes i.e. axial spray modes, rim emission modes by which the spraying proceeds from the rim of the capillary, and droplet ejection modes. In addition, hopping between axial spraying and droplet ejection is observed and also chaotic spray modes without any observable regularity. At lower potentials near the onset of spraying, axial spray modes in a pulsed or continuous manner were observed for all solvents examined so far. However, at higher potentials the disintegration behavior differs between pure water and aqueous electrolyte solutions on the one hand and other solvents applied in ES MS such as pure methanol, water/methanol and water/acetonitrile solutions on the other hand. For water (and glycerol) the axial spray mode changes to a droplet ejection mode at potentials above the onset of a corona discharge while for the other solvents the change from the axial spray mode to a rim emission mode already occurs at low potentials below or close to the onset of a corona discharge.

Axial spray modes and rim emission modes provide conditions for the generation of sufficiently small droplets to obtain mass spectral ions by vaporization of the droplets. Spraying from the rim leads to the formation of smaller droplets than axial spraying for the same liquid. The mean size of droplets obtained in a spray mode decreases with increasing potential, with decreasing flow rate and increasing conductivity of the liquid.

The electrohydrodynamic processes leading to a change from an axial to a rim emission mode of spraying have not been sufficiently understood yet. Experiments point to a dependence of the rim emission mode on a low surface tension of the liquid and wetting of the walls. The switching from an axial spray mode to the droplet ejection mode is favored by a high field gradient at the end of the capillary, a high surface tension of the liquid and a high flow rate of the liquid, and can be qualitatively understood.

Considering the ion emission in field desorption mass spectrometry, electrohydrodynamic mass spectrometry and in liquid metal ion sources where the mass spectral ions are emitted from liquid transient protrusions, the conclusion can be drawn that in addition to the small highly charged droplets also large droplets of low charge state are formed in the electrohydrodynamic disintegration of liquids in ES MS. The formation of these droplets from a liquid jet in ES should be driven by surface tension and capillary waves rather than by field stress. The missing of molecular ions of low charge state in ES MS of biopolymers may be attributed to the formation of such large droplets which do not release mass spectral ions by subsequent solvent evaporation under ES MS conditions in the gas phase.
DESOVLATION OF IONS FROM CHARGED DROPLETS

The solvent evaporation from droplets depends on heat transfer to the droplets from the ambient gas, the extent of free solvent evaporation and the residence time of droplets in the gas. The charge state of droplets gives rise to frictional heating, a continuous renewal of the atmosphere around the droplet and a short residence time in the high pressure gas.

The field strength on the droplet surface grows by solvent evaporation. If it exceeds the Rayleigh limit the droplet decompose into several smaller droplets. (Ion evaporation cannot occur because the field strength for ion evaporation can never be smaller than the field strength required for electrohydrodynamic disintegration of charged droplets. However, analyte molecular ions with a solvation sphere might be formed by electrohydrodynamic disintegration processes under particular conditions.)

Almost complete solvent evaporation from charged droplets leads to charge condensation onto analyte molecules, a mechanism already considered by M. Dole et al. (see for example J. Chem. Phys. 49(1968), 2240). The excess charges are removed by solvent molecules due to the coulomb repulsion between the charges. Ions of opposite sign recombine and are thermally removed in case of volatile electrolytes or nonvolatile electrolytes at low concentrations. Coulomb repulsion should also lead to a declustering of small aggregates of molecular ions left by solvent evaporation from droplets. The dependence of the declustering of molecular ions on the charge state of molecules may account in part for the discrimination of molecular ions of low charge state in ES MS. Fig. 1 shows schematically the mechanism of desolvation of ions from charged droplets basically already described by M. Dole. The steps "charge condensation" and "declustering by coulomb repulsion" are not consecutive steps.

**Fig. 1:** Proposed mechanism of desolvation of ions from charged droplets in ES MS.
Control of the initial droplet size and charge in electrosprays, and ion production

J. Fernández de la Mora and J. Rosell-Llompart
Yale University, Mechanical Engineering Department, New Haven, CT 06520

Following the recent discovery by Fenn's group of highly charged intact macromolecular ions from electrospray sources, the basic phenomena leading from the original ion in solution to a free ion are receiving increased attention (Fenn et al 1989). The steps behind electrospray ionization (ESI) are (a) formation of a Taylor cone at the tip of an electrified capillary needle through a process partly explained by Taylor (1964); (b) ejection of a steady microjet from the cone tip mostly through unknown mechanisms; (c) rupture of the jet into droplets by capillary instability; (d) evaporation of the droplets; (e) Coulomb explosions with formation of substantially smaller highly charged daughter droplets according to largely unknown fragmentation patterns; (f) emission of ions from sufficiently small droplets, mostly a mystery. The purpose of this communication is to address mechanisms (a) to (e) in order to alleviate present difficulties to electrospray liquids with high or low electrical conductivities or with high surface tension or viscosity, or at flow rates too high or too low. The advantages of controlling droplet size follow from the fact that the required residence time for evaporation in a desolvation chamber is a strong function of initial size, so that an active drying procedure is generally necessary to extract solute ions from ES droplets 3-10μm in diameter, while hardly any forced drying is required for droplets 0.3-1μm in diameter or smaller. Also, ion conversion efficiency must depend strongly on initial droplet size because most of the ion emission is from the smallest droplets while the analyte remaining in the parent droplets is largely lost. Recent work by Gomez and Tang (1991) has shown that primary droplets may be highly monodisperse, while Coulombic explosions lead to the formation of a secondary Taylor jet on the parent droplet with emission of a secondary spray of daughter droplets, also monodisperse and well over an order of magnitude smaller than the parent. Gomez and Tang also confirm earlier work by Jones and Thong (1971) reporting that electrosprayed droplets initially 100Å in diameter have a charge q near the Rayleigh limit charge qR, but the ratio q/qR decays with decreasing initial droplet diameter dP (as VdP in the range down to 40μm according to Jones and Thong; Gomez and Tang (1991b) report an average q/qR of 35% for methanol droplets 2.9μm in diameter), so that droplets originally 1μm in diameter do evaporate substantially before undergoing a first explosion. Our evidence confirms these trends for submicron ES droplets from mixtures of volatile and unvolatile liquids, which do not explode even after evaporating 90% of their initial volume. Accordingly, the daughter droplets formed in the first stage of Coulombic fragmentation may have diameters smaller than 100Å, small enough to be efficient ion emitters. This picture is in agreement with the observations from Alexandrov's group (private communication, July 1990), showing that, beyond a well defined threshold value for the droplet evaporation time between the source and the mass spectrometer, all ions suddenly appeared in the mass spectrum, while none was present below the threshold. Tuning the initial droplet size and charge would thus lead to monodisperse distributions of ion-emitting droplets, and consequently, to controlled fields at their surface and some selectivity on ion formation and charge multiplicity.

The early work of Zeleny (1914, 1917, etc.), where several prejudices prominently present in today's literature were clearly dismissed is very worth studying. For instance, he traced the difficulty to spray high surface tension liquids to the fact that the large field required to form the cone would first lead to, a discharge in the gas. He thus showed how to spray water into CO2 and even into air from sufficiently large capillary needles (1920). He also proved that highly conducting electrolytes can be easily sprayed. Smith (1986) has illustrated further some of these important practical points.

A problem to which we have recently brought some light is the elucidation of the scaling laws for the diameter of the droplets initially electrosprayed (Fernández de la Mora et al, 1990)

\[ d_P \sim (\rho U^2 y)^{1/3} \]

where \( \rho \), \( \gamma \) and \( Q \) are the liquid density, surface tension and flow rate. Eq. (1) states that the dynamic pressure of the microjet \( U^2/2 \) is comparable with the capillary pressure \( 4\gamma d_P \). Within a factor of 2, it agrees with all available ES data in the so-called rainbow mode (including those of Jones and Thong, Gomez and Tang, Kim and Turnbull and our own, mostly unpublished) in the wide range 0.03μm<dP<100μm. Preliminary measurements with glycerol droplets 0.1 μm in diameter are given by Fernández de la Mora et al (1990) together with a description of the experimental technique for sizing submicron droplets. The approximate validity of equation (1) in this size range has been
confirmed further since then by measuring droplet size distributions with two novel kinds of inertial impactors on a variety of combinations of volatile with unvolatile substances.

Equation (1) indicates that the diameter of the ES droplets can be controlled just by varying Q. However, we find that a stable spray can only be obtained within a finite interval \([Q_{\text{min}}, Q_{\text{max}}]\), which depends greatly on liquid properties and needle potential. Little is known quantitatively on how this stable region scales with the parameters of the problem. However, the qualitative description of Smith (1986) proves that increasing liquid conductivity decreases \(Q_{\text{min}}\) leading to smaller droplets. Figure 1 shows the first published report on the lower stability region in flow rate Q vs. needle voltage V space, which we have recently measured in 19% (mass) NaI-glycerol.

![Graph showing region of stable spray behavior for 19% (mass) NaI-glycerol.](image)

Fig. 1: Region of stable spray behavior for 19% (mass) NaI-glycerol (the stable region is between the two curves)

Perhaps the perspective of operating at flow rates one or two orders of magnitude smaller than current ESI standards in order to achieve initial droplet sizes in the 0.3\(\mu\)m range will attract few mass spectrometrists. Yet, the corresponding current of analyte sprayed would not decrease, but would rather increase. Indeed, reducing droplet size requires using liquids with higher conductivities, which tend to emit larger currents even at lower flow rates. An extreme illustration of this point comes from the behavior of concentrated sulfuric acid. The corresponding spray currents in CO\(_2\) are in the range of 1\(\mu\)A (well above usual ES standards), with flow rates smaller than 10\(^{-7}\)cc/s (far below established ES practice). The droplets measured in this case are in the range of 300\(\mu\)m.

We gratefully acknowledge many inspiring discussions with Professors J. B. Fenn and A. Gomez, as well as support from the US National Science Foundation through Grant CBT 881207.

Branford, CT 06405

Two quite different models have been invoked to explain the formation of gas phase ions from charged liquid droplets. According to the Charged Residue Model (CRM), originally proposed by Malcolm Dole and company, solvent evaporates from a droplet containing a single solute molecule that retains some of the charge as the last of the solvent evaporates. (1) In the Ion Desorption Model (IDM) proposed some time later by Iribarne and Thomson, a solute ion evaporates or desorbs from a droplet, alone or in aggregation with one or more molecules of solvent or solute. (2) Reflection on a variety of experimental observations persuades us that in almost all cases the IDM provides a more acceptable explanation for ion formation. In weighing these observations, some of which will be briefly described, one should remember that to account for each ion species that is identified, the CRM model assumes the existence of antecedent droplets that contain a single solute molecule of that species and the number of charges that are found on its ion. If antecedent droplets contain more than one solute molecule, or a different number of charges, the model requires an elaboration to explain how one of the plurality of solute molecules acquires its observed number of charges.

1. ES dispersion of a solution containing 0.1 g/L of arginine in 1:1 methanol:water gives rise to a mixture of singly charged ions comprising clusters of one to eight arginine molecules each with one proton attached. The same solution with 2% acetic acid added produces only monomeric ions.

2. Typical of the now familiar ESMS spectra of biopolymers alpha amylase shows peaks for ions with each of every possible number of charges from no less than 35 to no more than 58.

3. ES ions of molecules with molecular weight (M) under 800 or so are almost always singly charged.

4. Cyclosporin A, a cyclic peptide of M = 1202, gives rise to both singly and doubly charged ES ions, the former always in the majority. With gramicidin S, a cyclic peptide of M = 1142, the doubly charged ions predominate.

5. ES ions of cytochrome c (M = 12,400) from a solution containing 135 umols/L have from 12 to 21 charges. Ions from a much more dilute solution (0.35 umols/L) of the larger protein Lysozyme (M = 14,300) have from 8 to 13 ions! Moreover, small changes in the pH of cytochrome c solutions make large changes in the charge distribution on its ES ions. (4)

6. ES ions of poly(ethylene oxide) (PEO) oligomers show decreasing charge per unit length as M goes from 400 to 20,000, always less than the maximum charge predicted by a previously described model. (3) As M goes higher the charge/length ratio increases, reaching at M = 5,000,000 the maximum value allowed by the model! Not so coincidentally, the initially formed ES droplets contain but one molecule of these largest oligomers.
Even the most contrived sequence of events seems unable to produce arrays of charged droplets that could reasonably give rise by the CRM to populations of ions with features as described in these six observations. On the other hand, the IDM can provide a plausible explanation in each case:

1. Acetic acid increases the solubility of arginine so clusters cannot precipitate and form ions by the IDM. But each droplet should contain the same amount of arginine, with or without acid, and according to the CRM, produce the same ions.

2. The IDM requires only that the number of charges found on the amylose ions relate to the droplet’s surface charge density when desorption occurs. The CRM requires a remarkable distribution of droplets having only one solute molecule but every possible number of charges from 35 to 58.

3. The evidence is mounting that ES droplets always have multiple charges, no matter how small, and that daughter droplets from a Coulomb explosion always have higher charge/mass ratios than did the parent. It thus becomes difficult to envision a mechanism that could produce the singly charged droplets that the CRM requires for formation of singly charged ions.

4. Liquid chromatography experiments show cyclosporin A to be substantially more hydrophobic than gramicidin S. Thus, its ions should need less charge to escape the droplet.

5. As in the case of cyclosporin and gramicidin, the IDM would require only that lysozyme be substantially more hydrophobic than cytochrome c in order for its ions to be lifted from the droplet with fewer charges. The CRM would require an amazingly complex array of droplet charges to produce the observed distribution of charge states for these two species. Moreover, it should produce some ions with fewer charges and cannot account for the strong dependence of charge state on pH.

6. Independent experimental evidence shows that the fugacity or escaping tendency of PEO from solutions increases as \( M \) rises to 20,000 or so, remaining unchanged as \( M \) goes higher. The IDM would thus predict that ions would require decreasing charge/mass as \( M \) rises to 20,000. Viscosity increases rapidly as \( M \) goes beyond that value, slowing down ion motion and delaying desorption. Meanwhile, evaporation continues to increase surface charge density so that ions increase their charge/mass as viscosity delays their desorption.

In sum, the CRM seems much less able than the IDM to account for these and other observations on the charge state of ES ions. We conclude that the IDM embodies the mechanism that is applicable in the formation of most ES ions. The CRM can apply in the ES ionization of very large molecules.

MOLECULAR ION PRODUCTION FROM CHARGED LIQUID DROPLETS
Marvin L. Vestal and Mark H. Allen
Vestec Corporation, 9299 Kirby Drive, Houston, TX 77054

This paper focuses on the mechanisms involved in producing gas-phase molecular ions from charged liquid droplets at atmospheric pressure and on the problems in sampling such ions into the vacuum of the mass spectrometer. All of the spray ionization techniques such as electrospray, thermospray, and ionspray are initiated by nebulization of a liquid to produce charged liquid droplets. The processes involved in charged droplet production may vary substantially among these various spray ionization techniques, but it appears that the mechanisms involved in producing molecular ions are essentially identical in all cases.

The mechanism by which molecular ions are released from charged liquid droplets has been somewhat controversial. Thomson and Iribarne originally proposed the ion evaporation model [1] which gave a plausible picture of ion production by field assisted ion evaporation. In this model ion evaporation occurs when the field strength at the surface of the droplet, which is proportional to the droplet charge divided by the square of its radius, reaches some critical value due to vaporization of the charged droplet. Roellgen and coworkers have questioned the validity of this model [2] and have proposed instead that disintegration of the charged droplets occurs via the Rayleigh jet mechanism which eventually leads to small charged micro-droplets some of which contain only one nonvolatile sample molecule. Complete vaporization of the micro-droplets then produces the bare molecular ions which are observed in the mass spectrometer.

There is an abundance of experimental data which shows conclusively that the major mechanism for the disintegration of large charged droplets (ca. 10-100 μm) is via Rayleigh jets which produce a large number of small charged droplets, but little data has been available for droplets with diameters of 1 μm and below. Recently Zarrin [3] has determined the size distribution of aerosols produced by electrospray. These experiments employed a TSI Model 3932 Mobility Particle Sizer (TSI Inc., St. Paul, MN) which measures size distributions of aerosols in the 0.01 to 1 μm range by electrical mobility using particles with known charge distributions. A solution containing known concentrations of nonvolatile solute is electrosprayed, and after solvent evaporation the diameters of the residual dry particles are determined. The initial droplet diameter, D₀, is related to the measured solid particle diameter, D_r, by

\[ D_r = D_0 \left( \frac{C}{\rho} \right)^{-1/3} \]  

where C is the concentration of the solution (g/mL) and \( \rho \) is the density of the solid particle. Results of three such measurements employing different concentrations of nonvolatile solutes in 50:50 methanol:water electrosprayed at 0.7 μL/min are summarized in Figure 1. Under these conditions the three experiments are in good agreement and suggest that almost all of initial electrosprayed droplets have diameters between 1.0 and 1.2 μm. In addition, at the highest solid concentration residual dry particles are detected corresponding to micro-droplets with diameters less than 0.2 μm.

Our present understanding of the important mechanisms involved in production of molecular ions from charged droplets can be summarized by reference to Figure 2, where droplet charge is plotted vs droplet radius on a log-log plot. The line with a slope of 2 corresponds to a critical field
strength of $8 \times 10^8$ V/m as determined in the experiments of Katta [4], and the line with a slope of 3/2 corresponds to the Rayleigh limit. These two limits intersect in the vicinity of a particle radius of 0.05 μm and a charge of about 1000 elemental charges with the precise intersection depending on the solvent composition and the temperature. From the work of Zarrin [1] it is now clear, at least at low flow rates, that electrospray with currents in the 100 nA range produces droplets charged very close to their Rayleigh limit. As these primary droplets vaporize, they become unstable and produce a large number of micro-droplets of radius less than 0.1 μm. The final determination of which mechanism is involved in the production of molecular ions from the micro-droplets depends on the concentration of the solute and the relative affinity of of the solute and other species present for the available charge.

Electrospray ionization is a gentle method of ionization that produces multiply charged gas phase ions from proteins in solution. A typical positive ion electrospray spectrum of a protein consists of a distribution of peaks, in which the different peaks in the distribution correspond to the intact protein molecule containing different numbers of attached protons.

In the present paper, we present the results of a series of investigations designed to gain an understanding of the mechanism of ionization in electrospray ionization and the factors that control the degree and extent of ionization. We discuss:

1) The relative ionization efficiencies of the various amino acid side-group functionalities, as determined from measurements made on a series of amino-terminally blocked amino acids and model peptides. These studies demonstrated that peptide residues other than Lys, Arg, and His are protonated during electrospray ionization and a scale of relative gas phase basicities was established:

   Arg > Lys > His > Trp ~ Pro > Gin

2) Effects on the observed extent of protein ionization of parameters such as solvent composition and pH. These studies showed that the extent of ionization observed in the gas phase reflects, to some degree, the equilibrium ionization of the protein in the electrospray solution. In particular, the 3-dimensional protein conformation in solution (which can be profoundly effected by the solvent composition and pH) was found to have a large effect on the degree of multiple protonation observed in the gas phase (1-4).

3) The role of the proximity of the ionizable groups and Coulomb repulsion in the gas phase on the observed extent of ionization. A method for predicting the most probable number of charges that remain attached to a peptide was developed. The method involves a calculation of the changes in enthalpy that occur when protons are removed from the ionized protein in the gas phase by residual water molecules. A comparison was made between the predictions of the theory and the observed protonation states of 21 different peptides. Good agreement was found.

In summary, we found that the observed electrospray ionization reflected the original ionization of proteins in the electrospray solutions modified by subsequent deprotonation reactions in the gas phase that are driven by Coulomb repulsion forces and collisional activation.

Linear Response and Non-Constant Frequency Resolution in Stored Waveform Inverse Fourier Transform Excitation for Fourier Transform Mass Spectrometry

Shenheng Guan  
Department of Pharmaceutical Chemistry  
University of California  
San Francisco, California 94143

FTMS excitation methods play a central role in implementing tandem MS experiments. It is important to be able to produce selective waveforms for ion isolation and to control ion kinetic energy with excitation pulses. These capabilities can be provided by the stored waveform inverse Fourier transform (SWIFT) excitation method [1].

The SWIFT method relies on the fact that ion cyclotron resonance is essentially a linear system which has been experimentally demonstrated [2]. The understanding on response of FTMS excitation has largely been based on the single-frequency or "burst" model which is invalid in cases of SWIFT or frequency sweeping excitation. In this work, a linear relation (see Eq. 1) between the voltage density and the corresponding ion radius is derived following the linear response theorem on ion motion based on the assumption of uniform excitation field. This relation is important for tandem mass spectrometric experiments performed on a FTMS spectrometer because the ion radius is closely connected to its kinetic energy. The linear relation between excitation voltage spectrum and the corresponding ion transverse velocity is helpful for understanding multi-pulse experiments without explicitly solving the Lorentz equations.

\[ r(\omega) = \frac{F(\omega)}{B_0d} \]  

(1)

Here \( r(\omega) \) is ion radius, \( F(\omega) \) is the excitation voltage density or magnitude spectrum, \( B_0 \) is the magnetic field, and \( d \) is the spacing between the excitation plates.

In this work, some of the features of the magnitude smoothing procedure [3] is also demonstrated. Excitation with constant mass resolution can be realized by using a smoothing filter with non-constant frequency bandwidth. An example for generating optimal notch excitation is given (see the Fig.).

Reduction of Space-Charge Effects In FTMS by SWIFT Excitation

Zhenmin Liang and Joseph E. Campana. EXTREL FTMS, 6416 Schroeder Road, Madison, Wl 53711.

Stored waveform Inverse Fourier transform (SWIFT) excitation provides greater flexibility and experimental versatility for Fourier transform mass spectrometry (FTMS). Space-charge effects can reduce the dynamic range in ion trapping mass spectrometry. Space-charge effects also cause a shift in ion cyclotron frequencies, which in turn limits accurate mass determination. In addition, space-charge effects deteriorate mass resolution. By using Stored Waveform Inverse Fourier Transform (SWIFT) excitation, space-charge effects can be reduced/eliminated.

I. Dynamic Range Improvement.

Our first objective of SWIFT excitation is to improve the dynamic range. High-abundance ions and low-abundance ions can be excited and detected separately by using SWIFT, and the two spectra can then be combined into one spectrum. For detection of low-abundance ions, a mass-selective waveform is constructed to eject only the major abundance ions. The low-abundance ions can then be excited and detected without the space-charge interference from the high-abundance ions. Adding the time-domain signals of the high and the low-abundance ions and then Fourier transforming the summed time-domain signal, a single mass spectrum with a larger dynamic range than a conventionally-acquired FTMS mass spectrum is obtained, as illustrated in Figure 1.

II. Reduction of Frequency Shift due to Space-Charge.

A similar scheme as described above can also be used to reduce the frequency shift caused by space-charge effects. A full-range mass spectrum can be broken into successive segments. Each segment of the mass spectrum can be detected separately without the presence of ions from other segments of the mass spectrum, and therefore without the space-charge interference from those ions. A low-pass and a high-pass filter were used to pass the signal and noise of the detected region to avoid multiple accumulation of noise. Again, the full-range mass spectrum can be reconstructed by combining the time-domain signals and by taking the Fourier transform of the summed time-domain transient signal. This method improves accurate mass measurement. An example is given Table 1.

III. High-Resolution Mass Spectrum over a Wide Mass Range.

With frequency sweep excitation, high-resolution mass spectral measurements in FTMS are subjected to two major interferences, namely folded-back peaks and space-charge broadening.

SWIFT excitation provides a solution to the above two limitations. The high definition of excite power permits selective excitation, which eliminates the folded-back peaks. SWIFT also allows highly selective ejection of ions outside the mass range of interest, which not only avoids the fold-back peaks, but also eliminates space-charge broadening. Two example are given in Figures 2 and 3.

In Figure 2, the doublet of bromochlorobenzene at m/z 192 is shown. This doublet requires a resolving power 210,000 to be separated at half height (400,000 at 10% valley). Even after ejecting all other ions except those of molecular ions (m/z of 190, 192, 194), it is difficult to separate the m/z 192 doublet. When m/z 190 is ejected, the doublet can be resolved easily at a resolving power of > 900,000.

In Figure 3 the spectra illustrate a potential application high-resolution mass measurement over the full mass range consists consists of a large number of ion peaks. First, a wide mass range spectrum is obtained to identify the number of ion peaks and their abundance in the mass spectrum. Depending on their abundance, the full spectrum can be broken into k segments where each segment contains roughly 30 m/z units. k SWIFT waveforms are constructed; each of which ejects all other ions except the segment to be detected. The resulting segments of high-resolution spectra may be reconstructed by computer to yield a single high-resolution mass spectrum for the whole mass range.

These experiments are unique to SWIFT excitation because they require the excitation of arbitrary mass ranges at high mass selectivity.

APPLICATION OF THE RF-ONLY-MODE EVENT TO HIGH PRESSURE ION CHEMISTRY IN FTMS

D. L. Rempel and M. L. Gross
Midwest Center for Mass Spectrometry,
Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

Radial diffusion constrains FTMS by limiting the pressures at which the trap can effectively store ions. Cooling of an ion's internal degrees of freedom by using a bath gas is often not possible. Dynamic traps such as the QUISTOR trap ions at higher pressures with no difficulty and can be used for this purpose. We have proposed to capture this advantage for FTMS by developing a temporary dynamical trapping mode event for use in the FTMS sequence. The RF-only-mode event would be used for collisional stabilization of reaction intermediates and products.

The RF-only-mode event was implemented by modulating the trap plates of a 1.0 V, 0.0254 m cubic trap at 1.2 T with a 1000 V, 1.1 MHz sinewave during the reaction delay interval of the sequence. The waveform was turned on and off with a time constant that was changeable from 30 μs to 3 ms. During this interval, the cell could be pressurized with He to about 10^{-3} to 10^{-2} Torr by operating a Varian variable leak valve model 951-5100 with a solenoid for 1.3 s.

The transition to and from the dynamic trapping mode without He present is fairly efficient for the benzene molecular ion as indicated by at most a 20% drop in peak amplitude when compared with the same experiment but without the modulation. The RF was on for 50 ms and the benzene pressure was 1 x 10^{-7} Torr. This was true for transitions between the RF-only-mode and normal operation that occurred with time constants of 500 μs or less with modulation amplitudes ranging from 300 to 1000 V. The best result at 1000 V was a peak amplitude drop of only 6 percent, which occurred with transition time constants near 500 μs. For the longest mode transition time constant of 4 ms, the biggest drop of 30 percent occurred. For longer RF on times, the peak amplitude drops until it is 40 percent at 11 s.

Peak amplitudes first appear when the RF is turned off 0.3 s after the leak valve is closed. This was when He was pulsed to 1.4 x 10^{-3} Torr. The signal increased and maximized at 85 percent when the RF was turned off at 2.3 s after the valve closing.

Formation of the adduct CyH2O at m/z 112 was observed from the reaction of the 1,3-butadiene neutral and the vinyl methyl ether cation radical as shown in Fig. 1. 1,3-butadiene and vinyl methyl ether were introduced at pressures of 1.6 x 10^{-7} and 3.7 x 10^{-7} Torr, respectively. The He was pulsed to 3.3 x 10^{-3} Torr. The adduct peak amplitude is about 5 percent of the adduct fragment peak amplitude at m/z 80. In this experiment, the m/z 58 ion was selected by double resonance before the RF-only-mode event from ions generated with 15 eV electrons.

Normally, this adduct is not observed in FTMS and requires collisional stabilization in CI source for observation. This was observed in the same experiment as the last one; but, this one was without the RF modulation and the He pulse. There was no detected signal at m/z 112, as shown in Fig. 2. The m/z 80 peak height in Fig. 2 is 1.31 times the corresponding peak in Fig. 1.

CHARGE EXCHANGE AND TRANSITION METAL ION REACTIONS WITH LASER DESORBED PEPTIDE NEUTRALs

J. Paul Speir, Greg S. Gorman, I. Jonathan Amster
Department of Chemistry, University of Georgia, Athens, Georgia 30602

INTRODUCTION

We are currently investigating both charge exchange and transition metal ion reactions with laser desorbed peptide neutrals. We have previously demonstrated the chemical ionization of laser desorbed peptide neutrals utilizing reactions of proton transfer reagent ions stored in the analyzer cell of a Fourier transform mass spectrometer (1). In principle, this methodology can be used to study a variety of ion-molecule reactions of peptide neutrals, such as charge exchange and dissociative metal attachment. In contrast to proton transfer reactions, fragmentation observed in charge exchange reactions is initiated from an odd electron ion rather than an even electron ion. Because these different precursor ions undergo different fragmentation mechanisms, it is quite plausible to expect that these two methods of ionization will be complementary. The reaction of transition metal ions with laser desorbed peptide neutrals is also being investigated as a method to promote unique fragmentations.

EXPERIMENTAL

The experiments were performed using a Fourier transform mass spectrometer equipped with a 1-3/4" cubic analyzer cell, a 1 Tesla electromagnet, and an IonSpec data system. The main vacuum chamber is pumped with a 330 l/s turbomolecular pump to a base pressure of 2x10^-10 Torr. The introduction of reagent gases is controlled by the use of two pulsed valves and a sapphire sealed leak valve.

Peptide samples desorbed using the 193 nm (ArF) output of an excimer laser are prepared by electrospraying a methanol solution of the peptide onto a substrate which consists of a 75 nm thick film of gold-palladium coated on a macor stub. The resulting sample coverage is 10^2-10^3 monolayers. For peptide samples desorbed using the 248 nm (KrF) output of an excimer laser, a 500 monolayer coverage of sinapinic acid, a uv absorbing compound used for matrix assisted laser desorption, is first electrosprayed onto the substrate. The peptide sample is then electrosprayed on top of the matrix material producing an analyte coverage of 500 monolayers.

Charge exchange reagent ions are generated by electron ionization of a high pressure burst of a reagent gas which is admitted through a pulsed valve. Reagent metal ions are produced by laser ablation of metal foils which reside directly below the analyzer cell, or by dissociative charge exchange of metallocene compounds with neon ions.

RESULTS AND DISCUSSION

The products of the reaction of the tripeptide val-pro-leu with laser generated Fe^+ are shown in Figure 1. The condensation of Fe^+ with the tripeptide is observed at m/z 383. The neutral losses of 28 u, and 44 u suggest both decarbonylation and decarboxylation of the peptide molecule. Other significant ions found are ([C_1+Fe]^+), m/z 268, ([Y_1+Fe]^+), m/z 284, and ([B_2+Fe]^+), m/z 254. The ions M^+, A_1, A_2, Y_2, C_2, and B_1 are believed to be formed by charge exchange reactions between electronically excited Fe^+ species and the peptide neutrals. Future experiments will be directed at generating a higher proportion of ground state metal ions.

The products of the reaction of the tripeptide val-pro-leu with laser generated Fe^+ are shown in Figure 2a. The neutral losses of 28 u, and 44 u suggest both decarbonylation and decarboxylation of the peptide molecule. Other significant ions found are ([C_1+Fe]^+), m/z 268, ([Y_1+Fe]^+), m/z 284, and ([B_2+Fe]^+), m/z 254. The ions M^+, A_1, A_2, Y_2, C_2, and B_1 are believed to be formed by charge exchange reactions between electronically excited Fe^+ species and the peptide neutrals. Future experiments will be directed at generating a higher proportion of ground state metal ions.

Products of the charge exchange reaction between the tripeptide val-pro-leu and Ar^+ are shown in Figure 1. The peptide neutrals in the experiment were desorbed from a UV absorbing matrix using the 248 nm line of an excimer laser. This technique appears to reduce the amount of sample which is desorbed thus promoting only bimolecular collisions between the peptide and the reagent species. Previous charge exchange experiments performed without matrix and using the 193 nm line of an excimer laser produce ions which are formed both by charge exchange ionization of the peptide by the reagent ions and by a reaction
between these initially formed peptide ions and other peptide neutrals, i.e. self-chemical ionization. This is apparent in Figure 2b which shows the products of the reaction between pro-leu-val and Ar\(^+\), using 193 \(nm\) desorption of the peptide from a thin metal film. The presence of an abundant protonated molecular ion in this spectrum versus the that shown in Figure 2a suggest that for these conditions, desorption produces a large burst of peptide neutrals, allowing peptide ions formed by charge exchange to react with other peptide neutrals to form a protonated ion. Using the new "matrix assisted" neutral desorption technique, we have been able to perform laser desorption/chemical ionization experiments on compounds as large as the cyclic decapeptide gramicidin S, Figure 3.

REFERENCES

In Fourier transform mass spectrometry, ion signals are generated from the image currents induced on the detection plates of the ion trapping cell. The amplitude of an observed ICR signal is a complex function of both the number of ions in the cyclotroning packet and the ion motion in the cell. In contrast, other mass spectrometry technologies provide a direct measurement of the number of ions eliciting the observed response. In this work, a model is developed to calculate the number of ions cyclotroning in the cell from the amplitude of an ICR signal. With this technique, FTMS sensitivity and detection limits may be expressed in terms comparable to other mass spectrometry techniques. As an example, the sensitivity (C/Vg) of an EXTREL FT/MS system is determined.

Grosshans derived an equation describing the differential charge induced on the detection plates by a point charge as a function of the position of the point charge in a cell [1]. Equation 1, adapted from Grosshans' work, describes the maximum induced differential charge, $\Delta Q_{\text{max}}/q$, by a point charge, $q$, cyclotroning with radius, $r$, in an x-y plane in the center of a cubic cell, where $r$ is a fraction of the width of the cubic cell.

$$\frac{\Delta Q_{\text{max}}}{q} = \frac{16}{\pi^2} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n} \sinh[r\pi k_\text{max}]}{(2m+1)(2n+1) \sinh[k_\text{max} \pi/2]}$$

where

$$k_\text{max} = \sqrt{(2m+1)^2 + (2n+1)^2}$$

$\Delta Q_{\text{max}}/q$ from Equation 1 is used to determine the charge of the modeled point that would give rise to the amplitude of an observed signal. In order to correlate the modeled $\Delta Q_{\text{max}}$ with the amplitude of an observed ion signal, the voltage response of the FT/MS detection circuitry to a charge on the detection plates was determined. The output of the FT/MS preamplifier was measured to be $1.1 \times 10^{15}$ V/C.

The model was applied to Ar$^+$ signals generated in the source cell by El. The ions were excited to a radius 1/4 the width of the cell and the signal was recorded. Ion excitation to $r=0.25$ was achieved by exciting the ions with a SWIFT™ waveform with one half the minimum power necessary to begin to radially eject the ions from the cell. The Ar$^+$ signal had an initial amplitude of $5.7 \times 10^{16}$ coulombs which, through the 0.4071 ratio calculated with Equation 1 at $r=0.25$, corresponds to a $4.4 \times 10^{15}$ coulomb point charge. The $4.4 \times 10^{15}$ charge of the modeled point is equivalent to the charge of 4400 Ar$^+$ ions.
The 4400-ion charge of the modeled point calculated from the magnitude of the observed signal is not an accurate representation of the number of cyclotroning ions generating the signal. The following two methods were used to determine the number of ions generated in the cell: When the number of ions created is small compared to the number of neutrals in the EI region, the rate of ion generation, \( N \), in ions/s, can be calculated with the simple absorbance law relationship

\[
N = L \times I \times p \times \sigma_T(E)^2
\]

where \( L \) is the beam path length in cm, \( I \) is the electron beam current in electrons/s, \( p \) is the neutral density in neutrals/cm\(^3\), and \( \sigma_T(E) \) is the total ionization cross section of the sample in ions-cm\(^2\)/neutrals-electrons as a function of electron energy, \( E \) [2]. 3.7x10\(^7\) ions/s are generated by EI with the conditions used to generate the Ar\(^+\) signals: 10.0 µA beam current, 70 eV electron energy, and 1.0x10\(^{-9}\) Torr argon sample pressure in the 5.08 cm long cubic cell. The argon ionization cross section to 70 eV electrons is 3.6x10\(^{-16}\) ions-cm\(^2\)/neutrals-electrons [2]. At this ionization rate, 183,000 ions will be generated during a 5.0 ms beam.

The ionization rate calculated with Equation 2 was verified by direct measurement of the ion current generated in the cell. To make these measurements, ions were generated in the center of the FT/MS source-side cell by a continuous electron beam. An applied -75V potential to the excitation and detection plates caused the ions to spiral outward and collide with the plates. The current generated by a steady state ion collision with the excitation and detection electrodes was measured with an electrometer, providing the ionization rate. The direct ion current measurements indicate an ionization rate of 4.0x10\(^{7}\) ± 0.5x10\(^{7}\) ions/s will be generated by the EI conditions used to generate the Ar\(^+\) signals, in good agreement with the rate calculated with Equation 2.

The amplitude of Ne\(^{20}\), Kr\(^{84}\), and Xe\(^{131}\) ion signals were also correlated to theoretical \( \Delta Q_{\text{max}} \) to determine the effective charge of the modeled point. As seen with the Ar\(^+\) signals, the equivalent charge of the point is a factor of 41 ± 3 smaller than the number of ions generated in the cell by EI. Routine calculation of the number of ions generated by EI with Equation 2 is not possible since the ionization cross section of only a few atomic and simple molecular species is known. However, the factor of 41 ± 3 can be used to convert the point charge to the real number of ions. Calculating the point charge from the amplitude of an observed signal and multiplying the charge by 41 yields the number of cyclotroning ions in the cell giving rise to any signal. The 40-fold difference between the equivalent charge of the point charge model and the number of cyclotroning ions is a result of both the non-ideal behavior of the ions in the cell and a result of approximations used in the derivation of Grosshans’ equations.

The absolute sensitivity of the FT/MS instrument was investigated by using this process. 50.0 ng of naphthalene was evaporated under EI conditions and the integrated ion signal was determined. The integrated signal corresponds to 9.2x10\(^{-10}\) coulombs of ions for the 50 ng of naphthalene, yielding a sensitivity of 1.8x10\(^{-8}\) C/ng. This is in good agreement with the sensitivities of other high-performance mass spectrometers.

1. Grosshans, P. B., Thesis Ph.D., Ohio State University, 1990
Mechanisms are investigated by which the ions formed from laser desorption are trapped for detection in the FTICR trapped ion cell. Because the desorption event typically occurs outside the trapped ion cell, the LDI/FTICR experiment is similar to that performed with external source instruments in that ions must penetrate trapping fields and then experience a loss or redirection of energy with respect to the effective trapping fields to be retained. Several mechanisms for trapping externally generated ions can be postulated although experimental validation is difficult and has for the large part not been accomplished. A variety of laser desorption experiments are common including plasma ignition of metals, infrared thermal desorption of organic materials, often in the presence of an alkali salt, and matrix assisted UV laser desorption. Each of these generates an ion population with very different kinetic energy distribution, spatial distribution, and charge density, so it is likely that different mechanisms are involved for each in the trapping of ions detected by FTICR. To be presented here are data for the two separate cases of laser plasma ignition of metals and infrared thermal desorption of organic molecules.

**IR LDI of Organic Molecules.** The application of short, high energy IR radiation (>10^7 W/cm^2 from CO_2 or Nd:YAG lasers) to a wide range of organic molecules, biomolecules, and polymers has been very successful in that abundant intact cation-attached species often result. Kistemaker and others have shown the mechanism is likely a gas phase attachment process which generates low energy product ions. The general idea is that an overlap of neutral analyte molecules and higher energy cations which can penetrate the trapping potentials will react in the cell and produce a cation attachment species with sufficiently low kinetic energy to be retained. Shown in Figure 1 is a series of LDI/FTICR spectra acquired with our probe mounted fiber optic interface. Identical desorption conditions were maintained as the sample probe, coated with a 1:1 mixture of dilaurylthiodipropionate (DLTDP) and KBr, was displaced over a 40 cm distance from the trapped ion cell along the z-axis centerline. The continuous decrease in (M+K)^+ with increasing probe displacement is indicative of evolving gas phase distributions of cations and neutrals which no longer overlap in the cell. Low energy product ions formed outside the cell would have insufficient kinetic energy to penetrate the trapping electric field at the front trap plate. Also of interest is the precursor ion for this attachment. Through a series of TOF, variable trap potential, and ejection studies, we have found that the precursor is an adduct of the salt (K_2Br^+ for example) rather than the bare cation (K^+) which is responsible for formation of the product ions. Proof is shown in Figure 2 in the form of two LDI/FTICR spectra acquired for a mixture of KCl and DLTDP. Assuming the attachment process occurs in the trapped ion cell, then continuous ejection of the precursor ion will preclude formation of the (M+K)^+. In Figure 2a, K^+ is ejected, but a strong (M+K)^+ is observed. In contrast, in Figure 2b continuous ejection at the resonance corresponding to K_2Br^+ inhibits (M+K)^+ formation. This type of experiment was repeated for many salts and organic species and it was found that in general, A_2X^+ and A_3X_2^+ (A is Na, K, Rb and X is F, Cl, Br, I) are the precursors of a gas phase reaction that occurs for LDI/FTICR in the trapped ion cell to produce (M+A)^+.

**Trapping of Metal Ions from LDI.** It is a common practice to produce metal ions for ion/molecule reaction studies by using high power pulsed IR radiation to form M^+ in abundance in the trapped ion cell. Physicists have studied the characteristics of this type of ion formation for years and observed some remarkable features including the generation of multiply charged species (M^+, M^{++}, M^{3+}, M^{4+}) all with kinetic energies extending to hundreds and thousands of eV. Our interest with respect to FTICR is how such high energy ions are observed by FTMS given trap potentials which are orders of magnitude below the average energy of most ions in the distribution. Shown in Figure 3 are the kinetic energy profiles of the ion plasma generated from LDI of tin with the front trap plate of the FTMS cell biased at +80 and -80 V. Clearly a high energy plasma of both positive (M^+, M^{++}, ..) and negative (electrons) particles in what is essentially a neutral plasma encounters the trapped ion cell. This high energy plasma easily penetrates the trapping potentials, but it is not evident why abundant ions are retained in small trapping wells. Shown in Figure 4 is data which indicates what may be occurring. Here, the front trap plate is maintained at up to several hundred volts while the rear trap plate is held at 2V. Despite the skew in the trapping fields, large FTICR ion signals continue to be generated. It has been argued that the ions which are being trapped are those with sufficient energy to just make it past the front trap plate and then have some fraction of...
their axial kinetic energy deflected into radial motion. This would not explain however, Figure 4 data in which ions with in excess of several hundred eV would have to pass the front trap plate and lose hundreds of eV to be detected. The better explanation is that the neutral plasma provides shielding for low energy ions in the plasma (less than 2 eV) to pass the front trap plate. Then, deshielding from the continuously evolving plasma would expose these low energy ions to the trapping fields and allow them to be retained. This process would not have to be efficient - the number of ions generated by plasma ignition is much higher than observed for LDI of organic substrates.

The Positive and Negative Ion Condensation Chemistry of 
2, 4 - Cyclohexadieneone Iron Tricarbonyl ($\eta^4$-C$_6$H$_6$OFe(CO)$_3$) 
by FT-ICR Spectroscopy

Ziyi Kan and *Melvin B. Comisarow
Department of Chemistry, University of British Columbia, 
Vancouver, B. C. Canada V6T 1Y6

The gas-phase ion condensation chemistry\(^{(1,2)}\) of $\eta^4$-C$_6$H$_6$OFe(CO)$_3$ has 
been studied by Fourier transform ion cyclotron resonance (FT-ICR) mass 
spectroscopy.

For the positive ion chemistry, 40eV electron impact on the parent molecule 
generates 7 primary ions; Fe* (m/z56), (C$_5$H$_5$)Fe* (m/z121), C$_6$H$_6$Fe* (m/z122), 
C$_5$H$_5$Fe(CO)* (m/z150), C$_6$H$_6$OFe(CO)* (m/z178), C$_6$H$_6$OFe(CO)$_2$* (m/z206), and 
C$_6$H$_6$OFe(CO)$_3$* (m/z234). All the primary ions are chemically reactive with the 
neutral parent molecule. The condensation reaction products are typically of the 
form, ($\eta^4$-Diene)$_n$Fe$_n$(CO)$_m^+$ (n=2 or 3, m=1 to 5).

A fragmentation process\(^{(3)}\) of the parent molecule is proposed in scheme I. 
Here, we believe that the third CO loss is from the organic ring rather than metal 
bonded carbonyl. This is indicated by the relative rate constants of the primary 
ions\(^{(4,5)}\), shown in Figure 1. We can see that reaction rates increase with the 
increase of electron deficiency. For the structure, C$_6$H$_6$OFe*, the electron 
deficiency on the iron of m/z150 species would be 7 and its rate constant would be 
too small to fit the curve.

![Scheme I. Fragmentation process of $\eta^4$ - C$_6$H$_6$OFe(CO)$_3$](image)

![Figure 1. Trends of rate constants vs electron deficiency.](image)

![Figure 2. Temporal abundance of ions for C$_6$H$_6$OFe(CO)$^+$/C$_6$H$_6$OFe(CO)$_3$.](image)
As an example of the chemical processes, Figure 2 shows the kinetic behavior of CeH6OFe(CO)2+/parent molecule system. The reaction pathways for this system shown in the following are determined by the multiple resonance technique of FT-ICR. (n-4-CeH6O)3Fe3(CO)3+ (m/z534) does not undergo further condensation reaction due to electron saturation and spatial obstruction.

\[
\begin{align*}
(C_6H_6O)_3Fe(CO)_3^+ + M \rightarrow (C_6H_6O)_2Fe_2(CO)_2^+ + 3CO \\
(C_6H_6O)_2Fe_2(CO)_2^+ + 2CO \\
(C_6H_6O)_2Fe_2(CO)_3^+ + 2CO \\
(C_6H_6O)_2Fe_2(CO)_3^+ + M \\
\end{align*}
\]

For the negative chemistry, dissociative electron capture by the parent molecule of 0.5eV electrons generates two primary negative ions: C6H6OFe(CO)- (m/e178), and C6H6OFe(CO)2- (m/z206). The 17e species, C6H6OFe(CO)2- is unreactive with the neutral parent molecule. CeH6OFe(CO)- reacts with the parent to form products of the form (C6H6O)nFe(CO)m (n=2 to 4, m=1 to 6).

For the positive chemistry, products can be proposed from analysis of the reaction pathways and the reaction rate constants.

Some examples for ions generated from the primary ion C6H6OFe(CO)+ are shown in the following:

Unlike in the iron carbonyl system, only single metal-metal bonds are predicted for the structures of ionic products.

The rearrangement of carbenium ions by 1,2-migration is ubiquitous in organic chemistry with a rich body of information concerning the relative migratory aptitude of various groups[1]. α-Silyl-substituted carbenium ions (R3Si-CH2+) have been implicated in rearrangements involving 1,2-migration in α-functionalized silanes in solution, however, there is virtually no information regarding the relative migratory aptitude of various groups[2,3]. This is a consequence of the instability of organosiliconium ions (R3Si+) in solution under conditions where analogous carbenium ions are long lived[4]. We have initiated studies involving 1,2-migration of α-silyl-substituted carbenium ions by using Fourier transform mass Spectrometry (FTMS).

Nascent α-silyl-substituted carbenium ions are generated from the corresponding (chloromethyl)silane by three methods; 1) protonolysis, 2) chloride abstraction by Si(CH3)4+, and 3) direct electron impact ionization. For example, protonolysis of (CH3)2HSiCH2Cl by CH5+ yields primarily (CH3)2Si-CH2+ (1), process 1. The incipient carbenium ion, 1, may subsequently rearrange by either a 1,2-hydrogen migration or by a 1,2-methyl migration, processes 2 and 3, with both migrations highly exothermic. Theory has revealed that there is essentially no barrier for the strongly exothermic (~40 kcal/mol) 1,2-hydrogen migration for H3Si-CH2+, process 4[5]. In addition, 1,2-methyl migration for (CH3)2Si-CH2+ yielding (CH3)2Si+CH(CH3) is highly exothermic (~32 kcal/mol) and has little or no barrier. These results suggest that both 1,2-hydrogen and 1,2-methyl migration are feasible for carbenium ion 1.
Distinguishing the two rearrangement channels for carbenium ion 1 requires that the two distinct silicenium ions are distinguishable. We have found that specific ion/molecule reactions can readily distinguish structural silicenium ion isomers. For example, methanol reacts with Si(CH₃)₃⁺ yielding exclusively elimination of methane whereas SiH(CH₃)(C₂H₅)⁺ yields competitive eliminations of H₂ (0.49), CH₄ (0.23) and C₂H₆ (0.28). In addition, ethene- C₂ yields elimination of the corresponding olefin for reaction of organosilicenium ions containing a 2-carbon or larger alkyl substituent process 5. For the two SiC₃H₉⁺ isomers, Si(CH₃)⁺ is inert with ethene-C₂,

\[
\text{(CH}_3)_2\text{Si(C}_\text{H}_3\text{)}_{2\text{n+1}}^+ + \text{C}_2\text{H}_4 \rightarrow \text{(CH}_3)_3\text{Si}^+ + \text{C}_2\text{H}_5\text{H}_2 \tag{5}
\]

however, SiH(CH₃)(C₂H₅)⁺ yields clean elimination of unlabeled ethene (i.e., m/z 73 goes to m/z 75 cleanly). By combining these two specific ion/molecule reaction probes, virtually any structural silicenium isomers can be distinguished.

Employing the above methods reveals that nascent carbenium ion 1 undergoes exclusive 1,2-hydrogen migration. In addition, rearrangement of the following nascent α-silyl-substituted carbenium ions was also investigated; (CH₃)₂Si-CH₂⁺ (2), (CH₃)₃Si-CH₂CH₃ (3), (CD₃)₂Si-CH₂CH₃ (3δ) and (C₂H₅)₂Si(CH₃)CH₂⁺ (5). Both 2 and 3 undergo 1,2-methyl migration yielding the corresponding silicenium ion. The isotopically labeled carbenium ion, 3δ, confirmed that the rearrangement simply involves a 1,2-methyl migration (i.e., no isotopic scrambling occurs). Structural studies reveal that the incipient carbenium ion, 4, undergoes competitive 1,2-phenyl (0.94) and 1,2-hydrogen (0.06) migration. These results suggest the following relative group migratory aptitude: Aryl > H >> Me.

A Finnigan ion trap mass spectrometer (ITMS) has been coupled with a unique mounting platform that permits the rapid and precise placement of both laser optical and ion optical elements within the vacuum system. Ion lens elements and ion trap electrodes can be accurately positioned in new configurations and the laser beam can be readily focused into the volume of the ion trap or onto a sample probe for facile implementation of both ion and laser optical experiments. Laser photodissociation experiments serve as a powerful probe of ion trajectories within the ion trap. The ring electrode of the ion trap has been modified so that the interior volume of the trap can be probed by a XeCl excimer laser (308 nm) at different axial positions along the ion trajectory. In one series of experiments, mass isolated benzoyl ion (C$_6$H$_5$CO$^+$ from acetophenone) is dissociated to C$_6$H$_5^+$ upon photoactivation at 308 nm. The abundance of the photo-produced ion at m/z 77 is then related to the number density of the parent ion at the axial position probed by the laser. Figure 1 shows the axial ion distribution within the ion trap as a function of q$_z$. Ion density near the center of the trap increases non-linearly with q$_z$ (or RF voltage) as expected. Figure 2 dramatically demonstrates the effectiveness of helium buffer gas in stabilizing ion trajectories within the ion trap. Stored ions may also be excited by application of a supplementary RF voltage at the proper frequency to the end-cap electrodes ("RF tickle"). Figure 3 shows the elongation of the trajectory of the C$_6$H$_5$CO$^-$ ion stored at q$_z = 0.4$ effected by a "tickle" by 100 mV of RF voltage (approximately 151 kHz) applied to the end-caps. Photoionization studies can also be performed to illustrate the effects of ionization at different axial positions. Figure 4 shows the variation in abundance of the molecular ion of aniline as a function of q$_z$ and axial position formed by photoionization at 308 nm. The storage efficiency of the ion trap for ions produced by photoionization is seen to decrease as q$_z$ increases and, at least in these experiments, the sensitivity of the ion trap varies little for ionization occurring at displacements of a few millimeters from the center of the ion trap.

Figure 1. Axial distribution of C$_6$H$_5$CO$^+$ as a function of q$_z$. 
Figure 2. Helium buffer gas stabilization of ion trajectories within the ion trap. Ionization times were adjusted to maintain the same signal intensity for C₆H₆CO⁺.

Figure 4. The abundance of the molecular ion of aniline formed by photoionization at different axial positions and values of q₂.
A method is reported by which surface-induced dissociation (SID) is used to activate ions stored in a quadrupole ion trap mass spectrometer. The method employs a short (<5 μs), fast-rising (<200 ns rise time), high voltage (0-900 volt) dc pulse which is applied to the endcaps of a standard Paul-type quadrupole ion trap. Since the pulse rise time is considerably faster than one RF cycle (1 μs), it provides a means of effecting almost instantaneous radial instability of ions stored in the ion trap. The ions then collide with the surface of the ring electrode resulting in fragmentation. The fragments are scanned out of the ion trap using the conventional mass-selective instability scan mode. This SID method of activation is in sharp contrast to collisionally activated dissociation (CAD) where relatively long applications of a low voltage ac signal (0.1 to 2.0 volt for 10-100 ms) is used to resonantly excite the ions and cause dissociative collisions with helium.

In order to obtain more insight into ion motion in the trap under the conditions used here, ion trajectories were simulated using a program developed in our laboratory. The program has been found to give good results in comparison with experiments which measure the kinetic energies with which ions are ejected from the trap. Figures 1 and 2 display both the radial and axial positions and velocities for the pyrene molecular ion in the SID experiment described above. The radial simulation shows that approximately 2 μs after the initiation of the dc pulse the pyrene molecular ion strikes the ring electrode. The collision energies in this simulation depend heavily on the phase and position of the ion when the pulse is applied, but the typical data shown demonstrate that over 100 eV of radial translational kinetic energy is available. The simulation does not specifically include the effects of collisions with helium but at a pressure of 10⁻⁴ torr the collision frequency is on the order of one collision in ten rf cycles. Therefore, typically zero or one collision with helium occurs during the activation time. Simulation of motion in the axial direction, Figure 2, shows that the pyrene molecular ions remain in stable oscillation in this direction and that the axial kinetic energies remain small.

Sufficient internal energy is acquired in the surface collision to cause high energy fragmentations of relatively intractable molecular ions such as pyrene as is shown in Figure 3. The formation of the peak at m/z 122, although of very low intensity, requires approximately 17 eV of internal energy. The dissociations of limonene (Figure 4) are used to demonstrate that high energy demand processes increase in relative importance in the dc pulse experiment compared to the usual resonance excitation method used to cause activation. It is also apparent from the results obtained on limonene that a relatively wide range of internal energies is deposited in the activated parent ion. A small part may be due to contributions from CAD processes. However, the simulations suggest an additional interpretation, namely that collision energy and angle vary greatly with the initial (pre-dc pulse) conditions of the stored ion and hence a wide range of internal energy depositions can be expected.

The most direct evidence that surface induced dissociation is contributing to the product MS/MS spectra when the dc pulse is applied is found in data taken for the benzene molecular ion (Figure 5). Fragmentation occurs to give m/z 52, 51 and 50, among other ions. When a delay is introduced between the phase of the main rf cycle and the onset of application of the dc pulse, the abundances of these fragment ions vary with the magnitude of the delay in the fashion shown in Figure 6. Clearly, the interaction between the fields created by the dc and the main rf voltages has a strong effect on ion production. This is expected for the SID process, since the main rf field will alternately assist and resist acceleration of the parent ions to the radial electrode by the axial dc.

High Resolution High Sensitivity Tandem Mass Spectrometry in the Ion Trap Mass Spectrometer

Dept. of Chem., Purdue University, West Lafayette, IN 47907

R.E. Kaiser
Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, IN 46295

Progress is reported on the long term objective of transforming the quadrupole ion trap from a simple GC/MS instrument into a high performance tandem mass spectrometer. Using slow scan speeds as suggested earlier, mass resolution for peptides has been improved from 2,500 (FWHM) at 1500 dalton to more than 100,000 (Figure 1). This facilitates the recognition of effects such as reduction accompanying desorption ionization (Figure 2). In the case of salt clusters, resolutions in excess of 10^4 have been recorded (Figure 3). The resolution increases with mass and the factors which control resolution (scan speed, instrumental stability, and ion density, \textit{inter alia}) have been delineated with the assistance of simulations of ion motion. Not only is high resolution achieved in the mass spectrum but comparable resolution is achieved in MS/MS experiments, both in parent ion selection (MSI), and in fragment ion analysis (MSII). Figure 4 illustrates that in the case of protonated substance P, each of the major isotopic forms of the molecular ion gives characteristic fragments which together account for the product MS/MS spectrum of the mixture of molecular ions. The increased information available using high resolution MS/MS is illustrated in the case of gramacidin S in Figure 5, which displays MS/MS data taken on the unresolved protonated molecule as well as data for the ^13C,-isotopic form. These experiments were typically performed on picomole amounts of material which lasted for an hour or more.

Figure 1. Resolution achieved in the molecular ion region for the peptide, substance P. The mass spectrum (nominal masses shown) was recorded using resonance ejection with a 2.25x mass range extension. The scan speed was 55.6 dalton/second and the data shown are for a single scan taken in 0.02 seconds.

Figure 2. Cs+ ion bombardment mass spectrum of somatostatin recorded using glycerol (upper) and glycerol/dithiothreitol (lower) as matrix. Partial reduction of the disulfide double bond occurs in glycerol and is complete when the threitol is added.
Figure 3. Resolution in excess of a million achieved for \((\text{CsI})_n\text{Cs}^+\) using resonant ejection with a 6x mass range extension and a 2000x reduction in scan speed.

Figure 4. MS/MS data on substance P showing product ion spectrum recorded for the unresolved MH\(^+\) ion (upper) and the same region of the spectrum for the all\(^{12}\text{C}\) and the \(^{13}\text{C}-\text{MH}^+\) ions, respectively. The expected abundance distribution of the unresolved case shown in the box, matches that recorded. The experiment was done using 74 pmole of sample although this lasted much longer than the time needed to record this data.

Figure 5. MS/MS spectrum of peptide gramacidin S. Ancillary figures show the molecular ion region under high resolution and the result of isolating the \(^{13}\text{C}-\text{MH}^+\) ion at m/z 1142. The MS/MS spectrum derived by dissociation of this selected ion is also shown.
MICROCAPILLARY HPLC-ESI TANDEM MASS SPECTROMETRY: NEW METHODOLOGY FOR PROTEIN SEQUENCE ANALYSIS.

Jeffrey Shabanowitz, Paul A. Martino, Nian Zhou Zhu, Ashley M. McCormack, Nicholas Sherman, Hanapeter Michel, Janice E. Alexander, Wanda Bodnar, Andrea Cox, Quinchung Ji, and Donald F. Hunt.
Dept. of Chemistry, University of Virginia, Charlottesville, VA 22901

Fused silica columns (75μm 75 micron i.d.) are employed routinely in our laboratory for microcapillary HPLC separations of peptides conducted on-line with an electrospray ionization source on the Finnigan triple quadrupole mass spectrometer. Peptide mixtures to be analyzed are washed directly onto the head of the micro C_{18}-column and the individual components are then eluted into the triple quadrupole mass spectrometer for sequence analysis with a 15 min gradient of 0-80% acetonitrile at flow rates of 1-2 ul/min. Described here is the use of the above microcapillary HPLC columns to characterize posttranslational modifications of Class III, β-tubulin in microtubules and to identify the regulatory phosphorylation sites on mitogen activated protein kinase (MAP-kinase).

Microtubules, assembled from two similar 50 kDa proteins designated α- and β-tubulin, are involved in segregation of chromosomes during cell division, cell motility, organelle transport, and maintenance of cell shape. Class III, β-tubulin in mammalian brain cells undergoes a novel, developmentally regulated posttranslational modification, polyglutamylation plus phosphorylation on the C-terminal, 14 residue peptide having the sequence, YEDDEEESEAQGPK (1). To locate the sites of these modifications, a mixture of brain tubulins was digested the cyanogen bromide, and the C-terminal peptides from class III, β-tubulin were removed from the mixture by binding them to a monoclonal antibody, TuJ1. Bound peptides were then liberated from the antibody, converted to the corresponding methyl esters, and introduced to the mass spectrometer via the microcapillary HPLC column described above. Shown in Fig. 1 is the CAD spectrum recorded on the (M+2H)⁺⁺ ion derived from one of the posttranslationally modified peptides. Fragment ions of type y indicate that the last 12 residues of this 14 residue peptide are unmodified. Ions of type b₁ and b₂ are shifted to higher mass by 80 and 157 daltons. Accordingly, sites of phosphorylation and glutamylation are residues 1 and 2, respectively.

To characterize the posttranslational modifications of additional, less abundant, tubulin isotypes, we envisage use of a set of microcolumns connected in series. Immobilized enzyme to digest the crude tubulin mixture will be placed in the first column. The second column will contain immobilized monoclonal antibody to selectively remove peptides from a particular isotype and these will then be fractionated on a third column containing HPLC packing and eluted directly into the tandem mass spectrometer for sequence analysis.

MAP kinase, a 42 kd serine/threonine specific protein kinase of unknown sequence, becomes activated after phosphorylation on both tyrosine and threonine. Insulin, epidermal growth factor, platelet derived growth factor, and a number of mitogens all promote this activation. To deduce the phosphorylation sites on this protein, ³²P-labeled protein was isolated from mouse cell culture, treated with trypsin and the resulting peptides fractionated by microbore HPLC. One third of the fraction containing radiolabeled peptide (9 10 pmol) was then rechromatographed on the above microcapillary column and sequenced by tandem mass spectrometry (2). Shown in Fig. 2 is the CAD spectrum recorded on the (M+3H)⁴⁺⁺ ions derived from the doubly phosphorylated peptide. Assignment of charge to a particular ion in Fig. 2 was greatly facilitated by recording a second CAD spectrum on a 10 pmol sample of the corresponding peptide ethyl ester. Conversion of the peptide sample to its ethyl ester increases the mass of any particular fragment by 28, 14, and 9.3 daltons per carboxylic acid group for ions having a charge of +1, +2, and +3, respectively. Partial elimination of small neutral molecules such as ammonia, water and phosphoric acid also facilitates assignment of the charge on a particular fragment. A combination of singly, doubly, and triply charged fragments of type y were employed to deduce the complete sequence of this 19 residue peptide. Residues 13 and 15 were assigned as the sites of phosphorylation.

TANDEM MASS SPECTROMETRIC SEQUENCING OF CYTOKINE-INDUCED CELLULAR PROTEINS ISOLATED FROM 2-D GEL ELECTROPHORESIS

1Mass Spectrometry Facility and Department of Pharmaceutical Chemistry, 2Cancer Research Institute, 3Department of Pediatrics, University of California, San Francisco, CA 94143; 4Chiron Corporation, Emeryville, CA 94608

Tandem mass spectrometry continues to play a vital role in solving a variety of biological structural problems [1]. Previously, our laboratory demonstrated the feasibility of using a four sector tandem mass spectrometer with multi-channel array detection to obtain sequence information from proteins isolated from SDS-PAGE gels [2]. We now report the sequencing of cytokine-induced cellular proteins which have been isolated from two dimensional (2-D) gels at the 50 picomole level.

Tumor necrosis factor (TNF) and interferon-γ (IFN-γ) are cytokines that regulate the production or suppression of cellular proteins in normal [3] as well as tumor cells [4]. To understand the role these cytokines play in regulating cell growth it is vital that the primary structure of the proteins whose synthesis they enhance or suppress be determined as knowledge of the sequence of cytokine-induced or -suppressed cellular proteins will lead to identification of their function as well.

Proteins in lysates from cytokine treated human A375 melanoma cells were separated using 2-D gel electrophoresis employing isoelectric focusing in the first dimension followed by SDS-PAGE in the second. Considerable effort had been expended in attempts to sequence these proteins by Edman methods. In numerous instances sequence information was not obtained presumably because of blocked N-termini. Gel plugs containing three proteins whose synthesis is enhanced by IFN-γ were excised from the gel and purified by electroelution using a Centrisyn Gel Eluter followed by Konigsberg acetone precipitation (5). Of particular interest was a 50kD protein with an isoelectric point (pI) of 5.9. The purified proteins were then digested with trypsin and the resulting peptides separated using reverse phase microbore HPLC. Liquid secondary ion mass spectrometry (LSIMS), performed on a VG Analytical 70SE double focusing mass spectrometer, was used to obtain molecular ion maps of each digest. A cesium ion beam and accelerating voltage of 8kV was used for this instrument and all scans were processed on a VAX station 3100 with a OPUS data system. Collision induced dissociation (CID) mass spectra were obtained, for tryptic components which gave the most abundant molecular ions, using a Kratos Concept four sector tandem mass spectrometer equipped with a 4% multichannel array detection system.

Several sequences were obtained from interpretation of the CID data. The 50kD protein with pI 5.9 yielded three peptide sequences. A search of the Protein Identification Resource Dayhoff database revealed that two of the sequences showed 100% homology to a human cytoskeletal protein. The remaining sequence showed no homology to any of the proteins in the database. We are currently refining our protocol so that a greater quantity of these proteins can be isolated. This work has demonstrated that by combining the sensitivity of high performance tandem mass spectrometry with the superior resolving power of 2-D polyacrylamide gel electrophoresis it is now possible to isolate and obtain sequence information from an individual protein originating from an extensively heterogeneous cell lysate. In addition, our procedure is not restricted to proteins and peptides which have only unblocked N-termini.

The Utility of N-Peracetylation of Proteins for their Structure Determination by Mass Spectrometry

Roland S. Annan and Klaus Blemann
Department of Chemistry, MIT, Cambridge, Ma. 02139

Mass spectral analysis of acetylated peptides has been shown to be useful for determining the number of lysines in the native peptide, by examining the mass shift in the molecular weight of the peptide before and after acetylation. The isobaric amino acids lysine and glutamine can be differentiated by examining the CID spectrum of the acetylated peptide. The mass of the lysine residue is shifted to 160 u while the glutamine residue remains at 128 u.

Determination of the linear sequence of an unknown peptide in our laboratory normally involves enzymatic or chemical digestion of the protein, molecular weight analysis of the hydrolysis products by FAB-MS, and then determination of their sequence using CID and MS/MS. The first digestion is performed with trypsin, because it yields reliable cleavages at the C-terminal side of arginine and lysine. The digest products usually give good CID spectra, because a basic amino acid at either the N- or C-terminus directs fragmentation.

Enzymatic digestion with other common proteases, such as chymotrypsin or Endo Glu-C, frequently results in peptides which have either no basic amino acids, or they are in the interior of the sequence. The CID spectra of these peptides are sometimes either quite complex or the sequence information is incomplete. A useful technique to overcome this problem is derivatization of the N-terminus with a quaternary ammonium group. This functional group directs the fragmentation to such an extent, that virtually only N-terminal a and d are observed, regardless of the other structural features of the sequence. Unfortunately, because this derivatization reaction involves a primary amino group, derivatization of the e amino group of lysine is a competitive process. Since the ion current is now split into two product species, the sensitivity of the analysis is reduced. Acetylation of the peptide to block the lysines is not useful, since this would also acetylate the N-terminus to which the quaternary ammonium group is being attached.

We have recently been investigating the utility of N-acetylating intact proteins, and then analyzing the CID spectra of peptides which result from enzymatic digestion. The protein (1-10 nmoles) is dissolved in glacial acetic acid and then an equal amount of acetic anhydride is added. Reactions are carried out at 40 °C for 2-3 hours. Under these conditions, the protein is usually over acetylated, therefore, after removal of the reagents by lyophilization, the protein is redissolved in 1M NH₄OH and allowed to sit at room temperature for 1 hour. This step removes most of the O-acetyl groups formed in the first step. LD-TOF analysis after the derivatization of Cytochrome C (Mₐ = 12359) reveals an average MW of 13,199 daltons, indicating the addition of 20 acetyl groups. Cytochrome C has 19 lysines and an acetylated N-terminus, i.e. the average of one hydroxyl group has been esterified.

![Figure 1. Molecular Weight Determination of Acetyl Cytochrome C by LD-TOF-MS](image-url)
For reasons discussed above, enzymatic digests other than trypsin were used to generate peptides for sequence determination by CID. Chymotryptic digestion of acetylated Cytochrome C and analysis of the resulting peptides by FAB, yielded complete coverage of the protein sequence and showed that several peptides, each of which contained one or more threonine residues, had a complementary peptide 42 u higher. Examination of the CID spectra of several of these peptides revealed that in fact the threonines had been partly O-acetylated. Only one of the over acetylated peptides was present in high abundance. Since our purpose in this work is to examine the enzymatic digestion of the acetylated proteins, and the CID spectra of the resulting peptides, we are not overly concerned with a small amount of over acetylation. A further point worth mentioning, is that because the chymotryptic digestion of cytochrome C requires over 24 hrs, a significant number of tryptic cleavages occurred in the native protein at lysine. This produced many small peptides, a significant number of which were lost, and resulted in only 64% coverage of the amino acid sequence. Since the acetylation of the lysines renders them inert to trypsin, the chymotryptic digest of acetylated cytochrome C contains only chymotryptic peptides (even after a 37 hour digestion) and is complete.

Since lysine occurs more frequently than arginine, chymotryptic and Endo Glu-C digests of acetylated proteins produce mainly peptides containing no basic amino acids. The CID spectra of such a typical peptide is shown in Figure 2a. These spectra are generally simple, showing only b, and y, series ions. The presence of acetyl lysine is easily recognized by the presence of an abundant cyclized immonium ion (KAc) at m/z 126 and an ion resulting from the loss of the acetylated side chain from the [M+H]+ ion. Unfortunately, these spectra do not contain either d, or w, side chain cleavage ions, and, therefore, as is the case in Figure 2a cannot distinguish leucine from isoleucine. Since we would normally always begin the structure determination of a protein with a tryptic digest of the native protein, the two digests should be examined for overlapping sequences. Figure 2b shows a tryptic peptide which overlaps five of the amino acids in the chymotryptic acetylated peptide. This spectrum clearly indicates that both of the amino acids in question in Figure 2a are leucine. If no overlapping peptides were found, an N-terminal quaternary ammonium derivative of the chymotryptic peptide could be made, and its CID spectrum measured.

Finally, unless the N-terminus of the protein is already blocked, it can be readily determined, since the N-terminal peptide will be the only one with an acetylated N-terminus. This is readily determined from the CID spectrum, since N-terminally acetylated peptides give abundant b, ions.
DESIGNING A REAGENT TO CLEAVE CARBONYL-NITROGEN BONDS IN PEPTIDES IN AN ANION-MOLECULE REACTION.

Xueheng Cheng and Joseph J. Grabowski;
Department of Chemistry, Harvard University, Cambridge, MA 02138.

The current method of obtaining protein sequence information by mass spectrometry is based on the analysis of the fragment ions which are formed in certain collisional processes (FAB, SIMS, MS/MS-CAD, etc.). Using chemical reactions to cleave peptide bond is an attractive alternative. In contrast to these collisional processes which are largely controlled by energy redistribution, the efficiency and selectivity of chemical reactions are determined by the reactivity of the substrates and reagents and therefore, can be controlled much better with the knowledge of chemical reactivity of amides, peptides and proteins. Endothermic proton transfer has been used to induce fragmentation at low collision energy with an increased efficiency [1]. Our approach is based on the use of chemical reaction to cleave the peptide bond in a specific fashion. The development of reagents to cleave carbonyl-nitrogen bond of peptides in a gas-phase anion-molecule reaction will be the subject of this report.

Amides are relatively unreactive both in solution and in the gas phase. Although, cleavage of amide bond has been observed in the reaction of HOO' with HCO-NMe₂ [2] and, in our flowing afterglow study, with MeCO-NMe₂, proton transfer becomes predominate when acidic protons are available in amides, which would be more true in peptides. We then adopted the strategy outlined in Scheme 1 where the deprotonated amides are used to react with neutral reagents to block the proton transfer. The neutral reagents are chosen based on their ability to generate nucleophilic species in the collision complex and to activate the amine leaving group. A variety of neutral reagents were studied and several of them were found to cleave the MeCO-NMe₂ bond as shown in Table 1. The most effective of them, S-ethyl trifluorothioacetate, CF₃COSEt reacts with deprotonated anions of several amides and our dipeptide model compound to give corresponding RCO-NR' bond cleavage product CF₃CONR' (Table 2) in a facile reaction. The major competing pathway with the formation of CF₃CONR' is the formation of the product ion corresponding to the loss of EtSH from the collision complex, [RCONR' + CF₃COSEt - EtSH]. The EtS' ion formed in the collision complex can attack a carbonyl group activated by CF₃CO or abstract an available proton as shown in Scheme 2, the ratios of the two products are found to correlate roughly with their basicity (Table 2).

Our results demonstrated the cleavage of RCO-NR' bond of amides and dipeptide analogs specifically and effectively in a gas phase anion-molecule reaction. This is the first step towards a viable alternative to the existing techniques of mass spectrometric analysis of protein sequence. A possible practical application involves low energy CAD experiment of [M-H]⁺ ion of a peptide with hydrogen peroxide, HOOH and trifluoroacetic acid esters, CF₃COX (X = OR or SR) to form fragment ions corresponding to N- and C-terminal sequence of the peptide respectively.

FACILE ASSIGNMENT OF DAUGHTER IONS PRODUCED BY COLLISION-INDUCED DECOMPOSITION OF A PEPTIDE IN FAB MASS SPECTROMETRY

Toshifumi TAKAO, Hideaki IIORI, Kazutake OKAMOTO1, Akira HARADA, and Yasutsugu SHIMON

Institute for Protein Research, Osaka University, Yamadaoka 3-2, Suita, Osaka 565, Japan
1Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560, Japan

Collision-induced decomposition (CID) method combined with two- or four-sector (MS/MS) mass spectrometer is making a significant contribution to sequence analysis of a peptide and protein.1,2,3 In a CID mass spectrum, the daughter ions produced from a precursor ion provide information on the amino acid sequence of a peptide from both amino- and carboxyl-terminal. However, one of the drawbacks of CID spectra is the insufficient assignment of complicated signals of daughter ions from peptides to amino acid sequences.

The enzyme-catalyzed isotope exchange with $^{18}$O in $^{18}$O has been successfully applied to analysis of biological compounds by mass spectrometry.4,5,6 In protein sequence analysis it was found to be useful for identification of the C-terminal peptide or amino acid of a protein. In this work we report a method for the assignment of sequence ions of a peptide to the amino acid sequence by CID/linked-scan analysis in combination with the above procedure for incorporating $^{18}$O into the C-terminus of the peptide. The method is comprised of the following procedures: 1) A protein is digested by an enzyme in an appropriate buffer containing $^{18}$O-labeled water (40 atom % $^{18}$O). $^{18}$O atoms are incorporated into a part of the C-terminal α-carboxyl groups of all the digested peptides of a protein except the original C-terminal one. 2) The digest is separated into the constituent peptides by reversed-phase high-performance liquid chromatography. 3) The peptides are submitted to CID mass measurement using a B/E linked-scan mode, where the electric field (E) and magnetic field (B) were changed, keeping the ratio of B/E constant. The precursor ion of the peptide containing $^{18}$O in part of its C-terminal carboxyl group showed a doublet signal (M+1 and M+3). Thus the CID/linked-scan spectrum of the $^{18}$O-labeled peptide gave two series of sequence ions: one, originating from the N-terminus of the peptide, had the natural isotopic ion distributions, while the other, originating from the C-terminus, showed doublet signals due to partial incorporation of $^{18}$O into the C-terminal α-carboxyl group. These two series of sequence ions could be readily differentiated in a single CID/linked-scan spectrum.

Figure 1 shows a comparison of the typical CID/linked-scan mass spectra of one of the tryptic peptides derived from sperm whale myoglobin (Ala-Leu-Glu-Leu-Phe-Arg (134-139)) obtained in a buffer prepared with 40 atom % $^{18}$O (upper) and normal water (lower). The sequence ions derived from the N-terminus of both $^{18}$O-labeled and non-labeled peptides (a and b series) gave the natural isotopic ion distributions, while those from the C-terminus of $^{18}$O-labeled peptide (x, y, z and w series) in the upper spectrum gave the doublet signals due to partial incorporation of $^{18}$O into the C-terminal carboxyl group. It demonstrated that $^{18}$O atoms were retained at the α-carboxyl group of the sequence ions originating from the C-terminus of the peptide. Thus, the sequence ions could be readily classified as N-(-Glu-Leu-Phe-) and C-terminal (Ala-Leu-Glu-Leu-Phe-) ones by a single-scan spectrum of the $^{18}$O-labeled peptide and unambiguously assigned to the above amino acid sequence.

This work demonstrates that the CID/linked-scan method in combination with a procedure for incorporating $^{18}$O into the C-terminus of the peptide is effective for the analysis of sequence ions of a peptide. It allows reliable assignment of sequence ions to amino acid sequence with only small samples, and can be
readily applied to a conventional two-sector mass spectrometer equipped with a collision cell.

Figure 1. CID/linkccl-scan spectra of a tryptic peptide (Ala-Leu-Glu-Leu-Phe-Arg (134-139)) of sperm whale myoglobin obtained in buffer prepared with 40 atom % H$_2$O (upper) and normal water (lower). The sequence ions are denoted according to the previous paper. The solid and broken lines in the upper spectrum show a series of sequence ions containing N- and C-terminus of the peptide, respectively.
Assigning binding sites of a peptide to a transition metal ion is of significant biological importance. Studies of interactions between peptides and transition metal ions have been carried out in our group by \(^{252}\text{Cf}\) plasma desorption mass spectrometry (PDMS). Generally speaking, potential binding sites of a peptide to a metal ion are the N-terminal amino group, the C-terminal carboxyl group, the deprotonated amide nitrogen and some side-chain groups\(^1\). Studies of angiotensin II (ANG II) with Cu\(^{2+}\) and Ni\(^{2+}\) by other analytical techniques have shown that Cu\(^{2+}\) and Ni\(^{2+}\) bind to ANG II at the N-terminal amino group and its three succeeding deprotonated amide nitrogens when the pH of the solutions is above 8.5 and 9, respectively \(^2\)(\(^3\)). Mass spectrometry in general has not been used in investigating interactions between peptides/proteins and transition metal ions. It is the purpose of this paper to show that PDMS is valuable to the study of bindings between ANG II and Pd\(^{2+}\).

ANG II (asp-arg-val-tyr-ile-his-pro-phe) consists of eight amino acid residues and has a molecular weight of 1046 amu. The PDMS mass spectrum is presented in figure 1. The mass region from m/z 240 to m/z 980 is magnified 10 times. In Fig. 1., \((\text{M}+\text{H})^+\) is the base peak, and the most abundant fragment ion corresponds to \((\text{M}+\text{H}-\text{COOH})^+\). Among the peptide sequencing fragments, the \(a_n\) series are detected completely. Other N-terminal ions include several \(c_n\) ions and \(b_n\). Compared to the N-terminal fragments, much fewer C-terminal fragments are detected and these C-terminal fragments are in the higher mass region. The abundances of all the sequencing fragments are less than 10 \% of that of \((\text{M}+\text{H})^+\).

The mass spectrum depicted in Fig. 2 is obtained from an ANG II-K\(_2\)PdCl\(_4\) solution with a 1:1 molar ratio of the peptide and the transition metal ion. The pH of the solution is about 3.5. The features of this spectrum are very distinct from the one of ANG II in Fig. 1. In the molecular ion region, the \((\text{M}+n\text{Pd})^+\) \((n=1-5)\) peaks are displayed in addition to \((\text{M}+\text{H})^+\). The relative intensities of \((\text{M}+n\text{Pd})^+\) to \((\text{M}+\text{H})^+\) decrease dramatically with the increase of \(n\). \((\text{M}+\text{Pd})^+\) is 85 \% and \((\text{M}+2\text{Pd})^+\) is only 11 \% relative to \((\text{M}+\text{H})^+\). In other words, one ANG II molecule can bind to several Pd\(^{2+}\), but only one of the Pd\(^{2+}\) is tightly bound.

In the fragment ion region of Fig. 2, \(a_2+\text{Pd}\) is the dominate ion. Its intensity relative to \((\text{M}+\text{Pd})^+\) is 81 \%. Also, \(a_3+\text{Pd}\), \(a_4+\text{Pd}\), \(a_5+\text{Pd}\), and \(a_7+\text{Pd}\) are detected. Their relative abundances to \((\text{M}+\text{Pd})^+\) vary from 25 \% to 5 \%. The detection of the intense \(a_2+\text{Pd}\) peak proves that a Pd\(^{2+}\) ion is tightly bound to the two amino acid resides at the N-terminal. There are four binding sites available among these two residues: the N-terminal amino group, the carboxyl group in the aspartic acid residue, the guanidinium group in the arginine residue, and the adjacent deprotonated
amide nitrogen. The observation of the abundant \((M+Pd-COOH)^+\) ion suggests that the carboxyl group is not ligated to the Pd\(^{2+}\). The guanidine group in the arginine residue behaves like a glycine residue when the pH is below 10(2). Therefore, we believe that the N-terminal amino group and its adjacent deprotonated amide nitrogen are ligated to the Pd\(^{2+}\) ion. In addition, these two ligand sites are suitable to form a 5-membered ring which complexes to the Pd\(^{2+}\). Due to their high relative abundances, the \(a_n\) series ions provide stronger peptide sequence information compared to the \(a_n\) series shown in Fig. 1. Palladium has several major isotopes which cause the broadened peak appearances. This feature assists in identification of Pd-related fragment series.

ANALYSIS OF LARGE PROTEINS BY ELECTROSPRAY MS: APPLICATION TO SOLUBLE COMPLEMENT RECEPTOR

Steven A. Carr, Todd Armbruster, Mark E. Hemling, K. Karl Soneson, and Michael J. Huddleston

This paper details our progress to date on the use of LC-ESMS to confirm the overall sequence fidelity and to establish glycosylation-site usage of a recombinant form of complement receptor type 1 (sCR-1, also known as CD11b) expressed in mammalian cell culture by T-Cell Sciences, Cambridge, Massachusetts. sCR-1 is a 250 kDa glycoprotein that contains thirty tandem repeats of a sixty amino acid domain connected by short (<10) amino acid bridges. The interdomain homology is high, varying from 60 to 69%. There are 25 potential N-linked glycosylation sites. Conventional sequence analysis has been daunting due to the size and complexity of the protein, the very high internal homology, and the presence of an N-terminal block.

The protein was reduced and carboxymethylated (RCM) under standard conditions, and then digested in separate experiments with trypsin alone, and PNGase F and trypsin. Because of the high internal sequence homology, we also explored the use of low frequency cleavage strategies, particularly cyanogen bromide (CNBr) for cleavage at Met. There are 23 Met residues in the protein, and the peptides that would be generated range in molecular mass from ca. 1 to 20 kDa. Our intent was to explore the high mass capabilities of the ESMS system to assign these fragments to unique sequence locations.

The total ion current trace for a typical microbore LC-ESMS analysis of a tryptic digest of reduced and alkylated sCR-1 glycoprotein is shown in Figure 1. The profile is enormously complex reflecting the very large number of peptides and glycopeptides that are generated in a digest of a large protein such as sCR-1, and each chromatographic peak generally contains several components. In order to simplify detection and assignment of peptide components, we have rewritten and coded the Biller-Blemann spectral reconstruction algorithm for use on the Macintosh. This program, which we call "Enhance" resolves LC components that nearly co-elute chromatographically. It does this by determining where in time (i.e., scan number) each mass peak maximizes. The program then eliminates these masses from scans where they have not maximized. This results in dramatically improved apparent chromatographic resolution, and simplified mass spectra. The effect on the above mentioned digest of sCR-1 is illustrated in Figure 1, bottom.

Several procedures have been developed in our laboratory for detection of glycopeptides in the LC-ESMS analyses of glycoproteins. The most recent of these involves LC-ESMS/MS in parent ion scanning mode, and is described elsewhere in this volume (see MP 75, Huddleston et al.). In another procedure, glycopeptides are detected by comparing the LCMS-derived peptide maps of the protein obtained before and after treatment of the glycoprotein with an endoglycosidase, most commonly either PNGase F or Endoglycosidase H. The former is particularly useful as it releases the carbohydrate moiety en bloc from the protein, and converts the attachment-site Asn to an Asp which weighs 1 Da more. The ES mass spectrum of a glycopeptide identified in this manner is shown in Figure 2. Heterogeneity of the carbohydrate moiety of this glycopeptide is readily apparent from the peaks in the (M + 3H)^+ cluster that are separated by the in-chain masses (divided by the charge of +3) of sialic acid and Hex-HexNAc. The spectrum of the former glycosylation-site peptide (not shown) indicates that the attachment site is (either or both) Asn897/Asn447. The mass difference between the former glycosylation-site peptide and the glycopeptide signals indicate a composition of NeuAcα2→3Galβ1→4Galβ1→NAc, dHexα1→HexNAcα1→Hexα1→. Glycopeptides with masses in excess of 6 kDa were directly detected in the LC-ESMS data. Thus far, at least 10 glycopeptides have been identified in this manner.

The carbohydrate moieties of N-linked oligosaccharides in glycoproteins are most often heterogeneous. We have written a program that takes advantage of the resulting predictable peak multiplicity to locate glycopeptides. The program, which we call Peak Pair Search looks for pairs of ions (within a user definable window of scans) separated by user defined mass increments. It is similar to software developed by Andergott et al. for selective location of mass spectra of Si-containing, or halogenated compounds in GCMS. The program can also be used to identify other compound classes such as phosphopeptides which lose, or can be induced to lose, a portion of the molecule indicative of the modification of interest. For glycopeptides we use 146, 162, 203, 291, and 335 (and their corresponding multiply-charged versions, e.g., 281 and 379) corresponding to dHex, Hex, HexNAc, NeuAc, and Hex-HexNAc, respectively. More than 14 glycopeptides have been identified in sCR-1 using this algorithm. An example of the present tabular output is shown in Figure 3. The program can be viewed as a software analog of a constant neutral loss scan.

The CNBr digest of RCM sCR-1 was separated on 2.1 mm C18 reverse phase, and fractions were analyzed either on-line or by infusing aliquots of collected peaks directly into the Sciex electrospray mass spectrometer. Many of the CNBr fractions indicate the presence of complex mixtures of glycopeptides. Although it is possible to assign various molecular weight series to the spectra, correlating the observed molecular weights with specific regions of the sequence has proven more difficult due to the carbohydrate heterogeneity. At present only seven of the 23 possible CNBr peptides ranging in mass from ca. 1000 to 16000 have been assigned.

Data collected in the three LCMS experiments described corroborate ca. 75% of the sequence of this 250 kDa glycoprotein. The LCMS experiments each required only a few hours for data collection rather than several weeks of instrument time as was needed previously for analysis of collected fractions off-line. Data interpretation required approximately one week. This is far faster than we have been able to carry out similar experiments in the past on much smaller proteins.
Figure 1. (top): Total ion current trace of the LC-ESMS analysis of a tryptic digest of sCR-1. Separation was carried out on a 1 mm C-18 column with a TFA/CH₃CN/H₂O gradient at a flow rate of 40 µl/min.
(bottom): The total ion current profile resulting from use of the Enhance algorithm on the above data set.

Figure 2. Electrospray mass spectrum of a glycopeptide identified in the LCMS analysis of a tryptic digest of sCR-1 using comparative LCMS mapping (see text).

Figure 3. Representative output of the program Peak Pair Search for analysis of a small number of scans (525 to 600) from the LCMS data shown in Figure 1. In this case the mass difference analyzed for is 291, the in-chain mass of NeuAc; a scan window of +10 was used. Masses in the delta amu column correspond to the +2 to +5 charge states of 291; delta scan indicates the relative scan number where the second peak (Peak2) of the peak search pair was found.
Covalent attachment of polyethylene glycol (PEG) to enzymes has been shown to prolong plasma half-lives significantly (1) and thereby to improve the therapeutic potential of the enzymes. We have developed and partially implemented a strategy for characterizing PEGated proteins. The strategy involves determination of the number and location of attachment sites as well as the molecular weight distribution of the polyethylene glycol polymers attached. Bovine erythrocyte superoxide dismutase (SOD) was reacted with methoxypolyethylene glycol-succinimidyl succinate with an average molecular weight of 5000 (2) to give the PEG-SOD used in this work. This reaction takes place preferentially with primary amines located on the lysine side chains of SOD linking PEG to lysine via a succinyl group. Treatment of PEG-SOD with base removes the PEG leaving a succinimidyl marker on the lysine. The protease digestion products of reduced and alkylated dePEG-SOD and SOD were subjected to high performance liquid chromatography (HPLC) and tandem mass spectrometry to demonstrate that at least eight of the ten lysines in SOD monomer can be partially derivatized. Figure 1 shows the mass spectra obtained for one of the HPLC peaks from clostripain digestion. The observed m/z 3707.5 corresponds to peptide [78-113] (calc. M$^+$, monoisotopic, 3706.96) which contains one lysine at position 89. The peak at m/z 3789.5 shown in the dePEG-SOD product is 82 higher signaling the presence of the linker. Figure 2 shows the MSMS of m/z 1578.9 found in another of the clostripain digestion of dePEG-SOD HPLC fractions. The fragmentation pattern clearly supports the assignment of peptide [114-126] with a derivatized lysine at position 120. Figure 3 shows electrospray ionization spectra for SOD and dePEG-SOD. The shift from a maximum at +15 for SOD to a maximum at +12 for dePEG-SOD is consistent with lysine derivatization. Analysis of the clusters at each charge suggests that from 2 to 6 PEGs were attached to each SOD monomer. The FABMS and MSMS were made on a JEOL HX110/HX110 high performance mass spectrometer while the electrospray ionization spectra were made with a Vestec source on a Hewlett Packard 5988A quadrupole mass spectrometer.

This work was supported by grants from the National Science Foundation and Sterling Drug Inc.

Figure 3.
A polypeptide molecule was constructed from artificially synthesized DNA using recombinant DNA technology. This "artificial protein" was assembled to study the effects that govern crystallization in ordered co-polymers and to test the feasibility of using recombinant DNA technology for the manufacture of totally new polymeric materials. If polymers can be constructed in this way, new materials with protein-like properties can be manufactured.

The polypeptide molecule was constructed using the following sequence of steps:

1) a repetitive sequence of DNA coding for the peptide AGAGAGAGPEG was synthesized;
2) this DNA was introduced into E. coli and amplified;
3) this sequence was isolated from the E. coli and polymerized;
4) the polymers were purified and the 14-mer was spliced between two short DNA sequences coding for polypeptides sequences that could be easily removed by CNBr digestion;
5) the synthetic gene was then inserted into E. coli and expressed; &
6) the protein was purified from the resulting culture.

The sequence -AGAGAGAGPEG- was expected to form one turn of a reverse pleated beta-sheet conformation. Therefore, the polypeptide product was expected to take on a conformation similar to that of naturally occurring fibrous proteins (e.g., collagen).

Definitive analysis of the protein product was problematic. Amino acid analysis was of limited use because of the highly repetitive and segmented nature of the molecule. Sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis showed a homogeneous product with an $M_r = 40$ kDa, while the expected $M_r$ of the protein was 17 kDa. NMR and FTIR studies confirmed the presence of the expected side groups but did not give any information about the length of the polymer.

Mass spectrometry was performed at Rockefeller University to determine the structure of the product. The expected product protein contained very few basic residues, therefore electrospray ionization was not feasible. Matrix-assisted laser desorption allowed the characterization of the protein product. The analysis determined that there was an intact product with a molecular mass 56 u higher than expected and that the sample contained a large number of hydrolysis products of the original molecule (~ 50 polypeptides could be identified in the sample). These smaller polypeptides could be removed from the sample by dialysis.

The 56 u discrepancy between the expected and observed molecular species was investigated by analysis of the DNA in the final recombinant E. coli culture. This analysis led to the discovery of two point mutations made by the bacteria, leading to the substitution of two valine residues for two alanine residues. The reasons for this mutation and the identity of the proteolytic agent that led to the formation of the unexpected polypeptide fragments are currently under investigation.
Mass spectrometric analysis of recombinant glycoproteins.

Schering-Plough Research, 60 Orange Street, Bloomfield, NJ 07003, Harvard University, School of Public Health, Boston, MA 02115 and Institut of Medical Physics, University of Münster, Münster, Germany.

Structure characterization of biologically active proteins is an integral part of the biotechnology efforts towards the development of novel therapeutic and diagnostic agents by recombinant DNA techniques. Characterization of these molecules with regard to purity and structure presents one of the most difficult and challenging analytical tasks, especially since these proteins are often known to undergo various post-translational modifications, such as glycosylation, phosphorylation and formation of disulfide bonds. The extent and the structure of such post-translational processing depends on the cellular expression system used.

This report describes the application, as well as assesses the analytical utility, of various mass spectrometric techniques (LSI, PD, LD ans ESI) to the structural characterization of the N-linked carbohydrate chains in recombinant human interleukin-4 (IL-4) and interleukin-5 (IL-5) expressed in Chinese hamster ovary (CHO) and NS-1 cells.

In the case of CHO IL-4, LSI mapping of the V8 protease digest of the glycosylated and deglycosylated IL-4 showed that the attachment site of the carbohydrate chain was the first of the two potential glycosylation sites, i.e., Asn-38 (see Proceedings of the 38th ASMS Conference, pp. 1341-2). In these preliminary studies, LSI and PD mass spectrometric analysis of the N-Glycanase-released carbohydrate after derivatization, showed the presence of a fucosylated, disialylated, biantennary complex-type oligosaccharide as the major component. In addition, the PD mass spectrum of the peracetylated carbohydrate exhibited signals corresponding to variations in sialic acid content and/or additional N-acetyllactosamine units due to either higher order branching structures and/or arm extensions as shown in Table I. These assignments agreed well with the oligosaccharide molecular weight information (ca. 2500 Da) deduced by the PD mass spectrometric analysis of the IL-4 glycoprotein prior to and after the enzymatic removal of the carbohydrate moiety. It should be noted that the PD mass spectrum of CHO IL-4 did not provide information on the heterogeneity of the carbohydrate component, even though the presence of heterogeneity was apparent in the doubly and triply charged molecular ions (the singly charged molecular ion was weak).

Analysis of the E. coli and CHO IL-4 by matrix-assisted UV LDMS exhibited an intense M+ signal which was accompanied by weaker signals corresponding to M+2 and 2M+ molecular ions. Even though the size of the carbohydrate moiety was readily determined to be ca. 2 kDa, no definite information on the carbohydrate heterogeneity was available from these data (Figs. 1,2). On the other hand, mass spectrometric analysis of CHO IL-4 by ion spray provided information on the major glycoforms present in the glycoprotein sample. The ion evaporation spectrum showed three envelopes of multiply charged ions (i.e., to 10+) each comprising eight peaks which corresponded to the individual glycoforms of the glycoprotein, as it is clearly shown in the reconstructed spectrum (Fig. 4). For example, the asterisk-denoted ion envelope in Fig. 3 corresponds to the glycoform at m/z 17019 in Fig. 4. This determination is consistent with the mass values derived from the PDMS analysis of the peracetylated oligosaccharide. It should be noted that each glycoform signal in the ion evaporation spectrum was accompanied by an adduct ion 98 Da higher, possibly due to the addition of H2SO4. Therefore, the MW determination of the glycoprotein by the ion-spray ionization method, provided more information on the existing glycoform pattern. Nevertheless, in the analysis of the larger dimer- form of the IL-5 glycoprotein derived from CHO and NS-1 cell lines, no useful ion-spray data were obtained. On the contrary, UV LDMS analysis of the CHO IL-5 gave an intense signal at ~30700 Da with extensive heterogeneity. This mass value compared with the calculated value derived from the cDNA-derived protein sequence, gives an approximate value of 2200 Da for the size of the N-linked carbohydrate component per monomer. Similarly, the observed LD mass value for the NS-1 derived IL-5 was ~31500 Da, thus indicating that the size of the attached carbohydrate component is ~800 Da higher than that in CHO IL-5, possibly due to an additional O-glycosylation.

These results demonstrate the synergistic role of the ion spray and high-energy desorption ionization techniques, which in combination with enzymatic or chemical cleavage of the carbohydrate side chains can provide the composition of these side chains.

Atmospheric pressure plasma ion sources, such as direct current plasmas (DCP), inductively coupled plasmas (ICP) and microwave induced plasmas (MIP), have been used successfully for elemental mass spectrometry. However, only a few papers have dealt with the use of plasmas, such as the ICP(1) or the MIP(2-4) as sources for generating molecular ions. The original research using an atmospheric pressure ICP(1) and low pressure MIP(2) as molecular ionization sources produced extensive fragmentation. Potential advantages of using the MIP rather than the ICP as a soft molecular ion source include a relatively low plasma temperature and the flexibility to operate with various plasma support gases (such as He, Ar, N$_2$) and mixed gas (such as He/N$_2$, Ar/N$_2$, etc.). Generation of molecular ions using an atmospheric pressure plasma is difficult because the high excitation and ionization energy of the plasma produces considerable fragmentation. Recently, two reduced pressure MIP systems(3,4) operating at 1 to 2 torr did provide a means of using a plasma as a source of molecular ions. However, sample introduction into a low pressure MIP is limited to gaseous samples.

Advantages of an atmospheric pressure ion source include its simple design and ease of sample introduction because it can be easily interfaced directly to real world systems without a vacuum barrier. Since the majority of effluent from any chromatographic experiment consists of solvent, most of this can be eliminated to the atmosphere and not introduced to the vacuum chamber, resulting in reduced sample memory or contamination of the vacuum system. The API source utilizes conventional sample introduction techniques, and plasmas operating at atmospheric pressure can easily be sustained during introduction of a variety of sample matrices.

In this report, a new plasma API source for mass spectrometry, which generates molecular ions at atmospheric pressure, has been developed using a low power atmospheric pressure helium microwave-induced plasma (Figure 1). This new plasma API source design was developed from the Microwave Induced Plasma - Tantalum Injector Probe (MIP-TIP) which is described in a previous report(5). The plasma API source sustains a helium plasma at low (10-30 W) power levels and produces quasi-molecular parent ions and molecular fragments of analyte at atmospheric pressure. The design of this source enables soft molecular fragmentation with either gaseous (Figure 2, 3 and 4) or aqueous (Figure 5) sample introduction at atmospheric pressure. The potential for interfacing this plasma API source with liquid and gaseous chromatographic techniques will be discussed.

A comparative study of photo-ionization and electron impact ionization on hydrocarbons is of importance to evaluate the potential of photo-ionization mass spectrometry in the analysis of complex mixtures of hydrocarbons. The fixed energy of photons guarantees a high degree of reproducibility in the ionization and fragmentation processes. The energy of the photons can be set just above the ionization potential of the hydrocarbons, generating almost only molecular ions. However, the small number of photons available, roughly $10^{12}$-$10^{13}$ per second, and the relatively small cross sections for photo-ionization result in low ion currents. These low ion currents restrict the sensitivity of the analytical method. A drawback which can be partially overcome by using ion counting techniques.

Low energy electron impact ionization as an alternative for inducing limited fragmentation has various practical difficulties when using analytical mass spectrometers. Ionization by a well-defined low electron energy is difficult to achieve because of the lack of control on the energy spreading of the electrons. This energy spreading is mainly due to the potential across the filament. This problem impairs the ionization energy selectivity of the electron impact technique.

The instrument used in the experiments has already been described fully [1]. To test the performance of the photo-ionization source for the analysis of hydrocarbons, the total ion currents for electron impact ionization and photo-ionization for several linear alkanes (n-pentane up to n-decane) are measured. Also the pressure inside the ion source and the temperature of the ion source are measured. Taking two accurate measurements for the absolute total photo-ionization and electron impact ionization cross sections from literature, the total transmission loss of the instrument is determined. For the photo-ionization source one out of every 1500 ions created in the source is measured by the detector. For the electron impact ionization source this ratio is better. Out of every 180 ions created in the ion source, one ion is detected.

Having calculated the total transmission loss, we determined the absolute total photo-ionization and electron impact ionization cross sections of n-pentane up to n-decane. These are shown in figure 1 as function of the molecular weight. The absolute values and the gradual rise of the cross sections as function of the molecular weight are in agreement with literature [2,3].

A semi-empirical model is developed describing the total electron impact ionization cross section as function of the electron energy of alkanes, alkenes, alkynes and cyclo-alkanes. This model is based on the 'additivity rule', but uses two extra terms. One term to describe the CC- and CH-coupling and a second term to account for the effect of the double and/or triple bonds. In figure 2, the model is compared to several measured total electron impact ionization cross sections of alkanes as function of the electron energy. The model is represented by the solid line. The experimental values are represented by symbols referring to different measurements. We observe as function of energy a good fit of the model to the measured cross sections. The model also describes within the experimental uncertainty (15%-20%) the behaviour of the total electron impact ionization cross sections of alkenes, alkynes and cyclo-alkanes as function of the electron energy.

Methods to produce coherent vacuum ultraviolet radiation have been available for almost two decades. Widespread application to mass spectrometry, however, has occurred only recently. The method used in our laboratory to generate tunable radiation by third harmonic generation is shown in Figure 1. Tunable radiation in the 611 to 532 nm region is generated by a Nd:YAG laser pumped dye laser system. The visible radiation is frequency mixed with residual 1064 nm radiation from the Nd:YAG laser to produce radiation in the 355 to 388 nm region. The ultraviolet radiation is focused in a cell containing one or more rare gases to generate third harmonic radiation in the 129 to 118 nm (9.6 to 10.5 eV) region. The cell length of one meter is based upon a design developed by C.H. Becker and coworkers at SRI International. Vacuum ultraviolet radiation is generated collinearly with the ultraviolet radiation. Separation of the two is accomplished by sending them through the second lens off-axis. The difference in refractive index between the two wavelengths causes the two beams to be physically separated in the source region. Since the ultraviolet radiation passes through the source region away from the axis defined by the acceleration grids, ions produced by it are not detected.

![Figure 1](image-url)
The third harmonic power, $P_{3\omega}$, is given by the equation

$$P_{3\omega} \propto |X(3)|^2 N^2 P_{\omega} F$$

where $X(3)$ is the third order susceptibility, $N$ is the number density of the nonlinear medium, $P_{\omega}$ is the pump laser power, and $F$ is a phase matching function. Since $X(3)$ and $N$ are small, the conversion efficiency is usually low. $F$ is nonzero only when the medium exhibits negative dispersion. Therefore, continuous tuning across the vacuum ultraviolet region is not possible by this method. In our work, xenon is used to generate radiation at 118.2 nm and in the 127 to 129 nm region, while krypton is used to generate radiation in the 121 to 123 nm region. The conversion efficiency is optimized by mixing appropriate amounts of xenon (or krypton) with argon in the cell to maximize the product $N^2 F$ in the above equation.

Coherent vacuum ultraviolet radiation has several useful characteristics for photoionization including high power ($10^{11}$ to $10^{12}$ photons/pulse), narrow bandwidth ($\leq 1 \text{ cm}^{-1}$), low divergence (allows the radiation to be confined to a small spatial region), wavelength tunability (other four-wave mixing processes can provide continuous tuning throughout the vacuum ultraviolet region), and short pulse width ($\leq 6 \text{ ns}$; can be synchronized with other pulsed beams).

In our laboratory, this radiation is used for several experiments including photodissociation-photoionization mass spectrometry, photoionization of laser desorbed neutrals, and studying the rate of ion decomposition vs. molecular size. In photodissociation-photoionization mass spectrometry, molecules are dissociated with an excimer laser beam and the neutral products are softly ionized with coherent vacuum ultraviolet radiation. This method can be used to study neutral photochemistry and to distinguish isomeric structures. Photoionization of laser desorbed neutrals allows the mechanism of laser desorption to be studied. Kinetic energy distributions of neutrals desorbed from the surface can be determined from the delay time between the desorption and photoionization lasers. Internal energies of desorbed neutrals can be determined from the wavelength dependence of fragmentation in the photoionization mass spectrum. Elucidating the molecular size dependence of primary fragmentation is simplified with single photon ionization since $P(E)$ for ionization can be independent of molecular size and the photon energy can be adjusted to eliminate secondary fragmentation. Under these conditions, changes in the number of metastable product ions with increasing molecular size give an indication of the parent ion unimolecular decay rate dependence upon molecular size. Each of these areas is discussed in more detail in other conference presentations.
PULSED FAST ATOM BOMBARDMENT SAMPLE DESORPTION WITH MULTIPHOTON IONIZATION IN A SUPERSONIC JET/REFLECTRON TIME-OF-FLIGHT MASS SPECTROMETER

Liang Li*, Alan M. Hogg, Alan P.L. Wang, Jian-Yun Zhang, and Davinder S. Nagra
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2, Canada

Multiphoton ionization mass spectrometry (MPIMS) has been shown to be a very powerful technique for chemical analysis. Advantages of using MPI as an ionization source for mass spectrometry include high sensitivity, high selectivity and the ability of controlling mass fragmentation patterns. In this paper, an instrument for performing MPIMS and supersonic jet spectroscopy (SJS) studies of biological molecules and high molecular weight polyaromatic hydrocarbons (PAHs) is described. Specifically, pulsed fast atom bombardment (FAB) has been developed as a means of vaporizing thermally labile biological molecules and PAHs into the gas phase. The resulting neutral molecules are entrained into a CO₂ supersonic jet which prevents thermal decomposition by collisional cooling and carries the molecules into a time-of-flight mass spectrometer (TOFMS) where resonant two-photon ionization (R2PI) is performed by a UV laser beam.

Figure 1 shows the schematic diagram of the experimental setup for FAB/SJ-MPI. The system consists of an angular reflectron TOFMS (R.M.Jordan Co.) mounted vertically in a six-port cross pumped by a 6-in. diffusion pump. A pulsed nozzle with a 50-μs pulse width is used to form a supersonic jet. CO₂ is used as the expansion gas throughout this work. The jet expands into the acceleration region of the TOF and a laser beam perpendicular to both the jet and flight tube ionizes the sample. No skimmer was used in this study. The 1-meter-long flight tube is differentially pumped by a 4-in. diffusion pump. The pressure in the flight tube is below 2x10⁻⁷ Torr and the pressure in the ionization region is <10⁻⁶ Torr. The ionization source is a frequency quadrupled Nd:YAG laser (GCR-3, Spectra-Physics, CA) which generates a 266-nm radiation with a 7-ns pulse width. The laser is operated at 3 Hz repetition rate. A cylindrical lens is used to focus the laser beam to the mass spectrometer. The mass spectrum is recorded by a LeCroy 9400A digital oscilloscope, and data are stored in an IBM compatible 386SX PC for processing. Figure 1.

FAB/SJ-MPI is performed with a saddle-field FAB gun which is fitted into the test chamber through a 2-in. flange and placed close to the nozzle orifice. The distance between the FAB gun outlet and the nozzle orifice is about 40 mm. The distance between the FAB gun and the center axis of the jet is also about 40 mm. A 5-mm or 10-mm diameter sample probe made of machinable Macor ceramic is located at about 20 mm away from the center axis of the jet. About 100 μg sample is generally used and placed on the sample probe directly by either wetting or dissolving the compound in a solvent (i.e. methanol) and coating on the surface with the use of a spatula. Argon is used in the saddle-field discharge for the FAB gun. The anode potential is fixed at 10 kV and, by adjusting the pressure in the gun, the discharge current varies from 1 to 5 mA. The size of the FAB beam is approximately 1.5 mm in diameter. The high voltage power supply for the FAB gun is Spellman Model RHSR15PNS0 which is operated in a pulsed mode using an external trigger system. The actual sequence of events is controlled by several delay generators. The FAB gun is first turned on to desorb the sample, the pulsed nozzle opens to form a supersonic jet, and then the sample is entrained into the jet and carried into the ionization region of the TOFMS where the ionization proceeds.
In this presentation, we have shown that a variety of biological molecules can be studied without significant thermal decomposition, with both soft and hard ionization mass spectra obtainable. The chemicals studied by this FAB/SJ-MPI technique include amino acids, carboxylic acids, catecholamines, neuroleptic drugs, pineal indoles, small peptides, PAHs, and organic salts. For dipeptides, it is found that although the molecular ion peak can be observed, the ion peak at 18 mass units lower sometimes is the dominant peak in the mass spectrum. This interesting result is also obtained with laser desorption/SJ-MPI. However, one significant advantage of this FAB method over laser desorption is that the FAB gun can be easily constructed and maintained at a relatively low cost. In addition, we show that high molecular weight PAHs can be readily desorbed by FAB and studied by R2PI. The detection limit in our present system is found to be in the low nanogram regime. We have also demonstrated that this technique can be used for selective detection of the active substance in a drug tablet. Finally, we have shown that this technique provides a unique means for the studies of chemical reactions induced during the FAB desorption process. Figure 2 shows the MPI mass spectrum of dimethyl-4-phenyl piperazinium iodide. The direct FAB ionization mass spectrum of the same compound is shown in Figure 3. The FAB mass spectrum in Fig.3 displays a base peak at m/z 191, which is the molecular cation from the organic salt minus the iodide. However, the MPI mass spectrum shows the base peak at m/z 176. This peak is from the neutral species generated during the FAB desorption process. It is the organic salt minus CH4. The hard ionization mass spectrum shown in Fig. 2 is very useful for the structural analysis of the organic salt. With the combination of FAB and FAB/SJ-MPI, we can now detect not only the ions but also the neutrals and/or radicals produced during the FAB process, which is useful for the mechanistic studies of FAB.
The impact of key polaronic properties on collision studies through an indirect approach using the collision of secondary ions. The collision of secondary ions with atomic targets is an efficient method for investigating short-range atomic properties.

In our study, we use a novel approach to examine the collision of secondary ions from an energetic beam. The secondary ions are accelerated to energies that are in the range of several hundred eV. The ions are then allowed to collide with an atomic target. The collision results are analyzed using mass spectrometry.

The main finding of our study is that the polaronic properties of the secondary ions have a significant impact on the collision outcomes. This is particularly true for ions that are highly charged.

The results of our study suggest that future research should focus on developing new approaches to study polaronic properties using collisions. This could include the use of different target materials or the use of different ion beams.
enhancement is calculated as:
\[ e = \frac{Y_n(M)}{(2n+1)Y_0(M)} \]
where \( Y_n(M) \) is the yield of M from the \( n^{th} \) cluster (either Cs(CsI)\( n^+ \) or (CsI)\( n^+ \)) and \( Y_0(M) \) is the yield of M from the \( 0^{th} \) cluster. The enhancement in the yield of I" and Cs\( ^+ \) from cluster impacts was calculated at a projectile velocity of 0.04 keV/amu for the five projectiles available. The enhancement was found to be exponentially dependent on the number of atoms in the projectile over the range studied (1 to 9 constituent atoms). Though one might expect that the enhancement would plateau at a large number of constituent atoms, this was not observed in the range studied. Enhancements as large as -20 (with \( n = 4 \)) were observed. This corresponds to an increase in the yield of two orders of magnitude over that from the atomic projectile.

In addition to the yield enhancement, coincidence counting can be used to observe correlations between secondary ions. Once a secondary ion spectrum is obtained, species emitted coincidentally with an ion of interest can be identified and recorded in a coincidence spectrum. Comparing this coincidence spectrum with the secondary ion spectrum, it is possible to determine the relationships between the secondary ion of interest other ions in the spectrum. To quantitate these relationships, a correlation coefficient, \( Q \), is calculated:

\[ Q = \frac{N(A,B)S}{N(A)N(B)} \]
where A is the ion of interest, \( N(A,B) \) is the number of counts in peak B in the coincidence spectrum, \( S \) is the number of primary ions, and \( N(A) \) and \( N(B) \) are the number of counts in peaks A and B in the secondary ion spectrum. A correlation coefficient of one indicates independence of the ions from one another. A correlation coefficient greater or less than one indicates a correlation or anticorrelation between the ions. We chose to examine correlations between I" and other secondary ions desorbed by atomic and cluster projectiles. It was found that whether the projectiles are polyatomic or atomic, I" and hydrocarbon ions are independent (\( Q = 1.5 \)) whereas I" and (CsI)\( n^+ \) cluster secondary ions are strongly correlated (\( Q = 3 \)). This correlation indicates a chemical relationship between the I" and (CsI)\( n^+ \) ions and should be an indicator of the mechanism of ion formation. One possible mechanism would produce the ions by metastable decay. In this case, a large, multiply charged, cluster ion would be desorbed and rapidly decay to form I" and smaller cluster ions. These ions would then be correlated with one another.

This study demonstrates the usefulness of coincidence counting TOF-MS for obtaining additional information about the sample, secondary ions, and perhaps the ion formation process. The potential usefulness of clusters as projectiles is also apparent. These projectiles may be particularly well suited for molecular mapping of surfaces. Cluster ions produce higher yields, thus fewer primary ions are needed to obtain a given signal.

It has been shown a few years ago [1,2] that molecular ions can be desorbed from a plane surface when a constant electric field is applied between the sample and a grid placed at a small distance from this sample. No external ion source is needed to measure a time of flight mass spectrum between electrons and ions emitted simultaneously from the surface. A very simple arrangement can be used for analytical measurements [3] or for generating primary ions in SIMS [4]. The name "Spontaneous Desorption Mass Spectrometry" (SDMS) was given originally by us because of the unknown origin of the observed phenomena. Experimental investigations of the mechanisms have been pursued later on [5,6].

In ref. [2], evidences for secondary ion (SI) emission mechanisms were observed. Primary projectiles would originate from the grid and strike the sample with an energy equal to the potential difference applied between the sample and the grid. Field emission processes are involved in SDMS. Above a certain field value, SD occurs and the molecular ion yield is defined as the ratio between the number of molecular ions detected in a TOF spectrum and the number of electrons. The molecular secondary yield in SD is larger than the yield measured for atomic impacts on the same solid sample target (with Cs ions for example). This has suggested that cluster projectiles could hit the sample since it is known that large SI yields are observed under cluster impacts [8].
An experimental arrangement has been set up where both type of measurements: SD mass spectrometry and cluster induced desorption mass spectrometry, can be performed - alternatively - in the same experimental conditions (same sample, vacuum, detectors,...). Different organic molecules have been used as projectiles (from mass 50 to 166) at an energy equal to the accelerating potential in SDMS. It is concluded that molecular ions with masses around 60-70 could be the main primary projectiles emitted from the grid in SDMS. These ions originate from an organic contamination of the grid. Secondary ions in the same mass range have been observed when bombarding the grid by fission fragments.

Fig. 1a shows a normal SD TOF spectrum of a phenylalanine sample.

The time measurement is triggered by electrons produced by molecular ion impacts on the phenylalanine target. A time window ($\Delta t = 50$ nsec, $W_1$ in Fig. 1a) has been defined a few hundreds of nsec after the first triggering electrons and this time window has been used to define a new origin of time for a new time of flight spectrum where all time correlated events are being recorded during data acquisition. Fig. 1b shows this TOF spectrum that is similar to the total TOF spectrum in Fig. 1a. This means that shortly after a first impact on the target, another impact may occur that induces another simultaneous emission of electrons and ions. Several time windows can be set at different time values after the first triggering event. The yield of emission corresponding to these delayed impacts has been plotted in Fig. 2 as a function of time.

The bombardment of the same sample by well known molecular ions did not exhibit delayed emission effects. Therefore, in SDMS, the delayed emission of secondary particles - that gives rise to a smaller yield - may be due to:

1) in-flight fragmentations of small molecules during their acceleration from the grid. The neutral fragments arrive later at the surface with a smaller energy.
2) delayed emission from the grid after a very small micro-discharge.

Development of a Compact Tandem Time-of-Flight Mass Spectrometer for the Analysis of Small Biomolecules

Timothy Cornish, Ihor Lys, and Robert Cotter
Johns Hopkins School of Medicine; Baltimore, MD

A compact, versatile TOF-TOF mass spectrometer is currently under development for the purpose of studying small biological compounds. The dual reflectron instrument will incorporate a collision cell providing MS/MS capabilities. A key component of this design is the ability to independently adjust the flight tube potentials so that high, low, or reactive collisions may be utilized. The source is designed so that a number of different probe types and extraction optics can be employed in order to test a variety of laser desorption conditions and geometries.

Divided into two stages, the first part of this study (discussed here) involves testing of the linear and single reflectron geometries using an assortment of probe designs and laser conditions to optimize resolution and sensitivity. The second will incorporate the double reflectron geometry with the collision cell to allow MS/MS capabilities. Additionally, time delayed extraction will be employed to allow metastable decomposition to occur prior to initial acceleration.

The test probes include a 90° off-axis desorption source, a parallel prism, and a parallel grazing incidence design. The ion optics for the off-axis probe consist of a two-stage draw out region as prescribed by Wiley-McLaren space focussing conditions. While very high voltage extraction is desirable to minimize effects of desorption kinetic energy spread in the TOF peak widths, the asymmetry of this design in the source region (and therefore asymmetric field lines) requires the use of low voltage extraction in order to acquire precisely reproducible signals. Results indicate that under these conditions, the resolution is limited by the energy spread induced by laser desorption and would not be suitable for high resolution applications. The parallel prism probe is based on a design by Reilly et al. (see Analytical Instrumentation, 16, 133 (1987)) in which the sample is applied to the hypotenuse face of a right angle prism. This surface is coated with a thin layer of aerosol graphite to define the source potential. A laser beam is directed to its interior side at grazing incidence, ionizing the sample with no above-surface interference. Theory indicates that this technique can produce extraordinary TOF resolution if very short laser pulses are employed, although initial studies here indicate that the TOF peaks of samples applied to the surface are significantly broader than components found in the thin graphite layer (salts and propellant). The third probe is a flat metal surface oriented opposite to the ion extraction lenses with the ionizing laser directed at grazing incidence to this surface. Ions are extracted at high voltage (~2 kV) followed by deceleration to their drift velocities producing TOF peaks which appear to be limited by the laser pulse duration. This third design is likely to be incorporated for future studies.
Laser

Tandem Time of Flight MS
Surface-Induced Dissociation in a Hybrid Mass Spectrometer

B. Wright*, S. C. Davis*, K. B. Tomer† and S. R. McGown†

Kratos Analytical, Barton Dock Road, Manchester, UK
NIEHS, Research Triangle, NC 27709

Aberth has recently reported the use of a microchannel plate to achieve surface-induced dissociations (SID) in a Wien tandem mass spectrometer(1). Compared to gas collision processes, surface-induced collisions convert a larger amount of the incident ions translational energy into internal energy(2) and reduce the background pressure in the mass spectrometer. In the case of hybrid mass spectrometers there may be increased fragment ion transmission, particularly at low mass, if the fragment ions are formed at positions close to the axis of the Rf-only quadrupole(3). This can be achieved if the parent ion beam is focused onto the micro-channel plate at the entrance of the Rf-only quadrupole.

A Kratos CONCEPT SQ hybrid mass spectrometer was readily modified for microchannel plate SID studies by attaching commercially available microchannel plates to the entrance lens aperture of the Rf-only quadrupole.

Figure 1 shows a unimolecular decomposition spectrum (no collision gas) for triazine (m/z 1466). Figure 2 shows a daughter ion spectrum for triazine at 150eV with collision gas present and Figure 3 shows the spectrum for microchannel plate SID. It can be seen on comparison of Figures 2 and 3 that there is a significant increase in relative intensity of low mass fragments in the SID spectrum. This is probably due to the higher amount of energy available for conversion into internal energy in the collision, but may also have a contribution from better transmission at lower mass.

Transmission through the microchannel plate was, however, very low (<1%). Comparable quality SID spectra were obtained using wire meshes giving transmission of the order of 40%.

Low Energy Ion/Surface Reactive Collisions Investigated in a BEEQ Hybrid Mass Spectrometer

Department of Chemistry, Purdue University
West Lafayette, IN 47907
and
C. E. D. Chidsey
AT&T Bell Labs
Murray Hill, NJ 07974

A recently completed BEEQ hybrid mass spectrometer has been utilized to investigate ion/surface reactive collisions as a function of the nature of the surface and of the primary projectile's collision energy. Figure 1 is a diagram depicting the important ion optical elements of the instrument. With this arrangement, the primary ion collision energy can be varied from < 5 eV to 3000 eV. The low energy ion/surface reactive collisions presented were performed in the collision energy range of 2 eV to 100 eV. Experiments were performed using a number of specially prepared target surfaces ranging from nascent stainless steel to surfaces in which C-16 protonated or perdeuterated alkyl thiols are covalently bound to a gold substrate. The preparation of these surfaces results in the formation of self assembled monolayers (SAM) in which the bound molecules are oriented vertically. A surface consisting of CF3(CF2)11(CH2)2SH covalently bound to Au has also been investigated.

Experiments in which the pyrene molecular ion impinges upon a nascent stainless steel surface at various collision energies (30-100 eV) indicate the formation of C6 and C8 adducts. Figures 2a and 2b are representative reactive collision spectra for the pyrene molecular ion (m/z 202) at a) 50 eV and b) 100 eV impacting collision energy. The nature of these adducts appear to be dependent upon the impacting energy, indicated by the formation of the (M+11)+ and (M+13)+ ions at a collision energy of 50 eV, while the (M+9)+ and (M+11)+ ions are more abundant at a collision energy of 100 eV. Experiments in which the molecular ions from benzene and other polycyclic aromatic hydrocarbons (PAH's), such as naphthalene and anthracene, impinge upon a stainless steel surface also show formation of (M+CH3-nH2)n+ reaction product ions, where n is the number of H2 molecules lost. This trend is seen quite frequently for the production of the fragment ions from various PAH's, i.e., a stable CnH8+- and CnH7+ series as well as a CnH2+ and CnH3+ series are seen in the CID, SID and LD spectra of these molecules.

The above experiments were performed off of a stainless steel surface which most certainly contained various adsorbates on the uppermost portion of the surface. In order to perform more controlled experiments, i.e., the nature of the surface being well characterized, the molecular ion of pyrazine was used to investigate ion-surface reactive collisions with the SAM surfaces. Using the monolayer surface consisting of the C-16 deuterated thiol, the most abundant reactive collision products observed were (M+D)+ and (M+CD3)+, while the C-16 protonated surface yields (M+H)+ and (M+CH3)+. Figures 3a and 3b are representative reactive collision spectra for the pyrazine molecular ion impinging upon a) a C-16 perdeuterated thiol SAM and b) a CF3(CF2)11(CH2)2SH SAM. As noted, the interaction of the pyrazine molecular ion with the C-16 perdeuterated surface yields abundant reaction ions. However, the fluorinated monolayer surface suppresses the reaction channel and, in fact, enhances the fragmentation channel. Results from these experiments suggest a possible mechanism which may proceed via electron transfer to the incoming ion to yield an adsorbed ionized alkane. Further studies are underway to test this hypothesis.

Figure 3b
When analyzing complex samples using GC/MS it is very common to encounter components which are closely eluted. Most GC/MS data systems incorporate a Biller-Biemann type algorithm to help resolve spectral components in these situations. Successful application of this technology however, is limited to components with retention time differences greater than two scans. An alternative technique described by Rindfleisch allows the separation of components with retention time differences of as little as 1.5 scans but the computational overhead has limited its application. The Rindfleisch algorithm is capable of separating spectra of adjacent components which are closer because it involves estimating the retention time for each mass chromatogram maximum based on its peak shape rather than identifying the scan with the most intensity.

Using the Rindfleisch algorithm as a conceptual starting point, computational experiments were undertaken to determine if more precise methods for calculating mass chromatogram retention times could be identified and implemented in one of today's GC/MS data systems. This was done using a data set acquired on a VG Trio-I scanning from 35 to 500 amu once per second and using a 30 meter DB-5 column. Decafluorotriphenylphosphine was selected as the test compound because it provides a large number of mass peaks throughout the acquisition mass range and thus represents a worst case situation.

It was determined that acceptably reproducible mass chromatogram retention time centroids could be calculated by fitting the three intensities centered at the most intense value of a maximum to a second order curve. Using all mass peaks with intensities greater than or equal to one percent of the base peak, 68 peaks in all, the calculated centroids had a standard deviation of 0.04 scans (seconds). Based on this precision value, it is anticipated that two components with retention times which differ by 0.12 scans (seconds) should have spectra which are separable with 99 percent confidence. Testing of this algorithm on experimental data has shown that spectra for components eluted with centroid groupings as close as 0.48 scans can be resolved (Figure 1) and that peaks containing as many as six components in the space of 8.4 scans (Figure 2).

Acknowledgements: The author would like to thank VG MassLab Ltd. for coding the described algorithm into an experimental software set for testing.

Comparison of Calibration Methods for Multiple Tracer Studies

C.D. Warner, Shriner's Burns Institute, Boston, Biopure Corporation, Boston, MA 02111;  
S.K. Branch, MIT Clinical Research Center, Cambridge, MA 02142;  
A. Ajaml, Tracer Technologies, Somerville, MA 02145;  
V.R. Young, MIT Clinical Research Center, Cambridge, MA.

Rates for substrate kinetics from constant infusion of a tracer are determined by measuring the mole ratio of labeled tracer to unlabeled tracee after infusion of the tracer. Calibration of mass spectrometer responses to the mole ratio of tracer to tracee using linear regression is commonly used with one tracer and gives good results.

With multiple tracers the calibration is more problematic. Tracers which differ from one another and/or the tracee by only one mass unit often contribute significant amounts of ion abundance into the signals for the other isotopomers. Loss of label during derivatization, or during synthesis results in less than the theoretically derived abundances for the ions of the analytes. Finding useful combinations of tracers where the abundance of the mass measured does not overlap with one of the other tracers, is sometimes not possible or at best, expensive. In response to this problem, we have investigated a number of methods for accurately calculating mole ratios in multiple tracer studies with tyrosine, leucine and lysine.

In our studies of phenylalanine substrate kinetics, subjects were infused with both 13C phenylalanine and d2 tyrosine. The amino acids were isolated from plasma and derivatized as the heptafluorobutyryl propyl derivative using literature methods. A set of 24 calibration samples was prepared covering the expected range of tracer:tracee mole ratios for 13C phenylalanine, 13C tyrosine and d2 tyrosine. The calibration and plasma samples were analysed by three replicate injections into a HP 5988 GC-MS (methane NCI). The data was divided into two groups; the first and last injections were combined into a large calibration set. The predicted mole ratios from the second injection were calculated using calibration functions obtained by various methods. A small subset of this data was used as a mock daily calibration set. The mean squared error was used to compare the predictive accuracy of various methods including: overlap correction (1) which utilises an arithmetic correction for overlap, K matrix method (2) which is the classical linear regression method, Brauman's least squares (3), and the P matrix method or forward calibration (4). The results for these methods using various numbers of predictor variables for d2 tyrosine are:

The improvement using multiple predictors (abundance ratios) is marked. The lack of accuracy with one predictor is expected because of ion overlap.
1,3C, 1,2,3C, and 5,5,5-d3 leucine (L1, L2, L3) in a 4X4 calibration matrix (.01-2.5 mole percent) were measured by GC-MS-EI as the N-trifluoroacetyl methyl ester at m/z 183-185, 140-144, and 154-156. Principal Components regression (4) extracted the calibration function from the abundances even though one or more tracers were contributing abundances to the signal. Results for this calibration are:

HETEROLYTIC ENERGIES OF X-ALKYL BONDS

Yu-Ran Luo* and Philip D. Pacey, Department of Chemistry,
Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3

Following an approach taken earlier in estimating the homolytic BDEs of X-alkyl bonds, we have found that there are good linear relations between the differences \( \Delta H^o(X^-C^+(CH_3)_mH_{3-m}) \) and \( \Delta H^o(X^-CH_3^+) \) and the covalent potential of X, \( \psi_x \), which is a new scale of electronegativity by Luo and Benson.\(^1,2\) Here X is Cl, Br, I, H, OH, SH, NHg and CHg and m is the degree of methyl substitution in the group C(CH\(_3\))\(_m\)H\(_{3-m}\), which is ethyl, iso-propyl or tert-butyl when m = 1, 2 or 3, respectively. Then the heterolytic BDEs of X-C bonds can be reproduced by the following equation:

\[
\Delta H^o(X^-C^+(CH_3)_mH_{3-m}) = \Delta H^o(X^-CH_3^+) - m \psi_x + f^*(m) - \psi_x \ 
\]

Here \( f^*(m) = 27.91 + 2.38m + 11.07/m \).

For higher alkyl, we must include third, fourth, and higher order interactions between the formal charge and the paired electrons. As pointed out by Lossing and Holmes,\(^3\) the ionic charge is not localized at the formal charge site and must be distributed over the whole ion. We are inspired by the idea and give an approximate expression for the IPs of alkyl radicals

\[
\text{IP(alkyl)}_{\text{est}} = \text{IP}(C(CH_3)_mH_{3-m}) - 0.06 \gamma^+ \text{ eV} \quad (2)
\]

Here \( \gamma^+ \) is the total number of carbon atoms at and beyond the \( \gamma \)-position in the alkyl cation. The average deviation between the values estimated from eq. (2) and the observed values\(^4\) is 0.05 eV for 14 alkyl radicals.

For heats of formation of alkyl cations, we obtain

\[
\Delta_{f}H^o(\text{alkyl cation})_{\text{est}} = \Delta_{f}H^o(\text{alkyl radical})_{\text{est}} + \\
+ 23.06 \text{IP}(C(CH_3)_mH_{3-m}) - 1.4 \gamma^+ \text{ kcal/mol} \quad (3)
\]

Here heats of formation of alkyl radicals are estimated by well-known methods.
Benson's method. The average deviation from eq. (3) is 1.3 kcal/mol for 25 alkyl cations. For the heterolytic BDEs of X-alkyl bonds, we obtain

$$\text{DH}^o(X^-\text{-alkyl cation)}_{\text{est}} = \text{DH}^o(X^-\text{-C}^+(\text{CH}_3)_m\text{H}_3-m) - 1.4 \gamma^+ \quad (4)$$

The average deviation is 1.3 kcal/mol for 25 C-H bonds. Eq. (4) is valid for many substituents X, such as F, SiH$_3$, and so on, but the observed BDEs of many bonds are not available for comparison at present. The algorithms of eqs. (2) to (4) are so simple that one just counts the values of $\gamma^+$, if the values of IP(C(CH$_3)_m$H$_3-m$) and DH$^o$(X$^-$-C$^+(\text{CH}_3)_m\text{H}_3-m$) have been listed in the given Tables.

Lossing and Holmes found that the heterolytic BDEs of H-alkyl bonds are a linear function of the logarithms of the number of atoms in the alkyl cation. Beauchamp and co-workers found a qualitative correlation between the IPs of primary, secondary and tertiary alkyl radicals and the number of carbon atoms. The two groups, however, did not give an expression for estimating the heterolytic BDEs of H-alkyl bonds and the IPs of alkyl radicals. The qualitative and semi-quantitative descriptions of Drs. Holmes' and Beauchamp's groups have been quantified well in our work. The method used in this work has been extended to molecular cations, RX$^+$.

Molecular Dynamics Simulations of Bulk Desorption
In Molecular Matrices.

Jan Sunner and Jentaie Shiea
Department of Chemistry
Montana State University

The nature of the desorption process(es) in Fast Atom Bombardment, SIMS, Plasma Desorption and Laser Desorption is a longstanding and extremely important problem. The FAB mechanism, for example, has been the subject of extensive experimental studies. Much has been learned about the complexity of the process; for example on the importance of surface activity, radiation-induced chemistry, gas-phase basicities, etc. to the mass spectra. However, it has been very difficult to obtain unambiguous results as to the nature of the fundamental desorption process.

In other areas of science, such as protein chemistry, liquid structure, solvation and phase transitions, Molecular Dynamics (MD) has proven essential for deepening our understanding. There is every reason to believe that this is possible also for desorption ionization. MD simulations by Garrison et al. have successfully explored the collision cascade regime in SIMS (1). We have embarked on a program to extend such calculations into the "thermal spike" regime. Such calculations should reveal the nature of the "bulk desorption process", that is likely responsible for a neutral yield of about 10^-3.

Previously, we have presented MD simulations of sputtering from 2-dimensional Lennard-Jones fluids (2). These calculations have now been extended to 3-d Lennard-Jones (LJ) fluids and to 2-d diatomics. Figure 1 shows a "snapshot" from a 3-d calculation consisting of 2250 LJ atoms with mass 40 amu and with a pair interaction energy of 1 kcal/mol. A 15x15x10 grid of such atoms were first equilibrated for 3 ps at ca. 2000 K and then for 2 ps at 300 K. During this time they were confined to a rectangular box of 35x46x46 A. The walls were "wetted" by introducing a 1 kcal/mol Lennard-Jones potential between the atoms and the walls. The wall pressures were monitored to ensure that they were close to 0 at 300 K. One ps before impact, the right hand wall was removed. A 130 amu projectile then hit from the right with a (low) kinetic energy of 100 eV. Figure 1, at 1 ps after impact, shows three high-kinetic energy atoms leaving the impact site and some "disturbance" of the surface, but does not reveal the processes inside. A good way to visualize these is to "cut out" a central section of the system. Such a sequence of snapshots is shown in Figure 2. The atoms are shaded according to the temperature calculated for the local region within a 10 A radius: white to 300 K; light gray to 800 K, dark gray to 2000 K, and black above 2000 K. Further, the arrows show the velocity of that same local group of atoms (atom radius = 100 m/s). It is seen that the pressure waves easily propagate to the edges of the system. In this calculation, they were reflected at the walls. The local high temperature at the impact site is seen to be rapidly quenched by energy transport throughout this small system. Figure 3 shows a system with a higher ratio of projectile impact energy to total bonding energy. In this cases, the system undergoes a bulk disintegration and it empties into space. However, allowing thermal transport through the walls tend to quench the thermal excitation such that no bulk desorption occurs. In FAB, the projectile energy is 100 times larger, and the rate of thermal quenching therefore should be much slower.

Fig. 4. Naive picture of relation between present 100 eV calculation and typical 10 keV FAB process.
The MIKES spectrum of the [M-F] cation (Figure 1) of 1,1,2-trichloro-1,2,2-trifluoroethane (freon 113) exhibits a single peak that corresponds to a very curious fragmentation process that seems to involve migration of a Cl atom and subsequent formation of $\text{CCl}_3^+$ and the carbene $:\text{CF}_2$. The narrowness of the MIKES peak suggests that the formation of these two species involves a simple bond cleavage rather than a rearrangement. However, a rearrangement process prior to the C-C bond cleavage process is necessary. The MIKES spectrum of the [M-C1] cation (Figure 2) of freon 113 also contains a single narrow peak. However, this process can be rationalized as a simple bond cleavage. Semiempirical MO calculations have been used to complete a study of the energetics of the fragmentation processes observed in the metastable spectra of the [M-F] and [M-C1] cations. Similarly, the energetics of the various dissociation processes observed in the high-energy and low-energy CID spectra of the these two ions were also investigated for purposes of comparison with the metastable results.

The results of the semiempirical calculations concerning the low-energy processes observed in the metastable and low-energy CID spectra are shown in Figures 3 and 4. Figures 5 and 6 illustrate the results concerning the high-energy processes observed in the high-energy CID spectra, which all involve homolytic bond cleavages. The loss of the F atom bound to carbon one is favored over loss of one of the F atoms bound to carbon two by 8.5 kcal/mole during the formation of the [M-F] cation. Similar calculations for the [M-C1] cation show that loss of the Cl atom bound to carbon two is favored by only 3.3 kcal/mole. The barrier for isomerization of the higher energy form to the lower energy form is 28.8 kcal/mole for the [M-F] cation and 11.5 kcal/mole for the [M-C1] cation. A nearly symmetric transition state for Cl atom rearrangement was located for the lower energy form of the [M-F] cation. The energy barrier to this rearrangement is 8.8 kcal/mole. Overall, the semiempirical results show that the Cl atom rearrangement process is exothermic by 6.1 kcal/mole. The fragmentation of the rearranged ion to yield the $\text{CCl}_3^+$ and $:\text{CF}_2$ species is endothermic by 14.0 kcal/mole. A similar transition state was located for F atom rearrangement in the [M-C1] cation. The barrier to isomerization is 26.2 kcal/mole. However, it is not likely that a significant fraction of the ion population will isomerize because the enthalpy change for simple bond cleavage is only 15.7 kcal/mole. Simple bond cleavage of the respective higher energy forms of the [M-F] and [M-C1] cations is also possible; however, these are high-energy processes and are therefore only observed with low abundance in the high-energy CID spectra. Simple bond cleavage for the low-energy form of the [M-F] cation is also a high-energy process and is only present in the high-energy CID spectrum. The dissociation processes outlined in Figures 5 and 6 are all predicted to be high-energy homolytic bond cleavage processes and are, as expected, only observed in the high-energy CID spectra. The exceptional stability of the $:\text{CF}_2$ carbene compensates for large positive heats of formation of the methyl-type cations observed in metastable and low-energy CID mass spectra, thus making their appearance in these types of spectra possible. Similarly, the presence of the extra F atom in the [M-C1] ions increases their stability relative to those of the [M-F] ions. This would explain the fact that the electron ionization mass spectrum of freon 113 contains fragment ions that are mostly characteristic of the [M-C1] cation.

The bridging halogen atom in each of the transition states located in the study causes a shortening of the C-C bond in the transition state relative to that in the reactant ion, presumably by donating electron density to the carbon atoms. Not unexpectedly, the C-C bond order increases in parallel with the decreasing bond length in going from reactants to the transition states. It is also obvious that a bridging Cl atom produces lower energy transition states than a bridging F atom. One possible explanation of this is the higher electronegativity of the F atom.

The power of mass spectrometry as an analytical technique lies in the ability of the analyst to deduce the molecular structure of the compound under study from the data collected. Correlation analysis techniques (from information theory) can be applied to enhance the quantitative information present, as well as aid the analyst in the interpretation of low-resolution mass spectral data.

Although correlation analysis has been applied to data obtained from a variety of analytical techniques (including flame atomic fluorescence spectrometry (AFS), inductively-coupled plasma atomic emission spectrometry (ICP-AES), Fourier-transform infrared (FT-IR) spectrometry, UV/visible absorption spectrometry, multi-dimensional fluorescence spectroscopy, extended X-ray absorption fine-structure spectroscopy (EXAFS) and Mössbauer spectroscopy), its application to mass spectral data has been limited. This talk will demonstrate that the correlation procedure can be used to increase the discriminating power of the mass spectrometer (termed "compound specific detection") as well as aid in the determination of sequence information from peptide MS data.

**Compound Specific Detection:** In the early 1980's Anderegg described a technique called "isotope cluster chromatography", where the mass spectra obtained from a combined GC/MS analysis are analyzed automatically to identify those chromatographic peaks containing one of a number of different distinct isotope patterns (such as chlorine or bromine). While the correlation analysis technique can be used for such "substructure specific" detection, it is demonstrated here that this idea can be extended to enable the mass spectrometer/data analysis system to serve as a compound specific detector. This is accomplished by cross-correlating each mass spectrum obtained from the instrument with a library spectrum of the compound of interest. This is demonstrated using the GC/laser ionization TOFMS data for a series of alkyl-benzenes plus naphthalene presented by Opsal and Reilly.

**Neutral Loss Spectrum:** Crawford and Morrison noted that for many types of compounds, such as those containing a long aliphatic chain, that prominent peaks occur at periodic spacings on the mass axis. They suggested that a "mass periodicity spectrum" or "neutral loss spectrum" could be calculated from the raw data, and that the process is similar to auto-correlation. In fact, the auto-correlation function calculated from a mass spectrum is composed of two copies of the neutral loss spectrum, i.e., they consist of all those peaks at tau values other than zero. For example, any pairs of peaks in the original mass spectrum separated by 14 mass units will contribute intensity to the position in the auto-correlation function corresponding to a mass loss of 14. We would expect that different compounds of the same chemical class would show similar neutral loss spectra. Making use of this fact, a number of workers, have successfully used the auto-correlation procedure as a pre-processing step in chemical pattern recognition studies.

It is demonstrated here that neutral loss data (obtained directly from the auto-correlation procedure) may also aid in the elucidation of sequence information from the analysis of peptide MS data. This is demonstrated below in figures 1 and 2. Figure 1 shows the auto-correlation of the infrared laser desorption/UV laser post-ionization mass spectrum of the penta-peptide met-enkephaline (Tyr-Gly-Gly-Phe-Met) reported by Grotemeyer. The neutral loss spectrum corresponding to the positive side of the auto-correlation function, including all mass losses between 1 and 250 amu, is reproduced in detail in figure 2. Although there are a number of peaks due to non-structurally significant fragmentation, peaks corresponding to the residue mass of the amino acids glycine, methionine, tyrosine and phenylalanine are clearly visible. In addition, neutral losses corresponding to the dimers Gly-Gly and Gly-Phe are also observed. Most importantly, identification of the peaks in the neutral loss spectrum can be easily automated by cross-correlating the neutral loss spectrum with synthesized data class spectra, using the correlation procedure as a substructure specific detector.

TOWARDS AN INTUITIVE DATA SYSTEM FOR MASS SPECTROMETRY

P. R. Bates, M. S. Henderson, M. P. Stevenson, J. S. Cottrell,
Finnigan MAT Ltd., Hemel Hempstead, Herts., UK.

Introduction

A Microsoft Windows 3.0 based data system has been written to provide instrument control and data processing facilities for a new laser desorption time-of-flight mass spectrometer. The key design goal was ease of use.

Instrument Control

Instrument control is achieved through the use of a window containing a mimic diagram. Because only a few instrument parameters need to be adjusted, the control window can be kept relatively simple.

Viewing data

The data window contains the spectrum trace. Rescaling the display can be performed using menu commands or by dragging out an area with the mouse. A barbell which functions like a sophisticated scrollbar is also available.

Peak detection

If peak detection parameters need adjustment, a toolbox allows the user to define model peaks and model baseline segments. This information is then used by the software to refine the peak detection parameters.

Calibration

Time to mass conversion is performed automatically using two stored calibration constants. If reference peaks of known mass are present in the spectrum, the user may identify them graphically and obtain a more accurate internal calibration.
Reports

Peak detection generates a tabular report listing of peak masses and areas. Reports may be formatted to include any other system parameters or sample information. A report template editor provides limited desktop publishing facilities for customising report layout and content.

Multiple Samples

Multiple samples may be analysed or multiple data files reprocessed using a spreadsheet-like Sequence table. Each row represents a sample and each column a logical group of parameters controlling system operation.

Online Help

Online help is always available and provides assistance with operating procedures, commands, and terminology. The help system is context sensitive, taking the user directly to information relevant to the current display or action.

Data Exchange

One of the benefits of running under Windows 3.0 is the simplicity with which numerical and graphical data may be interchanged between applications. For example, it is possible to transfer data dynamically to a Microsoft Excel spreadsheet and perform a real time statistical analysis of the mass measurements.

Conclusion

An intuitive, graphical approach to instrument control and data processing has been adopted. Peak detection and calibration are simplified through the use of graphical toolboxes. Analysis of multiple samples uses a spreadsheet architecture. Data exchange to third party applications effectively extends the functionality of the software to include the enormous number of Windows based applications.
SOFTWARE PROGRAMS FOR PROCESSING
PCDF/PCDD GC/MS DATA

*David S. Weinberg, R. E. Adams, and M. Lisa Manier
Southern Research Institute
Birmingham, AL 35205

A. Target PCDFs/PCDDs

VG GC/MS PCDF/PCDD data are produced by window mix, initial calibration (ICAL), continuing calibration (CCAL), blank, sample, matrix-spike (MS), and matrix-spike-duplicate (MSD) runs. We initiate the processing of the acquired data on the VG 11-250J data system by using user-prepared RUN programs that employ VG-provided peak detection (PKD), peak report (PKR), peak quantification (PKQ), and report generation (RPG) programs and various user-written macro (MAC) programs.

We then further process the files on a microcomputer (PC) by using a user-interactive batch file named RUNZ.BAT (the "Z" in "RUNZ" is the number of LOTUS 123 spreadsheet files ultimately to be processed in the batch). While using the batch file, we employ a KERMIT protocol to transmit the ASCII report (RPT) files located in the VG RSX [70,42] directory to the C:\KERMITV subdirectory in the PC.

We then individually import the files into appropriate LOTUS 123 spreadsheets and use LOTUS 123 macros to perform calculations. (Three separate worksheets formats are used: one for an ICAL; one for a CCAL; and one for a sample, a blank, an MS, or an MSD). The worksheet files are then sent to the C:\DBXL subdirectory and are further processed by a DBXL database program named LOTUSZ (the "Z" in "LOTUSZ" is the same as defined above.) The newly created database files are saved as text files and are copied to the C:\KERMITV subdirectory. We then use a KERMIT protocol to transmit the files to the [DWEINBERG] subdirectory on the DEC VAX 8550 minicomputer and complete the preparation of reports using a SAS program named MENUDISP.SAS.

B. Total PCDFs/PCDDs

As mentioned above, we initiate the processing of the acquired data on the VG 11-250J data system using user-written RUN programs that employ VG-provided peak detection (PKD), peak report (PKR), peak quantification (PKQ), and report generation (RPG) programs and various user-written macro (MAC) programs. However, we determine total PCDFs and PCDDs only in blanks and samples. To that end, we further process only the ASCII files with the generic name VOXXXXS.RPT generated by those programs for blanks and samples. We also use a second RPG program on the same PKS files previously generated by the PKD program to produce a second type of ASCII file with the generic name VOXXXXSS.RPT.

We mentioned above that we further process the target-compound files on a microcomputer (PC) using a user-interactive batch file named RUNZ.BAT (the "Z" in "RUNZ" is the number of LOTUS 123 spreadsheet files ultimately to be processed in the batch). We indicated that ultimately we produce files with the generic name VOXXXXS.TXT, and we transfer them to the C:\KERMITV subdirectory. We use those same files generated for blanks and samples for the determination of total PCDFs and PCDDs. Consequently, we copy such files to the C:\LP77 subdirectory for final processing.

We process the files with the generic name VOXXXXSS.RPT using a user-interactive batch file named TOTZ.BAT. (Note: "Z" in "TOTZ" is the same as defined above.) While using the TOTZ.BAT batch file, we employ a KERMIT protocol to transfer the ASCII file VOXXXXSS.RPT to the KERMITV subdirectory. We then individually incorporate each such RPT file into a "TOTALS" spreadsheet in LOTUS 123 and then separately save each worksheet file. We copy each file to DBXL, use a DBXL program named TOTZ.PRG (Note: the "Z" in "TOTZ" is the same as defined above) to further process the data, and then separately save each processed file again. Then we transfer each of these files with the generic name VOXXXXS.TXT to the LP77 subdirectory for final processing along with the VOXXXXS.TXT files. We use a Fortran 77 program named "TOTALSF.FOR" to produce and print a final report for each blank or sample.

THE USE OF DYNAMICALLY PROGRAMMED SCANS TO GENERATE MS/MS/MS SPECTRA WITH AN ITMS®

J.F.J. Todd, A.D. Penman*, D.A. Thorner, A.M. Franklin and M.L. Langford, Chemical Laboratory, University of Kent, Canterbury, Kent, CT2 7NH, UK.

The ion trap mass spectrometer (ITMS®) allows successive stages of mass spectrometry to be performed within the same electrode structure [1]. A second useful feature of the instrument is contained within the controlling software, which allows key sequence files to be written which can then be incorporated into the data system. One application of this methodology has been proven in the automatic recording of tandem mass spectral data, where the need for a time-consuming setting up procedure has been obviated. By varying a parameter which permits fine tuning of the frequency of the excitation voltage (the DELTA-FREQUENCY), one can compensate for the discrepancy between the calculated and observed values of the resonant excitation frequency [2]. In this communication we report upon the application of techniques developed in this laboratory to the study of MS/MS/MS spectra of some simple compounds acquired under the control of dynamically programmed scans (DPS) [2] to yield 'familial' spectra of the type reported with a pentaquadrupole instrument [3].

A major difference between collision induced dissociation in the ion trap and in ion beam transport instruments, such as the triple- and pentaquadrupoles, is that in the former, one has to specifically tune each mass which is to be resonantly excited ('tickled') in order to ensure that collisional excitation always occurs at the same value of the parameter \( q \). This is equivalent to ensuring that the in the quadrupole the collision energy is held constant. It is therefore necessary to know which masses are to be tickled during the experiment before the tickling process is attempted. As an example, the operational sequence for a 'fixed parent ion' scan is shown in Fig. 1. Here the aim is to identify what daughter ions are formed from a single parent, and then acquire the grand-daughter mass spectrum for each of these daughter species (expressed as \( \bullet - O - O \) in the symbolism employed by Cooks and co-workers [3]). The operator first selects one or more possible parent ions which are to be studied on the basis of prior knowledge about the compound (or this could be done using DPS), after which the MS/MS/MS scan function for the experiment is loaded by the computer; note that some of the tickling parameters such as the TICKLE TIME, TICKLE VOLTS, the \( q \)-value and the DELTA-FREQUENCY have already been optimised and set in the scan function. The first selected parent ion, is then tickled in a 'pre-scan' in order to discover its daughter products and this information is read to a file. Each of these daughter ions is then selected in turn and tickled so as the generate the grand-daughter spectrum. Note that because the ion trap does not provide any external read-out to indicate which masses are being tickled it has been necessary to devise an 'internal' indicator. Thus for each daughter ion which has been discovered in the pre-scan, a sequence of three groups of ten spectra (which may then be averaged) are acquired, the parent-only, the daughter-only and the grand-daughter spectra (see Fig. 1). The resulting data takes the form of the 'fragmentogram' for the possible parent ions in 1,2-dichlorobenzene shown in Fig. 2, and which may be manipulated using the standard ITMS® software, or transferred to other programs which permit further refinement and display by means of graph-plotting software. An example of a partial 'familial' scan in which the grand-daughter spectra resulting from \( m/z 55 \) as a fixed daughter ion are plotted against the various parent \( m/z \)-values (\( O - \bullet - O \)) is shown in Fig. 3.

From this work we conclude that (1) it is possible to automate the acquisition of MS/MS/MS spectral data on the ITMS; (2) using the sequences outlined here it is possible to acquire data matrices from which different forms of tandem mass spectral display may be constructed; (3) the work points the way to the development of semi-intelligent compound identification and/or structure determination using multiple stages of sequential mass spectrometry.

Electrospray Combined with an Ion Trap Mass Spectrometer for the Determination of Neuropeptides

R. D. Voyksner and H. V. Lin
Research Triangle Institute, P. O. Box 12194
Research Triangle Park, NC 27709 USA

Introduction

Mass spectrometry methods for the detection and identification of neuropeptides in plasma or cerebrospinal fluid at physiological levels requires specificity and sensitivity exceeding that obtained from RIA methods. A mass spectrometric approach for neuropeptides which is potentially very sensitive and specific is the combination of electrospray with an ion trap mass spectrometer (ITMS). The electrospray technique offers the compatibility with HPLC separation and high ionization efficiencies for peptides in the 10-100 molecular weight range. The ITMS offers increased sensitivity over quadrupole instruments, it operates at higher pressure than many mass spectrometers making it ideal for HPLC coupling, and it has the ability to perform MS^n experiments for a fraction of the cost for most tandem MS instruments. This paper reports on the coupling of a commercial electrospray interface to an ITMS and the optimization of its performance for the detection of neuropeptides.

Experimental

Samples dissolved in 50% methanol in water containing either 0.1% trifluoroacetic acid or 3% acetic acid in the concentration range of 100 ng/mL to 0.01 ng/mL were introduced into the electrospray interface (Vestec Co.) 2 μL/min. The electrospray interface was operated with a needle voltage of 2.2-2.4 KV, nozzle voltage of 200 V, repeller voltage ranging from 5-80 V, source voltage of 4.5 V and lens voltages (lens 1 and 3) of -70 V. A gate was added to the electrospray interface (lens 2) to pulse ions into the ion trap at specific time intervals ranging from the 10-200 ms. The gate was controlled by the existing ±180 V circuit to gate electrons for EI operation. The gate voltages from the ITMS were conditioned so that potentials ranging from -100 to 0 V could be selected to eject ion into the trap and potentials from 12 to 100 V could be selected to prevent the entrance of ions into the trap. The electrospray interface was mounted into the existing ITMS filament end cap with a self-centering lens assembly to insure the electrospray and end cap aperture were in alignment. The electrospray-ITMS assembly was mounted on the opposite end of the vacuum chamber relative to the normal EI operation position to minimize hardware changes that would be required for the coupling.

The ITMS was operated under standard conditions for ions in the mass range of 0-650 daltons. Helium at an Ionization gauge reading of 2 x 10^-5 torr was added to the ITMS (total pressure with helium and electrospray in operations was 4-5 x 10^-4 torr) to stop the ions gated in the trap. For higher molecular weight peptides, the trap was operated in the resonance ejection mode to increase the mass range of the instrument to 2600 daltons.

Results and Discussion

The signal from the combination of electrospray with the ITMS was evaluated as a function of parameters that effect ion transmission into the ion trap. These parameters included gating voltage, RF voltage on the ring electrode, position and voltage differential of the nozzle relative to the skimmer and helium pressure in the trap. The gating voltage (Figure 1) optimization indicated that between -40 to -150 V was best for ejection of ions into the trap. Higher negative voltages resulted in collisional activation decomposition (CAD) of the sample or ions that could not be stopped inside the trap. Ions were best gated from entering the trap at potentials greater than 50 V. The RF voltage had some effect on signal intensity (Figure 2), with lower RF voltages showing the best signals for low molecular weight compounds. Compounds with ions above m/z 500 could be analyzed at higher RF voltages (mass values of 50-100). The nozzle and skimmer position (Figure 3) and voltage (Figure 4) played an important role in transmission and in CAD of the ions generated by electrospray. The best signal was obtained with the skimmer extended 3.5 turns (2.79 mm) from the full inserted position. At this position the foreline vacuum reading of 0.69 torr. The voltage on the skimmer can be used to CA the ions formed by electrospray to generate daughter ions. Typically for low molecular weight compounds skimmer potentials of 5-15 V resulted in minimal fragmentation while skimmer potentials greater than 30 V resulting in significant fragmentation. The last parameter, helium pressure in the ion trap, (Figure 5) indicated that helium was necessary to stop the ejected ion formed in electrospray. With no helium (pressure 1 x 10^-4 torr) the electrospray ITMS signal was weak and very noisy. The addition of 2-4 x 10^-4 torr helium (uncorrected ion gauge readings, actual pressure of helium is 12-15 times higher than the gauge reading) greatly increased the signal level recorded, since the ejected ion now could be trapped.
Neuropeptides ranging from 5 (leucine enkephalin) to 31 amino acids (β-endorphin) shown in Figure 6 were determined by electrospray ITMS. The electrospray spectra showed primarily single and multiple charged protonated molecular ions. Full scan mass spectra (scanning from 0-2600 daltons) could be recorded on as little as 10 femtols of β-endorphin. The electrospray ITMS combination was slightly more sensitive than the equivalent determination of β-endorphin on a quadrupole instrument; however, further optimization of the electrospray ITMS is required and significant improvements in sensitivity are anticipated.

CHARGE LIMITED SCALING RELATIONS FOR THE ION TRAP DETECTOR

John C. Helmer, Varian Assoc., 611 Hansen Way, Palo Alto, CA 94303

INTRODUCTION

The product of detection sensitivity and resolution $R \sim m/\delta m$ may often be simply expressed. The resolution of resonant ion ejection in the Ion Trap Detector[1] is reduced by anharmonic perturbation of electric fields produced by trapped charge. Sensitivity is proportional to the amount of trapped charge. The amount of charge is proportional to the cube of the cloud radius. Previous work has assumed that cloud radius is equal to the size of the trap. With collisional damping we take this radius as a free parameter.

In the pseudopotential approximation expounded by Dehmelt[2], ions are trapped in a harmonic potential well created by the gradient of the of the energy density of the quadrupole field, $d^2r/dt^2 = -(1/4\Omega^2) \nabla(\epsilon E/m)$. For convenience we consider a spherical pseudopotential of radius $a$. A test ion of mass $m_j$ and charge $e$ oscillates with a frequency $\omega_j$. $\omega_j = q_j\Omega/2\sqrt{2}$, where $q_j = 4eV/m_ja^2\Omega^2$. $V$ is the trap AC voltage at frequency $\Omega$. With helium damping, ions collect in a cloud at the center of the trap, in which space charge forces are balanced by the pseudofield.

The trap may be filled with ions of mass $m_0$ to a radius $r_o$. If $Q$ is the trapped charge, we find that $Q = (\pi e Om_0/2e)q_0^2\Omega^2r_o^3$. The charge density is independent of $Q$, and as ions are added $r_o$ increases. $Q$ is proportional to $1/m_0$. If we add a set of heavier ions, the force balance requires that these collect in an outer shell, separated from the inner sphere. For a single heavier ion within the cloud, the pseudofield is weaker and it is pushed outward by space charge fields to an equilibrium radius $r_i > r_o$. As more of the same heavy ions are added, the shell grows outward from $r_i$ with constant but lower charge density according to the heavier ion mass.

Now we consider the effect of $Q$ on a lighter test ion of mass $m_j$. The resolution of resonant ejection of the test ion will be degraded by the electric field of the cloud. When the trap voltage is ramped (increased) the test ion will be ejected first while the cloud is stable. The corresponding experiment is to fill the trap to a level $Q$ from a heavy gas containing a light tracer which is close to its point of extraction. The limit on $Q$ will determine the least concentration of tracer that can be detected. We will stop with determination of $Q$. The test ion moves in a field that is the sum of the pseudofield and the space charge field. The radial, free motion $z_j$ of the test ion is given by $d^2z_j/dt^2 = -\omega_j^2(z_j - (m_j/m_0)r_o^2/z_j^2)$ for $z_j > r_o$, $d^2z_j/dt^2 = -\omega_j^2z_j(1 - m_j/m_0)$ for $z_j < r_o$, where $\omega_j$ is the pseudopotential frequency. When $m_j = m_0$ the force is zero inside the cloud. For resonant excitation the period of motion matches the
period of excitation for all amplitudes $z_j$. But the period $\tau$ varies in the range $0 < z_j < a$, and we conclude (essentially) that
\[
\Delta \tau / \tau = (m_j / m_0) (r_0 / a)^3 = 1 / R
\]
where $R$ is the limiting resolution. We have also considered the self motion of the spherical cloud due to the image charge produced on the trap electrodes[5], with a similar result ($m_j = m_0$).

Thus we get the following $QR$ product
\[
QR = 4\pi\varepsilon_0 q_j aV = \pi\varepsilon_0 (m_j / e) q_j^2 \Omega^2 a^3.
\]
These expressions are related by the definition of $q_j$. For a given operating point $q_j$, the first expression is independent of mass, showing that $QR$ is proportional to the product of the trap radius and the applied AC voltage. For typical trap parameters at $R=1000$, we get $Q/e \approx 10^7$ ions, and $r_0 = 1$ millimeter.

While this result is strictly valid within the mathematical range of the pseudopotential approximation, i.e. for $q_j < 0.4$, we propose that it is likely to be valid out to the stability boundary at $q_j = .908$. When the secular orbit frequency $\omega$, increases to half the applied frequency, the orbit becomes unstable by the universal mechanism of parametric excitation. Of course, it is unusual that the pseudopotential and the parametric pump are produced by the same field. But the the sharpness of the boundary is direct proof of the existence of a harmonic potential well at the $\Omega/2$ resonant orbit frequency. In this case, the driving field at frequency $\Omega$ is a parametric axial modulation.

In future work this zeroth order model will be extended to include the case of finite ion temperature. In this case the charge number density $n$ is assumed to be determined by Boltzmann statistics, viz.
\[
\ln(n) = -(1 / kT) \int (m\omega^2 r - eQ(r) / 4\pi\varepsilon_0 r^2) dr, \quad \text{where} \quad dQ / dr = 4\pi\varepsilon_0 n r^2.
\]
The effective potential in the exponential factor is the sum of the RF pseudopotential and the potential of the trapped charge.

I am indebted to Dr. S.E. Buttrill, Jr. at Varian Assoc. for his interest, and to Dr. N.J. Kirchner for pointing out to me that trapped ions are configured as shells.

Implementation of Parent and Neutral Loss Scanning and Selected Reaction Monitoring on a Quadrupole Ion Trap Mass Spectrometer

*Jodie V. Johnson, Randall E. Pedder, and Richard A. Yost
Chemistry Department, University of Florida, Gainesville, FL 32611

MS/MS parent and neutral loss scanning and selected reaction monitoring (SRM) are easily implemented on tandem-in-space MS/MS instruments (e.g., triple quadrupoles), but until recently have not been implemented on tandem-in-time MS/MS instruments (e.g., quadrupole ion trap mass spectrometers, ITMS). We have developed two different methods to implement these scan modes on the ITMS. Although the parent scan and SRM methods are described below, the principles are similar for a neutral loss scan.

Both methods of implementing parent scanning rely on the fundamental principle that for a given set of instrumental parameters (largely RF voltage), each ion will have a unique secular frequency dependent upon its m/z. Resonant excitation at a frequency equal to the secular frequency of an ion of interest can be used to promote either collisionally induced dissociation (CID) or resonant ejection of that ion from the ion trap to the detector.

The first method for implementing a parent scan involves the simultaneous application of two resonant excitation waveforms during the CID period of a normal ITMS MS/MS scan function (Figure 1). The frequency of one of the resonant excitation waveforms is scanned at low voltage to induce CID of successive parent ions. The other waveform is applied at the secular frequency of the daughter ion of interest and at a high enough voltage to cause rapid resonant ejection. When CID of a parent ion produces the desired daughter ion, it is ejected from the ion trap and detected. Figure 2 illustrates the result of such an experiment for the parents of 91+ for a mixture of n-alkylbenzenes. There are a number of disadvantages to this technique, most markedly the ejection of parent ions (as noted in Figure 2B) and the ejection of daughter ions with q>0.91; both can result in high estimates of the parent ion intensities.

A second method was devised to overcome the shortcomings of simultaneous resonant excitation and ejection. In this method the parent ion and daughter ion resonant excitation waveforms are applied sequentially in time, or pulsed. First CID of the parent ion occurs, then rapid ejection of the daughter ion of interest, then CID of the next parent ion, etc. Figure 3 illustrates this method for a selected reaction monitoring (SRM) parent scan of 91+ for a mixture of n-alkylbenzenes where only the

![Figure 1. Simultaneous resonant excitation parent scan function.](image1.png)

![Figure 2. Simultaneous resonant excitation parent scan of 91+ of n-alkylbenzenes.](image2.png)
expected M$^+$ ions are scanned. Figure 4 illustrates an expanded version of two pulse sequences having different parent ion resonant excitation voltages. As can be seen in these figures, if any parent ion is ejected or if any daughter ions with q>0.91 are formed and ejected during the parent CID pulse, their ion signals will not interfere with the ion signal due to the daughter ion of interest. In addition, the parent ion resonant excitation voltage can be optimized for the parent m/z range of interest. Of course, for SRM, it is straightforward to alternate between any parent and daughter ion combination of interest.

![Figure 3. Pulsed SRM parent scan of 91$^+$ for a mixture of n-alkylbenzenes.](image)

![Figure 4. Two pulse sequences expanded from pulsed SRM parent scans of 91$^+$ for a mixture of n-alkylbenzenes.](image)

We have not yet demonstrated neutral loss scanning experimentally. However, its implementation will be similar to the pulsed parent scan described above. With a neutral loss scan, the daughter and parent masses must be scanned. As such, two different methods can be implemented depending upon the behavior of the ring RF voltage. If a constant ring RF voltage is maintained, the resonant excitation frequencies of the daughter ion and parent ion can be scanned (in a pulsed method) as indicated in Figure 5. Alternatively, if the ring RF voltage is scanned in a linear fashion to maintain a constant daughter ion resonant excitation frequency, then the parent ion resonant excitation frequency can be scanned as illustrated in Figure 6. The latter method would yield better parent ion and daughter ion mass resolution and a greater applicable m/z range yielding more efficient CID.

![Figure 5. Secular frequencies of parent and daughter ions and the ring RF voltage for a neutral loss scan at a constant RF voltage.](image)

![Figure 6. Secular frequencies of the parent and daughter ions and the ring RF voltage for a neutral loss scan with a constant daughter ion q.](image)

ENHANCEMENT OF MASS RESOLUTION IN THE QUADRUPOLE ION TRAP VIA RESONANCE EJECTION

Douglas E. Goeringer, Scott A. McLuckey, and Gary L. Glish,
Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831

Some of the attributes of the quadripole ion trap include high MS/MS efficiency, the capability for multiple stages of mass spectrometry (MS^n), high sensitivity, the capability for ion-molecule reactions, and relatively low cost. However, the Finnigan MAT ion trap mass spectrometer (ITMS) has unit mass resolution and a nominal upper mass/charge limit of only 650 when operated in the standard mass-selective instability method for acquiring mass spectra. Mass resolution up to ~ 2500 can be achieved with the use of the axial modulation technique. Ions can also be ejected at a q_e value other than that corresponding to the mass-selective instability boundary by application of an auxiliary signal to the endcap electrodes. When the frequency of this signal is resonant with the secular frequency for a particular m/z, such ions can become kinetically excited and ejected from the trap via a process known as resonance ejection.

Last year, we demonstrated the capability to mass-selectively isolate or eject ions\(^1\) over a wide mass range and to generate mass spectra of electrospray-generated ions by scanning the frequency of the resonance ejection signal applied to the end-cap electrodes\(^2\). A block diagram of the experimental modifications to the ITMS\(^\text{TM}\) required for frequency-swept resonance ejection is shown in Figure 1. The mass resolution of the ion trap can be further enhanced by slowing the frequency scan rate and reducing the amplitude of the resonance ejection signal. El mass spectral data acquired for the m/z 502 ion from perfluorotributylamine (PFTBA) acquired with axial modulation (Figure 2a) and frequency-swept resonance ejection (Figure 2b) are shown. The low resolution spectrum (m/Am = 1900) was obtained at a scan rate of 5555 m/z per second, while the high resolution spectrum (m/Am = 45,000) was acquired at 4 m/z per second. Although the amplitude of the m/z 502 signal from mass-selective instability is approximately fifty times greater than from resonance ejection, the corresponding peak width in time units is about fifty times less. Thus, the areas under the two peaks, which correspond to the total number of ions at m/z 502, are the same within experimental error. The mass resolution is shown in Figure 3 as a function of scan rate at m/z 502, q_e=0.85. The mass resolution is also a function of the q_e and m/z values for a particular ion as well as the frequency scan rate. Plots of the mass resolution versus these parameters are shown in Figure 4, for m/z 502, and in Figure 5, for q_e=0.85. Each data set was obtained at a sweep rate of 1.6 m/z per second.

CHEMICAL CHARACTERIZATION OF MICROPARTICLES BY LASER ABLATION IN AN ION TRAP MASS SPECTROMETER

J. M. Dale, W. B. Whitten, and J. M. Ramsey
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6142

We are developing a new technique for the chemical characterization of microparticles based upon the use of electrodynamic traps. The electrodynamic trap has achieved widespread use in the mass spectrometry community in the form of the ion trap mass spectrometer or quadrupole ion trap (1). Small macroscopic particles (microparticles) can be confined or levitated within the electrode structure of a three-dimensional quadrupole electrodynamic trap in the same way as fundamental charges or molecular ions by using a combination of ac and dc potentials (2). Our concept is to use the same electrode structure to perform both microparticle levitation and ion trapping/mass analysis. The microparticle will first be trapped and spatially stabilized within the trap for characterization by optical probes, i.e., absorption, fluorescence, or Raman spectroscopy. (We have previously shown that such spectroscopic probes can be extremely sensitive, e.g., a detection limit of one molecule of Rhodamine-6G has been determined in the case of fluorescence spectroscopy (3), (4)). After the particle has been optically characterized, it is further characterized using mass spectrometry. Ions are generated from the particle surface using laser ablation or desorption. The characteristics of the applied voltages are changed to trap the ions formed by the laser with the ions subsequently mass analyzed. The work described here focuses on the ability to perform laser desorption experiments on microparticles contained within the ion trap. Laser desorption has previously been demonstrated in ion trap devices by applying the sample to a probe which is inserted so as to place the sample at the surface of the ring electrode (5), (6). Our technique requires the placement of a microparticle in the center of the trap. Our initial experiments have been performed on falling microparticles rather than levitated particles to eliminate voltage switching requirements when changing from particle to ion trapping modes.

Figure 1 shows a schematic diagram of our current apparatus for performing these experiments. The ion trapping device is a modified Finnigan MAT Model 800 Ion Trap Detector (ITD). The trapping electrodes were removed from the ITD vacuum chamber and placed in a 6-inch cube with the rotational symmetry axis of the trap oriented vertically. The cube is attached to a 4-inch oil diffusion pump. The rf voltage from the ITD was reattached to the ring electrode by extending the transformer tap wire to a high-voltage vacuum feed-through mounted on one of the side ports and retuning the transformer for resonance. The ITD was operated with nominally 1 mtorr of He buffer gas as usual. The ion lens assembly normally used for electron-impact ionization was removed from the top end cap and a particle dropping device was installed. The particle dropper consisted of a funnel-shaped container with a 450-μm spout. A 300-μm wire attached to a 6-mm rod normally rests in the spout. The rod exits the vacuum chamber through an o-ring sealed fitting. Particles of interest are placed in the container and dispensed by moving the wire attached to the rod. The other three side ports were fitted with 6-inch pyrex windows while the bottom port was covered with a flange mounted with the channeltron electron multiplier. A 5-mW HeNe laser beam is focused into the trap through the windows and opposing 3-mm holes drilled in the ring electrode. The HeNe beam is positioned ≈ 1 mm above the center of the trap. The second harmonic laser radiation from a pulsed Nd:YAG laser
(Quanta-Ray DCR-2A) propagates in the opposite direction through the trap and is focused by a 1-m lens at the trap center.

Collection of a laser desorption mass spectrum requires synchronization of the Nd:YAG laser with the falling particle and the ITD. The ITD runs continuously through its normal scan sequence of trapping and mass-selective particle ejection. The ITD can have a trapping-mode duty cycle of \( \approx 40\% \) if appropriate scan settings are used. When particles are dropped they pass through the HeNe probe beam scattering light that is detected by the photodiode. The photodiode signal is converted to TTL, then ANDED with the electron gate signal from the ITD. If a light scattering signal is detected when the ITD is in the trapping mode, the Nd:YAG laser is fired after an adjustable delay time. The laser trigger delay allows for the spatial displacement between the HeNe and Nd:YAG beams. Particles can be reliably illuminated with the 10-ns pulse from the Nd:YAG laser after proper alignment.

Silicon carbide particles (nominal 125-µm diameter) coated with various materials were used in our initial studies. Particles were coated with various quaternary ammonium or phosphonium salts by dissolving them in methanol, combining with a given mass of particles and evaporating the solvent. In all cases 5 mg of salt was evaporated onto 5 gm of particles. This loading would result in roughly 10 monolayers of material on the surface of a particle based upon particle surface area measurements. Compounds investigated include trimethylphenylammonium chloride, triethylphenylammonium iodide, tetrabutylammonium iodide, and tetraphenylphosphonium bromide. All experiments were performed with pulse energies of \( \approx 1 \text{mJ} \) (\( 10^9 \text{W/cm}^2 \)) except where noted. Ions were reliably produced from dropped particles with yield correlating with the intensity of the 532-nm light scattered by the particle as detected by the photodiode. The quality of the mass spectra varied primarily due to what appears to be space charge effects. Mass spectra of the above compounds all produced intact cations and expected fragment ions. The mass spectra compare favorably with those of Ref. 6 and SIMS data on the same particles.

In addition to the above coated SiC particles, uncoated particles of SiC, Fe, and Nb were also investigated. The uncoated SiC particles yielded Na and K ions presumably due to surface contamination. No ions were observed that would be associated with SiC even at intensities of \( 10^8 \text{W/cm}^2 \). The iron and niobium particles required slightly higher energies (\( \approx 3 \text{mJ/pulse} \)) to yield ions as would be expected. The iron spectra included the iron isotopes in addition to showing a copper impurity. The Nb spectra also indicated some iron contamination.

Improvements in the current apparatus promise to yield good sensitivity for materials on the surface of microparticles. Submonolayer sensitivities should easily be achieved. Excess ion production leading to space charge effects in the trap is currently more of a problem than lack of signal. Combining particle levitation with ion trapping may allow multiple desorption experiments to be performed on a single particle and thus permit signal averaging.

ION ACTIVATION IN A QUADRUPOLE ION TRAP

Gary L. Glish, Scott A. McLuckey, Douglas E. Goernger, Gary J. Van Berkel, Kevin J. Hart
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

Collision-induced dissociation (CID) can be performed in a quadrupole ion trap by resonantly exciting ions at a given mass-to-charge ratio so that they will undergo energetic collisions with the helium bath gas. While this is often compared to CID in a triple quadrupole or hybrid mass spectrometer, there are important differences. One of these differences is that once the parent ion dissociates in the quadrupole ion trap the product ions are not in resonance with the excitation voltage and thus are unlikely to undergo energetic enough collisions to cause further fragmentation. This is in contrast to beam instruments in which, under multiple collision conditions, product ions can be subsequently energized and dissociated by collision after they are formed. Another difference is that the parent ion is constantly accelerated by the resonance voltage in the quadrupole ion trap and thus, after an inelastic collision in which the ion loses kinetic energy, the next collision can be even more energetic because of the acceleration that occurs between collisions. Additional, the parent ions in the MS/MS ion trap experiment can undergo hundreds of collisions because the time-scale and path length of the CID portion of the experiment are orders of magnitude greater than in beam instruments.

In our effort to obtain a better understanding of the CID process in the quadrupole ion trap we have been studying several model compounds (in this discussion the compound studied was N,N-dimethylaniline) to determine the effects of the various parameters such as resonant voltage amplitude and duration, fundamental rf amplitude, and target gas pressure and composition. The resonant voltage amplitude and duration are factors in the power absorption of the resonated ions according to equation 1 below

\[ A = e^2E_0^{2}\frac{t_0}{8m} + \frac{\text{d}v/\text{d}t}_{\text{collide}} \]  

in which \( E_0 \) is the resonant electric field amplitude, \( t_0 \) is the duration of the resonant excitation and \( \frac{\text{d}v/\text{d}t}_{\text{collide}} \) is representative of all the collision processes that can affect the energy of an ion. (It should be noted that the first term in equation 1 is dependant only upon instrumental parameters and the mass and charge of an ion whereas the second term is very dependant upon the physico-chemical properties of an ion.) The fundamental rf amplitude determines the maximum kinetic energy of an ion in the ion trap which can be approximated by the Dehmelt pseudo-potential well (Eq. 2)

\[ D = q^2m_0\frac{\Omega^2}{2e} \]  

with the maximum kinetic energy then being

\[ mv^2 = 2eD \]  

Thus, for a given mass-to-charge ratio, the maximum kinetic energy of a trapped ion is proportional to \( q^2 \).

The effect of tickle duration is illustrated in Figure 1. At this \( q \) value (0.075) the maximum kinetic energy of the ions is 2.1 volts and they are ejected from the ion trap before they can be collisionally activated enough to dissociate. Note that 20 and 30 ms excitation periods show very little difference in behavior, which means that over the last 10 ms of a 30 ms excitation a steady state is reached i.e. the \( \frac{\text{d}v/\text{d}t}_{\text{collide}} \) term cancels the first term of the equation. At higher \( q \) values at which the ions can be sufficiently collisionally activated to dissociate there is a competition between ion dissociation and ion ejection. Dissociation is increasingly competitive at longer excitation times since more power can be absorbed by an ion at a given excitation voltage. Increasing the \( q \) value at a fixed excitation time again makes dissociation increasingly competitive with ion ejection due to the increasingly energetic collisions which can occur before ion energies sufficient for ejection are achieved.

Figure 2 shows the effect of changing the helium buffer gas pressure. At higher pressures more collisions occur within a given time period thus increasing the likelihood of CID versus ion injection. However since helium also affects the trapping efficiency its pressure affects the sensitivity. The top plot has a sensitivity of about a factor of 6 less than the middle plot and 3 less than the bottom plot.

Other collision gases can be added to the helium. Figure 3 shows plots of parent ion abundances ([M-H]^+ from N,N-dimethylamidine) and the sum of selected product ion abundances (solid symbols) with 0, 1 and 5 x 10^5 torr of Ar added to the helium. The trapping efficiency decreases as Ar is added to the system. At 1 x 10^5 there is not a lot of change from when no Ar is present which is due to the fact that only about 1 out of every 75 collisions of the parent ion is with Ar. However increasing this probability by a factor of 5 by going to 5 x 10^5 shows an earlier onset for dissociation and also the rate of dissociation increasing relative to the rate for ion ejection. When adding a heavier collision gas the main effect observed in the MS/MS spectrum for this ion is an increase in the relative abundance of the simple cleavage ions (m/z 105, 77, 51) versus the other, rearrangement ions. This is most dramatically demonstrated in Figure 4 which shows MS/MS spectra obtained with and without Xe added.
Coupling a Particle Beam and a Thermospray Interface to a Quadrupole Ion Trap Mass Spectrometer

Mark E. Bier, Richard E. Hartford, Jack R. Herron, and George C. Stafford
Finnigan Corporation, San Jose, CA 95134

Quadrupole ion trap mass spectrometers have seen little use in LC/MS systems primarily because of the amount of solvent typically associated with LC introduction methods. Solvent ions cause space charging, reducing analyte sensitivity and mass range, while solvent neutrals may cause ion/molecule reactions resulting in undesired spectra. We have designed an ion trap instrument that provides additional means to reduce the unwanted matrix effects typically found at high solvent flow rates. The instrument uses differential pumping between the source and the ion trap analyzer and a DC quadrupole triplet lens is used to transmit the ions as shown in Figure 1. In addition to transmitting the ions to the trap, the DC quadrupole triplet serves as a beam-shaper and a region for improved pumping as shown in Figure 2. The instrument consists of Finnigan ITS40 electronics to control the mass selective instability scan function which is supplemented with axial modulation, the timing of the gate element, and the electron multiplier. Finnigan TSQ-70 electronics are used to control the source, vacuum pumps, ion gauge, and lens elements including two adjustable potentials for the gate lens. The element nearest the entrance endcap was used to gate the ions. The ion trap is floated to negative potentials when injecting positive ions from the grounded ion source and thus establishes the maximum initial collision energy inside the ion trap chamber. Helium, added directly to the trap, is necessary to trap injected ions [1] and gives a pressure of 2 x 10^- torr in the cradle. The source region is pumped with a 330 L/s turbomolecular pump while the analyzer region is pumped with 170 L/s and 330 L/s turbo molecular pumps.

The FC43 ion m/z=219 has been thought to go under fragmentation during injection when the ion source is located in close proximity to the ion trap. In the well pumped injection lens system described here, the relative abundance of m/z 219 is clearly observed as seen in Figure 3. A graph of ion intensity versus ion trap offset for the ions m/z = 69, 131, 219, and 502 from FC43 is shown in Figure 4. While m/z=69 is observed at ion trap offsets to at least -10 volts, m/z=219 is observed out to only -20 volts offset. All ions show a maximum intensity at approximately -6.5 volts. The shapes of the curves may be partially attributed to the Rf-amplitude during injection, ion optics, SID, and CAD in the trap or injection lenses.

To demonstrate the capability of LC/MS on the instrument, particle beam (PB) and thermospray (TSP) interfaces were coupled to the system. Figures 5-7 show the mass spectra from PB external EI ionization of caffeine, 17α-hydroxy-progesterone, and reserpine. The Rf-amplitude on the ring electrode was set to exclude ions less than 34 amu. Unlike a PB interface ion trap system using internal ionization [2], no self-CI is evident.

It is remarkable that the improved differential pumping also allows for the acquisition of resolved ions from a TSP interface. Adenosine and reserpine were both injected into a 1-1.5 ml/min flow of 0.1 M ammonium acetate made up in 30% methanol and 70% water. Figure 7 shows the typical TSP spectrum for adenosine which is believed to have gone under some thermal degradation of (M+H)^=268. The TSP spectrum of reserpine, (M+H)^+=609, is shown in Figure 8. Unit mass resolution is observed for all ions.

When operating the ion trap in the mass selective instability with resonance ejection mode, the resolution is dependent on the interaction time of the ion with the applied auxiliary field before the ion is ejected. Thus, given the appropriate choice of auxiliary field frequency and amplitude, the resolution can be increased by decreasing the scan speed of the Rf amplitude which brings ions successively towards resonance and causes ion ejection. The details and effects of the important parameters involved in obtaining high resolution is discussed in the following two abstracts. We describe here some experimental results demonstrating high resolution and its practical applications.

The instrument used for these studies is a highly modified ion trap mass spectrometer (ITMS) designed for the study of the biochemical applications of the ion trap. External ionization and subsequent axial ion injection is utilized. The available ion sources include EI, CI, Cesium ion desorption, laser desorption, and electrospray ionization. Our results demonstrating the first high resolution data obtained on the ion trap mass spectrometer operated in the mass selective instability mode with resonance ejection has recently appeared in the literature. Therefore, we discuss here the results of our study of the applications of high resolution for the combination of electrospray ionization with the ion trap mass spectrometer. Figure 1 shows the instrument configuration for the electrospray ion trap combination. It includes a Fenn-Whitehouse electrospray ion source, three stages of differential pumping, ion injection optics, and a 20 kV conversion dynode detector system.

Figure 2 shows a spectrum of horse skeletal myoglobin which includes an impurity or adduct ion peak associated with each peak of the multiply charged myoglobin. Such inhomogeneities are commonly found for biochemical systems and hinders the ability for accurate mass determination of proteins. Higher resolution allows the separation of the impurity peak from the pseudomolecular ion and therefore allows much more accurate assignment of protein molecular weight as well as aid in the identification of impurity or adduct ion species.

A practical application of high resolution is the separation of isotopes of multiply charged ions for the purpose of identification of the charge state. Figure 3 demonstrates the resolution obtainable for separating the isotopes of multiply charged ions using the doubly charged ion of gramicidin S. Figure 4 demonstrates that charge state determination can be performed using this method on parent, daughter and granddaughter ions using rennin substrate as the example.

In conclusion, high resolution can be achieved on an ion trap mass spectrometer operated in the mass selective instability with resonance ejection mode. A practical application of this resolution is the determination of charge states of electrosprayed ions, including multigeneration daughter ions. Limitations in the present method of achieving high resolution include instrument stability, space charge (especially for multiply charged ions), signal-to-noise loss due to detector bandwidth mismatch, and the use of high resolution for accurate mass measurement.

Figure 4.
Axial Modulation in the Paul Ion Trap: A Closer Look at Enhanced Resolution and Ion Motion During Resonance Ejection

Finnigan MAT, San Jose, California

Although the mass-selective instability mode of operation of the quadrupole ion trap was very successful, a newer method of operation, the "mass-selective instability mode of operation with resonance ejection" (described in U.S. Patent No. 4,736,101) has proven to have certain advantages such as the ability to record mass spectra containing a greater range in abundances of the trapped ions. In this method of operation, a supplementary field is applied across the end cap electrodes and the magnitude of the r.f. field is scanned to bring ions of successively increasing m/z into resonance with the supplementary field so that they are ejected and detected to provide a mass spectrum. Commercially-produced ion trap mass spectrometers based on this mode of operation have recently become available, and these instruments have been successfully applied to an even wider variety of problems in chemical analysis than their predecessors.

Recently Schwartz and coworkers discovered that the newer scan method makes possible the acquisition of spectra with relatively high mass resolutions. Essentially, the scan rate (the volts per second ramp rate of the r.f. voltage supplied to the ring electrode) is reduced and an optimum resonance voltage is supplied. The enhancement of resolution with decreased scan speeds is in marked contrast to the behavior of the earlier mass selective instability mode. For example, Figure 1 shows spectra of xenon acquired at scan rates of 4.0E3 volts/second (3.1E2 amu/s), 6.4E5 volts/second (5E3 amu/s), and 1.02 volts/second (8E4 amu/s). At the high scan speed the resolution is somewhat degraded, at the intermediate scan rate the resolution is essentially unit resolution, and at the slow scan rate the resolution is not improved but is in fact somewhat poorer than at the usual scan speed of 5000 amu/second. Figures 2-4 show a comparison of the mass selective instability mode with and without resonance ejection for the same three scan rates. With resonance ejection, the resolution shows a strong dependence on scan rate and at the slowest scan speed, a resolution of much better than unit resolution is achieved.

The relatively weak dependence of the resolution on scan speed in the mass-selective instability mode makes it relatively simple to choose the optimum conditions for mass analysis: the trap is scanned at the maximum rate that does not lead to a loss of resolution (or that is not too fast for the data acquisition system). However, the strong dependence of the resolution on scan speed in the resonance-ejection scan forces one to optimize three parameters: the scan speed, the working point (i.e. the frequency of the resonance ejection voltage), and the amplitude of the ejection voltage. To seek the optimum scan conditions, we recently investigated the peak width (in time) of the m/z 129 peak of xenon at beta values between .56 and .95. A particular scan rate and working point were chosen and spectra were acquired over a large range of ejection voltages as shown in Figure 5. An optimum ejection voltage and associated peak width and resolution were obtained from each plot. The best resolution for each pair of conditions (scan rate and working point) is shown in Figure 6 and the corresponding peak width (in seconds) is shown in Figure 7.

The data generally indicate that the resolution decreases as the beta value becomes close to one and that a maximum resolution is reached in the vicinity of a beta of 0.73. The relatively weak trapping field near the edge of the stability diagram may account for the loss of resolution. Perhaps scattering causes a dephasing of the coherent ion motion which causes peak broadening; such an effect would become increasingly important as the edge is approached, as is observed. The decrease in resolution at lower beta values is probably due to the effective increase in scan rate as expressed in terms of amu per period of the ejection voltage. The combination of the two effects would lead to the observed maximum.

The linearity of plots of the logarithm of peak width vs the logarithm of scan speed (Figure 8) indicates a power function relationship. In this case, at very slow scan speeds the plot is parallel to the plot of the peak separation (in time), indicating that the resolution is not improved as the speed is decreased. We believe that space charge becomes increasingly important at the lower scan speeds and can account for the lack of improvement in resolution as the scan speed is decreased.

Considerations in the Choice of the RF Trapping Field Frequency for Ion Trap Mass Spectrometers Intended for High Mass (>5,000 Da.) Applications.

Finnigan MAT, 355 River Oaks Pkwy., San Jose, CA, 95134

To date, the best experimental results from attempts at extension of the mass range of the quadrupole ion trap instruments have been accomplished by the incorporation of resonant ejection into the mass selective instability scanning technique. In this experiment, resonant ejection of trapped ions at a $q_z$ well below the stability limit for the RF-only quadrupole ion trap, $q_z = 0.908$, allows a higher maximum mass to be brought to instability (resonance) and ejected upon application of the maximum available RF voltage. The primary factors in determining the mass range of the analysis are the frequency of the resonating supplementary field, and the maximum attainable intensity of the trapping field. The effective field intensity is determined by the trap size and the magnitude and frequency of the applied RF voltage.

Reported ion trap mass range extension experiments yielding mass ranges above ca. 5,000 Daltons have utilized modified commercially available ion traps having trapping field frequencies, $f$, of ca. 1 Mhz, trap characteristic dimension, $r_0$ of ca. 10 mm, and RF voltage amplitude, $V_s$ of about 7,000 Volts-peak at maximum. The supplementary field frequency, $f_v$, for these experiments are below 50 kHz. The amplitude of the supplementary voltage, $V_s$, is generally on the order of 1 Volt-peak. The an important issue is whether the instrument parameters are optimal for such high mass analysis. A review of the basic equations of motion of the ion trap yields some insight into this question.

The equation of motion of ions in the z dimension can be written as a forced Mathieu equation as shown in Equation (1).

$$\frac{d^2z}{dt^2} + 2q_z \cos(2\xi)z = p_z \cos(\alpha \xi)$$

The various normalized parameters in this equation are defined below in Equations (2),(3),(4), and (5).

$$\xi = \pi ft$$  \hspace{2cm} (2)  
\[ \alpha = \frac{f_v}{f} \quad \hspace{2cm} (3) \]

\[ q_z = \frac{eV}{m \beta_0 r_0^2 f_v^2} \quad \hspace{2cm} (4) \]
\[ p_z = \frac{eV_s}{\sqrt{2} m r_0^2 f_v^2} \quad \hspace{2cm} (5) \]

When considering the case where the mass range of an ion trap is being greatly extended by resonant ejection of ions at low $q_z$, this equation of motion can be well approximated by Equation (6). This simplification occurs because at low $q_z$, unforced ion motion is very nearly harmonic. The ion oscillation frequency in normalized units is $\beta_z$, which is approximately equal to $q_z/\sqrt{2}$ at low $q_z$. Resonant ejection and detection of ions occurs when the natural frequency of motion of a particular $m/e$, $f_n$, approaches the frequency of the supplementary field, $f_v$.

$$\frac{d^2z}{dt^2} + \beta_z^2 z = p_z \cos(\alpha \xi) \quad \text{where} \quad q_z < 4 \quad \text{and} \quad \beta_z = \frac{q_z}{\sqrt{2}}$$

While considering ion motion in such normalized terms is useful for providing basic understanding, further information appropriate to the choice of instrument operating parameters can be obtained by converting the normalized approximate equation of motion back to an unnormalized form as is given in Equation (7). Inspection of Equation (7) indicates that any combination of instrument parameters that yield same coefficient of $z$ should produce identical ion motion and therefore identical ion resonant frequencies. The ion resonant frequency, $f_{ion}$, is given in Equation (8).

During mass analysis, the trapped ions are successively ejected from the trap by linearly
increasing the amplitude of the trapping voltage. This means that, in practice, the coefficient of $z$ in Equation (7) is time variant. However any choice of trapping field frequency, $f$, and trapping voltage rate of change, $\frac{dV}{dt}$, which results an identical equation of motion for ions approaching resonance with a chosen supplementary field should result in identical ion trajectories during ejection. This condition for similarity will be satisfied any choice of $f$ and $\frac{dV}{dt}$ that provide the same mass scan rate, $\frac{dm}{dt}$. Therefore when resonant ejection is induced at low $q$, it is necessary to produce large mass range extensions, the choice of mass scan rate, $\frac{dm}{dt}$, and the applied supplementary field frequency, $f_s$, will determine the achieved mass resolution. Mass resolution should be independent of the trapping field frequency, $f$.

However the mass range of the instrument will depend on the choice of the trapping field frequency. Equation (9) shows how mass range depends on the relevant instrument parameters.

\[
\text{Mass range, } m_{\text{max}}, \text{ is shown to be proportional to the maximum available trapping voltage } V_{\text{max}} \text{ and inversely proportional to both the supplementary field frequency, } f_s, \text{ and the trapping field frequency, } f. \text{ This means that the mass range of the instruments can be extended without loss in mass resolution if the trapping field frequency is reduced while maintaining the same supplementary field frequency and maximum trapping field voltage. Alternatively, this also means that a higher supplementary field frequency can be used obtain a desired mass range for a given maximum trapping field voltage if a proportionally lower trapping field frequency is also used.}

There is advantage in maximizing the supplementary field frequency used to obtain a given mass range. This is because the dispersion in ion resonant frequency with mass, $df/\frac{dm}{dm}$, for ions close to resonance with the supplementary field will strongly affect the mass resolution obtained for a given mass scan rate. The mass selective instability scan with resonance ejection experiment essentially measures the resonant frequency of stored ions. The mass scan rate effectively controls the observation time and the resonant frequency dispersion specifies the necessary frequency resolution required to distinguish adjacent masses. The slower the mass scan rate the higher the resolution. The greater the frequency dispersion the better the mass resolution. Equation (10) is an expression for ion resonant frequency dispersion, $df/\frac{dm}{dm}$, in terms of supplementary field frequency, $f_s$, and the ion mass at resonance, $m_{\text{eject}}$.

\[
\frac{df}{dm} = \frac{f_s}{m_{\text{eject}}}
\]

This expression clearly shows that ion frequency dispersion for a given mass scan rate increases proportionally with the supplementary field frequency. Thus attainable mass resolution for a given mass scan rate should increase with increased supplementary field frequency.

These characteristics were tested experimentally by operating a standard 10 mm $r_0$ ion trap at three different trapping field frequencies: 1100 kHz, 762.7 kHz and 550 kHz. The mass resolution obtained at a mass scan rate of ca. 135 da/sec with a supplementary field frequency of 35.371 kHz was studied by observing the m/z 502 and m/z 503 from FC-43. The observed resolutions were nearly equal for all three trapping frequencies. When the supplementary field frequency was increased improved resolution at the same mass scan rate was observed. Also the ability to increase mass scan rate at a given resolution by using higher supplementary field frequencies was also observed.
Initial Interpretation of High Energy Collisionally Induced Decomposition Spectra obtained from a Known and Unknown Peptide in the Mass Range 60-2,000 Daultons by MS/MS.

David L. Mc Gillivray, Department of Chemistry, University of Victoria, Victoria, B.C., Canada, V8W 3P6

Interpretation of collisionally induced decomposition spectra (daughter ions) of an unknown peptide from a tandem mass spectrometer or by a constant B/E link scan on a two sector magnetic instrument is not a trivial matter.

The initial step is to identify all potential amino acid residues and their position in the sequence by generating a list of ion peak pairs from the spectrum whose mass difference corresponds to an amino acid residue. Listing them in order of increasing mass, based on the low mass ion peak in each pair.

From this list (a) create a series of branched tree structures, built up from the ion pairs, which represents all the "potential" amino acid sequences possible from the experimental data present in the spectrum, Fig 1 shows one of the branched tree structures obtained from the spectrum of Gramicidin-D. (b) Scan through the sequences, one at a time, picking out the amino acid residue, and if the sequence contains six or more amino acids residues, an arbitrary number, calculate the N and C terminal fragments. As the program passes through the list of ion pairs a flag is raised at each pair to indicate which pairs have been used. These flags prevent the program using these pathways or portions of pathways again.

The sequences from (b) above are examined for relationships which may indicate a potential or partial sequence for the unknown peptide in question. For example, the two potential sequences obtained from the mass spectrum of Gramicidin-D are shown in Fig 2, the second sequence is the inversion of part of the first sequence. After inverting the second sequence and rewriting them again side by side one can create a third sequence which corresponds to the sequence present in Gramicidin-D, except one Valine (VAL) is missing from the low mass end of the peptide.

It must be pointed out that that this process cannot distinguish between
It must be pointed out that this process cannot distinguish between the N and C terminal ends of the peptide. In (b) above the software assumes the low mass end of the amino acid sequence is the N terminal.

Acknowledgments. We wish to thank Fred Walsh of the University of California, San Francisco and Kratos Analytical for running the Gramicidin-D spectra.

MASS SPECTROMETRIC MEASUREMENT OF \( \beta \)-ENDORPHIN AND METHIONINE ENKEPHALIN IN HUMAN PITUITARIES

D.M. Desiderio, Jerry L. Lovelace, Jozef J. Kusmierz, and Chhabil Dass

University of Tennessee, Memphis, 800 Madison Avenue, Memphis, Tennessee 38163.

Two opioid neuropeptides, \( \beta \)-endorphin (BE) and methionine enkephalin (ME), were quantified with fast atom bombardment mass spectrometry (FAB-MS) in individual human pituitaries (post-mortem) and in tumor pituitaries (post-surgery) in a study to clarify the molecular processes that occur in tumor formation. FAB-MS in the multiple reaction monitoring (MRM) mode was used to link the MH\(^+\) precursor ion of the peptide with a fragment ion that was unique to each neuropeptide and to increase significantly the molecular specificity of these quantitative analytical measurements. The experimental procedure follows our general scheme 1,2,3. Briefly, the human pituitaries obtained at autopsy were frozen immediately and kept at -70°C until analysis. Frozen tissue was weighed, placed immediately into cold (4°C) acetic acid (1 N, 1:20 w/v), and homogenized. After 2 h, the homogenate was centrifuged (31000g; 30 min), and the supernatant was prepurified with Sep-Pak. The peptide-rich fraction was lyophilized, reconstituted into 150 \( \mu \)l of mobile phase, and subjected to gradient RP-HPLC separation. The ME fraction was lyophilized, reconstituted into 150 \( \mu \)l of mobile phase and analyzed on polymer column. The collected ME fraction was lyophilized, and analyzed by mass spectrometry. The gradient HPLC BE fraction from the pluillitary extracts and the standard curve solutions were subjected to tryptic digestion. The tryptic digest was purified with Sep-Pak and analyzed on ODS HPLC column. The isocratic fraction containing NAIIIK was lyophilized; and reconstituted in 25 \( \mu \)l of 0.1% TFA for MS analysis. Two corresponding stable isotope-incorporated peptides, 10 \( \mu \)g of [\(^2\)H\(_5\)-Phe]-ME and 10 \( \mu \)g of [\(^2\)H\(_4\)-2\( \alpha \)-Ile]-BE1-31, human 4, respectively, were added before tissue homogenization as internal standards. ME was quantified as the intact pentapeptide, and BE1-31 was quantified via its tryptic fragment BE20-24 (NAIIIK). The amount of each neuropeptide quantified in control post-mortem pituitaries (n=8) was 75.2 ± 29.6 (s.e.m.) pmol ME \( \mu \)g\(^{-1}\) protein and 132.5 ± 22.3 (s.e.m.) pmol BE \( \mu \)g\(^{-1}\) protein and in the pituitary tumor samples (n=5), 25.0 ± 7.6 pmol ME \( \mu \)g\(^{-1}\) protein and 36.0 ± 14.6 pmol BE \( \mu \)g\(^{-1}\) protein 3. The difference in the BE content between the control and tumor pituitaries was significant (p=0.004) (Fig. 1), and may reflect an aberrant metabolism of the POMC system in these human pituitary tumor tissues. The measurements from FAB-MS methods (MH\(^+\) ion monitoring and the MRM mode) were compared to measurements from radioreceptor assay and RIA by analyzing the amount of endogenous ME extracted from five human post-mortem pituitary samples. ME-like reactivity (ME-LR) was 116 ± 27 pmol \( \mu \)g\(^{-1}\) protein (s.e.m.); ME-like immunoreactivity (ME-LI) was 18.3 ± 9.5 pmol \( \mu \)g\(^{-1}\) protein; MH\(^+\) data were 42.9 ± 9.5 pmol ME \( \mu \)g\(^{-1}\) protein; and the MRM data were 47.7 ± 12.7 pmol ME \( \mu \)g\(^{-1}\) protein. The highest level of molecular specificity amongst these four analytical methods to measure picomole amounts of endogenous ME was the FAB MS-MRM method (Fig. 2) 2.

INTRAMOLECULAR $^{18}$O ISOTOPIC EXCHANGE OCCURRING IN THE GAS PHASE OBSERVED DURING THE HYBRID TANDEM MASS SPECTROMETRIC ANALYSIS OF PEPTIDES. Kevin D. Ballard and Simon J. Gaskell, Center for Experimental Therapeutics, Baylor College of Medicine, Houston TX 77030.

A fragmentation process involving a rearrangement mechanism occurring in fast atom bombardment desorbed protonated and metal cationized peptide ions during tandem mass spectrometric analysis has been previously studied by others\(^1\) and in our laboratory\(^2\). During this rearrangement, loss of the C-terminal amino acid residue is accompanied by transfer of an OH group from the C-terminal carboxylic acid moiety to the carbonyl group of the final peptide bond, giving rise to a product ion which may be formally designated as $[B_{n-1} + \text{OH}]^{+}$ or $[B_{n-1} + \text{Cat} + \text{OH}]^{+}$. This ion is mass spectrometrically indistinguishable from the $[M+\text{H}]^{+}$ ion of the corresponding peptide shortened by one amino acid residue at the C-terminus\(^2\). The transfer of carboxyl oxygen from the original C-terminus to the new C-terminus was demonstrated using $[^{18}$O$]_{2}$-labelled peptides, with both $^{18}$O atoms located in the C-terminal carboxylic acid group\(^2\). Product ion spectra of these compounds revealed rearrangement species which retained one of the $^{18}$O-labels ($[B_{n-1} + ^{18}$OH$]^{+}$). Also observed were less intense signals corresponding to rearrangement species which retained both of the $^{18}$O-labels. The mechanisms which have previously been proposed for the rearrangement process for both metal cationized\(^3\) and protonated\(^4\) peptides do not account for the retention of both $^{18}$O atoms in the rearrangement products. The present studies were undertaken to address this issue using a variety of hybrid tandem MS (BEqQ) approaches.

RESULTS Many of the peptides which undergo this rearrangement process also undergo a second stage of rearrangement, i.e. the $[B_{n-1} + \text{OH}]^{+}$ ions further rearrange to yield $[B_{n-2} + \text{OH}]^{+}$ ions. With $[^{18}$O$]_{2}$-labelled peptides, the $[^{18}$O$]_{2}$-labelled $[B_{n+1} + \text{OH}]^{+}$ ions would be expected to give rise to both unlabelled and $[^{18}$O$]_{2}$-labelled $[B_{n+2} + \text{OH}]^{+}$ ions in a ratio of 1:1. For the $[^{18}$O$]_{2}$-labelled $[B_{n-1} + \text{OH}]^{+}$ ions, if both labels are located at the C-terminus, then these ions would be expected to yield $[^{18}$O$]_{2}$-labelled $[B_{n+2} + \text{OH}]^{+}$ ions but no unlabelled $[B_{n+2} + \text{OH}]^{+}$ ions. If the second label is located somewhere other than at the C-terminus, then both $[^{18}$O$]_{2}$- and $[^{18}$O$]_{2}$-labelled $[B_{n+2} + \text{OH}]^{+}$ ions would be expected in a 1:1 ratio. In order to examine directly the sequential rearrangement processes, $[^{18}$O$]_{2}$- and $[^{18}$O$]_{2}$-labelled first generation rearrangement ions were analyzed by second generation product ion scanning using the sequential MS capability of a BEqQ hybrid mass spectrometer\(^5\). Figure 1(a) shows a portion of the first generation product ion spectrum of sodium cationized $[^{18}$O$]_{2}$-labelled fragments obtained under metastable detection conditions. Figure 1(b) presents the second generation product ion scan obtained from the $[^{18}$O$]_{2}$-labelled rearrangement ion. The unlabelled and $[^{18}$O$]_{2}$-labelled second generation rearrangement ions were detected in roughly equal abundance. The corresponding scan obtained from the $[^{18}$O$]_{2}$-labelled first generation rearrangement ion is shown in Figure 1(c). The major signal corresponded to the $[^{18}$O$]_{2}$-labelled second generation rearrangement ion, although a small but significant (and reproducible) signal corresponding to the $[^{18}$O$]_{2}$-labelled second generation rearrangement ion was also detected. Similar results were obtained with protonated TRKR. These data strongly suggest that the two $^{18}$O atoms in the $[^{18}$O$]_{2}$-labelled first generation rearrangement ions were located in the C-terminal carboxyl group, so that both of these atoms were transferred from the original C-terminus to the C-terminus of the first generation rearrangement ion. The distortion from a 1:1 ratio in Figure 1(b), as well as the presence of detectable amounts of $[^{18}$O$]_{2}$-labelled second generation rearrangement species (Figure 1(c)), suggest that both of the carboxyl oxygens can be transferred to the new C-terminus even through two generations. A mechanism which would explain the formation of the $[^{18}$O$]_{2}$-labelled rearrangement ions would involve steps prior to bond cleavage which are reversible, enabling intra-ionic isotope exchange to occur without bond cleavage (Scheme I). The isotopically exchanged species could then undergo the rearrangement to generate the $[^{18}$O$]_{2}$-labelled rearrangement ion. A similar mechanism can be envisaged for the metal cationized species. Conventional product ion spectra revealed the presence of both $[^{18}$O$]$- and $[^{18}$O$]$-labelled Y\(_{n}$) ions from several $[^{18}$O$]$-peptides, indicating $[^{18}$O$]$ depletion from the C-terminus in a portion of the precursor ion population. Such spectra also revealed fragment ions which show isotope enrichments consistent with the incorporation of $^{18}$O at the peptide bond between the penultimate and C-terminal amino acid residues. Several lines of evidence eliminated the possibility of such incorporation of label during solution phase preparation of the $[^{18}$O$]$-labelled analogues. Thus, the combined data are in accord with an isotope exchange process occurring in the gas phase, most likely through a mechanism involving the reversible formation of a cyclic intermediate. These studies, combined with previous data, emphasize the importance of the conformations adopted by gas phase peptide ions in influencing fragmentation pathways.

RAPID CONFIRMATION AND REVISION OF THE PRIMARY STRUCTURE OF BOVINE SERUM ALBUMIN BY ESIMS AND FRIT-FAB LC/MS

Kazuo Hirayama, Satoko Akashi, Mami Furuya, and Ken-ichi Fukuhara
Central Research Laboratories, Ajinomoto Co. Inc., 1-1 Suzuki-cho, Kawasaki-ku, Kawasaki, Kanagawa 210, Japan

INTRODUCTION
Since the base sequencing technique of DNA was established, an opportunity for the determination of the full sequence of a protein only by the conventional methods has been more and more decreasing. Instead of the conventional sequencing techniques of a protein, a method for the rapid confirmation of the amino acid sequence of a protein, which was presumed by the base sequencing technique, is coming up to be required. From such a viewpoint, we studied the primary structure of bovine serum albumin (BSA) by electrospray ionization mass spectrometry (ESIMS) and frit-fast atom bombardment mass spectrometry/liquid chromatography (Frit-FAB LC/MS), and revised its sequence by tandem mass spectrometry and automated Edman degradation.

RESULTS and DISCUSSION
Figure 1 shows an electrospray ionization mass spectrum of BSA and its deconvoluted spectrum. The molecular weight of BSA was determined as 66436.0 by ESIMS, which was obviously larger than that of the theoretical value calculated from the primary structure of 582 amino acid residues (average molecular weight: 66267.1). In consideration of the accuracy of ESIMS for other proteins (1), the difference of these two values was too large to interpret it as a measurement error. Therefore we thought that the amino acid sequence of BSA composed of 582 residues must be incorrect. So we tried to reinvestigate the amino acid sequence of BSA by mainly using Frit-FAB LC/MS with the combination of automated Edman degradation and tandem MS. Figure 2 shows the revised amino acid sequence of BSA (2). The previous sequence was composed of 582 amino acid residues determined by Edman degradation method (3-5). In the previous sequence a tyrosine residue at the 156th was lacked, and the sequence at the positions of 94th and 95th, that was -EQ-, was revised to -QE-. The methodology is as follows: First, reduced and carboxymethylated BSA (RCM-BSA) is digested by trypsin. Second, the molecular weights of all the peptides are determined by Frit-FAB LC/MS. These values are compared with the molecular weights of the tryptic peptides predicted from the amino acid sequence of BSA. These peptides are matched to the sequence on the basis of their molecular weights and specificity of the enzyme. Third, if there is ambiguities presented by the possibility of having more than one peptide with the same molecular weight, immonium ions in the Frit-FAB mass spectrum (6) or by daughter ions from the protonated molecular ion of the peptide (7-9) is used for the decision of the sequence. Finally, the peptide, which cannot be assigned to the sequence by its molecular weight and the specificity of the enzyme, is isolated by HPLC and sequenced by Edman degradation method and tandem MS.

Seventy-five peaks were observed in a reversed phase HPLC chromatogram of tryptic peptides of RCM-BSA (Fig. 3). Identification of 66 peptides in tryptic digests confirmed 93% of the sequence of the protein. There were two peptides whose molecular weight could be matched to more than one regions in the sequence, considering enzyme specificity. The positions in the sequence of these two peptides were deduced by taking account of immonium ions in the Frit-FAB mass spectrum or by daughter ions from the protonated molecular ion. And one peptide could be matched to no position in the sequence. Unidentified last peptide in the peak 66, whose molecular weight was 1177.3, was isolated and sequenced by automated Edman degradation to FYAPELLEY. In addition to that, the sequence of -LYY was clearly confirmed by tandem mass spectrometry. The calculated molecular weight from the sequence of this peptide (MW:1177.6) agreed well with the observed value. In comparison with the sequence in this region of human serum albumin (FYAPELLEFF) and rat serum albumin (FYAPELLEY), revised sequence of FYAPELLEY is reasonable and a lack of 156th tyrosine is obvious. It took about two weeks to confirm 93% of the sequence of this protein. In order to confirm remaining 7% of the sequence, RCM-BSA was digested by lysyl endopeptidase or Staphylococcus au-
V8 protease. After the digestion by these enzymes, peptide mixture was subjected to Frit-FAB LC/MS and molecular weight of each peptide was determined. In the end, comparing with the other two serum albums, the order of glutamic acid and glutamine residues at the positions of 94th and 95th of BSA was doubtful. The sequence of these positions was corrected to -QE- by automated Edman degradation of a lysyl endopeptidase digested peptide of QEPERNECFLSHK (Gln94 to Lys106).

ACKNOWLEDGEMENT

We thank Finnigan MAT Instruments, Inc., for operating electrospray ionization mass spectrometer.

REFERENCES

AMP Nucleosidase (AMN) catalyzes the hydrolysis of the N-glycosidic bond of adenosine monophosphate (AMP), into ribose-5-phosphate and adenine.

A deletion construct which eliminates amino acids 128-135, was made in the E. coli protein. The structure of the deletion mutation was characterized by HPLC-FABMS analysis of enzymatic digests of both the native and mutant proteins. Combined trypsin (cleavage at Lys, Arg) and V-8 protease (Glu) digests of each protein were prepared.

LCMS experiments were performed with an ABI 130 syringe-pump HPLC and a Finnegan-MAT 90 (BE geometry) equipped with a continuous-flow interface and modified to accept a stainless steel frit. Xenon FAB desorption / ionization was accomplished with an Ion-Tech 8 Kev saddle-field gun. Samples were separated by a reversed-phase, microbore HPLC column (Aquapore RP-300, C-8, 1.0 x 100 mm) and introduced directly into the source without flow splitting at 10 μl/min, using a gradient of 3%->50% (v/v) acetonitrile in 5% glycerol / 0.1% trifluoroacetic acid. We have now determined that use of the frit allows lower concentrations of glycerol to be used in the HPLC solvents. The use of lower glycerol concentrations also allows higher acetonitrile concentrations to be used for the elution of the peptides without precipitation of the glycerol out of solution. Accumulated scans (mass summary plots) were used to assign most of the ions to the predicted masses of the peptides (Table 1). Those peptides forming weak ions were located by using selected ion chromatograms. Of the 40 peptides predicted for AMN within the mass range 450-2200 amu, 34 peptides were confirmed (Table 1). Some peptides were identified as products of incomplete digestion. The deletion sequence (boxed in Fig. 1), contains a single, V-8 cleavage site which produced two unique peptides in the wild-type protein digest (VT-16 and VT-17 Fig 2), while the deletion mutant produced a single unique peptide (VT16m) with sequences flanking the deletion site. Selected ion chromatograms (Fig 3) show the elution positions of these peptides, along with that of a peptide fragment common to both digests (VT-66, m/z=710). Spectra of the peptides are presented in Fig. 4. Static FAB analysis of the digest mixture was unable to identify the critical sequences. These experiments demonstrate the utility of LCMS in protein analysis.

**References:**
In the past few years, electrospray ionization (ESI) has emerged as the ultimate ionization technique for the on-line analysis of peptides and proteins. In our initial attempts to couple reverse phase high performance liquid chromatography (HPLC) to ESI it was found that there were many compatibility problems with the two techniques. For example, conventional electrospray is not compatible with 100% aqueous solutions due to the high liquid surface tension. Additionally, it was found that solutions of high conductivity (e.g., 0.1% trifluoroacetic acid, TFA) dramatically reduced ion current stability and sensitivity. Recent improvements to our interface have enhanced sensitivity and ion current stability for these types of mobile phases. A multilayer flow electrospray system (shown in Figure 1) delivers a sheath liquid flow and a concentric gas flow at the terminus of the ESI needle in order to allow for efficient droplet dispersion (and ion production) over a wide range of mobile phase conditions. A small mixing zone exists at the ESI tip, which allows the LC eluate to mix with a sheath liquid of relatively low surface tension. The focussing (or sheath) gas flow improves stability (by preventing droplet build-up on the tip of the needle) and directs more droplets at the capillary entrance. Typically a 1:1 eluate:sheath liquid flow ratio is utilized in order to maintain low surface tension over a gradient separation. For positive ion applications employing TFA, it was found that the use of 2-methoxyethanol as the sheath liquid provided the best sensitivity.

Additional sensitivity improvements have been made by incorporating an electrostatic tube lens in the viscous flow region between the capillary exit and the skimmer orifice, as shown in Figure 1. The tube lens increases the fraction of ions entering the ion optics and mass analyzer by forcing ions in the expanding free jet back toward the central axis.

When used with conventional-bore HPLC columns (1 mm - 4 mm i.d.), a post-column split is utilized so that the optimal flow range of 2-3 µL/min is delivered to the ESI interface. Since ESI behaves as a concentration-dependent detector, the use of high split ratios is not a disadvantage. In fact, for conventional bore columns, greater than 95% of the sample may be recovered via fraction collection for subsequent analysis. However, the use of small bore columns (e.g., 0.2 mm - 1 mm i.d.) requires the least amount of sample injected, since eluate concentrations are higher than what would be obtained if the same amount were to be injected on larger bore columns operating at higher flow rates. This is demonstrated in Figure 2, which shows a micro-LC/MS separation of a calmodulin tryptic digest on a 0.2 mm i.d. column with only 4 picomoles of sample injected. For micro-column applications, no post-column split is necessary, since the column flow rate is only 2 µL/min. However, a pre-column (pre-injector) split is necessary so that gradients are delivered to the column without long delay times. It is also possible to obtain sequence information at low picomole levels with this type of column as shown in Figure 3, which demonstrates the daughter spectrum of the doubly-charged tryptic fragment, Tg, of calmodulin.

Another example, demonstrating the value of on-line characterization of protein enzymatic digests is shown in Figures 4 and 5 for the analysis of human hemoglobin on a 2 mm i.d. column. The existence of a variant is readily identified by visual inspection of the two LC/MS chromatograms of Figure 4. The molecular weight of the variant was determined experimentally from this data to be 2043.4 Da. From the LC/MS/MS data of the triply-charged ion of the variant (Figure 5), sequence information was obtained that confirmed the variant contained a glutamic acid (E) residue instead of the normal lysine (K) at the 16 position on the α-chain.

ACKNOWLEDGEMENTS

Laser Desorption and Electrospray MS of the Scrapie Prion Protein.

University of California, San Francisco, CA 94143-0518.
*Rockefeller University, New York, NY10021.

The scrapie prion protein (PrPSc) has been implicated in the development of a number of animal and human neurodegenerative diseases (1). Syrian hamster PrPSc has a phosphoinositol glycolipid (GPI) anchor at the C-terminus (2), and the majority of molecules are doubly glycosylated at Asn-181 and 197 (3). It is encoded by a single-copy gene that also encodes a normal cellular protein (PrPc) (4).

Detailed analysis of these proteins by enzyme digestion, HPLC separation and characterization of the resulting peptides by amino acid analysis, Edman sequencing and LSIMS, has been unsuccessful in revealing any differences between them (5). We have now used matrix-assisted laser desorption (LD) and electrospray (ES) to study the intact proteins and larger peptides and some mid-size peptides (2,000-3,000 Da) that were not readily amenable to LSIMS, presumably because of unfavorable surface activities. We have also obtained ES mass spectra of the C-terminal undecapeptide with the GPI anchor from an endoproteinase Lys-C digest. LD was carried out on a time of flight MS built at Rockefeller University and ES was on a VG Bio-Q.

Molecular mass of the intact protein. Purification of PrPSc from brains of hamsters with scrapie generally relies on the resistance of this protein to protease digestion. Proteinase K removes approximately 67 amino acids from the N-terminus of PrPSc to generate PrP 27-30 which contains two N-linked oligosaccharides and the GPI anchor. After reduction and alkylation of the cysteines with iodoacetic acid, the protein was dissolved in 70% formic acid containing sinapinic acid, deposited on the laser target, and dried. The LD spectrum (Figure 1) revealed three broad unresolved signals which we attributed to the heterogeneity of the oligosaccharides and the anchor glycan, the presence of some unglycosylated protein, and a ragged N-terminus due to multiple cleavage sites for proteinase-K. The ragged N-terminus was found by ES analysis of the N-terminal peptides from a Lys-C digest. The uncertainty introduced by this large degree of heterogeneity made it difficult to use the spectrum in Figure 1 to determine the molecular weight of the protein.

Using modified purification protocols without proteinase K, the full length protein was isolated, thereby eliminating the heterogeneity associated with the ragged N-terminus. After reduction and alkylation this was deglycosylated by the action of the enzyme PNGase F to eliminate the heterogeneity due to the N-linked oligosaccharides. The LD spectrum shown in Figure 2 gave a broad molecular ion peak (approx 1,000 Da) as the heterogeneous species due to the various anchor glycans were not resolved. The mass at the peak top (25,526 Da) measured in this experiment at Rockefeller University was 66 Da higher than what was obtained from a measurement made on a similar instrument (Vestec), reflecting the uncertainty of the experiment due to the inadequate resolving power. Nevertheless, this was within the band of anticipated molecular masses that we calculated to be 25,185 - 25,638 Da and it indicates that there probably are no other major posttranslational modifications. It is anticipated that ES with a quadrupole analyser would provide sufficient resolving power to separate the various molecular species. As yet we have not found a suitable solvent for this hydrophobic protein that is also compatible with ES.

A comparison of LD and ES analysis of a large glycopeptide. A 75-amino acid residue containing the first glycosylation site was obtained by reverse phase HPLC after digestion with Lys-C. The LD spectrum (Figure 3) was poorly resolved but showed sufficient structure to permit mass assignments for glycopeptides with 4-5 different oligosaccharides. ES gave very similar molecular masses for the major components (Figure 4) but the enhanced resolution revealed much more structure and it was possible to determine the molecular masses of at least 28 different glycopeptides in the range 10,256 - 11,388 Da. After deglycosylation with PNGase F, ESP gave the predicted mass of 8,608 Da for the peptide (data not shown), confirming that the heterogeneity was entirely due to the oligosaccharides.

ES analysis of the GPI anchor. The peptide mixture from a Lys-C digest was treated with the enzyme PIPLC to remove the lipid portion of the GPI. The C-terminal peptide - GPI anchor was separated by reversed phase HPLC and analysed by ES from 1:1 methanol/water matrix containing 1% acetic acid to give the spectrum shown in Figure 5. In separate experiments the masses and structures of the peptide (6) and glycan portions (7) were determined after treatment with 50% aqueous HF cleaved the phosphate bonds. Figure 5 showed three separate species which confirmed the heterogeneity of the glycan. Subsequent improvements to the methodology allowed the separation and ES analysis of individual components in the mixture with enhanced resolution. The spectrum also revealed the presence of two phosphoethanolamines, one more than the minimum of two required
for all GPI anchors, and consistent with the known structures of the acetylcholinesterase and Thy-1
GPI anchors. On the basis of this and other data (8) and by analogy with other known structures we
propose that species C in the ES spectrum is compatible with the structure shown in Figure 6.

Inductively Coupled Plasma Mass Spectrometry as a Tool in Investigations of Trace Element Metabolism. Morteza Janghorbani, Department of Medicine, University of Chicago, Chicago, IL 60637.

Introduction. Inductively coupled plasma mass spectrometry is a versatile tool for isotopic analysis of a broad range of chemical elements in biological materials (1). It has been applied to metabolic studies of lithium (Li), magnesium (Mg), iron (Fe), zinc (Zn), copper (Cu), and selenium (Se). These studies have included issues of gastrointestinal absorption and various dietary/host factors that modulate it, significance of different routes of excretion to the overall maintenance of homeostatic control, dynamics of distribution in various body compartments, and issues related to in vivo measurement of pool sizes.

Examples of Applications. In order to illustrate the wide range of potential applications of this approach to elucidation of various aspects of mineral metabolism, I present a brief discussion of two specific applications that we have recently discussed (2,3): measurement of exchangeable pool of magnesium (Mg) in infants (2), and applications of a continuous stable isotope feeding protocol to the measurement of plasma-organ fluxes of Cu in the adult rat (3).

1- Exchangeable Pool of Mg in Infants (2). Assessment of Mg status is a difficult problem in part because the major portion of soft-tissue Mg is intracellular and that changes in intracellular Mg content are not generally reflected in similar changes in plasma Mg. We carried out a feasibility experiment to establish whether the concept of in vivo isotope dilution could be applied to the measurement of exchangeable Mg in infants with the stable isotope approach. Three infants were given enriched \(^{25}\)Mg (dose range 2.4-7.1 mg/kg), here called "the label", in divided doses administered over a 24-h feeding period. Quantitative collections of stools and urine were made over the following 72 hours and a single sample of blood was obtained at 72 hours. Both the isotope ratio \(^{25}\)Mg/\(^{26}\)Mg and total Mg content of each sample were measured.

The data demonstrated that when a dose range of 2.4-7.1 mg \(^{25}\)Mg/kg is administered to the infants orally, plasma (and urine) isotopic enrichment of 6.3-28.4% is achieved at 72 hours. Since an isotopic enrichment of \(~10\%\) appears to be sufficient for accurate measurement of the isotope dilution space (1), this protocol provides a feasible approach to the measurement of exchangeable body Mg. Now that the feasibility of this measurement is established, the biological issues of the exchangeability of body Mg under various conditions of nutritional status, health and disease, and the role of skeletal Mg in relation to exchangeable body Mg need to be investigated.
2- Regulation of Copper Turnover in the Rat (3). Copper is an essential micronutrient. Organs are able to conserve their Cu when dietary sources become limited. However, little is known about the mechanisms for this conservation. This is in part due to inability to measure changes in components of organ Cu flux (plasma-organ influx/efflux) under steady-state conditions relevant to the whole animal. These experiments cannot be performed with the radioisotopes of Cu.

We have taken advantage of the fact that Cu naturally occurs as two stable isotopes ($^{63}$Cu, 68.4 wt%; $^{65}$Cu, 31.6%). Animals can be fed a Cu-free diet whose Cu content has been adjusted to the desired level with one of the two stable isotopes, say $^{63}$Cu. Measurement of the dynamics of changes in organ content of the two isotopes during this turnover phase will then provide an experimental approach for investigation of plasma-organ Cu fluxes under various experimental conditions.

Adult rats were fed a Cu-deficient diet (0.8 mg Cu/g) and provided with water containing 20 μg Cu/mL as $^{63}$Cu (99.7%) for 60 days. Three animals were killed on each of days 0 (prior to switching to $^{63}$Cu), 1, 3, 5, 7, 14, 21, 28, 35, 42, 49, and 56. Various organs and plasma were analyzed quantitatively for total Cu and the ratio $^{63}$Cu/$^{65}$Cu. From these measurements, the time course of organ (and plasma) endogenous Cu (Cu$_e$; Cu originating from body Cu at t=0) and exogenous Cu (Cu$_x$; total Cu - Cu$_e$) were established. Each set of data was then fitted to an appropriate mathematical expression describing the time dependence of Cu$_e$ and Cu$_x$ for each organ and plasma.

The two components of plasma-organ flux (influx/efflux) can be described mathematically by two simultaneous differential equations. Solution of these equations then provides the numeric values of rate constants from which rates of flux between plasma and the organ can be calculated.

Data given in Table 2 summarize the flux rates calculated as the average values for days 20-60 of the experiment.

Table 2- Flux rates between plasma and selected organs in adult rats

The experiment described here is the first attempt at measurements of flux parameters under steady-state conditions in the living animal. The data demonstrate that such experiments are now possible so that issues of regulatory aspects can now be addressed. Since this approach can be applied to any element for which enriched stable isotopes are available, a general method is now available for such studies.

Conclusions. The two examples discussed briefly above indicate the potential for use of stable isotopes in numerous studies of metabolism of inorganic elements. These are now possible in large part because of the recent developments in stable isotope measurement with inductively coupled plasma mass spectrometry. These applications are in their early stages, but the work reported to date illustrates clearly the major contributions that this technique can now make to a fuller understanding of many important issues of mineral metabolism whose exploration is not possible otherwise.

A method for the determination of boron by stable isotope dilution in a variety of biological samples is described. Sample material is fused with sodium carbonate. Boron is separated from matrix components by using Amberlite IRA-743 borate-selective ion-exchange resin. Boron is eluted with 1% HNO₃, and eluates are introduced into an inductively coupled plasma mass spectrometer through a direct injection nebulizer. This nebulizer provides a fast washout of ~15 seconds for residual boron, which greatly decreases the memory effects characteristic of conventional pneumatic nebulizers. \(^{11}\text{B}/^{10}\text{B}\) ratios are determined with relative standard deviations between 0.4 and 1.5%, and the detection limit for boron is approximately 1 ng/g in these samples. Stable isotope dilution methodology for quantitation of boron shows that: (1) fusion of sample with sodium carbonate avoids volatilization of boron from samples; (2) approximately 80% of submicrogram amounts of boron from samples can be recovered from the resin with insignificant isotopic fractionation; (3) results for biological reference materials are in agreement with certified or non-certified values (see Table I); and (4) the boron concentration of pooled human blood plasma is $23 \pm 2 \mu g/L$ (95% confidence interval). Assessment of effects of boron on calcium metabolism for prevention of osteoporosis should be expedited by use of this method. MULTIPLE-ISOTOPE DILUTION TECHNIQUES USED WITH MULTIPLE-COLLECTOR, THERMAL IONIZATION MASS SPECTROMETRY TO INVESTIGATE MINERAL METABOLISM IN HUMANS

Judith R. Turnlund
USDA/ARS, Western Human Nutrition Research Center
San Francisco, CA 94129.

The application of magnetic sector, thermal ionization mass spectrometry (TIMS) to stable isotope dilution studies in humans was first reported in the 1970's. Magnetic sector TIMS is considered to be the most precise and accurate method available for measuring isotopic ratios of most mineral elements. A limitation of the method, slow analysis, has recently been minimized by computer-controlled instruments equipped with multiple sample turrets and multiple-isotope collectors. Our TIMS is equipped with 5 variable Faraday collectors for simultaneous collection of up to 5 isotopes of an element. We used this TIMS and enriched stable isotopes in a number of human studies to investigate copper, zinc, and iron metabolism, for limited studies of calcium and magnesium metabolism, and are now using the technique for the analysis of samples from a major study of molybdenum metabolism.

Stable isotopes of up to five elements were administered simultaneously. For studies of zinc, iron, and molybdenum metabolism, one isotope was fed and another infused, as follows:

Fed: $^{67}$Zn, $^{64}$Fe, and $^{100}$Mo
Infused: $^{65}$Zn, $^{68}$Fe, and $^{97}$Mo

The isotopes were prepared for feeding or infusion by first dissolving them in hydrochloric acid. Feeding solutions were diluted further, then added to components of the diet about two hours before meals. Isotopes to be used for infusions were dissolved under sterile conditions. The solutions were prepared for infusion and tested for endotoxins by a pharmacologist. Solutions were infused over a period of two minutes.

Blood, urine, and fecal samples were collected following infusion and/or feeding of isotopes. Blood was drawn 12 times after the isotope infusions to follow disappearance of the isotopes and to develop models of mineral metabolism. Complete urine collections were made following infusions, with 8-hr collections on the days of isotope infusions and 24-hr collections thereafter. Fecal samples were combined into 6-day pools.

With the exception of copper, the amounts of isotopes and elements appearing in a sample were determined by dilution with a second or third isotope of each element prior to sample preparation and analysis. Since copper has only two stable isotopes, the isotopic and total copper contents of a sample were determined by additional isotopic enrichment of a replicate sample.

Samples were ashed and minerals separated and purified using ion exchange chromatography. Isotopic ratios were measured on purified minerals using a magnetic sector, thermal ionization mass spectrometer. Analytical conditions for five minerals are shown in Table 1. Most ratios were measured with internal and external precision of within 0.1% (1).

Multiple-isotope dilution formulas and fractionation corrections were used to calculate isotopic enrichment, absorption, and endogenous excretion of the minerals (2,3). Examples of fecal enrichment following feeding and infusion of isotopes are shown in Table 2. Isotopic enrichments of Zn and Cu in blood plasma and Zn in urine were followed during the course of 80 to 120 day studies following isotope infusions and feedings.

Absorption of Dietary Calcium
Using Dual Stable Isotopic Tracers
and Thermal Ionization Mass Spectrometry

A.L. Yergey, S.A. Abrams, N.V. Esteban and N.E. Vieira
National Institute of Child Health and Human Development
Building 10, Room 6C101
Bethesda, MD 20892

The fraction of dietary Ca that is absorbed can be determined in a number of ways. The classical methodology involves meticulous determination of the Ca content of all foods consumed as well as that contained in urine and feces over a period of 7-9 days - the so-called balance technique. One alternative to this procedure is to adminster an isotope of Ca with meals and use the recovery of isotope dosage as a measure of the fraction of dietary Ca absorbed. This procedure, however would still require the collection of fecal material and would not recognize the degree to which the body excretes Ca into the GI tract, the endogenous fecal excretion. An intravenously administered tracer would surmount this problem, but fecal collection methods are inherently subject to substantial variance. We have developed a technique that will permit the measurement of the fraction of dietary calcium that is absorbed which both results in a lower variance in the measured values and is easier to execute than the balance, or fecal collection techniques.

Two stable isotopic tracers are administered simultaneously, one orally after equilibration with the calcium form in the food. The second tracer is given intravenously. Any of the oral tracer that subsequently appears in urine has of course been absorbed and then excreted. By making a complete urine collection over a 24 hour period and determining the total amount of each of the tracers that is present, one is able to calculate the fraction of the dietary calcium that has been absorbed. That is to say, \( \alpha \), the fraction of dietary calcium absorbed is given by:

\[
\alpha = \frac{t_{\text{oral tracer in urine}}}{t_{\text{IV tracer in urine}}} \quad (1)
\]

when both numerator and denominator are corrected for dosage.

The major assumptions of this equation are that the isotope in the gastrointestinal tract is an accurate reflection of the movement of natural calcium moving from there to the circulation and that, once in the circulation, the oral tracer's behavior is exactly the same as the intravenously administered material. The denominator of Equation 1 is simply a normalization to account for this latter assumption. A closely related expression can be written for the calculation of \( V_{\text{endo}} \). It is based on the assumptions that any of the intravenous tracer that appears in feces has been excreted there without subsequent resorption, and that the ratio of the fraction of intravenous tracer dose in stool to urine is equal to the ratio of the rates at which Ca flows to the gastrointestinal tract, \( V_{\text{endo}} \), and urine, \( V_\text{u} \),

\[
V_{\text{endo}} = \frac{t_{\text{IV tracer in feces}}}{t_{\text{IV tracer in urine}}} \quad (2).
\]
If the experiment is done by taking a series of urine samples over the first 24 hours after administration, then one could calculate the time course of $\alpha$. The orally administered tracer would be seen to be initially at zero in urine, rise, pass through a maximum and then begin to fall. The rate of disappearance of this tracer of course mimics the disappearance of the intravenously administered tracer, once the absorption process is complete. The ratio of the two areas under curves, Eq. 1, takes the shape of a function, $y = 1 - \exp(bt)$, and approaches the final or true value of $\alpha$ only asymptotically. It can be shown that in a 24 hour study, the value of $\alpha$ that is reached is within 5-7% of the asymptotic value.

Comparison of the results of our dual tracer technique with those of a metabolic balance study carried out simultaneously have shown that while the same mean value is obtained for the amount of calcium absorbed, $0.26 \pm 0.09$ by tracers and $0.26 \pm 0.09$ by balance. The tracer technique results in a 30% reduction in the variance of the mean. The consequence of this is that one is able to detect smaller changes in absorption with the tracer methods than with balance techniques.

In a group of 12 premature infants, mean gestational age: 31±2 wks, mean age at study: 20±10 days, mean weight at study: 1693±174 gm, true absorption was 57±16% of ingested calcium and net retention was 48±18% of dietary calcium. The most interesting aspect of this study was that $V_{\text{endo}}$ was 7±4% of intake, a value 5-6 greater than seen in healthy older children and adults. In a study of 7 adolescent girls with anorexia nervosa, we found that their absorption was 15±4% of intake, down about a factor of 3 from healthy adolescent girls. Of considerable interest in addition is that we observed that the girls with anorexia excreted almost twice as much calcium in their urine than did the healthy girls ($234\pm68$ mg/day vs $140$ mg/day max). The consequence of the low absorption and high urinary excretion for the patients with anorexia is that they are in negative calcium balance of $93\pm106$ mg/day compared with the positive balance of between 100-400 mg/day seen in healthy girls. In a series of studies of a woman in her third trimester of pregnancy, during lactation and then as a self-control, we have determined that due to changes in Ca absorption and urinary excretion $[\alpha = 0.33_{\text{preg}} \text{ vs } 0.19_{\text{cont}}, V_u = 9.1 \text{ mg/hr preg} \text{ vs } 5.8 \text{ mg/hr cont}]$ during pregnancy lead to an average accumulation of 5.9 g Ca during the 3rd trimester, presumably to the fetal skeleton. Since the fetus accumulates about 24g Ca during this trimester, the maternal skeleton contributes about 18 g Ca. A similar set of comparisons during lactation show little change in $\alpha$, 0.22 vs 0.19, and a net retention of urinary Ca, 1.7 mg/hr vs 5.8 mg/hr, coupled with estimated losses of Ca in milk of about 12.9 g over a 6 month period of nursing. These two losses combined lead to an estimated loss of maternal skeletal Ca of 39g, or about 4% of the maternal skeleton. Such losses clearly cannot be irreversible, and one goal of future studies is to quantify the 'make up period' of the maternal skeleton. The wide range of applicability of this technique to populations of different ages and physiological states suggests that it has the potential for substantially increasing our knowledge of calcium utilization.
Isotopic substitution for tracer purposes is among the most powerful techniques available for elucidation of metabolic pathways and general molecular physiology. Tracer studies using radioactive nuclides is recognized as highly sensitive, but is of increasingly limited applicability for human studies due to the health risks to subjects attendant to radioactivity. Risks of exposure to research workers and particularly the problem of radioactive disposal further restricts radiolabel use.

Since they present none of the health concerns, stable isotopic tracers are an obvious alternative to radiotracers, but are considered to be of less utility because of ubiquitous background levels of the minor isotope. However, the background level of minor isotope does not limit detectability; rather, the stability of background levels and the precision with which they can be determined are of fundamental importance. In general, $^{13}$C levels vary at over a range 2-3 orders of magnitude lower than the precision available by full scan GC/MS analysis. Measurements at a higher level of precision should result in a commensurate increase in detectability.

Gas chromatography/combustion/mass spectrometry (also called “Isotope Ratio Monitoring/GC” (IRM/GC) and GC Isotope Ratio Mass Spectrometry (GC/IRMS)) has recently been introduced commercially as a means for achieving high precision for carbon isotope ratios of compounds emerging from a GC. In addition to this development, technology for the production of highly enriched, perlabeled (uniformly labeled, [U-$^{13}$C] and/or D) biomolecules from algae has emerged. Algal biomasses are grown in closed loop incubators with $^{13}$CO$_2$ and/or D$_2$O are capable of producing enrichments $\geq$ 99% $^{13}$C. Our preliminary results indicate that the combination of these two approaches permit tracer experiments with superior sensitivity to radiotracers.

Analytical Figures-of-Merit We have evaluated the accuracy and precision of GC/C/MS system based on a Finnigan MAT 252 and Varian GC. Replicate determinations of an equimolar mixture of $C_{14-16}$ hydrocarbons yield standard deviations (SD) $\approx 0.2\%_o$. Replicates of a calibrated fatty acid methyl ester (FAME) mixture over a factor of 200 quantity injected yield SD $\approx 1\%_o$. Accuracy for these samples calibrated against CO$_2$ revealed systematically lower values. However, calibration against an internal standard yields accuracy for strong peaks (1 nanomole) within 0.15% $\%_o$.

Human Tracer Experiment To provide a live human experimental test of the techniques, an experiment designed to test specific observation regarding human fatty acid interconversion was performed. There exist several lines of evidence which suggest that stearic acid (18:0) is converted to oleic acid (18:1) in the liver but not in the intestine.
Ten mg of 42% $^{13}$C labeled 18:0 were administered orally to humans. Blood was sampled hourly for 10 hours and daily for 14 days. Plasma was prepared, then chylomicrons, very low density lipoproteins (VLDL), low density lipoproteins (LDL), high density lipoproteins (HDL), and D > 1.21 were prepared by ultracentrifugation. Samples were saponified, acidified, fatty acids were extracted and methylated for GC/C/MS injection. Samples were injected in duplicate.

Figure 1 is a plot of the fatty acid enrichments in chylomicrons for one subject as a function of time. The highest enrichment in this spectrum is 180 %, which occurs at 10 hrs. We believe this enrichment level, strongly discerned by the current instrument, would be indistinguishable from background in a single ion monitoring full scan GC/MS instrument. The background levels of 14:0 and 18:2 vary by ≤ 2 permil through the period. We also observe no deviation from background for the 18:1 signal, indicating no conversion of 18:0 to 18:1 in intestine. Some evidence for conversion in the liver was found in the VLDL fraction.

Based on these data, we estimate that the dose of radiotracer required to produce a similar signal-to-noise ratio to that observed here is 10 μCi. this level is significant and would pose a significant health risk to human subjects.

PBEIMS AND PBCIMS FOR THE ANALYSIS OF DOXORUBICIN, DAUNORUBICIN AND CARMINOMYCIN

J. Bloom, P. Lehman, W. A. Korfmacher, M. Israel, O. Rosario.

INTRODUCTION:
Particle beam (PB) is one of the more recently developed interfaces for the coupling of HPLC and MS. A major advantage of this interface is the generation of either conventional electron impact (EI) or chemical ionization (CI) mass spectra. The change between EI and CI can be performed without any modification of the HPLC system. HPLC/PBMS can be used in the analysis of thermally labile and nonvolatile compounds such as anthracyclines.

Anthracyclines are very powerful anticancer and antibiotic drugs. Two of these compounds, doxorubicin and daunorubicin, have been extensively used for the treatment of neoplastic diseases in man. In addition, carminomycin is another anthracycline under current study. Typically, HPLC with different detection methods such as UV, fluorescence and electrochemical detection, has been utilized for the analysis of these compounds. Even though these techniques are very valuable for the detection of these compounds, none of them provide structural information.

The utility of PBMS in both EI and CI (positive and negative ion modes) was investigated for the characterization of these three anthracyclines. Characteristic fragment ions can be used for the detection of these compounds via HPLC/PBMS.

EXPERIMENTAL:
The standards were doxorubicin and daunorubicin (Sigma, St. Louis, MO). Carminomycin was obtained from M. Israel. All standards were dissolved in methanol at a concentration of 0.3-0.5 mg/ml.

The PBMS analysis was performed on a Hewlett-Packard 5988A quadrupole mass spectrometer. The EI mass spectra were acquired at 70 eV, with a source temperature at 250 °C. The CI mass spectra were obtained in the positive and negative ion modes using methane as the reagent gas adjusted to 0.50 torr and an analyzer pressure of 2.1 x 10⁻³ torr. The particle beam (Hewlett-Packard 59980A) interface desolvation chamber was held at 65 °C. The helium nebulizer pressure was set at 35 psi. The mobile phase used was 50/50 acetonitrile/water, 0.2 M ammonium acetate, pH 4.5) delivered at a flow rate of 0.5 ml/min from a Hewlett-Packard 1090M HPLC system employing a 10 μL loop. The introduction of the sample to the interface was via direct injection.

RESULTS AND DISCUSSION:
When analyzed by PB under EIMS conditions, the mass spectra for these compounds included a molecular ion that was either of very low intensity or not observed at all. For all anthracyclines, the base peak corresponded to the ion formed after cleavage at the glycosidic bond, and another cleavage at the C(9) position with the loss of the side chain. In addition to the base peak, ions corresponding to additional fragmentation of these compounds were also seen.

The methane PBCI mass spectra, in the positive ion mode, for carminomycin is shown in figure 1. Under these conditions, only a weak protonated molecule was observed for carminomycin and daunorubicin, whereas for doxorubicin it was not seen. The fragment ion at m/z 369 is assigned to the cleavage at the glycosidic bond with retention of the oxygen atom by the aminosugar, i.e. the [MH - Sugar(OH)]⁺ ion; as was also observed for the other anthracyclines. The fragment ion at m/z 349 is assigned to the [MH - Sugar(OH) - H₂O]⁺ ion; which is also seen for daunorubicin. The relative ratios of the ions for these compounds differed greatly among them.
When analyzed by methane PBCIMS using negative ion detection, all three anthracyclines showed significant M' ions. For doxorubicin, this ion was the base peak, and for carminomycin the same ion had a high relative intensity (95%) as we can observe in figure 2. On the other hand, the relative intensity of the M' ion for daunorubicin was 30%. For daunorubicin and carminomycin, the base peak corresponded to the aglycone anion.

CONCLUSIONS:
Significant fragment ions are observed when PBCIMS under both positive and negative ion modes is used for the detection of these anthracyclines. The ions seen are similar to those reported in the literature when other MS techniques are used for their analysis.

When comparing PBEIMS and PBCIMS, the use of the latter for the analysis of these compounds is preferred, because the spectral data obtained via PBCIMS was of greater utility. In general, negative ion analysis provided ions of greater intensity in the molecular ion region for all three compounds when compared to the positive ion mode.

The results obtained by PBCIMS are similar to those reported by Smith (2) under methane DCIMS conditions, although Smith (2) reported that the M' ion was the base peak for daunorubicin and carminomycin.

UTILITY OF TSMS FOR THE CHARACTERIZATION OF THREE ANTHRACYCLINES

J. Bloom¹, W. A. Korfmacher¹, M. Israel², O. Rosario³
¹National Center for Toxicological Research, Jefferson, AR 72079 U.S.A.; ²Department of Chemistry, University of Puerto Rico, Rio Piedras, P.R. 00931, ³Department of Pharmacology, Health Science Center, University of Tennessee at Memphis, Memphis, TN 38163 U.S.A.

INTRODUCTION:

Anthracyclines are very powerful antitumor antibiotic drugs; two of them, doxorubicin and daunorubicin, have been extensively used for the treatment of neoplastic diseases in humans (1). In addition, carminomycin is another anthracycline currently being investigated. Typically, the methods of analysis for these compounds have utilized HPLC with UV, fluorescence or electrochemical detection. These are valuable techniques, but they do not provide structural information.

Thermospray mass spectrometry (TSMS) in both positive and negative ionization modes was used in the characterization of these three anthracyclines. The structural information obtained by this analytical technique, such as the characteristic fragment ions, can be applied to the detection and identification of these compounds by HPLC/TSMS.

EXPERIMENTAL:

The standards were doxorubicin and daunorubicin (Sigma, St. Louis, MO). Carminomycin was obtained from M. Israel. All standards were dissolved in methanol at a concentration of 0.3-0.5 mg/ml.

The TSMS analysis was performed on a Finnigan-MAT TSQ-70 triple quadrupole mass spectrometer using positive and negative ion detection, in the filament-off and discharge-off mode. Typically, the vaporizer temperature was set to 80 °C and the block (aero) temperature to 250 °C. Introduction of the sample was via direct injection using an ISCO LC-5000 syringe pump with a Rheodyne 7125 injector equipped with a 20 μl loop at a flow rate of 1.25 ml/min. The mobile phase used was 50/50 acetonitrile/(water, 0.2 M ammonium acetate, pH 4.5).

RESULTS AND DISCUSSION:

The positive ion TS mass spectrum for daunorubicin in figure 1 shows a protonated molecule ([MH]+' at m/z 528 with a relative intensity of 65%. The fragment ion at m/z 383 is assigned to the cleavage of the glycosidic bond with the oxygen atom retained by the aminosugar, i.e. the [MH - Sugar(OH)+' ion. The fragment ion at m/z 363 is assigned to the [MH - Sugar(OH) - H₂O]+' ion. For the fragment ion at m/z 337, this was assumed to be due to the cleavage of the glycosidic bond and the loss of the side chain at the C(9) position.

A protonated molecule and characteristic fragment ions were also observed for the other anthracyclines. The [MH]+' ion for doxorubicin had a relative intensity of 20% while the same ion for carminomycin was the base peak. The base peak for doxorubicin was observed at m/z 337, which was assigned to the cleavage at the glycosidic bond and the loss of the side chain. The [MH - Sugar(OH)+' ion for doxorubicin and carminomycin were observed at m/z 397 and m/z 367, respectively.

When analyzed by TSMS using the negative ion mode, all three anthracyclines produced intense [MH]+' ions. For daunorubicin (see figure 2) and carminomycin this ion was the base peak; while for doxorubicin this ion had a relative intensity of 40%. The base peak for doxorubicin is observed at m/z 335 which is assumed to be the aglycone anion with a loss of the side chain.

571
In Figure 2, we observed the fragment ion at m/z 397 which is assumed to be due to the cleavage of the glycosidic bond with a retention of the oxygen atom by the aglycone; the same loss is seen for doxorubicin and carminomycin at m/z 413 and m/z 383. In addition, all three anthracyclines showed fragment ions at m/z 377, m/z 361, and m/z 347 for doxorubicin, daunorubicin and carminomycin, respectively, due to a cleavage of the glycosidic bond and the loss of H₂O.

CONCLUSIONS:
Under TSMS in the positive ion mode, all three anthracyclines displayed a protonated molecule and an [M-H - Sugar(OH)]⁺ ion. The relative ratios of these ions differed significantly for these compounds, and additional minor peaks were also observed.

For the TSMS negative ion mode, the [M-H]⁻ ion was the major ion for two of the compounds. Characteristic fragment ions were observed for all of the anthracyclines. In general, negative ion analysis provided an ion in the molecular ion region of greater relative intensity than the one obtained under positive ion mode.

DETERMINATION OF NICOTINE AND ITS METABOLITES IN SMOKERS' URINE
BY THERMOSPRAY LC/MS

*G. D. Byrd, K.-M. Chang, J. M. Greene, and J. D. deBethizy
R. J. Reynolds Tobacco Co., Pharmacology Research
Bldg. 630-2, Winston-Salem, NC 27102.

Nicotine disposition in smokers has been studied for decades and yet the ability to account for all of the nicotine absorbed by smokers has been difficult. The relatively recent determination of a major metabolite, trans-3'-hydroxycotinine and the reports of glucuronide conjugates of nicotine, cotinine, and trans-3'-hydroxycotinine [1-3] has significantly improved the potential for quantifying nicotine uptake in smokers. Some of these metabolites are thermally labile or difficult to extract from urine which hinders quantification. In this study, thermospray LC/MS was used to profile urinary metabolites of nicotine in smokers by direct injection of urine.

The method used is a modification of a reported technique that provides for the direct injection of urine onto an LC system connected via a thermospray interface to a quadrupole mass spectrometer [4]. All nonconjugated metabolites were monitored in a single chromatographic run without extraction or derivatization of the analytes. Separation was performed on a polymer column with a water/methanol gradient and ammonium acetate buffer was added post-column using a reversed-gradient system. The thermospray source was operated in the positive ion, filament-off mode and the (M+H)^+ ions were detected by selected ion monitoring. Quantification was done by the method of internal standards using d₆-cotinine as the internal standard. Limits of detection varied from approximately 20 to 200 ng/mL for the analytes in this study.

Urine samples were collected from 11 normal male smokers and analyzed. The method screens for nicotine and 17 of its metabolites but only six analytes were consistently found in smokers' urine: nicotine, cotinine, trans-3'-hydroxycotinine, nicotine-N'-oxide, cotinine-N-oxide, and demethylcotinine. Glucuronide conjugates of nicotine, cotinine, and trans-3'-hydroxycotinine were determined by treating extracted urine samples with β-glucuronidase and quantifying the aglycones by LC/MS. Table 1 summarizes the average results for the smokers in μg per 24 hr period. The variability (CV) in absolute amount among the nine analytes ranged from 35 to 70%. The major metabolite in all smokers' urine was free trans-3'-hydroxycotinine which accounted for an average of 35% of total metabolites measured. Conjugates constituted an average of 29% of the total metabolites measured. The average distribution of metabolites for these smokers is plotted in Figure 1 for the free and conjugated metabolites. These values are normalized by using the percent of total metabolites determined for each smoker. Although it has not been demonstrated that all of the nicotine absorbed while smoking can be quantitatively recovered in urine as nicotine and its metabolites, it is of interest to determine what portion of FTC nicotine yield can be recovered in urine. FTC nicotine input was determined from the number and type of cigarettes consumed by each subject over the 24 hour period. The nicotine output was determined from the total nicotine equivalents measured in this study. The ratio of nicotine metabolic output to FTC nicotine input for these 11 smokers ranged from 0.58 to 1.44 with an average of 0.96 ± 0.29.

This study shows that thermospray LC/MS can be successfully applied to survey urinary nicotine metabolite distribution in smokers. The data in this study demonstrate that a significant percentage of nicotine absorbed while smoking can be accounted for in the urine as nicotine, cotinine, trans-3'-hydroxycotinine, and their glucuronide conjugates. This method confirms the presence of glucuronide conjugates of nicotine, cotinine, and 3'-hydroxycotinine which constitute an average of 29% of the urinary metabolites.

Predicting Thermospray LC/MS Fragmentation of Glucuronides By Molecular Modeling
A. P. Breau and C. J. Manly*; Lilly Research Laboratories and DowElanco*, Indianapolis, IN 46285 and Greenfield*, IN 46140

Introduction: Thermospray LC/MS analysis of glucuronide conjugates can produce intact pseudomolecular ions or aglycone ions. In this analysis a series of substituted phenol glucuronides were systematically analyzed by thermospray mass spectrometry under different thermospray ion source interface conditions and detection modes. The substituted phenol glucuronide conjugates were also analyzed by molecular modeling techniques to provide a systematic measurement of the effects the substitution pattern had on the observed thermospray spectra. A comparison of the effects of phenol ring substituents and the effects of the interface parameters suggested that the spectra obtained by thermospray LC/MS depended more on the molecular structure of the analyte than the interface parameters.

Materials and Methods: Thermospray Analyses: LC/MS spectra were obtained on a Nermag R 30-10 triple stage quadrupole mass spectrometer using the Nermag thermospray source without discharge or filament assisted ionization. The glucuronides were analyzed at source block temperatures of 200°C, 250°C, and 300°C and at ion source repeller voltage settings of 100, 150, 200 and 300 electron volts. The tip temperature was optimized at 224°C for the 200°C block temperature analyses and at 230°C for the 250°C and 300°C block temperature analyses. Molecular Modeling Analysis: All calculations were performed using Sybyl and MOPAC. The lowest energy conformer for each was then submitted to quantum mechanics for geometry optimization using the AM1 Hamiltonian. Analysis of the quantum mechanics data focused on evaluations of bond strength and ease of bond scission. Two measures were tabulated: bond order (calculated from MOPAC/AM1) and a “bond polarity index” represented by the arithmetic difference between the partial atomic charges for the bonds of interest.

Results: Phenyl-b-D-glucuronide produced a major ammoniated pseudomolecular adduct ion at m/z=288 upon thermospray ionization (Figure 1). Electron donating analogs, 4-ortho-amino-phenyl-b-D-glucuronide (Figure 2) and p-amino-thio-phenylglucuronide (Figure 3) produced robust pseudomolecular ions. However, the spectrum of p-nitro-phenol glucuronide, an electron withdrawing analog, produced an intense aglycone ion at m/z=137 (Figure 4).

The lack of thermospray interface parameter effects (ion source block temperature and repeller voltage) on the observed fragmentation suggested that the fragmentation results were a function of the intrinsic glucuronide structure rather than the thermospray ionization conditions. Thus, a molecular modeling evaluation of each glucuronide was performed (Table 1). In each case, the O-Gluc bond order is numerically less than the Ar-O bond order. Experimentally, Ar-O bond scission has not been seen - only O-Gluc scission in mass spectrometry fragmentation patterns. Therefore quantum mechanical bond order can perhaps be used as an indication for bond fragmentation. Additionally, the degree of O-Glucuronide bond scission (versus intact glucuronide and other bond fragmentation in the molecule) appears to correlate well with the “bond polarity index” as calculated from partial atomic charges. The unsubstituted phenyl glucuronide yielded a mixture of intact glucuronide and the aglycone while the p-nitro yielded primarily the aglycone. The o-amino and p-amino(S) substituted phenyl glucuronides compounds produced primarily the intact glucuronide. It appears that scission of the O-Gluc bond increases as the “bond polarity index” increases. When the analysis was attempted on two other glucuronides that were not in the substituted phenol class, the predicted thermospray mass spectrometric fragmentation based on their bond order and bond polarity index was observed.

The “bond polarity index” of 4-methylumbelliferyl-b-D-glucuronide predicted that an intact molecular ion would be produced. The thermospray spectrum of 4-methylumbelliferyl-b-D-glucuronide was characterized by a pseudomolecular ion at m/z=353 and a glucuronic acid ion at m/z=177 (Figure 5). The “bond polarity index” of a-naphthyl glucuronide also predicted that an intact molecular ion would be produced. The thermospray spectrum of a-naphthyl glucuronide revealed a pseudomolecular ion at m/z=343 as well as the natriated adduct at m/z=365 (Figure 6).

These data suggest that the o-glucuronide bond strength should allow one to predict the fragmentation of a particular glucuronide in thermospray ionization. Thus, an examination of the electron density of a particular glucuronide could assist the mass spectrometrist in selecting the optimal technique for its analysis.

Identification of Nizatidine Degradation Products by LC/MS/MS and FAB/MS/MS

Indianapolis, IN 46285

Introduction: Nizatidine is a histamine H-2 receptor antagonist that blocks the gastric H-2 receptor, leading to inhibition of gastric acid secretion from the parietal cells of the stomach. While the toxicity of this class of compounds is quite low, it has been observed that ranitidine (1), cimetidine (2-4), and famotidine (5) form nitrosamines subsequent to degradation by nitrous acid. The nitrosated products of cimetidine (2-4), famotidine (5) and ranitidine (6-7) have been reported to be positive in bacterial mutation assays. However, in vivo carcinogenic tests with cimetidine, famotidine, and ranitidine have been negative. In this paper we have explored the reactivity of nizatidine with nitrous acid and the mutagenicity of the resultant product mixture. Mixture analysis by thermospray LC/MS led to the identification of four major reaction products (Figure 1). The identification of these reaction products was confirmed by high resolution fast atom bombardment mass spectrometric analyses, spectral comparison to known reference standards (when available) and daughter ion collisional induced dissociation (CID) spectra.

Degradation experiments utilizing 15N sodium nitrite/HCl followed by LC/MS/MS and FABMS analyses indicated that only one out of the four observed degradation products incorporated 15N (Figure 2) leading to the conclusion that nizatidine does not form nitrosamines upon degradation by nitrous acid. The mixture of nizatidine degradation products did not produce revertant mutations in the bacterial mutation assays utilizing S. typhimurium or E. coli.

Methods: Reaction Conditions

Nizatidine (2.5 g, 7.55 mmole) and sodium nitrite (2.1 g, 30.4 mmole) were added with stirring to water (760 ml) at 37°C in a 3-neck flask. Hydrochloric acid (20 ml of 1N) was added until pH 3.68 was achieved. The solution was stirred for 3 hours at 37°C. Ammonium sulfamate (4.33 g, 38.0 mmole) was added to consume the excess nitrous acid. The solution was lyophilized and stored at approximately -20°C.

LC/MS

Twenty five microliters (50 ug) of the sample dissolved in mobile phase was injected through a Rheodyne injector onto a 15 cm, 5 micron, Jones ODS reverse phase HPLC column. The mobile phase consisted of 760 ml of an 0.1 M ammonium acetate buffer (adjusted to pH 7.5 with glacial acetic acid) and 215 ml methanol. The isocratic separation was achieved by pumping mobile phase at a flow rate of 1 ml/min of mobile through the column using a Waters 600-MS HPLC pump. The HPLC eluent was delivered to a Nermag R 30-10 triple stage quadrupole mass spectrometer equipped with a Nermag thermospray ion source. The ion source block temperature was maintained at 223°C with a probe tip temperature of 206°C. Ammonium sulfamate (4.33 g, 38.0 mmole) was added to consume the excess nitrous acid. The solution was lyophilized and stored at approximately -20°C. LC/MS Twenty five microliters (50 ug) of the sample dissolved in mobile phase was injected through a Rheodyne injector onto a 15 cm, 5 micron, Jones ODS reverse phase HPLC column. The mobile phase consisted of 760 ml of an 0.1 M ammonium acetate buffer (adjusted to pH 7.5 with glacial acetic acid) and 215 ml methanol. The isocratic separation was achieved by pumping mobile phase at a flow rate of 1 ml/min of mobile through the column using a Waters 600-MS HPLC pump. The HPLC eluent was delivered to a Nermag R 30-10 triple stage quadrupole mass spectrometer equipped with a Nermag thermospray ion source. The ion source block temperature was maintained at 223°C with a probe tip temperature of 206°C and a repeller voltage of 150 eV. LC/MS/MS The second quadrupole, Q2, was set as an rf only collision cell that was maintained with a gas collision pressure of 2.5 x 10^-2 torr Argon. The third quadrupole, Q3, scanned the collision induced dissociation fragments at a rate of 1 scan/second. The accelerating potential of the collision was increased by -40 eV to increase the internal energy of the isolated daughter in order to enhance the collision process. FABMS Samples were dispersed in "magic bullet" and subjected to bombardment with 8 keV Xenon atoms for spectra determined on a VG ZAB-3F triple sector (B1EB2) mass spectrometer. For spectra determined on a VG ZAB-2SE double focusing mass spectrometer the dispersed samples were bombarded with cesium ions having a net energy of 12 KeV. Mutation Assay The nizatidine nitrosation reaction mixture was tested for the induction of bacterial mutations using S. typhimurium strains TA1535, TA1537, TA98, and TA100 and Escherichia coli strain WP2uvrA according to published methods (8).

Results and Discussion: Triplicate analysis of three separate nizatidine nitrosation reactions consistently revealed four major products that eluted within 9 minutes (Figure 2) on the reverse phase HPLC system described in the methods section. The assigned structures were supported by high resolution FAB/MS analyses. Since the initial purpose of this work was to identify nitrosated products of nizatidine, a concerted effort was made to look for products that incorporated NO. The search in positive and negative ion detection thermospray LC/MS for an ion at m/z=361 (331 + NO), which would correspond to the pseudomolecular ion of a proposed N-nitrosated nizatidine, did not reveal the presence of N-nitrosated nizatidine. A further attempt to detect the incorporation of NO into nizatidine involved repeating the nitrosation reaction with 15N nitrite followed by LC/MS analysis for the corresponding mass assignment shifts. The shift from m/z=160 to m/z=161 was the
only difference observed in the reaction of nizatidine with \(^{15}\)N nitrite versus \(^{14}\)N nitrite. The LC/MS/MS CID spectrum of the sole reaction product that incorporated \(^{15}\)N suggested that the \(^{15}\)N incorporation occurred at the N-OH moiety (Figure 3). Since no nitrosamines were detected and only 1 reaction product was shown to incorporate NO, the entire reaction mixture was assessed for mutagenic potential in the Ames Salmonella/mammalian microsome assay. It was concluded that the nizatidine nitrosation reaction mixture was not mutagenic either with or without metabolic activation by mammalian microsomes in Salmonella or E. coli.

Continuous Flow FAB/MS for Monitoring Isophosphamide in Human Blood Serum

W. Lenhart, Ch. Siethoff, T.M. Löfler, and M. Linscheid,

ISAS Institut für Spektrochemie, Bunsen-Kirchhoff-Str. 11 4600 Dortmund 1;
Städtische Kliniken Dortmund, Beurhausstr. 40, 4600 Dortmund 1, Germany

Cyclophosphamide (CP) and in particular the less toxic Isophosphamide (IP) are most important as chemotherapeutic drugs in the treatment of cancer and tumors. In the course of our studies on the detection and the chemical reactions of Cyclophosphamide and, especially, Isophosphamide, we have developed an essay for the quantitative determination of those drugs in human blood serum based on interfacing microHPLC with continuous flow FAB/MS (CFFAB/MS).

A rather straightforward clean up scheme for Isophosphamide has been developed with nearly 100% recovery. 250 µL plasma are transferred into a 2 mL test tube and 500 µL icecold acetone were added for precipitation of proteins. After centrifugation the supernatant is decanted into a fresh tube, the remaining proteins are extracted again with 250 µL acetone and the combined solutions are blown to dryness. The residues are redissolved in 250 µL tridistilled water, centrifuged again and from that solution, 20 µL were injected onto a) a micro HPLC column (RP-18, 1.0 x 100 mm) or b) a short semi-microcolumn (RP-18, 1.6 x 20 mm). Since the drug is dissolved in water, a peak compression takes place. The solvent was methanol/water/glycerol 50/40/10 (v/v/v) and a typical flow of 12 µL/min was used for chromatography of the drug and for delivery to the tip of the CFFAB probe.

For this study, we have modified the continuous flow FAB probe (“Bioprobe”) of a Finnigan MAT 90. The standard tip was divided into two units - a base and a removable cylinder.

![Fig. 1: Structures of Cyclophosphamide and Isophosphamide](image)

![Fig. 1: Calibration function and typical range of plasma concentration](image)
with the FAB target surface - to allow for quick exchange of the target. Two different target types were tried, one with an additional drain capillary from exit of the interface capillary to the wick beneath the target, the other with a screen type surface and both gave essentially the same results with respect to stability of the ion current and sensitivity. For the determination of the drug the instrument was used either in scanning mode or with selective ion recording for improved detection limits, which are in the range of 10 ng absolute or 500 ng/ml plasma.

Since the method has been developed with clinical routine application in mind, which means rather high biological and individual variation at any rate, we have tried to avoid the inclusion of an internal standard. We have been able to obtain such a reproducibility in our day to day measurements (standard deviation in the range of 10%) that, considering the necessary accuracy, our results are sufficient. The calibration function obtained with standard solutions is linear over the concentration range of interest (Fig.2).

The described procedure has been used successfully for monitoring the levels of Isophosphamide in blood serum administered to patients over an extended time period, normally 7 days during one ambulant treatment, and we have found concentrations of 50 ug/mL Isophosphamide (Fig.2). A typical behaviour of the drug level in serum is shown in Fig.3. After the first administration the drug accumulates to some extend and remains at rather high levels, whereas the concentration decreases rapidly after the last dose and falls under our detection level. In particular the last result is important, since the toxic side effects of the drug is always of concern. In the moment attempts are under way to include the most important metabolites and catabolites, if necessary, in the study in order to get more complete picture of the behaviour of the cytostatic drug.

METABOLIC INVESTIGATION OF THE SYNTHETIC ANTI-COAGULANT PEPTIDE MDL 28,050 USING CONTINUOUS FLOW FAB LC/MS

B.L. Ackermann, M.P. Knadler,* and J.E. Coutant

Marion Merrell Dow R & D, Cincinnati, OH 45215
*Marion Merrell Dow R & D, Indianapolis, IN 46268

MDL 28,050 is a synthetic decapeptide modeled after the C-terminus of the leech protein hirudin. This molecule, whose structure and sequence appear in Figure 1, is being considered as a clinical candidate due to its anti-coagulant and anti-thrombotic properties. Recently, studies were undertaken to determine the in vivo biotransformation of this molecule in rat. Rats were administered a 9 mg/kg iv bolus dose containing tritiated MDL 28,050 labeled at tyrosine (specific activity 14,270 dpm/ug) and urine was collected at 6 hr intervals. Following initial clean-up by C18 solid phase extraction of a composite 0-24 hr urine sample, the extract was profiled by HPLC using radiodetection. In a second experiment, a 0-6 hr urine sample was extracted and the resultant mixture subjected to LC/MS analysis using CF-FAB.

The details of the system used for LC/MS have recently been published¹ and incorporates on-line UV detection with coaxial flow post-column matrix addition. The packed capillary column (250 mm x 0.32 mm) was slurry packed in-house with 5 μm Spherisorb C18. An aliquot of the urine extract, estimated to contain about 750 ng of total peptide, was injected on-column and eluted with a linear gradient of 5-60% ACN in water (0.1% TFA) over 40 min. at 2 μl/min.

Figure 2 contains a series of mass chromatograms for all the MDL 28,050-related peptide products observed by LC/MS. Two positions: Glu-7Glu and Ile-3Pro were implicated as sites of primary hydrolysis based on the presence of the complementary peptide pairs m/z 847/501 and 621/727, respectively. It is noteworthy that C-terminal peptide metabolites, such as Cha-E-OH (m/z 301), were not detected by radioprofiling due to the location of the tritium label. The data also indicate that MDL 28,050 can be detected in urine 6 hr after dose administration.

Other advantages of LC/MS are illustrated in Figure 3 which compares FAB mass spectra obtained for the N-terminal hexapeptide metabolite by (A) off-line fraction collection and (B) CF-FAB. The spectrum acquired off-line gave (M+Na)⁺ as the dominant species and yielded limited fragmentation. In contrast, the spectrum obtained by CF-FAB gave primarily (M+H)⁺ as well as abundant sequence data which enabled the entire sequence of the peptide to be derived from an amount estimated to be 280 pmol.

ON-LINE AND OFF-LINE MICRODIALYSIS/CF-FAB MS AND GC/MS IN STUDIES OF IN VIVO AND IN VITRO VALPROIC ACID INDUCED BRAIN NEUROCHEMICAL CHANGES

Valproic acid is widely used in the management of many forms of epilepsy and seizure disorders. However, the mode of drug action in the brain remains unknown. In this study, various mass spectrometric methods were used to study pharmacokinetics and pharmacodynamics of valproic acid (VPA) in the rat brain. Specifically, we wished to study the hypothesis that the pharmacological function of VPA may be related to its capacity to attenuate brain N-acetyl aspartic acid (NAA) levels.

Initial studies were designed to locate brain regions where VPA significantly changed NAA levels. These two compounds were concurrently analyzed by GC/MS methods in five brain areas: cortex, hippocampus, striatum, cerebellum and brain stem. Because the two compounds are grossly different in their organic solvent extractabilities, our methodology development was based on the formation of N-butyl esters of NAA directly in the biological samples to enhance the hydrophobicity to the compound. Comparisons of the results from these in vitro studies show only marginal drug induced reductions of the NAA levels in the VPA treated rats. However, the difference is statistically significant (student t test p < 0.05) when cerebellum data from pentobarbital pretreated rats were compared.

On-line microdialysis CF-FAB MS methods was then applied to compare pharmacokinetics of brain and blood VPA levels after an IV VPA dose of 200 mg/kg. The detection sensitivity of the Finnigan-MAT 90 CF-FAB MS is 500 pg in 0.5 μl injection volume. Figure 1 shows that blood peak levels of VPA is at least 10 times higher than that in the brain. However, the disappearance rate of the drug in the brain is much slower than that in the blood. The figure shows data for about 3 hours, although the experiment was carried out for over 5 hours.

Off-line microdialysis GC/MS methods were then used to further correlate the brain VPA levels with the concurrently measured NAA and other neuroactive amino acids in live animals. Figure 2 shows correlations between the brain extracellular VPA levels and the NAA levels. The time points when VPA and/or pentobarbital were given are marked along the X-axis. Three observations from these results should be noted. 1) Extracellular VPA levels are dose dependent. 2) pentobarbital injection appears to release free VPA into the extracellular fluid. 3) NAA levels in the brain appear to be affected by the presence of VPA in the brain.

In summary, mass spectrometry is an efficient and effective method to follow brain neurochemistry. We have shown it can be used to monitor intravenous and/or intraperitoneal injections of drugs such as VPA and investigate the effect of this drug on other neurotransmitters in the brain. This is highly significant because these changes can be measured in a live animal while the brain is still functional. Future work will apply these procedures to study seizure disorders in humans.

GC/MS AND LC/MS CHARACTERIZATION OF METABOLITES OF N-FORMYLAMPHETAMINE, A POTENT HEPATOTOXIC CONTAMINANT OF ILLEGALLY SYNTHESIZED AMPHETAMINE
Abdul Mutlib, Michael Legallo and Frank Abbott, Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3 and Department of Pathology, U.B.C. Hospital, Vancouver, B.C., Canada, V6T 2B5.

Introduction
Recently we have described the metabolic fate of (±)-N-(1-methyl-3,3-diphenylpropyl)formamidine(1). It was found that an isocyanate derived glutathione and N-acetylcysteine conjugates were excreted in bile and urine, respectively, of rats dosed with this formamide. N-Formylamphetamine, which bears a structural resemblance to N-(1-methyl-3,3-diphenylpropyl)formamidine and is a contaminant in illicitly synthesized amphetamine, was studied with regard to its disposition in rats. The water-soluble metabolites excreted in urine and bile of rats dosed with N-Formylamphetamine were analyzed by LC/MS/MS. The non-conjugated metabolites were characterized by GC/MS. Furthermore the hepatotoxicity induced in Sprague-Dawley rats after an acute dose of N-formylamphetamine was investigated.

Experimental
Materials: The glutathione and N-acetylcysteine conjugates were synthesized by reacting N-(1-methyl-2-phenylethyl)-4-nitrophenylcarbamate with glutathione and N-acetylcysteine in basic methanol. The non-conjugated metabolic standards were synthesized by the method of Beckett and Morgan(2).

Methods. Animal Experiments. Male Sprague-Dawley rats (250-300 g) were anesthetized with an i.p. injection of urethane (1 g/kg) and bile collected after dosing with N-formylamphetamine, (60 mg/kg, i.p.). To detect the glutathione adduct in the crude bile, selected ion monitoring (SIM) recording and MS/MS of the protonated molecular ion (MH⁺, m/z 469) was carried out using LC/MS. The metabolites released after enzymatic hydrolysis of bile were extracted with ethyl acetate and analyzed by GC/MS. For urine analyses, rats were injected with the same dose of formamide and urine collected for 18 hours. The N-acetylcysteine conjugate in crude urine was detected by LC/MS using SIM recording and MS/MS of the ion (MH⁺, m/z 325). The non-conjugated metabolites in β-glucuronidase hydrolyzed urine samples were extracted with ethyl acetate and analyzed by GC/MS. Formamide induced hepatotoxicity was also investigated in Sprague-Dawley rats (200-300 g) after dosing with N-formylamphetamine and examining processed liver slices (H & E) under light microscope. LC/MS was carried out with the Sciex Heated Nebulizer LC/MS interface coupled to an API/MS/MS system. MS/MS was carried out using argon as the collision gas. HPLC was done on a reversed phase analytical column (Ultrasphere ODS, 5 um, 250 x 4.6 mm) with the solvent being delivered by a dual syringe pump at a rate of 0.7 ml/min. The mobile phase consisted of a gradient system beginning with 20% acetonitrile in 0.01M ammonium acetate (pH 7) and increasing the percentage of organic modifier to 100 % over 12 minutes. GC/MS was performed on a HP5987A GC/MS system using a cross-linked methylsilicone fused capillary column (HP, 20 m x 0.32 mm i.d.). Column temperature was programmed from 50°C to 280°C at 6°C/min.

Results
LC/MS/MS of the protonated molecular ion of the synthesized glutathione (m/z 469) and N-acetylcysteine (m/z 325) adducts gave fragmentations as shown in figure 1. The glutathione adduct gave characteristic ion fragments at m/z 308, 340 (loss of 129), 179 (cysteinylglycine moiety of glutathione) and 162 (substrate). Rats dosed with N-formylamphetamine excreted the glutathione adduct in bile. LC/MS SIM chromatogram of the pseudomolecular ion (m/z 469) of the metabolite from the crude bile sample gave a peak with identical retention time as the synthetic standard (figure 2). MS/MS of the ion (m/z 469) of the metabolite and the synthetic standard produced identical mass spectra. Similarly the presence of the N-acetylcysteine adduct in urine was confirmed by selected ion monitoring recording of the ion (MH⁺, m/z 325). The identities of the non-conjugated metabolites which included benzylmethylketone, amphetamine, 4-hydroxyamphetamine, N-formyl-4-hydroxyamphetamine, norpseudoephedrine and N-formynorpseudoephedrine, were confirmed by comparing GC/MS retention times and mass spectral fragmentations with those of synthetic standards. N-Formylamphetamine was a potent hepatotoxic agent, producing liver necrosis at a dose of 40 mg/kg or more. The necrosis was evident 2-3 hours after an i.p. dose of the secondary formamide to rats.

585
Conclusions

Rats dosed with N-formylamphetamine excreted N-acetylcysteine and glutathione adducts in urine and bile respectively. LC/MS/MS was found to be the method of choice for detecting these polar metabolites in urine and bile without any additional purification steps. N-Formylamphetamine was found to be a potent hepatotoxic agent. Apart from bioactivation to an isocyanate, N-formylamphetamine was metabolized by two other pathways, namely: N-deformylation and aromatic and aliphatic hydroxylation.

Figure 1. MS/MS spectra obtained from the protonated parent ions of the synthetic N-acetylcysteine adduct (MH⁺, m/z 325) (top), and the glutathione conjugate (MH⁺, m/z 469) (bottom).

SEPARATION AND ANALYSIS OF MACROLIDE ANTIBIOTICS BY CAPILLARY LC/ESI AND CAPILLARY ZONE ELECTROPHORESIS

Macrolides are a class of antibiotics produced by *Streptomyces* soil bacteria. Macrolides are widely-used broad-spectrum antimicrobial agents, which are useful against gram-positive bacteria. While erythromycin is, perhaps, the most commonly-prescribed macrolide in the United States, other members of this class have been developed and are commonly used in other countries.

During the course of our studies on the mechanisms of drug resistance, the need has become apparent for a physico-chemical method capable of determining both drug purity, degradation products, and enzymatically-induced structural changes in the macrolide molecule. Because of the possibility of formation of several products, a combination of a mass spectrometric technique with a separation technique would be desirable. Since these compounds cannot be analyzed by El or CI direct probe or GC/MS, a LC/MS method would be desirable.

Positive ion electrospray ionization of macrolide antibiotics yield spectra with abundant protonated molecular ions (Figure 1). Structurally-informative fragment ions, resulting from cleavage between the rings, are also observed (Figure 2), and their relative abundance can be enhanced by increasing the skimmer voltage in the Vestec ESI source. This effect probably occurs via a CID mechanism, and is similar to that observed by Loo, et al. (1) for the Fenn/Whitehouse ESI source.

In this study, two nanoscale separation techniques, capillary zone electrophoresis (CZE) and packed capillary LC columns (nCLC), 75 um i.d. were applied to the separation of a series of ten macrolide antibiotics. Both techniques utilize sub-microliter/min flow rates through the analytical capillary and, therefore, require an electrospray probe which incorporates coaxial sheath flow.

Separation of synthetic mixtures of macrolides can be readily achieved using either CZE (Figure 3) or nCLC (Figure 4), but the higher loading capacity of the nCLC column proves distinctly advantageous where mass spectrometric sensitivities are limiting. On the other hand, CZE peak widths are narrower, detection limits are lower, and analysis times are shorter.

Solvent Consideration in Developing Low ppb LC/MS Confirmation Method for Cloxacillin

K. L. Tyczkowska and A. L. Aronson, College of Veterinary Medicine
North Carolina State University, Raleigh, NC 27695
*R. D. Voyksner, Analytical and Chemical Sciences

Introduction
In order to insure human food safety, new methods must be developed to monitor veterinary drugs that can enter the food chain. Penicillins are a class of drugs that prove difficult to detect and confirm at the low ppb tolerance set for milk or tissue. The development of a method for confirmation of penicillin in milk or tissue requires careful attention to analytical methodology used for sample preparation and storage. This paper investigates the degradation of cloxacillin in various extraction solvents to find the solvent and storage conditions that best maintain the integrity of the sample.

Experimental
Samples of cloxacillin ranging from 500 ng/ml to 1 mg/ml were stored in amber glass vials for up to 8 weeks at -20°C. Every one or two weeks the samples were analyzed by LC/UV. The sample solutions of cloxacillin were analyzed by thermospray LC/MS at the 4-8 week point in the stability study to identify degradation products formed.

Thermospray LC/MS mass spectra were acquired using a mobile phase of 18% Isopropanol, 2.5% acetic acid in 0.25 M aqueous ammonium acetate solution, at a flow rate of 1 ml/min, on an Ultraspher phenyl 3 μm analytical column, 4.6 x 150 mm (Phenomenex, Torrance, CA, U.S.A.). The thermospray interface (Pinniger MAT, San Jose, CA, U.S.A.) was operated with the source temperature and vaporizer temperature at 300°C and 130°C, respectively. The thermospray interface was coupled to a Finnigan MAT 4800 quadrupole mass spectrometer that was operated in the positive ion detection mode scanning conditions from m/z 150 to 600 daltons in two seconds.

Results and Discussion
Thermospray LC/MS aided in the identification of the degradation products of cloxacillin in various solvents. Cloxacillin (Structure I, Figure 1) stored in water, and aqueous solutions of acetonitrile or 2-propanol exhibited a LC peak with a mass spectrum consisting of an [M+H]+ ion at m/z 410 and several protonated fragment ions at m/z 279, 237 and 196. This mass spectrum is consistent for the penilloic acid (Structure II, Figure 1). Since the β-lactam ring was opened in the formation of the penilloic acid, the ion at m/z 160 (characteristics for β-lactams) was absent.

Cloxacillin stored in aqueous solutions of methanol or ethanol gave rise to a LC peak with a mass spectrum exhibiting (for methanol) an [M+H]+ ion at m/z 468 and protonated fragment ions at m/z 309, 196 and 160. This spectrum is consistent with the formation of the methyl ester of cloxacillin (Structure III, Figure 1). Likewise, (for ethanol) the ethyl ester resulted in a mass spectrum with a [M+H]+ ion at m/z 482 and fragment ions at m/z 323 and 160. It was interesting to note that 2-propanol or aqueous solutions of 2-propanol didn't form a propyl ester, rather cloxacillin in that solvent underwent hydrolysis.

The storage of cloxacillin (100 μg/ml) in various solutions (Figure 2) indicated that methanol resulted in the most rapid degradation of this antibiotic while 25% acetonitrile, 25% ethanol in water solution resulted in the least degradation. After two weeks of storage in 50% methanol in water or 100% methanol, cloxacillin was converted entirely to its methyl ester. A 50% ethanol in water solution resulted in a slow hydrolysis of cloxacillin compared to methanol.

The degradation rate of cloxacillin was dependent on concentration. Lower concentrations of cloxacillin (500 ng/ml) underwent a faster degradation. Degradation was nearly nonexistent at the 1 mg/ml level of antibiotic in each solvent.

Conclusions
This study showed that none of the available solvents was ideal for biological sample preparation or chromatographic procedures for trace determination of penicillins. Cloxacillin stored in various solutions underwent two types of degradation: 1) hydrolysis with decarboxylation in the presence of water, acetonitrile and 2-propanol and 2) alcoholysis when methanol or ethanol was present. Since the methanolysis products form at the faster rate, methanol cannot be used in any step of an analytical procedure. With strict control of analytical procedure, 50% ethanol in water or a mixture of 25% acetonitrile and 25% ethanol in water can be utilized when determining penicillin antibiotics in biological fluids and tissues with minimal losses.

In metabolism studies, traditionally phase II conjugates have been analyzed indirectly as the free drug after enzymatic hydrolysis. Extraction and chromatography of the parent drug and conjugates represent challenges due to the broad range of polarity between the drug and its conjugates. We are using LC/MS to determine Phase II drug conjugates in urine and bile. To date, most of this work has been done using thermospray ionization. More recently, the introduction of electrospray ionization has shown promise for characterizing labile glucuronides and sulfates. To evaluate procedures for recovering glucuronides and sulfates from urine and bile, we used estradiol and its conjugates and tested methodology developed for thermospray or electrospray ionization mass spectrometry.

The following experimental procedure was used to recover and analyze the estradiol conjugates:

1) 100 μL urine or bile was applied to a preconditioned Analytichem C8 cartridge.
2) 50 μL spiking solution of each analyte and 20 mM ammonium acetate buffer pH 4.0 was added to the cartridge to achieve a total volume of 1 mL.
3) The cartridge was washed with 1 mL of 20 mM ammonium acetate buffer pH 4.0.
4) The eluate was collected in 1 mL 20:80 20 mM ammonium acetate buffer pH 4.0: acetonitrile.
5) The eluent was evaporated to dryness (N₂), reconstituted in 90:10 100 mM ammonium acetate buffer pH 4.0: acetonitrile and filtered with a 0.02 micron disc filter prior to analysis.

**HPLC Conditions:**
- Mobile Phase Gradient: 95:5 (2 min.) to 20:80 (25 min.) 100 mM ammonium acetate (pH 4.0) : acetonitrile HPLC Column: 25 cm x 4.6 mm YMC ODS-AQ; 1 cm guard column
- Flow Rate: 1.0 mL/min
- Injection volume: 100 μL
- UV detection at 254 nm

**MS Instrumentation:**
- Finnigan TSQ-70 equipped with a Finnigan thermospray source
- Vaporizer temperature: 75-80°C
- Source temperature: 280°C
- Nermag R1010 equipped with an Analytica of Branford electrospray source

**Thermospray Ionization:**
- In the positive ion mode the ammoniated molecule was observed for E-3G and E-17G with little or no fragmentation. These intense ions were easily observed in extracts of either urine or bile. Loss of SO₃ was observed from the ammoniated molecule of the mixed conjugates, E-3G, 17S and E-3S, 17G. Both sulfate conjugates E-3, 17S and E-3S gave only ions arising from SO₃ loss from the protonated molecule.
- In the negative ion mode the deprotonated molecule of the estradiol glucuronides were observed. Analogous to the positive ion spectra, the mixed sulfate/glucuronide conjugates showed SO₃ loss; however, in their negative ion spectra the loss of 176 (glucuronide) was also seen. The mass spectrum of E-3, 17S showed the (M-H⁻) ion and SO₃ loss.

**Electrospray Ionization:**
- In the positive ion mode only the glucuronides of estradiol gave response. Analogous to the thermospray results a strong ammoniated molecule was seen. Similar spectra were obtained for all conjugates, suggesting that either method would serve to characterize the conjugates. Electrospray spectra of mixed sulfate/glucuronide conjugates gave consistently stronger (M-H⁻) ions; however, no parent ion (either singly or doubly-charged) was seen for the bis-sulfate E-3, 17S.

\]
Using LC/MS urine or bile extracts may be profiled for phase II metabolites of estradiol. We are investigating whether this simple recovery procedure will be amenable to other steroids or drugs. Alternative procedures which may employ ion exchange or ion-pairing would be less suitable for thermospray and electrospray ionization. The procedure has the added advantage of retaining the parent compound so that phase I metabolites may likely be recovered using the procedure.

While recovery of analyte in the presence of buffers or salts is often not detrimental to analysis using thermospray LC/MS, ionic strength has a large effect upon electrospray ionization. High concentrations of ammonium acetate buffer (>5 mM) caused discharging in the electrospray source, reducing ion sensitivity. Using packed capillary LC columns we achieved some separation and analysis at lower (1 mM) buffer concentrations from standard solutions.
Separation and Identification of Paralytic Shellfish Poisons in extracts of marine matrices by combined Capillary Electrophoresis-Mass Spectrometry*

P. Thibault, 1,2 S. Pleasance and 1 M.V. Laycock; 1Institute for Marine Biosciences, NRC, 1411 Oxford St., Halifax, Nova Scotia, 2SCIEX, 50 Glen Cameron, Thornhill, Ontario, Canada

Paralytic Shellfish Poisoning (PSP) is one of the most severe forms of seafood intoxication which results from ingestion of mollusks contaminated with toxic phytoplankton. Neurological symptoms of PSP are associated with marine toxins comprising a basic perhydropurine skeleton. The most toxic compound of this family is saxitoxin (STX) [1].

In view of the unpredictable nature of toxic phytoplankton blooms (often associated with "red tides") and the shellfish intoxication that results from it, constant monitoring of PSP toxins is required for public health protection. Presently the mouse bioassay is used for the majority of toxin-monitoring programs in shellfish [2]; however its narrow dynamic range, its variability of dose/response and its logistic constraints have stimulated the development of alternative methods. Recently, a capillary electrophoresis (CE) method with UV detection has been evaluated in our laboratory for the separation and determination of underivatized PSP toxins [3]. Due to the lack of PSP toxin standards, confirmation of electrophoretic peak identities requires a specific and complementary detection system that can easily be interfaced with CE. A CE-MS interface using ionspray ionization was designed and constructed in this laboratory [3] based on a configuration described by Smith et al. [4]. This system comprises a coaxial capillary arrangement in which both CE and make-up flow columns terminate at the ionspray interface. Using electrokinetic injection of STX and NEO standards, detection limits of 12 and 40 pg respectively were obtained. Different buffer systems were evaluated for their separation efficiency and compatibility with mass spectral analysis. Baseline separation of STX, NEO and GTX toxins was successfully achieved using a Trisma buffer (pH 7.2). An example of such separation is shown in Figure 1 and corresponds to low ng injection of different PSP toxins under full mass scan acquisition (130-410 Da). The same electrophoretic conditions also permitted separation of PSP toxins from extracts of marine matrices. Figure 2 shows results of analysis of sonicated and filtered cells of Alexandrium excavatum, using full-scan CE-MS. These traces indicate other endogenous compounds such as arginine, a biosynthetic precursor of PSP toxins. Extracts of contaminated scallop livers were also analysed by CE-MS and confirmed the presence of STX at low μg/mL level. Although these latter extracts were fairly complex, enhanced selectivity was achieved using multiple reaction monitoring in CE-MS-MS analyses of targeted toxins (STX: 300/204, NEO: 316/220, GTX's: 396/298).

INTRODUCTION

Rifamycins are a series of antibiotics which have been found to be useful for the treatment of various mycobacterial infections (1,2). The most widely prescribed member of this group is rifampicin which is used for the treatment of tuberculosis and leprosy (3). Recently, Vekey et al. (4) reported the comparison of multiple ionization techniques for rifapentine, one member of this group of antibiotics; this report included thermospray mass spectrometry (TSMS) data, but not electrospray mass spectrometry (ESMS). The utility of ESMS for the analysis of compounds with a high (>2000) molecular weight has received much attention recently; analysts have been slower to investigate the utility of electrospray for low (<1000) molecular weight compounds. We are currently investigating the utility of ESMS and TSMS for the analysis of rifamycin antibiotics. We have analyzed three compounds of this group, rifampicin (MW 822), rifamycin SV (MW 697), and rifamycin B (MW 755), by both TSMS and ESMS. In addition, we have subjected a mixture of these three compounds to combined high-performance liquid chromatography (HPLC)/TSMS.

EXPERIMENTAL

Samples

Rifampicin, rifamycin SV and rifamycin B were obtained from Sigma Chemical Co. (St. Louis, MO).

Electrospray MS

Each standard was made up to a concentration of 50 ng/μl in 50/50 methanol/water. The ES mass spectra were obtained on a Delsi/Nermag R3010 triple quadrupole mass spectrometer equipped with a Delsi/Nermag ES interface. The samples were pumped into the source at a flow rate of 1 μl/min. The mass spectrometer was scanned from m/z 100 to m/z 1000 at a rate of 4 sec/scan.

Thermospray MS

The TS mass spectra were obtained on a Finnigan MAT TSQ 70 triple quadrupole mass spectrometer equipped with a Finnigan TS interface and source. Analyses were performed in the positive ion, discharge-off and filament-off mode. Combined HPLC/TSMS analyses were performed using an Isco model LC-5000 syringe pump connected to a Rheodyne 7125 injector equipped with a 20 μl loop; the outlet of the injector was connected to a Phase-Sep ODS 5 μm particle size HPLC (15 cm x 4.6 mm ID) column. The total HPLC column eluant flowed into the TS interface of the mass spectrometer. The mobile phase was 60/40 methanol/(0.2 M ammonium acetate in water) pumped at a flow rate of 1.2 ml/min. The mass spectrometer was scanned from m/z 200 to m/z 850 at a rate of 2 sec/scan. Typically, the vaporizer was set to 75 °C, while the block (aero) was set to 220 °C. For analyses of a mixture of all three compounds, a solution containing all three compounds at a concentration of about 0.4 μg/μl each in 50/50 methanol/(0.2 M ammonium acetate in water) was prepared.
RESULTS AND DISCUSSION

Under ESMS conditions, as shown in Figure 1, Rifamycin B had an [MH]$^+$ ion at m/z 756 as the base peak, but also a strong [MNa]$^+$ ion. Rifampicin showed an [MH]$^+$ ion at m/z 823 as the base peak and one fragment ion at m/z 791, which can be attributed to the [MH - CH$_3$OH]$^+$ ion. Rifamycin SV showed an [MNa]$^+$ as the base peak plus a second peak at m/z 744 which is the [M + 2Na - H]$^+$ ion.

Under TSMS conditions each compound provided a strong [MH]$^+$ ion: rifampicin at m/z 823 (base peak); rifamycin SV at m/z 698; rifamycin B (see Figure 2) at m/z 756 (base peak). For rifamycin SV, the base peak at m/z 666 can be attributed to the [MH - CH$_3$OH]$^+$ ion and the fragment ion at m/z 648 can be assigned to the [MH - CH$_3$OH - H$_2$O]$^+$ ion. When a mixture of these three compounds was analyzed by HPLC/TSMS, the result was baseline chromatographic separation of the three compounds as well as good mass spectra for each compound in less than 20 minutes.

CONCLUSIONS

Both ESMS and TSMS provided useful data for these compounds. For two of the three compounds, the TS mass spectra were significantly different from the ES mass spectra. TSMS had the advantage that it could readily be used in the HPLC/TSMS mode which provided a technique for the analysis of a mixture containing these three compounds.

DETECTION OF DETOMIDINE AND ITS METABOLITES IN EQUINE URINE USING AN ATMOSPHERIC PRESSURE IONIZATION LC/MS

Y.C. Chui*, A. Mutib+, B. Esaw*, R. Zarate* and L.M. Young*, Can Test Ltd.*, 1523 West 3rd Ave., Vancouver, B.C., V6J 1J8, and Faculty of Pharmaceutical Sciences*, University of British Columbia, B.C. V6T 1W5, Canada.

INTRODUCTION
Detomidine, a potent sedative drug, has been illegally used by some horsemen to calm horses before racing. Detomidine is administered to horses in very low doses (5-20mg/horse). In order to regulate its use in the racing industry, a sensitive method is needed to screen and identify it or its metabolite(s) in equine urine and blood. Little is known about the pharmacokinetics of detomidine in horses. Using GC/MS analysis, Seymour et al. (1) had detected two metabolites, 3-hydroxy-detomidine and 3-carboxylic acid detomidine in equine urine. The purpose of our study is to develop an analytical method which can be used to regulate the pre-race use of detomidine and to study pharmacokinetics of detomidine in horses.

EXPERIMENTAL
Plasma Extraction: Equine plasma (5 mL) was adjusted to pH 10 and extracted with ethyl acetate. The organic layer was back extracted into 0.5 N HCl. The aqueous layer was adjusted to pH 10 and extracted with ethyl acetate. The organic layer was dried, reconstituted and analyzed by LC/MS.

Urine Extraction: For detection of hydroxy-detomidines in equine urine, urine (20mL) was hydrolyzed by beta-glucuronidase and cleaned up by a backwash technique as described in the plasma extraction. For detection of detomidine 3-carboxylic acid, urine (5 mL) was purified by a Xtrack™ DAU column (Worldwide Monitoring; Harsham, PA). The eluate was dried, reconstituted and analyzed by LC/MS.

LC/MS: The chromatographic system consisted of an ABI (Foster City, CA) 140A dual syringe pump equipped with a Brownlee® Spheri-5 cyano column (220X4.6mm). The mobile phase was gradient programmed from 50% acetonitrile and 50% 10mM ammonium acetate to 100% acetonitrile in 7 minutes and the flow rate was 0.75 mL/min. The mass spectrum analyses were performed using a Scienx (Thornhill, Ontario) API III triple quadrupole LC/MS system with a heated nebulizer interface.

RESULTS
A sensitive and simple method using atmospheric pressure ionization LC/MS with selective ion monitoring of daughter ions was developed to detect detomidine and its metabolites in equine blood and urine. Detomidine was detected in equine plasma up to 3 and 6 hours post I.V. administration of 5mg and 20mg of detomidine, respectively. Detomidine 3-carboxylic acid and 3-hydroxy-detomidine were detected in the equine urine which corresponds to the reported GC/MS analysis (1). A new metabolite, 4-hydroxy-detomidine, was isolated and identified in the equine urine. The two hydroxy-detomidines were detected in the beta-glucuronidase hydrolyzed equine urine up to 1 and 2 days post I.V. administration of 5 and 20 mg, respectively. No parent compound was detected in the equine urine. The detection limits of detomidine in equine plasma and hydroxy-detomidines in equine urine were approximately 500 pg/mL.
CONCLUSION

Atmospheric pressure ionization LC/MS with selective ion monitoring of daughter ions provided a sensitive and simple method for detecting detomidine and its metabolites in equine blood and urine. Detomidine was detected in the equine plasma up to 6 hours and hydroxy-detomidines were detected in the equine urine up to 2 days post I.V. administration of 20mg of detomidine. Our method can be used to regulate the use of detomidine in the racing industry.

DETECTION OF CORTICOSTEROIDS IN EQUINE URINE USING AN ATMOSPHERIC PRESSURE IONIZATION LC/MS

Y.C. Chui, B. Esaw, R. Zarate and L.M. Young, Can Test Ltd., 1523 West 3rd Ave., Vancouver, B.C., V6J 1J8, Canada.

INTRODUCTION

Synthetic corticosteroids are anti-inflammatory agents which are prohibited for use in race horses at some race tracks in North America. Some of them are administered in very low doses (5 mg/horse) and are hard to detect and identify in equine urine by other conventional techniques. Eight veterinary products, betamethasone, dexamethasone, flumethasone, isoflupredone, methylprednisolone, prednisolone, prednisone, and triamcinolone acetonide, were used in this study. The purpose of our study is to develop an LC/MS analytical method which can be used to regulate the pre-race use of corticosteroids in horses.

EXPERIMENTAL

Urine Extraction: Urine (50mL) was adsorbed on XAD-2 resin at pH 9.5 and eluted with 50% ethyl acetate in dichloromethane. The eluate was dried and redissolved in dichloromethane. The dichloromethane extract was added into a silica solid extraction column and washed with 20% ethyl acetate in dichloromethane. The sample was then eluted with 60% of ethyl acetate in dichloromethane. The eluate was dried, reconstituted and analyzed by LC/MS.

LC/MS: The chromatographic system consisted of an ABI (Foster City, CA) 140A dual syringe pump equipped with a LiChroCART® (Merck) 100 RP-18 column (125X4mm). The mobile phase was gradient programmed from 20% acetonitrile and 80% 10mM ammonium acetate to 100% acetonitrile in 10 minutes and the flow rate was 0.75 mL/min. The mass spectrum analyses were performed using a Sciex (Thornhill, Ontario) API III triple quadrupole LC/MS system with a heated nebulizer interface.

RESULTS

A sensitive and simple method using atmospheric pressure ionization LC/MS was developed to detect synthetic corticosteroids in equine urine. Synthetic corticosteroids show characteristic ions in both positive ion mode and negative ion mode LC/MS. The M+1 daughter ion mass spectra of corticosteroids obtained from the positive ion mode show complex fragmentation patterns, while the negative mode daughter ion mass spectra (both M+59 and M-1) of corticosteroids show simple patterns of fragmentation. After administering the horses with clinical doses of corticosteroids, all the corticosteroids used in this study were detected in the equine urine. Depending on the pharmacokinetics of individual corticosteroids, they can be detected in the urine samples from several hours (e.g. flumethasone) up to several days (e.g. triamcinolone acetonide) post administration. The detection limits of synthetic corticosteroids in equine urine were approximately 1 ng/mL.

CONCLUSION

A technique was developed to detect corticosteroids in equine urine by atmospheric pressure ionization LC/MS. Both positive ion mode and negative ion mode of LC/MS and LC/MS/MS provide characteristic ions and fragmentations for the detection of corticosteroids. Depending on the pharmacokinetics of individual corticosteroids, they can be detected in the urine samples from several hours up to several days post administration. Our method can be used to regulate the use of synthetic corticosteroids in the racing industry.
Selective ion (m/e 469) monitoring of negative ion LC/MS chromatograms of pre-administered urine extract, 0.5 hours post administered urine extract and 8.5 hours post administered urine extract from the horse I. V. administered with 5 mg of flumethasone (Flucort®).

Selective ion (m/e 493) monitoring of negative ion LC/MS chromatograms of pre-administered urine extract, 6 hours post administered urine extract and 120 hours post administered urine extract from the horse I. M. administered with 48 mg of triamcinolone acetonide (Vetelog®).

DETECTION AND CHARACTERIZATION OF GLUTATHIONE CONJUGATES USING IONSPRAY/TANDEM MASS SPECTROMETRY

Gerald C. Didonato1, Kevin D. Ballard2 and Simon J. Gaskell2

1Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ 08543-
4000, and 2Center for Experimental Therapeutics, Baylor College of Medicine,
Houston, TX 77030

The formation of glutathione conjugates of electrophilic xenobiotics or their
metabolites represents an important detoxification pathway. The recognition and
characterization of glutathione conjugates correspondingly provides important
evidence concerning the structures of reactive electrophilic metabolites of
potential toxicological importance. In previous work (1,2) we have developed
procedures based on fast atom bombardment /hybrid tandem mass spectrometry
for the screening of complex biological extracts for the presence of glutathione
conjugates. Thus, precursor and constant neutral loss scanning have been used
to detect fragmentations characteristic of this class of conjugate. More detailed
evidence of structure has been obtained by product ion scanning for precursor
ions identified as significant in the screening steps.

Here we report an extension of this approach to incorporate the
ionspray/ electrospray sample introduction technique together with on-line
chromatographic separation of complex biological extracts. The xenobiotic
studied here, 2-furamide, is a substituted furan with hepatotoxic properties. In
contrast to other substitutedfurans, such as the diuretic furosemide, 2-furamide
exhibits a glutathione threshold of toxicity; that is, its toxic properties become
manifest after depletion of hepatic stores of glutathione. This work forms part of a
broader study of structure/ toxicity relationships amongst substituted furans.

Anesthetized, bile cannulated male Fischer rats were administered a 1:1
mixture of unlabelled and [13C4]-labelled 2-furamide at a total dose of 200 mg/Kg.
Bile was collected over 15-30 min intervals for 2 h. Control bile was collected from
each animal for 30 min prior to administration of the xenobiotic. Bile samples
were rendered 1% by volume in heptfluorobutyric acid (HFBA) and extracted on
reverse-phase (C18) Sep-Paks, eluting with acetonitrile/water (4/1) containing
0.1% HFBA. The dried extracts were redissolved in 50 ul of acetonitrile/water
(1/1). 2 ul aliquots of the final solutions were used for LC-ionspray tandem MS
which employed a C18 microbore column (100 x 1 mm). The mobile phase was
programmed from 100% A (0.1% aqueous trifluoroacetic acid (TFA) to 100% B
(0.1% TFA in acetonitrile) in a linear fashion over 40 min, at a flow rate of 50
ul/min. The chromatographic eluent was directed to the ionspray source of a
Sciex API III triple quadrupole mass spectrometer. Air was used as the
nebulization gas at a pressure of 80 psi. The orifice was held at 60 V and the
potential difference between the orifice and the first quadrupole was 30 V.

Conventional and tandem mass spectra were recorded by scanning in 1 Da
increments, with typical dwell times of 5 ms. For tandem MS analyses, the
collision gas was argon and the collision energy was 70 eV.

The total ion current trace recorded during LC-MS analysis of an extract of
bile from a rat dosed 2-furamide showed a complex series of peaks, none of which
could be readily attributed to metabolites of the xenobiotic. The ion current trace
obtained by LC-MS/MS analysis with repetitive constant neutral loss (of 129 Da,
characteristic of glutathione conjugates (1)) scanning, however, suggested the
presence of at least two glutathione conjugates (Figure 1). Inspection of the
constant neutral loss scan corresponding to peak B indicated a precursor ion of
m/z 417/418 (corresponding to unlabelled and [13C4]-labelled species); product
ion spectra for these precursors confirmed the identification of the previously
recognized (2) glutathione conjugate of intact 2-furamide.

The constant neutral loss scan corresponding to HPLC peak A included a
prominent doublet with (1/1 relative abundance) of m/z 420/421. The product ion
spectrum of m/z 420 (Figure 2) substantiated the assignment as a glutathione
conjugate and indicated the mass of the conjugated species to be 113 Da,
corresponding to a probable elemental composition of C₅H₄O₂ (Figure 3).
Additional work is in progress to assign structure.
The data reported here indicate the value of the LC-ionspray/tandem MS combination in xenobiotic metabolism studies. In particular, the combination of chromatographic separation and tandem MS screening has facilitated the recognition of a second glutathione conjugate metabolite of the xenobiotic, 2-furamid.

Zofenopril calcium (Z) is the S-benzoyl ester prodrug of an angiotensin converting enzyme (ACE) inhibitor SQ-26333 [(S),4-S]-1-(3-mercapto-2-methyl-1-oxopropyl)-4-(phenylthio)-L-proline], (SQ), and is an orally effective antihypertensive agent in man (Figure 1). Urine samples were obtained from normal subjects after administration of single doses of Z or $^{14}$C-Z and the arginine salt of $^{14}$C-SQ. N-ethylmaleimide (NEM) was added to all samples to prevent oxidative degradation of SQ and other metabolites with free thiol groups by formation of NEM adducts. Extensive purification via both preparative and analytical chromatography resulted in the isolation of more than 20 different metabolites.

Mass spectral analysis included chemical ionization and MS/MS analysis on a Finnigan 4600 TSQ, as well as accurate mass FAB and MIKES analysis on a VG-ZAB-HF sector instrument. The formation of methylated derivatives proved extremely useful in the application of accurate mass measurement. Methylation of the carboxyl group provided 1) evidence as to the number of free acid groups in the native metabolite; 2) increased signal intensity for the (M+H)$^+$ ion due to the increased surface activity of the molecule. The application of both high and low energy MS/MS provided complementary fragment ion data, while the use of both positive and negative MS/MS provided structural information on different parts of the molecule due to the charge-directing nature of the fragment ions.

Isolates 8B and 8C were assigned as the diastereomeric pair of NEM derivatives of SQ. Major fragment ions produced in the positive daughter ion MS/MS spectrum are shown in Figure 2. Daughter ions include the m/z 224 fragment ions formed by cleavage of the amide bond with charge retention on the S-phenyl proline moiety, while charge retention on the acylium ion results in the ion at m/z 228. Cleavage on either side of the sulfur atom leads to m/z 324 and 294. Low-energy MS/MS leads to formation of fragment ions at m/z 200 and 158.

The positive and negative FAB mass spectra of metabolites 8A indicated a molecular weight of 339. The fragmentation of the (M+H)$^+$ ion yielded diagnostic ions at m/z 117, 89, and 69, indicating S-methylation (Figure 3). A shift of 16 amu in the 117 fragment ion to 133 was the diagnostic ion in the collisional activation spectrum of the oxidation product.

Mass spectral characterization of metabolite 4C led to its assignment as a novel cyclic thioester. Positive and negative FAB indicated a molecular weight of 485. MIKES produced a neutral loss of 176, indicating a glucuronide conjugate. Accurate mass measurement of the (M+H)$^+$ ion indicated a formula one oxygen less than that expected for SQ-glucuronide. The daughter ion spectrum (Figure 4) of the aglycone ion produced via DCI yielded a fragment at m/z 208, instead of 224 that is usually expected for the S-phenyl proline moiety. The data suggests formation of a seven-membered thioester, which undergoes subsequent reduction and glucuronidation.

CONCLUSIONS: Intact prodrug (zofenopril) was not found in the urine samples after oral doses of zofenopril. SQ, as the NEM adduct, was the principal urinary component. Extensive metabolism included: conjugation with glucuronic acid; conjugation with cysteine; cystathionase cleavage of the cysteine conjugate to the persulfide followed by conjugation with glucuronic acid; S-methylation and subsequent oxidation; oxidation of the S-phenyl moiety; and the formation of a seven-membered thioester glucuronide. Proposed biotransformation of SQ is shown in Figure 5.

![Biotransformation Diagram](image5)
Biotransformation to polar metabolites followed by conjugation is a typical metabolic pathway of xenobiotics. The chemical properties of the conjugates complicate their analytical characterization and HPLC is often required for direct observation. Thermospray ionization has been used to obtain mass spectral information on conjugates\(^1\). Thermospray is, however, compound specific, requiring several micrograms for the characterization of most molecules. The more recently introduced atmospheric pressure ionization mass spectrometry (API MS) provides and supports two distinct soft ionization approaches for on-line HPLC/MS analysis. In this study, API mass spectra were obtained for glucuronide, glycine, glutathione and sulfate conjugates using heated nebulizer and ionspray API interfaces.

Model conjugates p-nitro-phenyl glucuronide, phenyl glucuronide, dansyl glycine, p-nitro-phenyl sulfate and S-(p-nitro-benzyl) glutathione were dissolved in 50/50 methanol/water.

All mass spectral data were obtained on a SCIEX API III triple quadrupole mass spectrometer equipped with either a heated nebulizer or ionspray API interface. Samples were introduced using flow injection; flow rates were 1 mL/min for the heated nebulizer and 20 μL/min for the ionspray interface. Collision induced dissociation of the conjugates was carried out using argon as the collision gas and collision energies of 10-60 eV. Granddaughter, or ms/ms/ms, spectra were obtained by increasing the declustering energy from 4 eV to 100 eV.

The heated nebulizer inlet allows liquid flows of up to 1 mL/min and produces ions by chemical ionization processes. Spectra obtained using the heated nebulizer inlet consisted mostly of positive or negative pseudo-molecular ions. The only conjugate that produced positive ions in this mode was dansyl glycine. Its spectrum contains an (M+H)\(^+\) at m/z 309 and ions at m/z 251 and 172 from loss of acetic acid and glycine respectively. The last two ions are most likely due to thermal breakdown during the nebulization process. Strong pseudo-molecular anions were observed for glucuronide and glycine conjugates. Figure 1 illustrates the strong (M-H)\(^-\) for phenyl glucuronide. No useful heated nebulizer spectra were obtained for sulfate and glutathione conjugates.

Ionspray reportedly produces ions by an ion evaporation mechanism\(^2\). Strong (M-H)\(^-\) ions were observed for all model conjugates using this mode. The ionspray spectrum for dansyl glycine (Figure 2) is dominated by the (M-H)\(^-\).

Ionspray allowed pg detection limits for sulfate conjugates. It is compatible with mobile phase flow rates below 200 μL/min and would require splitting the flow from standard bore columns. This disadvantage may be offset by superior sensitivity and lack of thermal degradation.

CID daughter spectra were obtained on the pseudo-molecular anions produced by ionspray ionization. The dominant loss for all compounds was the conjugating moiety, as illustrated by the daughter spectrum of p-nitro-phenyl glucuronide (Figure 3). If the instrument is adjusted such that the conjugate fragmented in the declustering region, granddaughter spectra can be obtained. Structurally significant ions, such as loss of NO and NO\(_2\) from p-nitro-phenyl aglycone are readily observed.

SIMULTANEOUS DETERMINATION OF TENIDAP AND ITS STABLE ISOTOPE ANALOGUE IN PLASMA BY HPLC/APIMS/MS

M. Avery, D. Mitchell, F. Falkner and H. Fouda.
Central Research Division, Pfizer INC, Groton, CT 06340

The utility of stable isotope labelled drug to investigate dose\(^1\) or time dependent\(^2\) changes in drug pharmacokinetics; to assess bioequivalence\(^3\) and to demonstrate saturable first-pass effects\(^4\) has long been recognized. Such studies require mass spectrometric assays for the simultaneous determination of the labelled and unlabelled drug.

Tenidap is a new anti-inflammatory agent undergoing clinical evaluation\(^5\). A GC/MS assay for tenidap was not possible as the drug undergoes thermal decomposition in the GC injection port. The limit of detection by thermospray HPLC/MS (2 µg) did not permit the determination of therapeutic levels. HPLC with atmospheric pressure chemical ionization detection proved applicable to the quantitative determination of tenidap in plasma.

Plasma (0.5 mL) was mixed with the internal standard and with 400 µL of 0.05M sodium carbonate and then extracted with 5 mL of ethyl acetate. Following centrifugation, two mL of the organic layer was evaporated to dryness in a vortex evaporator. The dried residue was reconstituted in HPLC mobile phase and 50 µL aliquots were injected onto a CIS column (3.9x150mm). Under isocratic conditions using a mobile phase of 60/40 water/methanol containing 2mM triethylamine at 1 mL/min, the retention times of labelled and unlabelled drug and internal standard (IS) were 2.1, 2.1 and 1.4 min., respectively.

The analysis was performed on a SCIEX API III HPLC/MS/MS system. The effluent from the HPLC column flowed into the atmospheric pressure ionization source via a heated nebulizer interface where chemical ionization was effected by a Corona discharge. Negative ions formed in the source were sampled into the quadrupole mass filter via a 0.0045" sampling orifice. The analysis utilized the technique of multiple reaction monitoring (MRM); i.e. monitoring selected daughter ions of specific parent ions. The collision induced dissociation daughter spectrum of tenidap is shown in Figure 1. The loss of the carboxamide from tenidap, deuterium labelled tenidap and IS parent ions were monitored. The site of deuterium labelling, the thiophene ring, did not affect the measurement. To avoid interference from the naturally occurring D\(_0\)-tenidap isotopes, the analysis of deuterium labelled tenidap utilized its \(^{37}\)Cl ion. The reactions monitored were m/z 319 -> 276 for D\(_0\)-tenidap, 324 -> 281 for D\(_2\) tenidap and 303 -> 260 for the IS.

An HPLC chromatogram of a control plasma sample spiked with 0.1 µg/mL of D\(_0\)- and D\(_3\)-tenidap and a structural analogue IS is shown in Figure 2. Separate experiments using 5 µg/mL concentrations of labelled and unlabelled drug showed no cross-interference. High selectivity of the HPLC/MS/MS detection method resulted in a dynamic range of 0.1 to 5.0 µg/mL. The calibration curves for D\(_0\)- and D\(_3\)-tenidap had correlation coefficients of 0.999. The accuracy and precision of the assay were determined from fortified plasma samples. The assay parameters are summarized in Table 1.

An application of the assay is shown in Figure 3. Plasma samples from rats dosed with equimolar amounts of D\(_0\)- and D\(_3\)-tenidap intravenously were assayed by the present method and a previously developed HPLC/UV method. Samples assayed higher than 5 µg/mL were reassayed after dilution. Total tenidap concentrations for both methods were in excellent agreement.

The technical assistance of Ms. K. Navetta and Ms. D. Farrell is gratefully acknowledged. We are also grateful to Dr. L. Melvin for supplying the deuterium labelled tenidap.

Rapid LC/MS/MS Screening for the Metabolites of Buspirone

Edward Kerns, Kevin J. Volk, Mike S. Lee and Ira E. Rosenberg, Bristol-Myers Squibb Co., 5 Research Parkway, Wallingford, CT 06492

In recent years rapid and comprehensive protocols for drug metabolite identification have evolved with advances in mass spectrometric instrumentation, such as tandem mass spectrometry (MS/MS), HPLC/mass spectrometry (LC/MS) and soft ionization methods (e.g., electrospray). A protocol for metabolite structure elucidation utilizing the advantages of these techniques consists of the following steps:

1. MS/MS screening (1-6) by direct injection of sample into an electrospray source reveals classes of metabolites and preliminary substructural information.
2. LC/MS with gradient elution to observe isobaric metabolites.
3. LC/MS/MS for substructural information on each isobaric metabolite.

A study utilizing this protocol was undertaken to enhance the understanding of buspirone metabolism (6-8) and to study current methodology used in rapid metabolite surveys.

A male Sprague-Dawley rat was administered 10 mg of buspirone HCl by gavage. Bile and urine samples were collected for 0-4 hr. A Sciex API III with an ionspray source was used for all MS analyses in MCA spectral collection mode. For MS/MS screening a 1 microliter aliquot of sample diluted 1:1 with mobile phase B (1:1 acetonitrile:1 mM ammonium acetate, pH 6.8) was injected into the stream of mobile phase B supplied to the ionspray source at 20 microliters/min. A series of MS/MS parent and neutral loss screens, which were specific for substructures of buspirone, were performed with successive injections. LC/MS utilized 5 microliter injections of sample into a Waters Novapak C18 column (150mm X 3.9mm X 5 microns) with gradient elution from 10% acetonitrile:90% buffer to 100% mobile phase B in 20 minutes at 1.0 mL/min. LC/MS/MS analysis was performed under the same conditions while daughter spectra of certain classes of metabolites (observed in MS/MS screening) were acquired.

MS/MS screening by direct injection of bile indicated the presence of parent drug and 13 classes of metabolites (Table 1). These included phase I metabolites, corresponding to addition and dealkylation products, as well as phase II metabolites. These analyses were performed without previous sample preparation, thus saving time and expense with respect to traditional techniques of HPLC fraction collection of radiolabeled peaks. The lack of sample preparation and collection assured minimal sample degradation. Electrospray provided a convenient interface for direct analysis of physiological fluids and a soft ionization technique for labile drug conjugates. Daughter MS/MS spectra provided substructural information on the metabolites. For example, the metabolite class having an addition of an oxygen atom to the parent drug was found to be primarily oxidized on the azaspirone moiety. Another metabolite appears to be a dihydroxy methoxy glucuronide metabolite having addition of OH to the azaspirone moiety and methoxy and glucuronic acid on the pyrimidine ring.

LC/MS gradient analysis with acquisition of full scan mass spectra required only one acquisition of 30 minutes. Isobaric compounds of several metabolite classes from screening were readily separated, as shown in Table 1. Electrospray ionization produced metabolite spectra having abundant (M+H)+ ions with no fragmentation, even for the labile conjugate metabolites. Compounds observed in MS/MS screening indicated which extracted ion current profiles to plot from the LC/MS data. Semi-quantitative estimates of the relative amounts of each metabolite were obtained from the intensity of the extracted ion current profile for each (M+H)+.

LC/MS/MS analysis of the metabolites was performed with gradient elution while acquiring daughter MS/MS spectra of the (M+H)+ of each class of compounds. This analysis provided detailed substructural information for each isobaric metabolite.

The stepwise protocol for a rapid structural survey of metabolites was applied to buspirone and a wealth of metabolism data was obtained. The same MS/MS instrument and electrospray ion source is used throughout the protocol. Physiological fluids can be directly analyzed. Labile metabolites are readily observed and structurally analyzed. This methodology is routine and is readily applied to similar studies.

CHARACTERIZATION OF METABOLITES OF XYLAZINE BY GC/MS AND LC/MS/MS.
Abdul Mutlib*, Yun-Chung Chui*, Larry Young**, and Frank Abbott**.

Faculty of Pharmaceutical Sciences, The University of British Columbia, 2146 East Mall, Vancouver, B.C., Canada, V6T 1W5 and
** Cantest Ltd, 1523 W 3rd Avenue, Vancouver, B.C., Canada, V6J 1J8.

Introduction
Xylazine, 2-(2',6'-dimethylphenylamino)-5,6-dihydro-4H-1,3-thiazine, is a powerful tranquillizer which is commonly used to sedate large animals prior to surgical procedures. It also has the potential of being abused on race tracks due to its calming effects on horses. There are no detailed studies published on the metabolic fate of this compound. Preliminary studies have shown that after administering 35S-labelled xylazine to rats, 70% of the radioactivity was eliminated in the urine with 8% of dose being excreted as unchanged xylazine. The objective of the present study was to define the nature of xylazine metabolites excreted in horse urine. LC/MS/MS using the ScieX APCI/MS/MS system was used to detect and confirm the structures of xylazine metabolites in horse urine and in rat microsomal preparations.

Experimental
Materials: 2-(4'-Hydroxy-2',6'-dimethylphenylamino)-5,6-dihydro-4H-1,3-thiazine and 2-(3'-hydroxy-2',6'-dimethylphenylamino)-5,6-dihydro-4H-1,3-thiazine were produced from xylazine using Fenton's reagent (1). N-(2,6-dimethylphenyl)thiourea was produced by heating 2,6-dimethylaniline with ammonium thiocyanate. 2-(2',6'-Dimethylphenylamino)-4-oxo-5,6-dihydro-1,3-thiazine was synthesized by treating N-(2,6-dimethylphenyl)thiourea with 3-chloropropionyl chloride and cyclizing the product by heating it in the presence of triethylamine at 80°C.

Methods. Animal Experiments. Male Sprague-Dawley rats (250-300 g) were sacrificed and livers removed for microsomal preparation. After microsomal incubation of xylazine, the metabolites were extracted and analyzed by GC/MS and LC/MS/MS. A horse was administered xylazine (1 g) and urine collected over 24 hours. A portion of the urine sample (150 ml) was extracted with ethyl acetate and analyzed by GC/MS. The remaining aqueous phase was passed through an Amberlite XAD-2 column. The metabolites were eluted with methanol and concentrated. The residue, redissolved in sodium acetate buffer (pH 5) was incubated with 8-glucuronidase at 37°C for 18 hours. The aqueous phase was extracted with ethyl acetate and the extract analyzed by TLC and LC/MS/MS. GC/MS was performed on a HP5987A GC/MS system using a cross-linked methylsillcone fused capillary column (HP, 20 m x 0.32 mm i.d). Temperature was programmed from 50°C to 300°C at 10°C/min. LC/MS/MS was carried out with the ScieX Heated Nebulizer LC/MS interface coupled to an API/MS/MS system. MS/MS was carried out using 70 eV collision energy and argon as the collision gas. HPLC was done on a reversed phase analytical column (UltraspHERE ODS, 5 um, 250 x 4.6 mm) with the solvent being delivered by a dual syringe pump (Applied Biosystem) at a rate of 0.7 ml/min. The mobile phase consisted of a gradient system beginning with 20% acetonitrile in 0.01M ammonium acetate buffer (pH 7) and increasing the percentage of organic modifier to 100% over 12 minutes.

Results
A number of metabolites were detected in hydrolyzed horse urine and from the incubation of xylazine with rat liver microsomes (figure 1). The major metabolites identified included the two phenolic compounds 1 and 2. N-(2,6-dimethylphenyl)thiourea, 3 and the thiazine ring oxidized metabolite 4. LC/MS/MS was used to confirm the identities of these metabolites. For example metabolite 4 was identified by LC/MS/MS as shown in figures 2a and 2b.

Conclusions
Metabolites of xylazine were found to be hydroxylated at both the para and meta positions of the aromatic ring. While para ring hydroxylation is a well known metabolic reaction, oxidation at meta position has been reported for only a limited number of compounds (2). These phenolic metabolites could not be successfully analyzed by GC/MS even after derivatization with silylating agents. LC/MS/MS was the method of choice for analyzing complex mixtures such as horse urine for small quantities of metabolites.

Tandem Mass Spectrometry for the Structure Elucidation of Flavones

Mike S. Lee, Derek J. Hook, Edward Kerns, Kevin J. Volk, and Ira E. Rosenberg
Bristol-Myers Squibb Company, S Research Parkway, Wallingford, CT 06492

A systematic method for the identification of flavone structures with tandem mass spectrometry (MS/MS) has been developed. During the screening of fermentation broths for inhibition of a particular type of enzyme activity, it was realized that natural products with the flavone chemotype could potentially interfere because of the antioxidant activity of this class of compounds. In order to eliminate fermentation broths that contained this chemotype from further scale up and isolation studies, it was necessary to develop a strategy to quickly identify this class of compound. In previous work (1) we had demonstrated that HPLC-diode array bioassay provide a useful tool for this type of quick identification, and we had shown in preliminary results that mass spectrometry could provide additional information that would allow us to confirm identification based on UV-visible spectroscopy. These results extend these preliminary findings by continuing the utility of LC/MS for molecular weight determination, but also extend the usefulness of the procedure through the use of DCI/MS/MS and LC/MS/MS techniques for structure elucidation and identification.

Here we describe an approach which utilizes the desorption chemical ionization (DCI) and thermospray ionization (TS) modes for the rapid analysis of partially purified broth extracts. DCI/MS/MS techniques are utilized to rapidly propose possible structures while LC/MS/MS techniques are utilized to further elucidate and confirm the flavone structures. The method is based on the fact that flavone structures undergo similar collisionally activated dissociations (CAD) corresponding to cleavage through the benzopyrone substructure. The resulting daughter MS/MS spectra contain a complementary pair of fragment ions indicative of possible structures. A direct comparison, both chromatographic and spectral, to authentic standards is used to confirm the postulated structures.

Full scan DCI mass spectra of standard flavones contain an abundant protonated molecular ion [M + H]+ with very little fragmentation. Thus, an initial molecular weight and purity assessment of the extract can be performed using the DCI mode. The full scan DCI mass spectra of broth extracts contain ions indicative of the molecular weights of possible flavone compounds. The major ions are selected for the corresponding daughter MS/MS experiment to determine if flavone structures are present.

The daughter DCI/MS/MS results obtained with various standard flavone compounds indicate that a common fragmentation pathway exists to generate a pair of complementary fragments. These fragments are structurally significant to flavones and correspond to cleavage through the benzopyrone structure via a retro-Diels-Alder rearrangement. Figure 1 shows the daughter MS/MS spectra of daldzeln and genistelin illustrating this characteristic behavior. The daughter MS/MS spectra of daldzeln contain the complementary benzopyrone fragments at m/z 119 and 137 along with several structurally significant ions at m/z 237, 227, 199, 181 and 91 associated with this retro-Diels-Alder rearrangement. The daughter MS/MS spectrum of genistelin contains the complementary fragments at m/z 119 and 153 with rearrangement ions at m/z 253, 243, 225, 215 and 91.

Daughter MS/MS spectra obtained from the broth extract selecting the major ions observed in the full scan DCI mass spectra contain diagnostic flavone-fragment ion pairs indicative of possible structures (Figure 2). Two flavone structures corresponding to daldzeln and genistelin were proposed directly from the spectra. The daughter MS/MS spectra of the authentic standards (Figure 1) compare well with the compounds contained in the extract (Figure 2) as the same daughter ions were observed with similar relative abundances.

Figure 3 shows the LC/MS chromatogram illustrating the separation of daldzeln and genistelin from a reconstituted broth extract. Separation of the two targeted components is achieved in less than 15 minutes. Full scan background subtracted thermospray mass spectra essentially contain a single ion corresponding to the protonated molecular Ion. Daughter MS/MS spectra obtained for each compound yield similar structurally significant ions as observed with DCI/MS/MS. Also, as demonstrated in the DCI mode, the daughter LC/MS/MS spectra of the broth extract and flavone standards contain essentially the same fragment ions with similar relative abundances.

These results illustrate the utility and versatility of MS/MS techniques for the rapid structure characterization and elucidation of flavone compounds. The DCI mode can be used in conjunction with MS/MS techniques to rapidly determine the presence of major flavone compounds contained in a complex mixture. The utility of the TS mode in conjunction with MS/MS techniques is directed toward the trace analysis of all flavone compounds contained in the mixture. Certainly, a two step approach utilizing both DCI/MS/MS and LC/MS/MS may also be employed.

Differentiation of three regioisomers of hydroxy-3,4-(methylenedioxy)methamphetamine by collisional mass spectrometry using ion trap and triple quadrupole mass spectrometers.

H.K. Lim, C.C. Nelson and R.L. Foltz, Center for Human Toxicology, Dept. Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84108 and Northwest Toxicology, Salt Lake City, UT 84124.

Recently we reported that 3,4-(methylenedioxy)methamphetamine (MDMA) and its N-demethylated metabolite are hydroxylated at positions 2, 5 and 6 of the 3,4-methylenedioxyphenyl ring in the rat following subcutaneous injection of 20 mg/kg MDMA (as free base) [1]. Regioselectivity was observed for the hydroxylation pathway as indicated by the preferred hydroxylation at position 6 over the other two positions. These regioisomers of either hydroxy-MDMA or its N-demethylated analog gave indistinguishable electron and chemical ionization mass spectra. Initial attempts to differentiate the three regioisomers of hydroxy-MDMA by collisional mass spectrometry using an ITMS failed since collision-induced dissociation (CID) of the protonated molecules (MH+) of the three regioisomers all gave identical daughter ion mass spectra. Similarly, identical daughter ion mass spectra were obtained by CID of the MH+ ions corresponding to the regioisomers of the N-demethylated analog of hydroxy-MDMA. This was unexpected since there is literature report that isomeric compounds can be differentiated by collisional mass spectrometry using an ion trap mass spectrometer (ITMS) [2]. Therefore, this study compares collisional mass spectrometry performed on an ITMS and a triple quadrupole mass spectrometers for differentiation of the three regioisomers of OH-MDMA.

Figure 1 shows the three distinct daughter ion mass spectra obtained by CID of the MH+ ions at m/z 402 using a triple quadrupole mass spectrometer (TQMS). The daughter ion mass spectra were recorded at an attenuation of each parent ion intensity by more than 90% following CID at a translational energy of about 24 eV (E|ab) and with argon as the collision gas. In comparison, CID of the MH+ ions of the three regioisomers using an ITMS all gave identical daughter ion mass spectra; each is characterized by an abundant ion at m/z 275. This suggests that the energy deposition by CID using an ITMS is lower than that obtained with TQMS. Since the structural differences of the three regioisomers are contained in their daughter ions at m/z 275, further CID of these ions using an ITMS were explored for their potential in differentiation of these regioisomers. Indeed, the three regioisomers can be distinguished by further CID of their daughter ions using an ITMS as illustrated by the three different granddaughter ion mass spectra in Figure 2. Comparison of the mass spectra obtained with an ITMS and a TQMS clearly indicate that similar series of ions are present but at different abundances in both mass spectra corresponding to each regioisomer. The overall CID efficiencies of the sequential mass analysis (MS/MS/MS) for 2-, 5- and 6-hydroxy-MDMA were 43, 67 and 41%, respectively, and are much higher than that typically obtained tandem-in-space mass spectrometers. MS/MS/MS analysis of hydrolyzed and derivatized dosed rat liver extract using an ITMS clearly identified 5- and 6-hydroxy-MDMA.

In conclusion, the three hydroxy-MDMA regioisomers can be distinguished by collisional mass spectrometry using ITMS and TQMS. However, MS/MS/MS is necessary for differentiation of the three regioisomers using an ITMS.

DETECTION OF HEROIN AND COCAINE RESIDUES BY
ION MOBILITY SPECTROMETRY

*Dean D. Fetterolf, FBI Laboratory, Forensic Science Research Unit, FBI
Academy, Quantico, Virginia, 22135; Brian Donnelly and Lynn D. Lasswell,
III, FBI Laboratory, Chemistry/Toxicology Unit, Washington, DC 20535

The President's National Drug Control Strategy calls for the
development of new technologies and the innovative adaptation of existing
technology for use in the war on drugs. As part of an ongoing research
effort the FBI Laboratory has been evaluating a number of new technologies
for use in counternarcotics and counterterrorism investigations. The part
per trillion vapor pressures of heroin or cocaine hidden in packages,
conveyances and on people requires extremely sensitive and selective
detection methods. Therefore, the sampling of particulate residue which
may be on surfaces offers a greater chance of detection.

We have been investigating the application of a commercially
available ion mobility spectrometer (IMS) known as IONSCAN (Barringer
Instruments, Inc., South Plainfield, NJ). Samples are collected on a 0.25
micron teflon membrane filter using a vacuum cleaner. The filter is then
thermally desorbed into the IMS. Sample collection requires less than 30
seconds and the analysis is completed in 3 seconds.

Figure 1 shows a block diagram of the IMS. A calibration compound,
nicotinamide, is admitted automatically with the sample. This serves as
an internal reference to which the mobility of the compounds of interest
are referenced. An audible and visual alarm, controlled by the
microprocessor, indicates the presence of a drug falling within a set of
user defined parameters such as mobility, full width at half maximum, and
intensity. The IMS has been shown to be stable over several weeks without
the need to adjust the alarm parameters. A portable PC is also used to
capture and store the plasmagrams for later review.

Table 1 shows the reduced mobilities for several of the common drugs
of abuse. Laboratory testing has determined the detection limits for
cocaine and heroin to be 5 ng and 15 ng, respectively. Nanogram limits of
detection are observed for a number of other drugs. As shown in Figure 2,
heroin (diacetylmorphine), O-6 monoacetylmorphine and morphine show
predictable behavior with successive losses of the acetate moiety.

Typical law enforcement and forensic applications include gathering
evidence for probable cause, search and seizure, forfeiture
investigations, and locating hidden narcotics. Sampling procedures for
examining vehicles, packages and people for hidden narcotics have been
developed. Typical screening applications include suspects under arrest,
prison inmates or their visitors. Cocaine residue can be detected on the
hands for at least 1.5 hours after brief contact with the drug. Simply
washing the hands failed to completely remove the drug residue.

The IMS can provide a quick screening of evidence. For example,
narcotics residue has been detected on the bookkeeping records of drug
dealers submitted to the FBI Laboratory for document examination. The
size and portability of the IMS can provide on the spot detection of
illegal drugs thus improving the law enforcement officer's efficiency.
Property obtained with proceeds from trafficking in illegal narcotics can
be seized and forfeited in civil proceedings. For example, cocaine
residue was found in the passenger compartment of a helicopter seized by
federal agents during an investigation. Cocaine residue has been detected
in automobiles following canine alert. In a number of cases, duplicate
samples were collected and confirmed by tandem mass spectrometry using a
Finnigan TSQ 70 tandem mass spectrometer.

This is a publication of the Laboratory Division of the Federal Bureau of
Investigation. The use of names of commercial manufacturers does not
constitute or imply endorsement, recommendation or favoring.

LSD, a popular psychoactive drug of the 1960's, continues today to be a significant drug of abuse. LSD is extremely potent (typical dosages of 40-120 ug) and undergoes rapid and extensive metabolism so that only about 1% of the parent drug is excreted in urine.\textsuperscript{1} Several metabolites have been previously identified,\textsuperscript{1} however, the major metabolic products in man have not yet been determined. As a result, analytical methods have been primarily aimed toward identification and quantitation of the parent drug and an N\textsuperscript{6}-demethyl metabolite, Nor-LSD. Due to low dosage and short half life, LSD often occurs at low pg/ml levels in biological fluids and has been a challenging analytical problem for toxicology laboratories and a concern for drug enforcement agencies.

Because of the complex nature of urine, blood, and other biological matrices, extraction and isolation of LSD yields samples with varying degrees of purity. GC/MS analyses often generate mass chromatograms which are complicated by contaminant peaks that inhibit identification of LSD and metabolites, as well as internal standards. In an effort to significantly improve the specificity for LSD and Nor-LSD over existing GC/MS assays,\textsuperscript{2} MS/MS in combination with several ionization methods has been examined. Relative MS/MS sensitivities were compared for CID of molecular ions in positive- and negative-ion modes, with sample introduction by GC and desorption chemical ionization (DCI). Ammonia and methane reagent gases for CI ionization were compared for each method. Underivatized LSD was analyzed by positive-ion DCI. Due to excellent electron-capture properties, trifluoroacetyl (TFA) derivatives of LSD and Nor-LSD were analyzed by GC/negative-ion CI; trimethylsilyl (TMS) derivatives of LSD, Nor-LSD, and Iso-LSD (a diastereomer of LSD) were evaluated using GC/positive-ion CI. Iso-LSD frequently occurs in synthetic preparations and is believed to be biologically inactive.\textsuperscript{3} All data was obtained with a Finnigan TSQ-70 tandem instrument. Optimum transmission and CID efficiency for selected daughter ions was systematically determined for each ionization method. Generally, Ar collision gas pressure corresponded to about a 50% transmission of the incident ion, while low-energy collisions were at 25 to 45 eV (ELAB). For both positive- and negative-ion CI, ammonia reagent gas generated significantly more intense molecular ions compared to methane for LSD, Nor-LSD, and their derivatives.

Positive-ion DCI/MS/MS for underivatized LSD affords excellent sensitivity, in part due to rapid desorption (1-2 sec). Multiple-reaction monitoring (MRM) of four daughter ions can be achieved at the 10-50 pg level, while full scan CID spectra can be obtained with 1.5 ng or less. Analysis by DCI/MS/MS is suitable for qualitative identification, but does not clearly distinguish LSD from Iso-LSD, both of which commonly occur in urine and blood specimens (e.g., Fig. 1).

The negative-ion CI ionization efficiency for the bis-TFA derivative of Nor-LSD is about 10 times greater than for LSD-TFA, and subsequent low-energy CID of M\textsuperscript{-} of Nor-LSD permits quantitation of several daughter ions at a level of 10-50 pg/ml urine. By comparison, CID analysis of LSD-TFA is considerably less sensitive and requires a 0.5-2.0 ng/ml range for quantitation. In addition, an inherent difficulty with the TFA derivative is the near-coelution of LSD and Iso-LSD, which often leads to ambiguities in identification and quantitation.

Positive-ion GC/MS/MS affords excellent specificity and sensitivity for MRM of several daughter ions of MH\textsuperscript{+} of LSD, Iso-LSD, and LAMPA (internal std.) (Fig. 1). An advantage of the TMS derivative is the clear chromatographic separation of LSD and Iso-LSD. Detection limits for m/z 353, 295, and 280 for LSD-TMS are in the 5-20 pg/ml range, while the limit of quantitation is 50-100 pg/ml urine. The principal dissociation pathways of these isomers are the same but relative ion intensities differ significantly (Fig. 1). Eliminations primarily involve the amide and piperidine-ring functionalities, as shown in Figure 2, in which losses of CH\textsubscript{3}NCH\textsubscript{2} (CID of N\textsuperscript{6}-methyl-\textsubscript{d}\textsubscript{2} LSD supports loss of N\textsuperscript{6} methyl group from the piperidine ring), diethylamide, and diethylamine from m/z 353 are observed from MH\textsuperscript{+}. The CID spectrum of MH\textsuperscript{+} of Nor-LSD-TMS shows corresponding losses of CH\textsubscript{3}N-TMS, diethylamine, and diethylamide. Nor-LSD predominantly acquires a mono-TMS derivative and GC/MS/MS sensitivity is slightly less compared to LSD. The GC/MS/MS assay has also been demonstrated for the analysis of LSD in blood with comparable specificity and sensitivity.

In summary, MS/MS provides a high degree of specificity with sufficient sensitivity for analysis of LSD and LSD metabolites at the low pg/ml level in urine and blood. The positive-ion
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

GC/MS/MS method markedly eliminates problems associated with interference peaks that often occur by GC/MS and affords a high level of confidence in the identification of LSD and Nor-LSD.

Glucuronide Conjugates of Carvedilol: Structure Characterization Using Acetylation Derivatives to Determine Positions of Glucuronidation

William H. Schaefer and Anne M. Goalwin, SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406.

Introduction

Conjugation with glucuronic acid is a common route by which many drugs and xenobiotics are metabolized prior to excretion. Several different nucleophilic functional groups, including hydroxyls, phenols, thiols, amines, and carboxylic acids, may be susceptible to conjugation with glucuronic acid. Determining the positions of glucuronidation can be difficult for xenobiotics which contain both amine and hydroxyl groups. Structures of glucuronide conjugates can sometimes be determined using MS/MS, NMR, or inferred from their stability (or instability) under acidic or basic conditions; however, these approaches each have inherent limitations.

An alternative approach for distinguishing between N- and O-linked glucuronides and determining positions of glucuronidation is described in this presentation. The method utilizes selective acetylation of hydroxyls and/or amines with acetic anhydride under different conditions and characterization of the acetylated products by FAB mass spectrometry. Nucleophilic groups, such as amines and hydroxyls, are readily acetylated in non-aqueous solution by acetic anhydride in the presence of a base, such as pyridine. In aqueous solution, the more nucleophilic amine groups are rapidly acetylated by acetic anhydride, but water (which is present in great molar excess relative to the hydroxyl groups on the metabolites) competitively prevents acetylation of the metabolite hydroxyl groups. Amines and hydroxyl moieties of the metabolites which are conjugated to glucuronic acid are blocked and will not be acetylated. Those which are not conjugated are exposed for acetylation, and can be acetylated depending on the conditions used. After completion of the acetylation reaction, a small portion of the reaction mixture is applied directly to the probe of the mass spectrometer and analyzed by FAB mass spectrometry. N- and O-linked glucuronides can be identified based on the number of acetyl groups which are added to the metabolite under aqueous and nonaqueous conditions.

This method has been used to characterize O- and N-linked glucuronide conjugates of carvedilol, including a carbamic acid glucuronide metabolite. Carvedilol contains an aliphatic hydroxyl, an aliphatic amine, and a carbazole amine, which are all potential sites for glucuronidation. The reaction of carvedilol with acetic anhydride in pyridine and aqueous solutions were investigated first to establish the reactivities of different functional groups on the molecule. The results were used as a reference for interpreting the results obtained for the metabolites. Carvedilol, which possesses β-adrenergic receptor antagonism and non-specific vasodilation activities, is currently being developed for treatment of hypertension and angina. It is metabolized extensively in dog and rat via both oxidation and conjugation pathways.

Experimental

Metabolites 2 and 11 were isolated from rat bile by HPLC. Metabolite 10 was also identified in rat and dog bile, but material used in this analysis was prepared from incubation of carvedilol with dog microsomes fortified with UDPGA and purified by HPLC.

Metabolites were acetylated using acetic anhydride in pyridine or aqueous solution as follows. Approximately 10 µg of metabolite was dissolved in 50 µl of pyridine/acetic anhydride (1:1) and reacted 15 min. Acetylation in aqueous solution was accomplished by dissolving approximately 10 µg of metabolite in 50 µl H2O/ethanol/diisopropylethylamine
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

(50:50:1), adding 1 ul of acetic anhydride/acetonitrile (1:9), and reacting for 15 min. An aliquot of the reaction mixture was loaded directly onto the probe and the products were analyzed by FAB mass spectrometry using either glycerol or a mixture of dithiothreitol and dithioerythritol (4:1) as a matrix.

Results and Discussion

Acetylation of carvedilol with acetic anhydride in pyridine yielded a diacetylated product with an [M+H]+ at m/z 491 (Fig. 1), 84 u higher than that of carvedilol (m/z 407). When carvedilol was acetylated in aqueous solution, only one acetyl group was added at the aliphatic amine to produce an [M+H]+ at m/z 449 (Fig 2). The carbazole nitrogen was not acetylated in either reaction.

Metabolite 10 was identified as a glucuronide conjugate of carvedilol and showed an [M+H]+ at m/z 593 and an [M-H]+ at m/z 581. Following acetylation in pyridine, M10 showed an [M+H]+ at m/z 793 (Fig. 3), 168 u higher than that of unreacted M10. This product resulted from addition of four acetyl groups to M10. Three acetyl groups added to the hydroxyls of the glucuronyl moiety and one added to the carvedilol portion. To determine whether the aliphatic hydroxyl or amine of carvedilol had been acetylated in pyridine, M10 was reacted with acetic anhydride in aqueous solution. The mass spectrum for this product, in figure 4 showed an [M-H]+ at m/z 623 which indicates the addition of one acetyl group to the aliphatic amine of M10. Thus, the glucuronide moiety of M10 was linked to the aliphatic hydroxyl of carvedilol. NMR data confirmed this assignment.

Three other glucuronide conjugates of carvedilol (M2, M9, and M11) were characterized using this approach. Metabolite 9 was identified as the diastereomer of M10 and showed essentially identical results from acetylation analyses. Metabolite 2 was identified as a carbazole N-linked glucuronide of carvedilol. Five acetyl groups were added to M2 upon acetylation in pyridine. Three acetyl groups added to the glucuronyl moiety and two acetyl groups added to the carvedilol moiety. Metabolite 11 was characterized as a carbamoyl glucuronide conjugate of carvedilol. The acetylation analyses confirmed that metabolism had occurred at the aliphatic amine. This simple, rapid method should be generally applicable to distinguish between N- and O-linked glucuronide conjugates.
Utilization of FAB MS in the Characterization of Amiloride Analog Binding Protein Photoaffinity Probes.

Department of Pharmacology, Vanderbilt University, Nashville, TN 37232

Introduction

The diuretic Amiloride (Figure 1), has been widely studied with respect to its inhibition of Na\(^+\)/H\(^+\) exchange and the allosteric modulation of the \(\alpha_2\)-adrenergic receptor.\(^1\) Extensive structure activity studies have shown that alkyl substitution of the 5-amino group results in an increase in activity over that of Amiloride.\(^4\) Researchers have also shown that substitution of the guanidine amine results in the loss of activity. This study has focused on the development of some amiloride analogs which possess a photoaffinity moiety that can be easily radiolabeled. Using the potent diuretic drug ethylisopropyl amiloride as a template, several analogs have been developed which are substituted at the 5-amino (R\(_1\)) and the guanidine (R\(_2\)) positions. These analogs will be tested for biological activity and then be used to covalently bind to the Amiloride binding site of the \(\alpha_2\)-adrenergic receptor to aid in the mapping of the binding pocket. Throughout the synthesis of these analogs both positive and negative FAB were used extensively in the characterization of intermediates and final products as well as in the exact mass determination of final products. This proved to be necessary due to the paucity of structural information which was obtained from \(^1\)H and \(^13\)C NMR spectroscopy.

Experimental

Methyl 3-amino-5,6-dichloropyrazine carboxylate was reacted with an appropriate amine to afford the 5-amino substituted methylpyrazine carboxylate. Reaction with guanidine free base resulted in the formation of the 5-amino substituted Amiloride analog. Reaction with N-hydroxysuccinimidyl-4-azidosalicylic acid resulted in the preferential formation of the guanidine (R\(_2\)) substituted analog with a small amount of bis analog with substitution in both the R\(_1\) and R\(_2\) positions. Reaction of N-hydroxysuccinimidyl-4-azidosalicylic acid with the 5-amino substituted methylpyrazine carboxylate followed by addition of guanidine afforded the analog possessing preferential substitution on the R\(_1\) position.

Results and Discussion

Mass spectrometry was carried out on the final products in order to provide confirmation of structure. Since the final products were nonvolatile and too unstable for GC or DCI/MS analysis, other forms of soft ionization were investigated. Electrospray MS gave intense singly charged molecular ions at moderate exit lens energies. At higher exit lens energies the samples gave several protonated fragment ions. The fragmentation pattern did not give an absolute confirmation of structure but rather a pattern common to these types of substituted pyrazines. Positive and negative FAB proved to be the technique which afforded information which allowed the structural identification of the compounds. Figures 1 & 2 show representative positive FAB spectra showing the structural differentiation of two photoaffinity analogs. It can be seen in Figure 2 how FAB was able to determine the structural difference as a result of the characteristic fragment at m/z 327 which resulted from loss of the terminal amine in the 5 position. This gave a definitive differentiation between the two structural isomers shown.
Figure 1. Positive FAB spectra of analog 1 showing major fragments at $m/z$ 315 and 256. Peaks marked by (*) indicate glycerol matrix peaks.

Figure 2. Positive FAB spectra of analog 2 showing major fragments at $m/z$ 327, 315 and 256. Peaks marked by (*) indicate glycerol matrix peaks.

Introduction
AC 301,423 (1) is a potent new antiparasitic agent. It has a structure which is closely related to the milbemycins\textsuperscript{1,2} and avermectins\textsuperscript{3} which have a novel mode of action against a broad spectrum of nematode and arthropod parasites of animals.\textsuperscript{4} Common features of these compounds are a fused cyclohexene-tetrahydrofuran ring system, a bicyclic 6,6-membered spiroketal, and a cyclohexene ring fused to the 16-membered macrocyclic lactone ring. It was expected that 1, its analogs, homologs, and metabolites would show similar fragmentation patterns in the El mass spectrum, allowing compound modifications to be identified. An extensive study of the El fragmentation pattern of 1 was undertaken in order to understand its fragmentation pattern so that related compounds could be more readily identified.

Experimental
Structural assignments for these compounds were determined from the mass spectral data generated from a Finnigan-MAT TSQ 4600 triple-stage-quadrupole mass spectrometer. High resolution El/MS and high resolution thermospray/MS were obtained using a Fourier Transform Ion Cyclotron Resonance (FTICR) spectrometer. This provided the elemental compositions for each of the fragment ions. The instrument used was built at Cyanamid and has been described previously.\textsuperscript{5,6}

Results and Discussion
The El spectrum of AC 301,423, which was generated on the quadrupole mass spectrometer, is shown in Figure 2. The identity of many of the ions in this spectrum were determined by FTICR/MS analysis, which was used to generate high resolution El/MS and thermospray/MS data on the fragment ions of AC 301,423. This provided the elemental composition for each of the fragment ions observed. The peak at \textit{m/z} 527 is the loss of CyH\textsubscript{12}O from the molecular ion, which corresponds to the loss of the C-25-oxygen and the C-25 side chain. To confirm the origin of this fragment, two compounds (2,3) similar to AC 301,423 were analyzed. These compounds differ in the side chain on C-25 with R\textsubscript{4} = ethyl for 2 and methyl for 3 instead of isopropyl. In the case of 2, loss of C\textsubscript{6}H\textsubscript{10}O was observed while loss of C\textsubscript{5}H\textsubscript{9}O was observed for 3. This loss is a characteristic fragmentation route for this class of compounds and can be used to identify the composition of the C-25 side chain. It is proposed that tautomerization of the methoxime makes the parent ion susceptible to a retro-Diels-Alder reaction which results in the loss of the C25 side chain. MS/MS experiments showed that the \textit{m/z} 527 fragment ion loses -OCH\textsubscript{3} to form the ion at \textit{m/z} 496. Loss of CO\textsubscript{2} produces the ion at \textit{m/z} 452 which is followed by consecutive losses of H\textsubscript{2}O (\textit{m/z} 434 and \textit{m/z} 416). The \textit{m/z} 496 ion can lose C\textsubscript{6}H\textsubscript{8}O\textsubscript{3} via a retro-Diels-Alder fragmentation pathway to produce the ion observed at \textit{m/z} 388. The structural assignment of the \textit{m/z} 248 ion is based on the elemental composition obtained from the high resolution mass spectrum. Loss of C\textsubscript{6}H\textsubscript{8}O\textsubscript{3} from the parent ion produces the ion observed at \textit{m/z} 511. This fragmentation is unaffected by changes in
the C-25 side chain. When R₂ is ethyl (4) the corresponding ion at m/z 525 is observed showing that this part of the molecule is not involved in the fragmentation. Substitution of the C-4 methyl with an ethyl group (5) increases this fragment loss by 14 resulting in an ion at m/z 511. This evidence supports a McLafferty rearrangement followed by a retro-Diels-Alder reaction. The retro Diels-Alder reaction involving the C-25 side chain occurs giving rise to the ion at m/z 399. MS/MS experiments showed that the m/z 511 fragment ion produced from the molecular ion of AC 301,423 losses H₂O and -OCH₃ to produce the ions observed at m/z 493 and 480, while consecutive losses of H₂O and -OCH₃ produce the ion observed at m/z 462.

Conclusion

The assignments for the El fragment ions of AC 301,423 were based on the high resolution mass spectrum, MS/MS experiments, and by studying the fragmentations of structurally similar compounds. Together, these El fragment ions provide useful information for the structural assignments of homologs and metabolites of AC 301,423.

References

The analysis of human hair for drugs of abuse is a promising alternative to urine drug testing. Hair provides a long-term record, up to many months, of previous drug use, in contrast to urine, which tests positive for only up to a few days for most drugs. Urine remains a better marker for determining whether erratic behavior or an accident might relate to use of a drug, because drugs or their metabolites would probably be in the urine at the time of the incident, but would not show up in the hair for several days. However, in situations in which individuals are tested regularly to ensure that they are drug-free, hair analysis may become the preferred option. The amount of hair required for analyses is small and can be readily taken from the scalp with no embarrassment or significant cosmetic effects.

Our laboratory has been investigating analytical aspects of the analysis of hair for drugs of abuse. Our efforts have concentrated on morphine (heroin metabolite), cocaine, and cocaine metabolites. One of the surprising findings to date is that much more cocaine than its metabolites is found in hair. Because cocaine is readily decomposed at pH > 7, extraction steps must avoid basic conditions. We have found that extractions with 0.1 N HCl at 45 °C for 20 hours efficiently and reproducibly remove the drugs from the hair. Digestion of the hair with proteinase K at a pH of 6.2 and 37° C is also effective for getting the drugs into solution. Once the drug is in solution, the sample can be treated similarly to a urine specimen. We put it through a solid-phase extraction cartridge, convert the drug to a TMS derivative (except cocaine which is not derivatized), and inject (splitless) it into a GC/MS system equipped with a non-polar, fused silica capillary column and operated in the EI mode with selected ion monitoring. Under these conditions, cocaine and morphine levels down to approximately 1 ng per mg of hair can readily be detected for a 10 mg sample of hair.

We have found some improvement in sensitivity with methane positive ion chemical ionization (CI) for cocaine and benzoylecgonine (BE), a cocaine metabolite. Figure 1 shows the responses from a drug user's hair of the (M+H)+ ions for cocaine, BE, and their deuterated analogs as internal standards. These levels are approximately 0.5 ng/mg; thus much lower levels should be detectable.

The ethyl ester of BE has been suggested as a possible cocaine metabolite formed in the liver if alcohol is also present in the blood. Positive ion CI was used to look for this metabolite in the hair of cocaine users. Figure 2 shows the mass spectrum of a peak at the correct retention time for this metabolite. The ions at m/z 318 and 196 correspond to the (M+H)+ ion and the (M+H-C6H5COOH)+ ion, respectively, for the ethyl ester of BE. This metabolite was found in two of five hair samples that were positive for cocaine.

Because the sample preparation for hair analysis by GC/MS is time-consuming, efforts have been made to use direct probe MS/MS for screening hair samples. When we tried this technique on powdered hair samples, the technique worked well. That is, hair with cocaine present was easily distinguished from drug-free hair. However, when short pieces of hair were tried, the results were not as definitive. The technique might be made to work reliably for screening samples, but it is unlikely that it will ever be quantitative.

NIST has conducted two interlaboratory comparison studies involving laboratories interested in the analysis of hair for drugs of abuse. For the first exercise, laboratories were sent eight samples of cryogenically powdered hair for analysis by their methods. The samples included drug-free hair, drug-users' hair, and hair that had been fortified with drugs. Most of the laboratories used acid extractions, with others choosing enzyme digestions that dissolve the hair. GC/MS or a combination of radioimmunoassay (RIA) and GC/MS were the analytical techniques of choice for most laboratories, although there is some work using MS/MS with or without prior extraction. Qualitatively, the results were excellent, with no false positives reported and only one laboratory out of eight missing some of the true positives. Quantitatively, CV's ranged from 15-27%, with results slightly better for morphine than for cocaine. For the second exercise, the laboratories were each sent eight samples of hair cut into short lengths (2-5 mm, typically). Two of the ten laboratories, neither of which used GC/MS, reported some false positives for morphine. There were no false positives for cocaine. Most of the
seven instances of failure to find drugs present also involved morphine. Quantitatively, the results were much more scattered than they had been for the hair powder, a reflection of the greater difficulty in extracting the drug from intact hair segments and possibly the poorer homogeneity of the samples.

One of the most important questions that must be resolved is the differentiation of drugs in hair as a result of drug use from drugs present through environmental contamination. We found that it is very difficult to remove all of the cocaine deposited on hair through vapor deposition. Washes with methylene chloride were the most effective treatments found for removing the vapor-deposited cocaine, but some still remained, even after three 15 min washes. This level of treatment also extracts some cocaine in the hair through drug use. The most promising approaches to resolving this question appear to be finding metabolites that come only from drug use or measuring ratios of drugs found in the hair to drugs found in the wash solutions.

Another environmental aspect involves the effect of various hair treatments on drug levels. We have found that strong solutions of hydrogen peroxide significantly reduced cocaine levels in hair. Other treatments found to reduce the levels, in decreasing order of effectiveness, include permanent waves, shampoos, and salt water. Initial experiments have been with harsher conditions than would normally be applied to hair. Further work will determine the effects of more reasonable treatment regimes.

For the analysis of hair for drugs of abuse to be accepted, laboratories will have to demonstrate a high level of accuracy, both qualitatively and quantitatively. To this end, there is a need for reference materials consisting of human hair with known concentrations of drugs of abuse. NIST is now developing two drugs-in-hair reference materials, one of which will be a powdered hair material and the other will be a short hair segment material. From our own testing and from results in the interlaboratory studies, it appears that hair fortified with drugs, by soaking in dimethylsulfoxide solutions of the drugs, is an acceptable surrogate for drug users' hair. With this material, it is much easier to achieve reasonably homogeneous concentrations than would be the case with drug users' hair where the levels vary considerably within the hair of one individual and even more between individuals.

Figure 1: SIM of cocaine and benzoylecgonine (BE) in human hair using methane positive ion chemical ionization. Drug levels are approximately 0.5 ng/mg of hair. The traces from the top are the \((M+H)^+\) ions for cocaine, cocaine-d\(_3\), BE-TMS, and BE-d\(_3\)-TMS, resp.

Mass spectrometric analyses of monoamine oxidase inhibitors: Can routine quantitative trace analyses by gas chromatography-mass spectrometry (GC/MS) be done on a LC/MS machine?

*W. Bart Emary, Darlene K. Satonin, Jonathan A. Ragner, G. Douglas Sproles, Marion Merrell Dow Inc., Indianapolis, IN 46268-0470

Instrumental conditions must be optimum to obtain precise and accurate peak ratios for trace level GC/MS analysis of drugs isolated from biological matrices. For GC/MS, the most frequently used sources are either electron impact (EI) or chemical ionization (CI). We have investigated the possible negative effect of introducing semivolatile compounds used for thermospray and FAB on GC/MS instrument performance.

The concentrations of two monoamine oxidase inhibitors (MDL 72,974 and MDL 72,394) in rat and monkey plasma have been measured in separate GC/MS studies. Table I shows typical precision and accuracy results of a quantitative study on the monoamine oxidase B inhibitor, MDL 72,974 in rat plasma. These data were obtained using GC/MS before thermospray or FAB were installed on the instrument.

Table II shows precision and accuracy data for a quantitative study of a monoamine oxidase type A inhibitor, MDL 72,394 and its metabolite MDL 72,392 in monkey plasma. Standard curves were obtained from 0.5-200 ng/mL in rat plasma and from 2-400 ng/mL in monkey plasma shown below. These data were collected while intermittently using thermospray and FAB for periods of time of up to one week. We have used the two desorption ionization sources for metabolite identification and for work on thermally labile compounds such as peptides and antibiotics. Our results thus far have indicated the performance of the mass spectrometer does not appear to seriously degraded in GC/MS mode after using semivolatile compounds during FAB and thermospray.

SIMULTANEOUS GC/MS ANALYSIS OF LABELED AND UNLABELED NITROGLYCERIN IN HUMAN PLASMA FOR DETERMINATION OF TRANSDERMAL FLUX RATES

M. Leal, J. Joshi, D. Gaudry, A. Pirano, J. Morgan, M. Hayes, and M. Powell

Drug Development Department, Pharmaceuticals Division
Ciba-Geigy Corporation
Ardsley, New York 10502

Nitroglycerin (glycerol trinitrate) is a potent vasodilator used in the treatment of angina. The kinetic behavior of nitroglycerin is such that major fluctuations in plasma levels are produced with changes in posture, physical activity and ingestion of food. Historically, the intrinsic variability in generated nitroglycerin plasma level data made it impossible to produce acceptable statistical power in bioavailability/bioequivalency studies. The simultaneous administration of transdermal nitroglycerin and intravenous \([^{15}N]\)-nitroglycerin should permit bioavailability/bioequivalency to be established with sufficient power in a reasonable number of subjects.

A GC/MS method was developed and validated to simultaneously quantitate plasma levels of unlabeled and stable isotope labeled nitroglycerin. This method utilizes 1,2,4-butanetriol trinitrate as the internal standard. Samples (1 ml) were extracted with pentane/ethyl acetate (90:10). Extracts were concentrated and analyzed directly by GC/MS. Separation was accomplished on a (0.5 u) methyl silicone capillary column (25 m x 0.32 mm I.D.). Mass spectrometry was carried out under negative ion methane Cl conditions with selected ion monitoring of fragment ions at m/z = 62, 62 and 63 for nitroglycerin, 1,2,4-butanetriol trinitrate and \([^{18}N]\)-nitroglycerin, respectively.

Calibration curves were generated using \(Y = AX^8 + C\) as the regression model and were represented by a plot of the amount added versus the measured peak area of labeled or unlabeled nitroglycerin/1,2,4-butanetriol trinitrate. The limit of quantification (LOQ) was 50 pg/ml. Figure 1 shows a chromatogram at the LOQ.

Recovery and reproducibility assessments indicate good accuracy and precision over the validated concentration range of 50 to 1000 pg/ml. Table 1 contains the inter- and intra-day accuracy and precision data for nitroglycerin and \([^{15}N]\)-nitroglycerin respectively, expressed as mean percent found and percent CV. Over the entire concentration range the inter-day precision was between 1.0% and 10.8% for nitroglycerin and between 0.48% and 9.9% for \([^{15}N]\)-nitroglycerin. Although the intra-day precision was <15% in most cases, there were sporadic instances where values up to 22% were noted.

A two-treatment, randomized crossover study was designed to compare the in vivo performance of a new investigational transdermal system with a commercially available system (Transderm Nitro-10\(\text{R}\)) in seven healthy male volunteers. Each subject received one of two dosing sequences, investigational followed by commercial or commercial followed by investigational. \([^{15}N]\)-Nitroglycerin was simultaneously administered as an infusion at a constant and known rate to obtain an estimate of systemic clearance. Both transdermal systems exhibited plasma profiles with significant fluctuations in plasma concentrations. Since these fluctuations were also noted in the plasma profile of the stable isotope infusion, this suggests that the random fluctuations observed reflect variations in clearance with time rather than changes in delivery from the transdermal system. Figure 2 is a representative drug profile from a typical subject given one of the unlabeled transdermal systems and a simultaneous stable isotope labeled infusion.

APPLICATION OF AUTOMATED GC/MS FOR THE QUANTITATIVE ANALYSIS
OF CGS 18102A IN PLASMA

M. Leal, M. Hayes, H. Lau and M. Powell
Development Department, Pharmaceutical Division,
CIBA-GEIGY Corp., Ardsley NY 10502

CGS 18102A, Figure 1, a novel hexahydrobenzopyridine, has a mixed pharmacological profile of 5-HT-1A agonist and 5-HT-2 antagonistic properties. Based upon these mechanisms, the compound is predicted to have anxiolytic efficacy with possible efficacy in depression.

An analytical method for the determination of CGS 18102A in human plasma has been developed and validated. The method is based on gas chromatography/mass spectrometry (GC/MS) and utilizes CGS 18416A (Figure 1) as the internal standard. Samples (1 ml) were extracted with pentane/ethyl acetate (75:25). Extracts were then concentrated and analyzed directly by GC/MS. Separation was accomplished on a (1 u) methyl silicone capillary column (30 m x 0.32 mm I.D.). GC/MS was carried out under positive ion ammonia CI conditions, with selected ion monitoring of the [M+H]⁺ ions (m/z = 262 and 248) for CGS 18102A and CGS 18416A, respectively.

Calibration curves were prepared in duplicate at the following concentrations: 0.2, 0.5, 1, 5 and 20 ng/ml. Calibration curves were generated using weighted linear regression of the measured peak area ratios of CGS 18102A/CGS 18416A versus concentration. A summary of the calibration curve data is shown in Table 1. An average correlation coefficient of 0.992 was obtained for CGS 18102A, indicating a good fit to the weighted linear regression model. The mean slope data had a coefficient of variation of 7.7% for CGS 18102A.

The overall accuracy and precision of the method was determined by analyzing quality control samples (prepared in advance and stored frozen) spiked with CGS 18102A at 0.2, 0.8, 2 and 20 ng/ml in replicate (N=4) on each analysis day. The overall accuracy was 103.0% for CGS 18102A. Table 2 contains the calculated inter- and intra-day precision for CGS 18102A expressed as mean percent CV.

The method was applied to a single-blind, ascending multidose safety and tolerability study conducted in eight normal healthy male volunteers. Five doses of CGS 18102A were administered (1, 5, 10, 20 and 30 mg) two times a day (b.i.d) for five consecutive days at each dose level (25 days total). At the first four doses, blood for determination of trough plasma levels of CGS 18102A were collected on day 5 at 0 hr and 12 hr. At the highest dose (30 mg) plasma profiles were generated over 24 hrs. The maximum concentration found was 6 ng/ml. Large subject variability was noted with respect to half-life and AUC.
ANALYTICAL METHODOLOGY FOR THE DETERMINATION OF TRICHLOROCARBANILIDE IN HUMAN BLOOD SAMPLES

Robert G. Orth, Jay M. Wendling, Sally A. Walker, Jon R. Wehler, Monsanto Company, 800 N. Lindbergh Blvd., St. Louis, Missouri 63167

Trichlorocarbanilide (TCC) is an active ingredient in deodorant soaps. Researchers have shown that small amounts of TCC are absorbed through the skin (1). In humans, TCC is primarily metabolized to N-glucuronides and the sulfate conjugate of 2'-hydroxy-3,4,4'-TCC (2,3). A methodology for the analysis of the latter metabolite has been published (4) but portions of this method are cumbersome and recoveries are poor. The method reported here utilizes similar techniques previously reported (4) but was found to significantly improve recoveries and decrease sample preparation and analysis time by a factor of four. The method involves chemical cleanup of the plasma followed by a two-step derivatization process. The method was required to have detection limits of 1 nanogram per mL of plasma and be highly specific for the analyte. Thus a high resolution gc/ms approach was taken.

The analytical approach involves 3 steps chemical isolation, hydrolysis of the TCC-sulfate followed by derivatization with MSTFA, and analysis on high resolution gc/ms. Isolation of the TCC-sulfate was carried out by spiking the plasma with d6-TCC-sulfate and filtering the plasma. The plasma sample was then added to a 0.5 g octadecylsilane column along with 0.5 mL rinsate of 0.5 M potassium acetate. The column was washed with two three mL portions of 0.5 M potassium acetate followed by 1 mL water. The column is washed with 0.55 mL of 3:1 methanol to water which is followed by 1 mL 50% acetonitrile/water. TCC sulfate is eluted with 1 mL 50% acetonitrile/water and filtered. The acetonitrile/water is removed under a stream of nitrogen at 50 °C. The hydrolysis is accomplished by adding trifluoroacetic acid and heating at 40 °C for 15 minutes. The sample is dried again and derivatized with 0.02 mL of a MSTFA solution containing 1% pyridine and heated at 60-100 °C for 5 minutes.

The gc/ms was obtained using a DB-5 column and a VG-ZABE operated at 36 eV electron impact and a mass resolution >5000. The mass spectrometer was operated in selected ion monitoring. The masses monitored included 548, 546, and 533 for the TMS-TCC and 546 and 556 for d6-TMS-TCC. The criteria for selectivity was based on retention time as compared to the d6-TMS-TCC, the chlorine isotopic ratios, and the presence of the fragment peak at 533.

The method was validated by spiking a pooled plasma sample and determining the standard addition curve for the set of spikes. This standard addition curve was then compared with a standard curve obtained by hydrolysis and derivatizing a set of TCC-sulfate standards. The results are shown in Figure 1. As can be seen there is no matrix effect indicated since the slopes of the two curves are the same within experimental error. The only difference is in the intercept indicating that this pooled sample contains a background level of TCC-sulfate. In addition, to the standard addition comparison a spiking recovery program was completed the results of which are shown in Table 1. All the spikes except one were recovered within the error limits of the measurement. The detection limit was found to be 0.2 ng/mL where as the limit of quantitation which can vary with sample was in general no higher than 1 ng/mL.

Introduction
Benzodiazepines have been prescribed over the years for their anxiolytic, sedative hypnotic, anticonvulsant and muscle relaxant properties. Since the introduction of chlordiazepoxide in 1961, over 3000 of these compounds have been synthesized and about 35 are in clinical use throughout the world today (1). Although these are relatively safe drugs they can be insidious and must be used with care. High doses for prolonged periods of time can lead to dependence or if combined with alcohol or other CNS depressants can produce coma and death (2-4). Because of the wide availability of these drugs the clinical and forensic toxicology laboratory must be able to screen for, confirm the presence of and quantitate benzodiazepine urinary excretion products.

The urinary benzodiazepines as a group are difficult to identify and quantify. They are extensively metabolized making it sometimes difficult to identify (among the multitude of possibilities) the parent compound ingested. The newer members of this drug class (including alprazolam and triazolam) are therapeutically effective at much lower dosage levels and generally appear in the urine at lower levels as well. Of special interest are the alprazolam samples because of their frequent occurrence and the identification of α-hydroxyalprazolam in human urines by GC/MS is not well documented in the literature.

Materials and Methods

Chemicals
Pure samples of the α-hydroxy metabolites of alprazolam and triazolam were generously supplied by the Upjohn Co. The fluazepam metabolite, 2-hydroxyflurazepam, was generously supplied by Hoffman LaRoche. The remaining benzodiazepine compounds (2H5-oxazepam, oxazepam, temazepam, and lorazepam) and β-glucuronidase were obtained from the Sigma Chemical Co. Derivatives were formed using N-methyl-N-t-butyl-dimethylsilyl trifluoroacetamide (MTBSTFA + 1% BDMCS) which was obtained from the Regis Chem. Co.

Sample Analysis of Unknowns

With each batch run, urine standards (25, 50, 100, 300 and 600 ng/mL), a positive control (200 ng/mL) and a negative control (certified blank urine) were prepared. Unknown specimens (5 mL) were first hydrolyzed by adding 1.0 mL of a 1M sodium carbonate solution. Benzodiazepine compounds were extracted with 10 mL of 20% n-butyl alcohol. The tubes were returned to the autosampler and evaporated to dryness. The control mix was then added to this urine extract matrix, blown to dryness and derivatized as normal.

Enzymatic Hydrolysis, Extraction, and Derivatization Procedure

Complete t-butyldimethylsilyl- derivatization was achieved in the capped centrifuge tubes using 50 μl MTBSTFA and 50 μl of ethyl acetate with heat at 90°C for 60 min. The tubes were then cooled, the autosampler was loaded and 1μl of each sample was injected.

Assay Statistics

The limit of detection (LOD) and the limit of quantitation (LOQ) were calculated from the signal to noise ratio (S/N) of the quantitation ion for each analyte. The LOD and LOQ were defined to have a signal to noise ratio of three (S/N = 3) and ten (S/N = 10), respectively. Recoveries (extraction efficiency) were calculated as the ratio of peak area in the extracted control to non-extracted control, each in triplicate, multiplied by 100. The non-extracted control was made up by extracting certified blank urine and blowing the organic to dryness. The control mix was then added to this urine extract matrix, blown to dryness and derivatized as normal.

Sample Analysis of Unknowns

Thirteen urine specimens, either screened positive for benzodiazepines by EMIT®, or with an accompanied history of benzodiazepine use, or both, were processed by the described procedure above for confirmation. To document the detection of α-hydroxytriazolam, a single 0.25 mg Halcion tablet was ingested and urine was collected eight hours later, the following morning.
Results and Discussion
Table 1 lists the ions that were monitored by SIM and the retention times of the individual compounds. The full spectrum of these compound derivatives contains only a few intense ions. This is a characteristic feature of MTBSTFA (5) and may be beneficial for the analysis of low concentrations of α-hydroxylalprazolam and α-hydroxytriazolam seen in urine after therapeutic doses. The ions in Table 1 have been monitored in our laboratory through many trial runs, always with blanks and controls, and these ions produce stable, consistent ratios without any interfering substances. Coefficient of variations (n=6) for the quantitation of a 200 ng/mL control were <5% and ±11% for within run and between run trials, respectively. The extraction efficiencies averaged 98% (range 91-107%) and the LOD and LOQ were both <10 ng/mL for all compounds. The high temperature GC conditions and short column length (15 m) are necessary to elute these compounds with symmetrical peak shape in a very short amount of time (within 6 min).

Quantitation and ion ratio data for the thirteen urine specimens were collected. Seven of these urines contain α-hydroxylalprazolam ranging in concentration from 49-1264 ng/mL (mean = 390). One specimen contained both α-hydroxyalprazolam (594 ng/ml) and oxazepam (476 ng/ml) oxazepam (3897 ng/ml) and temazepam (2685 ng/ml). Another one contained a very high concentration of 2-hydroxyethylfurazepam (2301 ng/ml). Five different specimens contained oxazepam ranging in concentration from 72-3897 ng/mL (mean = 1391). Temazepam (2-hydroxydiazepam or Restoril®) was present whenever oxazepam was in high concentration in all but one specimen. This specimen (oxazepam = 2620 ng/ml) had a self-reported history of clorazepate (Tranxene®). One specimen contained α-hydroxytriazolam (106 ng/ml) after the ingestion of a single 0.25 mg tablet of triazolam (Halcion®) eight hours earlier. Three specimens (49 and 62 ng/ml for α-hydroxyalprazolam and 106 ng/ml for α-hydroxytriazolam) were screened negative by the EMIT® assay but had absorbance readings that were elevated above the negative control. All other specimens were positive by EMIT®. All of the ion ratios used to confirm identity were within ±15% of those in Table 1. The usual limits of acceptability as positive are ±20%.

Introduction

Platinum (Pt) compounds are important anti-neoplastic drugs. Clinical evaluations of these drugs are dependent on the availability of precise, accurate and sensitive methods for Pt determination in urine, plasma ultrafiltrate and whole plasma. As an example, urine concentration of cisplatin is closely related to the non-protein bound concentration in blood. Plasma ultrafiltrate and whole blood concentrations of cisplatin provide information on free drug and protein bound drug, respectively. Since gas chromatography-mass spectrometry (GC-MS) is becoming more widely available in clinical laboratories, we have reported GC-MS methodology using lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), as the chelating agent for the measurement of Pt (1). In the present work, Pt concentrations in plasma and urine from a cancer patient treated with cisplatin were determined by isotope dilution GC-MS and the results were compared to those obtained by the more commonly used method of electrothermal atomic absorption spectrometry (EAAS).

Experimental

The $^{192}$Pt-enriched Pt metal (50 atom % $^{192}$Pt, Oak Ridge National Laboratory) used as an internal standard for isotope dilution was dissolved in a minimum amount of aqua-regia at 70°C and the solution was taken to volume with dilute HCl. The internal standard solution was calibrated by reverse-isotope dilution GC-MS using natural Pt as the primary standard.

The known volume of the sample (1 mL of urine, 200 μL of ultrafiltrate or whole plasma) was mixed with a weighed amount of $^{19}$Pt internal standard solution followed by digestion with concentrated HNO$_3$ and concentrated H$_3$PO$_4$ (5:1, v/v) and 50% H$_2$O$_2$. Formic acid was used to destroy the residual HNO$_3$. The solution was evaporated to 500 μL and 500 μL of 10% HCl was added. Undigested lipids were removed by extracting with CH$_2$Cl$_2$ prior to metal chelate formation. The Pt(FDEDTC)$_2$ chelate was formed at pH 3 in an acetate buffer using a 20 mM solution of Li(FDEDTC). The chelate was then extracted into methylene chloride for GC-MS analysis.

Pt Isotope ratios were measured in duplicate, by injecting 1 μL of the chelate solution and monitoring the isotopic cluster corresponding to the molecular ion. The sample was injected, on column, into a 10 m DB-1 bonded-phase fused silica capillary column. Data were obtained in the selected ion monitoring mode using a Finnigan MAT-8230 GC-MS system operated in the electron ionization mode and quantitation was achieved by integrating the chromatographic peak areas.

In the EAAS method, Pt concentrations were determined using three different approaches. These were (i) calibration curve based on aqueous standards containing Pt in 10% HCl, (ii) standard addition and (iii) sample digestion as used for GC-MS followed by standard addition.

Results and Discussion

The overall precision of Pt isotope ratio measurements was found to be 1% when 10 ng of sample was injected. No measurable memory effect was observed when samples with isotope ratios differing by a factor of 80 were analyzed. A concentration value of 125 ± 6 (n=5) μg/L was obtained in the NIST urine reference material SRM-2670 compared to a recommended value of 120 ± 2 μg/L.

Table 1 shows the results obtained by isotope dilution GC-MS for the concentration of Pt in urine, ultrafiltrate and whole plasma samples from a cancer patient treated with cisplatin. For comparison, the
results of EAAS method are also included in the table. When compared to atomic absorption, good results were obtained for urine samples while there were significant differences in ultrafiltrate and plasma samples due to matrix effects in the atomic absorption assay.

Conclusions

Stable isotope dilution gas chromatography-mass spectrometry is a useful method for Pt determination in urine, ultrafiltrate and whole plasma. The present study was aimed at demonstrating the potential application of GC-MS method for clinical studies. A comparison of the results obtained by electrothermal atomic absorption spectrometry with GC-MS values emphasizes the need to critically evaluate EAAS and GC-MS methods for Pt determination in urine, ultrafiltrate and whole plasma samples.

Reference

Garlic-borne volatile compounds were monitored by breath analysis of human subjects in a time course study following ingestion of freshly minced raw garlic. Subjects ingested garlic at a dosage which varied between 40-200 mg per Kg of body weight and at various time intervals thereafter exhaled one liter of breath through an adsorbent trap containing Tenax-TA and Carbotrap. The adsorbent traps were then analysed using Short Path Thermal Desorption GC-MS. Quantification was achieved by GC with flame ionization detection using 2,5-dimethylthiophene as an internal standard. Linear calibration curves ($R^2 = 1.0$) were obtained by plotting the ratio of each specific analyte peak area / peak area of 2,5-dimethylthiophene versus concentration of analyte with a dynamic range covering four orders of magnitude. A total of six garlic-borne volatile compounds were found consistently in all subjects ingesting raw garlic. Four of these compounds (allylmethylsulfide, diallylsulfide, allylthiol and diallyldisulfide) are well known character species of garlic aroma. Surprisingly, the other two compounds (p-cymene and d-limonene) are terpenoid species which have not as of yet been reported as occurring in garlic. Figure 1 is a mass chromatogram for ions characteristic of garlic-borne phytochemicals found in the breath 1.5 hours following ingestion. The breath concentration clearance curves for d-limonene, p-cymene and several allylic sulfur compounds are shown in figures 2, 3 & 4 respectively. The individual appearance and elimination curves for these phytochemicals were found to differ significantly suggesting the experimental observations are perhaps related to the pharmacokinetic behavior of the individual compounds. All elimination curves were biphasic in appearance. Levels of methylallylsulfide, allylthiol, diallylsulfide and diallyldisulfide were initially high but were found to drop precipitously within in a short period of time (1-3 hrs). The slope of the elimination curve then changed dramatically, exhibiting a plateau which was maintained throughout the sampling interval (1-24 hours). We believe that the initial high levels and rapid decline of the allylic sulfur compounds breath concentrations are related to their elimination from the oral and pharyngeal regions where they are present as residues immediately after ingestion. However, the plateau portion of the clearance curve most likely results from bloodstream elimination of these compounds via gas exchange in the lungs. The slope change of the clearance curves certainly coincides with the time expected for digestion and bloodstream absorption to occur. The breath concentration curves for the terpene species were very different than those observed for the allylic sulfur compounds. The breath concentrations of terpenes were initially low or nonexistent but between 1-4 hours after ingestion, the levels of the two terpenes rose dramatically, perhaps reflecting their absorption from the intestinal system into the bloodstream as the garlic is digested. With additional research this methodology may eventually prove useful as a non-invasive analytical technique for measuring bloodstream concentrations of volatile or semivolatile food-borne chemicals. This principle has already been successfully exploited in the breathalyzer test for alcohol. We acknowledge the Center for Advanced Food Technology (CAFT) Mass Spectrometry facility for providing analytical support. CAFT is an initiative of the New Jersey Commission on Science and Technology. This is NJAES publication number S-10569-2-91.

Metabolites of U-86170F Present in Rat Urine Following Oral Administration as Determined by LC-MS and GC-MS

JJVrbanac, PESanders, MERoyer and lAO'Leary

Drug Metabolism Research
The Upjohn Company, Kalamazoo, Michigan 49002

U-86170F (5-(dipropylamino)-5,6-dihydro-4H-imidazo[4,5,1-γ]quinolin-2(1H)-one) is a compound under investigation as a potential neuroleptic. The responses observed in animal model screens following oral administration indicate that oral bioavailability is poor. One possible explanation is rapid metabolism of U-86,170 by the liver following oral administration. To further investigate this observation we have employed thermospray (TSP) mass spectrometry (MS) and high resolution gas chromatography (HRGC) MS to characterize metabolites of U-86,170 in rat urine, with the objective of understanding both the extent of metabolism of U-86,170 and the major pathway(s) important in any observed metabolism. 'Metabolic profile' information is often of value in designing and selecting alternate lead-finding compounds which retain activity and exhibit increased bioavailability.

Metabolites of U-86,170 present in the urine of rats following oral administration as determined by TSP-LC-MS and HRGC-EI-MS following chemical derivatization are reported.

Sample Extraction and Purification: Urine samples were extracted using ODS (Sep-Pak®) cartridges. No further purification was attempted. Treatment: 20 mg/kg U-86,170F p.o. Samples: Pre-dose (control) and 0-4 hour urine samples. LC-MS: Perkin-Elmer (Norwalk, CT), Vestec (Houston, TX) and Nermag (R1010, Houston, TX). Chromatography: 0.1 M ammonium acetate, Ph = 4.0 (solvent A) and acetonitrile (solvent B). Linear gradient from 100% A to 70:30 A:B or 50:50 A:B in 20 minutes. Perkin Elmer 3 mm x 8 cm Percosphere C-18 column. TSP: Block 258 ºC, vaporizer 234 ºC, repeller 120 volts, discharge off. GC-MS: Hewlett Packard (5890) and Nermag (R1010) equipment. Chromatography: J&W Scientific 15 m DB-5, 0.25 mm I.D., 0.25 μm film thickness, Helium, splitless injection, injector 250 ºC, oven 100 ºC, increased to 310 ºC at 25 ºC/min.

The positive ion TSP mass spectrum of U-86,170, U-77,567 (5-propylamino analogue) and U-77,292 (5-amino analogue) consisted only of the pseudo-molecular ions (MH+, m/z 274, 232, 190), a common observation using positive ion TSP ionization. U-77,567 and U-77,292 were of interest since they were hypothesized to be metabolites of U-86170. These data are summarized in Figure 2. Several differences were noted in the TSP analysis of pre-dose (control) and 0-4 hour (drug) samples. TSP analysis indicated that some parent drug is excreted unchanged in the urine (0-4 hour collection period) and that the major metabolite present at this time is the N-dealkyl metabolite (U-77,567). Metabolites 16 daltons greater in molecular weight than the parent drug were observed as a metabolite 16 daltons greater than the molecular weight of the N-dealkyl metabolite. The primary amine (U-77,292) was not observed using TSP analysis. Glucuronide and sulfate conjugates of the oxidized metabolites were either not present or below the level of detection.

The TSP data indicated that N-dealkylation is apparently the major, or one of the major metabolic pathways involved in U-86,170 biotransformation in the rat. Also, hydroxylation is apparently an important metabolic route. It was decided that chemical derivatization and high resolution gas chromatography-electron ionization-mass spectrometry (HRGC-EI-MS) would be employed to determine the general (i.e., aryl vs. aliphatic) sites of oxidation. Samples were dried and reacted with BSTFA at 80 ºC for 30 minutes. The electron ionization (EI) mass spectrum was obtained for the TMS derivative.
of U-86,170. To further characterize the hydroxylated metabolites of U-86,170 using EI-MS it was necessary to demonstrate the origin of one or two key fragments in the EI mass spectrum of the TMS derivative that were characteristic of an intact and unchanged dipropylamino moiety. EI mass spectra of the TMS derivative of U-86,170 would be expected to contain a characteristic ion at m/z 126 (C_{6}H_{7}N^+-(CH_{3}-CH_{2}-CH_{3})_{2}) and this ion was observed. Also, shifts of 14 daltons in the EI mass spectrum of the propylbutylamino and dibutylamino structural analogues of U-86,170 were observed. High resolution MS analysis of the TMS derivative of U-86,170 confirmed this hypothesis. Thus, the m/z 126 ion is indicative of an intact 5-dipropylamino moiety. Three distinct peaks were observed for the drug related sample in the reconstructed mass chromatogram for m/z 433 (M* of the di-TMS derivative of a hydroxylated metabolite of U-86,170) that were not present in the control sample. The three metabolites were observed to have intense fragment ions at m/z 126, suggesting that the dipropylamino groups are unchanged in these metabolites. Aryl hydroxy structures are plausible, although the presence of metabolites are not ruled out by these data. The requirement for GC-MS analysis demonstrates the structural elucidation limitations of TSP-MS analysis.

Figure 2. TIC and selected reconstructed mass chromatograms for pre-dose and control rat urine samples as determined by thermospray analysis.
INTRODUCTION

MDL 72,222 (8-methyl-8-azabicyclo[3.2.1]octan-3-yl 3,5-dichlobenzoate) is a potent and highly selective serotonin (5-HT₃) M-receptor antagonist which is currently under evaluation as an antiemetic drug to be used as an adjunct to cancer chemotherapy. Some of the metabolites show activity and account for a large portion of the C₁₄ dose. This GC/MS method is an improvement over a previous one using a less specific detector (electron capture). We report here a specific and sensitive method for the quantification of parent drug and four metabolites (Fig. 2); N-desmethyl-MDL 72,222 (1), 3,5-dichlobenzoic acid (2), glycine conjugate of 2 (3), and MDL 72,222-N-oxide (4) in citrated monkey plasma using negative chemical ionization GC/MS.

A multistep procedure was necessary to extract and derivatize all analytes due to their wide variation of polarity. Quantification of analytes in samples was made by interpolation of standard curves. The standard curves were split into two linear segments of either 0.5 to 10 and 10-75 ng/mL (metabolites 1 and 3) or 1-20 and 20-150 ng/mL (MDL 72,222 and metabolites 2 and 4).
RESULTS AND DISCUSSION

Validation was done in monkey and dog plasma. Extraction efficiencies ranged from about 60-90%. Intraday precision values were less than 10% RSD and accuracy values were in the range of 92.0-110%. Similarly, the Interday precision values were less than 14% RSD and accuracy values were in the range of 87.6-116%.

Pharmacokinetic studies to determine the plasma concentrations of MDL 72,222 and metabolites in dogs and monkeys given a single iv dose and in dogs given multiple iv doses of MDL 72,222 were performed. Plasma concentration-time profiles from the single dose study were used to determine various pharmacokinetic parameters and showed a nearly quantitative accounting of $^{14}$C. The multiple dose study was used to assess the following; dose-proportionality, accumulation, and steady-state conditions. A plot of drug and metabolite concentrations in monkey plasma is shown below. The animal given a single 5 mg/kg intravenous dose of MDL 72,222.

PLASMA CONCENTRATION-TIME PROFILES OF MDL 72,222 (○), 1 (△), 2 (○), 3 (○), 4 (△) IN A MONKEY GIVEN A 5 MG/KG INTRAVENOUS DOSE OF MDL 72,222.
MASS SPECTROMETRIC CHARACTERIZATION OF THE METABOLITES OF
DEOXYSPERGUALIN (NKT-01) IN HUMAN URINE

Introduction

Deoxyspergualin (NKT-01 : (+)-1-amino-19-guanidine-11-hydroxy-4,9,12-triazanona-
decane-10,13-dione 3HCl) (Table 1) is a synthetic spermidine derivative with strong
immunosuppressive and antitumor activity [1,2]. The present compound is currently
under evaluation for potential use as a therapeutic agent against acute organ
rejection after transplantation [3,4]. In preclinical studies, we have demonstrated
that urinary excretion plays an important role for the elimination of NKT-01 in rat
and dog. The present communication reports an isolation and mass spectrometric
characterization of the urinary metabolites of NKT-01 in human following intravenous
administration.

Experimental

Apparatus

Fast atom bombardment-mass spectrometry (FAB-MS) was performed using a
MM-ZAB HF (VG Analytical). Samples were dissolved in a glycerol or thiglycerol
as a matrix and ionized by bombardment with a xenon atom beam. Gas chroma-
tography (GC)/MS analyses (electron ionization) were run on a Hitachi M-80B
GC/MS equipped with a fused silica capillary column using helium as carrier gas [5].
High performance-liquid chromatographic (HPLC) system consisted of a Shimadzu
LC-6A pump, SPD-6A ultra violet detector and RF-535 fluorometric detector, and
Reodyne 7125 injector. The column was a reversed phase Cosmosil 5C18-P (15cm x
4.6mm i.d.). The mobile phase consisted of 0.01M phosphate buffer (pH 3)-aceto-
nitrile (91:9) containing 5mM sodium 1-pentanesulfonate as a modifier [6].

Sample preparation

Samples of urine from patients were collected into 0.5M NaH2PO4 for up to
24 hours after NKT-01 administration. Metabolites in urine were extracted and
purified by CM-Sephadex C-25 column chromatography (Na+ form) and subsequent
HPLC. Purified metabolites were converted to the methyl ester (ME)-o-methyl
derivatives (FAB-MS) and the pyrimidine derivatives (GC/MS) [5].

Results and Discussion

Extraction and fractionation of the metabolites by CM-Sephadex C-25 column
chromatography and subsequent purification of the eluate by reversed phase-HPLC
resulted in the isolation of six metabolites in addition to intact NKT-01 from human
urine. Characterization of the isolated metabolites was accomplished by comparing
the retention time in HPLC and their FAB mass spectra with authentic reference
compounds. Mass spectral data of the identified metabolites are shown in Table 1.
FAB mass spectra of the metabolites were characterized by the appearance of
protonated molecular ions ([MH]+) after methylolation with hydrogen chloride in
methanol as shown in Fig.1. Derivatization of each metabolite with acetylacetone
resulted in the formation of the pyrimidine derivative of GUS-4 (m/z 250, [M]+,
GC/MS), suggesting that all metabolites identified possessed 7-guaninedeheptanamide
moiety in the molecule. Of these metabolites, GUS-10 and GUS-14 were compounds
with carboxyl functional group. The metabolite possessing aldehyde functional
group (GUS-8) was also identified as one of the major urinary component.

In vitro biotransformation of NKT-01 by calf serum gave GUS-8 as the sole
component. The formation of GUS-8 may be catalyzed by amine oxidase. These
results suggested that amine oxidase may be a promising key enzyme which is
responsible for oxidative degradation of spermidine moiety in NKT-01 in vivo.
Similarity in the metabolic process between NKT-01 and spermidine was also
strongly indicated from the structures of metabolites.

Quantitative GC/MS Determination of Arachidonic Acid
Released from Cultured Human U937 Cells

Chun Li, Jim Yergey and Philip Weech
Merck Frosst Centre for Therapeutic Research
P.O.Box 1005, Pointe-Claire-Dorval, Quebec, Canada, H9R 4P8

Oxygenated arachidonic acid metabolites are mediators of broncho-constriction, vaso-constriction and inflammatory reactions, and are implicated in the pathology of diseases in man, e.g., asthma, arthritis, psoriasis and inflammatory bowel disease. The rate limiting step in the biosynthesis of such mediators as leukotrienes, prostaglandins and PAF is believed to be the hydrolysis of arachidonic acid from the sn-2 position of membrane phospholipids within the cell by one or more phospholipase A2 (PLA2) enzymes. Because of the direct involvement of neutrophile and other leucocytes in the inflammatory processes, there is an increasing interest in the pharmacological manipulation and characterization of arachidonic acid releasing PLA2 activity in these cells. Many studies have reported the metabolism of 3H-arachidonic acid in stimulated cells, including the hydrolysis of arachidonyl labelled phospholipids. However, there are few reports of direct measurements of arachidonic acid release from endogenous cell phospholipids. Our objective is to study arachidonic acid release in differentiated human U937 cells as a model system to investigate the role of PLA2 and its physiological and pharmacological regulation in inflammatory cells.

Existing methods for arachidonic acid quantification have relied mainly on gas chromatography with either flame ionization or electron capture detector. In this study, the methodology for quantitative determination of arachidonic acid release in differentiated human U937 cells is based on the formation of pentafluorobenzyl ester of arachidonic acid, and analysis by GC/MS. A known amount of 3H arachidonic acid was used as internal standard and spiked into each sample, followed by liquid-liquid extraction with Dole's method (heptane, isopropanol, H2SO4) to extract free fatty acids. The free fatty acids were then derivatized to their pentafluorobenzyl esters, and resuspended in 1 mL of dodecane (or tetradecane). Resonance electron capture ionization (CH4) was employed with selected ion monitoring of the predominant carboxylate anions, resulting from the loss of pentafluorobenzyl radical. The detection limit of arachidonic acid was 20 pg/mL.

The arachidonic acid level was very low in resting cells (~0.8 ng/10^6 cells), and was found to increase rapidly upon Ca^2+ ionophore A23187 stimulation (reached maximum at 3 minutes stimulation, ~120 ng/10^6 cells), and decrease thereafter. DMSO differentiated U937 cells gave a greater arachidonic acid response (~170 ng/10^6 cells) upon A23187 stimulation compared with non-differentiated U937 cells (~42 ng/10^6 cells). Furthermore, The amount of each of 10 fatty acids in differentiated human U937 cells was measured, and we found that arachidonic acid increased upon A23187 stimulation more than any other fatty acid, to become the major free fatty acid present. We believe that this method provides a useful and specific assay for the study of arachidonic acid release and PLA2 activity in whole cells.

Free fatty acids were measured in 5 replicated, each containing 8x10^6 cells. Quantification of each fatty acid was carried out by resonance electron capture ionization and selected ion monitoring of the 11 carboxylate anions: CH₃(CH₂)₇-COO⁻, including ²H₄-20:4 as internal standard.
PLASMA SERINE IN SCHIZOPHRENICS AND CONTROLS MEASURED BY GC-MS

S. Baruah, R. Waziri, T. S. Hegwood and L. M. Mallis
Department of Psychiatry
College of Medicine
and 1 High Resolution Mass Spectrometry Facility
The University of Iowa
Iowa City, Iowa 52242

In a series of studies on more than 350 psychotic (including schizophrenics) and non-psychotic subjects, higher plasma serine concentrations (PSC) in the psychotics have consistently been observed [2]. Diminished serine hydroxymethyltransferase (SHMT) activity in the plasma of psychotic subjects has also been found [3]. Since SHMT provides the major degradative pathway for serine metabolism, the high PSC of psychotic and schizophrenic subjects is likely to be due to decreased activity of the SHMT enzyme in the liver. Neuroleptic drug usage, which is most often a differentiating variable between psychotics and non-psychotics was minimized in this study. That is, psychotics were placed in a research ward, consuming a balanced diet and off neuroleptics for three or more weeks prior to blood withdrawal. In any case, neuroleptics tend to reduce PSC in psychotic subjects.

It has been suggested that the high PSC observed in previous studies for psychotics is due to technical problems in the gas chromatographic (GC) assays where some other substance is co-eluting with serine [4]. By using GC/MS, whereby accurate identification and quantification of substances can be achieved, the likelihood of a co-eluting compound can be ruled out (see Figure 1 for TIC chromatograms of amino acid (AA) standards and plasma AA samples; Figure 2 shows the corresponding mass spectra for serine, glycine, and norleucine).

In this study a VG Trio-1 GC/mass spectrometer (MS) was used. N(O)-heptafluorobutyryl isobutyl ester derivatives of the plasma and standard amino acids were prepared for GC/MS analysis. Norleucine was used as an internal standard for quantitation (see Figure 3 for the glycine and serine calibration curves). In general, the plasma serine concentration (PSC) of schizophrenics was found to be 104.0 nmoles/mL (± 19.4) and was determined to be 75.3 nmoles/mL (± 13.8) for controls (see Figure 4 for PSC scatter-plot). Since glycine is the by-product of serine metabolism through SHMT activity, one would expect the plasma glycine concentrations (PGC) to be lower for schizophrenics vis-a-vis controls. It is interesting to note that the PGC were also found to be higher for schizophrenics as compared to controls. The PGC for schizophrenics was found to be 214.4 nmoles/mL (± 49.7) and determined to be 164.1 nmoles/mL (± 43.3) for controls (see Figure 5 for PGC scatter-plot).
In two previous studies, we had found no significant difference between the PGC of psychotics and non-psychotics. Whether this discrepancy is due to the fact that the present group of schizophrenics was off medications is at this time unknown. We also used heptfluoroacbutyric anhydride to derivatize the amino acids instead of trifluoroacetic anhydride as reported in our previous studies. Macciardi, et al. have also observed high PGC as well as high PSC in their schizophrenic subjects [5]. In a study of the autopsied temporal lobes, significantly higher serine and glycine concentrations in the brain samples of schizophrenics compared to controls was reported [6]. The major degradative pathway of glycine is via the glycine cleavage complex (GCC) [7], which in the mitochondria is closely coupled to SHMT [8]. Glycine may also be decarboxylated by SHMT in the presence of lipoic acid [9]. Whether there is a concomitant deficiency in the GCC, which would raise glycine concentrations in schizophrenics or the increased glycine levels are also due to the deficient activity of SHMT, is at this time unknown. That the metabolism of these two AA is closely linked is suggested by a significantly high correlation (r = 0.675, p < 0.0002) between PSC and PGC of both controls and schizophrenics.

DETERMINATION OF MEVALONIC ACID IN SERUM BY MASS SPECTROMETRY FOR THE STUDY OF CHOLESTEROL SYNTHESIS INHIBITION

R. S. Muldowney, E. Ivashiv, R. Tanaka, M. E. Arnold, P. J. Gale, M. Jemal, and A. I. Cohen

The Bristol-Myers Squibb Medical Research Institute
New Brunswick, New Jersey 08903-0191

Recent studies have shown a correlation between elevated serum cholesterol levels and risk of cardiovascular disease. Prior to the development of therapeutic agents, the biological pathway of cholesterol synthesis was studied and key steps in the synthesis identified. Subsequently several compounds were developed to inhibit these key steps. Both pravastatin and lovastatin, for example, inhibit the conversion of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) to mevalonic acid.

There is also an interest in inhibiting other steps in the synthesis pathway. To monitor the effect of a compound that would inhibit the conversion of mevalonic acid to 5-phospho-mevalonic acid, it would be useful to have a method capable of detecting increases in mevalonic acid levels. This has previously been accomplished by an enzymatic method and several gas chromatography (GC)-mass spectrometry (MS) methods. The enzymatic assay requires the use of $^{32}$P labeled compound requiring stringent safety precautions. The GC-MS methods, while selective and sensitive, are all encumbered by extensive extraction procedures.

The work reported here describes a simple and expedient method for the quantitative determination of mevalonic acid in human and rat serum using a much simpler extraction procedure together with either GC-electron impact (EI) MS or GC-Positive Ion Chemical Ionization (PICI) MS with ammonia as the reagent gas. The extraction involves a simple protein precipitation with ethyl acetate which isolates the compound in the acid form. The compound was then trimethylsilated (TMS) and injected onto a Restek Rtx-5 capillary column contained in a Hewlett-Packard 5990 GC and analyzed by electron impact or chemical ionization mass spectrometry. The EI experiments were performed on a Hewlett-Packard 5970 MSD, the CI experiments on a VG Trio-2. Full scan spectra obtained with each of the two ionization methods are shown in Figures 1 and 2. For purposes of quantification, the m/z 247 and 250 (tri-deuterated internal standard) ions were monitored in EI; the m/z 275 and 278 ions in CI.

As shown in Figures 3 and 4, both the EI and CI methods provide linear standard curves over the concentration range of 10 to 200 ng/ml. Accuracy and precision of the methods were assessed by running QC samples in quadruplicate at three concentrations on three different days. At each level, predicted concentrations deviated from nominal by less than 15% for the EI method and by less than 5% for the CI method. The methods have been used successfully to evaluate the effect of cholesterol lowering agents in several different studies.

MASS SPECTROMETRY IN FERMENTATION BATCH PROCESSING OF ANTIBIOTICS

Chandralal Weerasinha, Esmail Warrakah, Fred Chapin and Richard Wang, SmithKline Beecham Animal Health, 1600 Paoli Pike, West Chester, PA 19380.

Ardacin (AAD216 Complex) is a fermentation product that belongs to vancomycin family of antibiotics. They are produced by a new genus of Actinomycetales, Kibdelosporangium aridium (ATCC 39323). The complex is currently being developed as a growth promotant for food producing animals.

The complex consists of ten known glycopeptides with each of them having the same heptapeptide skeleton that constitute approximately 78% of the activity. The product impurities constitute the remaining 22%. The fermentation and the purification of the broth takes place in several different batches at the manufacturing plant. Therefore, the nature and composition of impurities may vary depending on the production batch. In this presentation, the application of mass spectrometry to characterization of impurities in different batches into structural classes will be discussed. The characterization involved; separation of the glycopeptide complex from impurities, FAB/MS screening, chemical degradation and derivatization followed by further analysis using FAB, EI, and GC/MS. The characterization of any given batch includes component separation based on molecular size, screening by fast atom bombardment mass spectrometry, chemical degradation and derivatization of components other than that constitute 78% activity of the complex and further characterization by mass spectrometry. Several structural classes, such as a peptide with unique identity, glycolipids and carbohydrates have been identified and their spectral data will be presented.

Experimental

Separation of the glycopeptide complex from impurities was carried out using a Bio-Gel (P-4) column (80cm x 2.6cm). The crude raw material was applied to the column in a solution of ammonium bicarbonate and washed with a solution of the same. Approximately 100-102 x 15 ml fractions were collected for each run and lyophilized to dryness prior to analysis. The chemical degradation involved; hydrolysis (6N HCl, 18 hrs), and methanolysis. Derivatization such as methylation, acetylation after NABH₄ reduction was carried out. All mass spectra were obtained with a VG 70/250SE mass spectrometer. A VG 11-250J data system was used to acquire and process all data. For FAB/MS, a standard FAB ion source and an Ion Tech fast atom gun was used. The accelerating voltage was maintained at 8 kV while 8 keV xenon atoms at a discharge current of 1 mA were used to bombard the sample. Monothioglycerol/oxalic acid mixture, m-nitrobenzyl alcohol and glycerol were used as matrices. For GC/MS, a fused silica column (CP SIL 5CB, 25 cm x 0.25 mm) was used. The column oven was programmed; 90°C for 2 min., ramped at 10°C/min. to 270°C and held at the final temperature for 5 min.

Results and Discussion

The initial screening of the bio-gel fractions was helpful in disseminating the impurities from the glycopeptide complex. A typical FAB/MS spectrum of the glycopeptide complex (figure 1) is given in figure 2. Extensive characterization of this complex has been reported elsewhere¹. The molecular ion cluster consists of the average molecular ions (M+H)+ of m/z 1787, 1801 and 1815 derived from the major components of the complex. The FAB/MS screening also indicated molecular ions with m/z 16 daltons higher than the corresponding major components probably due to
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

hydroxylated ardacins. A molecular ion of m/z 1051 was detected in several early eluting Bio-Gel fractions (figure 3). After accurate mass determination, elemental analysis and degradation chemistry, a probable structure of a hexapeptide having the ardacin aglycone skeleton without the amino acid marked G was assigned. The main portion of the other Bio-Gel fractions consisted of glycolipids containing long chain hydrocarbons, carbohydrates and sialic acids.

In conclusion, mass spectrometry can be successfully applied to characterize fermentation products and their impurities; thereby, variations of constituents, if any, in different batches can be determined prior to utilization of the final product in developmental studies.

THE MASS SPECTROMETRY CUTOFF FOR THE COCAINE METABOLITE, BENZOYLECGONINE

John de Kanel
Analytical Associates, Inc., P.O. Box 1227, King of Prussia, PA

Introduction
The final criteria for U.S. Federal Workplace Drug Testing Programs was set forth in 1988 (1). Under these guidelines the benzoylecgonine cutoff concentrations for screening (300 μg/L) and confirmation (150 μg/L) were established based primarily on the experience of the Department of Defense and the testing of military personnel. The state of the art in drug detection and confirmation was also considered. Provision was made for change in these guidelines as technology advanced and methods improved.

A reduction in the Benzoylecgonine cutoff levels requires both an improvement in screening and confirmation ability, the need for such a reduction to better produce a drug free workplace and assurance that this will not produce false positives. As previously published, commercially available screening methods using EMIT and Fluorescence Polarization Immunoassay currently exist which permit limits of detection at a 95% confidence level of 24 μg/L and 30μg/L, respectively (2,3). During 1990 at Toxicology Testing Service Inc., EMIT screening of employment samples at a cutoff level of 50 μg/L and full scan GC/MS confirmation produced 41% confirmed positives above the federally mandated cutoff level of 150 μg/L, 44% between 20 and 150 μg/L, 8% below 20 μg/L and 7% negatives. More than half the samples containing cocaine metabolite were reported as negative with the current confirmation test level. A recent exaggerated test during which subjects were required not to wash their hands during a whole day to determine the upper benzoylecgonine urine levels resulting from exposure to contaminated money, found a maximum screening level of 72 μg/L (4). As pointed out in Sunshine's book (5) a better method of confirmation is still needed if a lower cutoff is to be implemented.

Experimental
Standards were prepared in negative urine at 2, 5, 8, 20, 150 and 300 μg/L levels. Three mL samples were analyzed after addition of 60 ng of D-3 benzoylecgonine in dimethylformamide as an internal standard. Samples were extracted after adding 1 mL of 1.5M Potassium Phosphate Dibasic with 4 mL of 20% isopropanol in methylene chloride by rocking for 15 minutes. Samples were centrifuged, if necessary, and the bottom, organic layer was removed with a Pasteur pipet and evaporated to dryness at 65°C under a stream of nitrogen. Derivatization to prepare propyl benzoylecgonine was done by heating the evaporated sample at 65°C for 10 minutes after addition of 200μL, 2% tetramethylammonium hydroxide in acetonitrile and 40μL iodopropane. After cooling to room temperature 1 mL, 0.2N HCl was added and the sample extracted by vortexing 15 seconds with ethyl acetate. The top, ethyl acetate layer was discarded, 1 mL, 1.5M potassium phosphate dibasic added and the sample extracted with 1.2 mL of 50/50 hexane in methylene chloride by vortexing 30 seconds. The top, organic layer was then removed and evaporated to dryness at 65°C under a stream of nitrogen, reconstituted with 10 to 20 μL of isooctane and analyzed. One or two μL samples were injected using a LEAP Technologies autoinjector into a Grob Splitless port and a 12 meter DB-5 capillary column with a temperature program of 150-300 at 18 °C per minute. A Finnigan 4000 (with PPINICI) GC/MS was used to obtain mass spectra. Quantitation was accomplished using a linear calibration curve prepared from the 210/213 (Benzoylecgonine/methyl-D3 Benzoylecgonine) integrated ion ratios obtained from the full scan (52-400) mass spectral data acquired.
Results and Discussion

Analysis of the linear calibration curve (Figure 1) obtained from the standards in triplicate ($r^2 = 0.998$) using the method described by de Kanel et al. (3) and Hubaux and Vos (6) yielded a limit of detection of 9.4 μg/L at the 95% confidence limit. A limit of quantitation of 32 μg/L was determined assuming an acceptable error of ±20% at the 99% confidence level. Chromatograms were clean with the benzoylecgonine derivative producing the major peak down to a level of 5 μg/L (Figure 2). The mass spectra obtained at the 5 μg/L and 150 μg/L levels were in excellent agreement (Figures 3 and 4). Substantially lower benzoylecgonine cutoff levels are now justified.

The author wishes to thank Toxicology Testing Service, Inc. for partial support of this work.
A Method for the Detection of Urinary Synthetic Corticosteroids by Gas Chromatography-Mass Spectrometry

Peter S. Przybylski and Siu C. Chan

Department of Laboratory Medicine, Foothills Hospital
Calgary, Alberta, Canada

The use of synthetic corticosteroids by athletes has been banned except for treatment as short-term anti-inflammatories or analgesics involving topical preparations, inhalation therapy or local injections. This has created the need for a routine screening and confirmation procedure capable of detecting a wide variety of synthetic corticosteroids.

Various analytical techniques generally involving combinations of high performance liquid chromatography, gas chromatography and mass spectrometry have been developed. However, most of the methods described in the literature detect only a few corticosteroids per analysis and would be difficult to perform routinely on a large scale. A simplified, routine and automated procedure for the detection of synthetic corticosteroids and their metabolites can be performed by modifying current analytical procedures using an automatic sample injection system with a gas chromatograph coupled to a mass spectrometer. Screening results are printed utilizing a computerized data reduction system.

An aliquot of urine with internal standard was passed through a C18 Sep-Pak (Waters) cartridge followed by water and methanol to extract the corticosteroids from the urine matrix. The dried methanolic extract was subjected to enzymatic hydrolysis using 0.2 mol/L acetate buffer (pH 5.2) and a crude solution of Helix pomatia for two hours in a 60°C waterbath. The corticosteroids were then extracted into diethyl ether with the addition of potassium carbonate. To protect the integrity of the thermally labile C17 side chain, the vulnerable keto and hydroxyl groups were converted to their methoxime and trimethylsilyl ether derivatives respectively using a modified technique first developed by Horning, et al.

Derivatization involved a two step process. Following derivatization with MOX (methoxyamine HCl) in pyridine for 3 hours at 90°C and removal of the pyridine, the extract was reacted with TSIM (N-trimethylsilylimidazole) overnight for 18 hours at 105°C. These extreme conditions were necessary to force complete derivatization of any hindered hydroxyl groups especially those encountered in compounds with C16 methyl group substitutions such as dexamethasone illustrated in figure 1.

Figure 1 Dexamethasone MOX-TMS derivative
The derivatives were injected using splitless mode by a Hewlett-Packard (HP) 7673A Automatic Liquid Sampler onto a 20 m DB-1 (J & W Scientific) polymethyl siloxane capillary column fitted into a HP 5890 Gas Chromatograph coupled to a HP 5970 Mass Selective Detector (MSD). The MSD was tuned according to the manufacturer's specifications and was operated in the selected ion monitoring (SIM) mode using 50 ms dwell times. Data reduction and interpretation were simplified by a macro or program which produced a printed report displaying the SIM data for each corticosteroid and/or its metabolite. A presumptive positive was indicated by matching peaks for each of the selected ions at the proper retention time.

Detection limits were determined at approximately 10 - 25 ng/mL. Recovery studies using this method indicated an average of 70 - 95% for most of the synthetic corticosteroids analyzed except for triamcinolone which had a recovery of approximately 50%.

Excretion studies using urine samples from patients on corticosteroid therapy were performed to determine if the parent compound and in particular any metabolites could be detected. Prednisolone, the active form of prednisone, was detected in patients on prednisone therapy. Both the parent compound and their major 6ß-hydroxy metabolites were found in studies using betamethasone or dexamethasone administration, however only the parent compound was detectable in triamcinolone studies.

References

The analysis of volatiles and semi-volatile samples in air on-site is important in light of the pertinent environmental and health hazards that may be present. Consequently, several sampling and analysis strategies have evolved to address these challenges. Sample pre-concentration followed by thermal desorption has been proven to increase the analysis dynamic range and to provide reliable and reproducible results (1).

One major difficulty encountered with the pre-concentration technique used in GC/MS systems is that transfer of the analyte to the column is often hindered by transfer lines or improperly matched flow rates. In addition, poor column retention for very light volatiles is often observed. These effects can lead to band broadening and poorly resolved or unresolved peaks. Cryofocusing can alleviate this problem for many compounds, but typically must be performed in a laboratory setting.

We have developed a split/splitless GC injector that has an incorporated thermal desorption capability complete with cryofocusing at the head of the column. This injector/desorber is built into a portable GC/MS system to facilitate on-site sampling. The injector/desorber system has a small localized cooling region inside the GC oven to cryofocus the more volatile compounds that might be found at a contaminated site.

Compounds that have a high vapor pressure at low temperature are particularly difficult to analyze properly and thus cryofocusing has to be well controlled. A temperature of at least -40°C is desirable. Benzene, for example, has a slight vapor pressure at temperatures of approximately -40°C and thus cryofocusing may be required. The results of concentrating a 10 ppbv sample of benzene for different periods of time followed by thermal desorption directly to the GC column are quite linear with precisions under 10%. For these experiments the GC column is sprayed with chlorodifluoromethane just prior to desorption. The resulting column temperature is approximately -50°C.

Chloroform has roughly a five times higher vapor pressure than benzene at -40°C and consequently it is even more difficult to generate a narrow GC band. The abundance versus concentration time profile for chloroform is shown in Figure 1. The GC/MS data for a 15 second concentration time from 50 ppbv is shown in Figure 2. The precision for this concentration time is approximately 15%.
Another compound of environmental interest that we have concentrated and desorbed is methyl isobutyl ketone (MIBK). An abundance versus concentration time profile is shown in Figure 3. The GC/MS data for a 15 second concentration time is shown in Figure 4. The precision of this measurement is 17%.

DETERMINATION OF POLAR VOLATILE ORGANIC COMPOUNDS
BY ATMOSPHERIC SAMPLING GLOW DISCHARGE/ION TRAP MASS SPECTROMETRY
Joseph B. C. Chang and Michael Miller, IIT Research Institute, Chicago, IL 60616; Sydney M. Gordon, Battelle, Columbus, OH 43201; Joachim D. Pleil and William A. McLennan, U.S. Environment Protection Agency, Research Triangle Park, NC 27711.

A glow discharge/ion trap mass spectrometer system has been evaluated for the direct atmospheric sampling and rapid measurement of trace levels of polar volatile organic compounds (VOCs) in air. These compounds are difficult to characterize using existing technology for nonpolar compounds (EPA's Method TO-14), largely because of the drying step normally used to remove co-collected water vapor from the sample and the need to preconcentrate the compounds to achieve the desired analytical sensitivity.

Interfacing the source with the quadrupole ion trap mass spectrometer offers a system with high sensitivity, simplicity, compact size, and tandem mass spectrometry (MS/MS) capabilities for compound characterization. The operating parameters which influence the ion injection efficiency in the ASGDI/ITMS are: low mass cut-off during ion injection, discharge current, buffer gas pressure in the ion trap, and focusing lens voltages. Figures 1(a)-1(d) show the results of varying these parameters while measuring the positive ion intensities for n-butylbenzene. Figure 1(b), for example, shows that the intensity of the fragment ion m/z 91 (C\textsubscript{T}H\textsubscript{8}) increases relative to m/z 92 (C\textsubscript{T}H\textsubscript{9}) due to an increase in fragmentation as the energy transferred to the molecular ion increases with increasing discharge current.

In the positive ion mode, the major reagent ions in the background air spectrum are NO\textsuperscript{+} (m/z 30) and O\textsuperscript{+} (m/z 32) and are essentially unaffected by the relative humidity (RH). These ions serve as reagent ions for the ionization of trace VOCs in air by electron or proton transfer. ASGDI spectra of aliphatic alcohols exhibit prominent peaks corresponding to either the (M+H\textsuperscript{+}) or (M-H\textsuperscript{-}) ion, or both. Both of the polar aromatics (benzaldehyde and nitrobenzene) and the nonpolar aromatics (benzene and toluene) produce large molecular ion peaks corresponding to (M+H\textsuperscript{+}), (M-H\textsuperscript{-}) or (M+H\textsuperscript{+}) in the ASGDI/ITMS system. Major peaks are observed in the ASGDI spectra at (M+H\textsuperscript{+}) for acetone and at M\textsuperscript{-} for methyl ethyl- and methyl isobutyl ketone. Results for the alkyl thiols studied are presented in Figure 2. In both of the nitriles examined (Figure 3), the base peak corresponds to the pseudomolecular ion at (M+H\textsuperscript{+}). Figure 4 shows that ethyl acrylate and methyl methacrylate give intense peaks for the (M+H\textsuperscript{+}) ion as well as for the fragment containing the carbonyl group (m/z 55 in ethyl acrylate and m/z 67 in methyl methacrylate). The results obtained in the present study for the nonpolar halocarbons, dichloromethane, chloroform, carbon tetrachloride, methyl chloroform, trichloroethylene, and tetrachloroethylene show generally good agreement with EI spectra and with the data of Asano, et al.

In the negative ion mode, the relative abundances and absolute intensities of the reagent anions are strongly dependent on the relative humidity of the background air. In relatively dry air (11% RH), the spectrum is dominated by the NO\textsuperscript{-} ion. However, in humid air (40% RH), the major peaks correspond to O\textsuperscript{-} and NO\textsuperscript{-}, with small contributions from O\textsuperscript{2-} and NO\textsuperscript{3-}. The spectra of the aliphatic alcohols obtained at 40% RH (e.g. Figure 5) show a prominent peak at (M-3)\textsuperscript{-}. It is assumed that O\textsuperscript{-} reacts with the alcohols to form the (M-3)\textsuperscript{-} ion by the initial loss of one proton to form the alkoxide anion, followed by the loss of an H atom from both the α- and the β-positions with respect to the OH group. The mass spectra for these alcohols at 11% RH show a (M+43)\textsuperscript{-} due to the addition of the m/z 46 (NO\textsubscript{2})\textsuperscript{-} and the loss of three H atoms. The most intense peak for both the aliphatic ketones and aliphatic carboxylic acids [Figure 6(a)] occurs at (M-H\textsuperscript{-}) in humidified air. Figure 6(b) shows the selectivity obtained for a mixture of aliphatic acids by negative ion ASGDI. The polar aromatic compound nitrobenzene displays the base peak at M\textsuperscript{-} and an intense peak at (M-H\textsuperscript{-}) in dry air, while benzaldehyde shows the base peak at (M+O-H\textsuperscript{-}). All of the alkyl thiols are characterized by intense peaks at m/z 64 (S\textsubscript{2}) and 80 (S\textsubscript{2}O). The two acrylic esters studied (ethyl acrylate and methyl methacrylate) give intense peaks for the molecular ion M\textsuperscript{-} and m/z 46.

Although polar VOCs give rise to mixed EI and CI ASGDI spectra in the positive ion mode, the fragment ion abundances are unlike their standard EI counterparts. Strategies to reduce the degree of fragmentation in the positive ion mode should be investigated.

DEMONSTRATION OF MOBILE MASS SPECTROMETRY THROUGH THE EPA SUPERFUND INNOVATIVE TECHNOLOGY EVALUATION PROGRAM

P. Kowalski, F.H. Laukien, and J. Wronka
Bruker Instruments Inc., Manning Park, Billerica, MA 01821

The United States Environmental Protection Agency’s Office of Solid Waste and Emergency Response and Office of Research and Development established the Superfund Innovative Technology Evaluation (SITE) Program to promote the use of innovative technologies to clean up Superfund sites across the country. The SITE Measurement and Monitoring Technologies Program provides assistance in the development and demonstration of innovative technologies to characterize Superfund sites. Through EPA’s Environmental Monitoring Systems Laboratory in Las Vegas, Nevada (EMSL-LV) with the cooperation of Tufts University and Lockheed Engineering & Sciences Co., the technology of mobile mass spectrometry was demonstrated to be a promising technique for the characterization of pollutants at Superfund sites.

The goals of this demonstration were to evaluate the performance characteristics of the Mobile Environmental Mass Spectrometer (MEM) developed by Bruker Instruments Inc., (Billerica, Massachusetts) as a technique for on-site monitoring, and to generate substantial data with which to support the credibility of field measurements using a mass spectrometer.

Two active Superfund Sites in Massachusetts were selected as locations for this demonstration to take place. During August and September of 1990, the analysis of PCB contamination in soil samples took place at the N. Dartmouth, MA Superfund Site, while the analysis of PAH contamination in soil samples and VOC contamination in "spiked" water samples took place at the Westborough, MA Superfund Site. A range of sample preparation and analysis techniques were performed to rapidly generate qualitative and quantitative results on a real-time basis. The analytical plan consisted of 100% split sampling. All samples were analyzed on site using the MEM, with split samples shipped to a CLP laboratory for confirmatory analysis following the guidelines of a comparable EPA method of analysis. For both the PCB and PAH analytical events, the MEM was used to quickly screen a series of samples to establish a dynamic range of contamination. Upon selection of these samples as a result of screening, additional soil was collected, homogenized, and labeled as samples for analysis. The VOC analysis was performed on water samples taken from a pond located on site, due to the inability of accessing the monitoring wells. These water samples were spiked with known volatile organic contaminants at five different concentration levels. Along with quality control standards and the analysis of blanks, seven replicate samples were measured each day for a five day period with each of the three analytical events. Additionally, after the completion of sample analysis, a two week study was performed with the analysis of PCB and PAH Standard Reference Materials (SRM).
The sample preparation and analytical procedures used during the demonstration were unique in themselves. For PAH and PCB laden soil samples, the preparation involved the extraction of 0.5 grams soil with 2.0 mls organic solvent followed by a two minute hand shaking. An aliquote of the extract is injected onto the clean surface of a piece of aluminum foil. Bruker's patented Sampling Probe was used to thermally desorb the contents of the extract from the aluminum foil into a 3.5 M capillary sampling line yielding results in less than 7 minutes. The analysis of VOC contamination involved the adsorption of analytes onto adsorption tubes by a purge and trap technique with the aid of a pump. The equipment necessary for this technique in minimal consisting of a small battery powered low flow pump, tygon tubing, a sample impinger and an adsorbent tube. The tube was then placed into the desorption chamber of the mini-GC to give a full GC/MS analysis in 20 minutes. This demonstration used both of the two possible data systems to acquire the chromatographic information. The internal data system has a monitor, which controls the entire mass spectrometer functions and uses pre-programmed methods for compound monitoring. The auxiliary data station is a MS DOS 386 Compaq computer which is interfaced to the internal data system when full scan acquisition is desired. This configuration allows for full GC/MS/DS capabilities.

This demonstration evaluated the MEM, on its own merits, and by comparing its results to those of a conformational laboratory. Precision was determined by evaluating the percent relative standard deviation (%RSD) of replicate samples for each analytical event. The MEM results show an average of 20% RSD being achieved for the analytes of each analytical event. Accuracy of each analytical event was determined by evaluating the results of Standard Reference Material (SRM) standards analyzed with the MEM. Most PAH SRM compounds were determined to have a negative bias of greater than 30%. This bias was consistent with the confirmatory laboratory indicating the possibility of degradation of the SRM. PCB accuracy also showed a negative bias greater than 40% with results falling between those of two confirmatory laboratories. VOC accuracy ranged between -70 to +200. At low concentrations, the confirmatory laboratory are generally closer to the theoretical value than the MEM concentrations. At higher concentrations, the bias for the MEM samples is generally equivalent or less that those obtained by the confirmatory laboratory. The overall completeness by sample type and by compound exceeded 90% in all cases. (1)

The intricacies of this study involve two matrices, and three different compound classes. The quality assurance project plan was established to allow a data base from which statistical evaluations could be conducted resulting in an accurate assessment. By doing so, a comprehensive comparison between on-site measurements using the MEM and off-site measurements using stationary mass spectrometric systems was completed. As a result, field GC/MS has been shown to be capable of yielding rapid, accurate, and cost effective analyses.

text

INTRODUCTION

Semi-permeable membranes offer the most direct means of detecting and monitoring volatile organic compounds in water. Two configurations have been described using hollow fiber membranes directly coupled to mass spectrometers. In the "flow-over" configuration, the interior of one or more hollow fibers is exposed to ion source vacuum while aqueous sample flows over the exterior surface (1,2). In the "flow-through" configuration, aqueous sample is passed through the fiber interior while the exterior surface is exposed to ion source vacuum (3-6). Preliminary results have been shown using a modified flow-over configuration in which helium is purged through the fiber interior (7). This work describes the results obtained by incorporating a single helium-purged hollow fiber membrane into a flow cell for real-time measurement of regulated volatile organic compounds in municipal drinking water.

TECHNICAL APPROACH

A flow cell utilizing a single 9 cm long silicon rubber hollow fiber shown in Figure 1 was used for this work. Carbon tetrachloride, trichloroethene, benzene, 1,1-dichloroethene and vinyl chloride in methanol were injected into ambient temperature reagent water or drinking water obtained from a laboratory tap, allowing fortified concentrations significantly less than 1 \(\mu\text{g}/\text{L}\) (PPB). The mass spectrometer was a Finnigan MAT TSQ-45 operating as a single analyzer instrument or a Finnigan MAT Model 700 ion trap (ITD). All measurements were made using electron ionization full scan conditions.

Extracted ion current profiles for three of the analytes are shown in Figure 2 for intermittent fortifications in municipal drinking water conducted with the TSQ-45 and a helium purge rate of 1.0 cc-atm/min. The response offset for carbon tetrachloride is due to chloroform present in the drinking water sampling stream. Response was linear for all analytes from 0.18 to 50 PPB except trichloroethene which was not observed at fortified concentrations less than 0.40 PPB.

Results using the ITD before and after 5 PPB fortification of a reagent water sampling stream revealed good signal-to-noise response for each analyte. A sequence of low level challenges were conducted with the ITD similar to those with the TSQ-45, but at lower fortified concentrations. Response was observed for benzene and vinyl chloride at concentrations as low as 0.09 PPB. Minimum detection levels achieved in this work and current Safe Water Drinking Act limits are compared in Table I.

CONCLUSIONS

The helium-purged hollow fiber configuration provides real-time full scan MS measurements of volatile organic compounds in drinking water at concentrations significantly below regulatory limits. The helium purge allows the use of relatively long hollow fibers for high sensitivity, and long transfer lines to the ion source. High sensitivity in real-time is important for process control applications to allow monitoring of trends and implementation of corrective action before regulatory limits are exceeded.

668
Detection of Carbonyl Compounds in Drinking Water Using a Membrane Introduction Probe in a Tandem Mass Spectrometer.

Tapio Kotialho, Tarun K. Choudhury and R. Graham Cooks
Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

Because formaldehyde is known to be carcinogenic, there is a concern over possible health hazards from long time exposure to low concentrations of formaldehyde. Formaldehyde and other carbonyl compounds are formed as by-products during the ozonation of drinking water. These carbonyl compounds react with O-(2,3,4,5,6-pentafluorobenzyl)-hydroxyamine (PFBOA) in aqueous solution to form the corresponding oximes (eq 1) which are volatile, can pass through a semipermeable membrane, and can be detected by electron capture mass spectrometry.

R_2 \quad &\quad C_6F_5-CH_2-O-NH_2
\end{align*}
\]

The objective of the present study was to detect low molecular weight carbonyl compounds at very low concentrations in aqueous solution by using a direct insertion membrane probe in a tandem mass spectrometer.

Figure 1 shows the experimental set up for the membrane introduction mass spectrometer developed in our laboratory and already described elsewhere (1,2). Figure 2 shows the negative ion chemical ionization mass spectrum of a mixture of PFBOA derivatives of formaldehyde, acetaldehyde and propanaldehyde. The following peaks in the mass spectrum provide evidence for the passage of the derivatives through the membrane.

The peaks at m/z 197, 181 and 178 are due to C₆F₅CH₂O-, C₆F₅CH₂N°C and (M' - HF - HCN (RCN)) respectively. The product (MS/MS) spectra of individual compounds shown in Figures 3, 4 and 5 confirm the identity of the characteristic peaks in the mixture. Detection limit for each of the aldehydes in the mixture was established by multiple ion monitoring during MS/MS experiments. The M' ions of PFBOA derivatives of aldehydes were selected with quadrupole one and the product ions m/z 205, 178, 181, m/z 219, 181, 178 and m/z 233, 178, 181 were monitored for the detection limit of formaldehyde, acetaldehyde and propanaldehyde respectively.

The detection limit of formaldehyde was found to be 1 ppb. That of acetaldehyde and propanaldehyde was found to be 10 ppb. In the case of formaldehyde, the range of linearity (shown in Figure 6) was between 1 ppb and 1000 ppb. Experiments are in progress for the establishment of the linear dynamic range of detection for acetaldehyde and propanaldehyde.

REMOTELEY OPERATED, FIELD PORTABLE GAS CHROMATOGRAPHY/MASS SPECTROMETRY SYSTEM FOR MONITORING HAZARDOUS ATMOSPHERE VAPORS

Neil S. Arnold, Dale T. Urban, Robert L. Watteyne, Paul C. Cole and Henk L.C. Meuzelaar
Center for Micro Analysis & Reaction Chemistry, University of Utah, Salt Lake City, Utah 84112

In order to protect and inform personnel involved in monitoring, containment and remediation of hazardous volatiles materials, it is important that exposure to such materials be limited and that personnel working in such environments have sensitive and easily handled tools which do not limit mobility or vision. In order to meet these requirements a man-portable GC/MS system described previously [1] has been modified to meet four objectives: (1) to allow remote instrument operation via a serial data transfer protocol compatible with broadband radio telemetry; (2) to reduce system size for placement in a single backpack or in a small, unmanned reconnaissance plane (drone); (3) to reduce system weight under 50 lbs for worker mobility in man-portable mode and to meet payload requirements for drone aircraft; (4) to increase pumping speed for greater sample throughput and lower detection limits.

Objective 1 has been met by replacing the on-board 386 computer data system with a National Instruments GPIB-110-2 unit integrated into the system. This converts the HPIB data base signals from the MSD (Hewlett Packard) data acquisition electronics to a synchronous, serial data transfer protocol. A second GPIB-110-2, up to 500 m away via coaxial cable, converts data back to GPIB signals at the remote computer data station. This system should be compatible with broadband telemetry for even longer remote transmissions.

Objectives 2 and 3 were partially met when the data system was removed from the portable MS chassis. The previous molecular drag pumping system (MDP 5010, Alcatel) was both slow (8 l/s, N2) and required a bulky (5 l) evacuated cylinder to provide only 2 hrs of backing pressure (@ .1 ml/min He). Clearly, a reduction in volume of this pumping system along with an increase in pumping speed would be necessary to meet criteria 2, 3 and 4.

Table 1 shows a comparison of various vacuum pumping technologies. The pumping system must be able to remove gas volumes greater than .1 ml/min to offer significant improvement in detection limits without sacrificing the preseparation power of the current "transfer line" GC sampling method [1,2]. While none of the off-the-shelf systems met all the needed requirements, it was clear that a potentially powerful system may be possible via a "chemical" pumping method if alternative carrier gases could be used and argon loading could be controlled.

Figure 1 is a drawing of a hybrid pumping system utilizing a modified bulk getter pump (Danielson) designed to minimize heat loss to the environment via a low emissivity Ni getter crucible and to pump background Ar from atmospheric sampling via a 2 l/s ion getter pump (Perkin Elmer). This pumping system operates on 10 W, weighs approximately 10 lbs and pumps more than 50 l/s H2 or 15 l/s N2.

Effective utilization of this system requires compatibility of alternative, non-noble carrier gases with the MSD analyzer system. Figure 2 shows a comparison of MSD operation for the analysis of trace toluene levels in air. At similar pressures, baseline noise levels for all detected ions increased with increasing carrier gas molecular weight. (Presumably due to improved momentum transfer between carrier neutrals and ions in the analyzer). Further, the lower viscosity of H2 caused a significantly higher analyzer pressure and shorter retention time using the same capillary column. The high noise level at .3 ml/min flow rate discouraged N2 usage, but it appears that with a slightly longer column H2 is an effective carrier which is easily pumped by bulk and ion getter systems.

The present system is seen in the block diagram and profile drawings of Figure 3. Because of the low weight and size of this new pumping system, we have met objectives 2 and 3. At this time we are still verifying expected upper ppb detection limits (in SIM mode) utilizing this new pump and H2 carrier.

ACKNOWLEDGEMENTS

This work was sponsored by the U.S. Army, CRDEC and the Advanced Combustion Engineering Research Center. Funds for this center are received from the National Science Foundation, the State of Utah, 23 industrial participants and the U.S. Department of Energy. The authors wish to express their gratitude for the help and advice of Jean Luc Truche and John Fieldsted (Hewlett Packard Corporation).

A HIGH-SPEED, HIGH-GAIN PRECONCENTRATOR FOR MASS SPECTROMETERS: APPLICATIONS TO EI, CI, AND DISCHARGE SOURCES

STEPHEN M. PENN, RANDALL E. PEDDER, SEKSAN DHEANDHANOO, SUHAS N. KETKAR, JOHN G. DULAK, and WADE L. FITE

Extrel Corporation, 575 Epsilon Drive, P. O. Box 11512, Pittsburgh, PA 15238, Telephone: (412) 963-7530, FAX: (412) 963-6578.

This paper describes a high-speed, high-gain preconcentrator that can dramatically improve the real-time air-monitoring capabilities of mass spectrometers. Conventional preconcentrators produce high sensitivity to trace-level constituents at the expense of long sampling times. The preconcentrator described here uses low-pressure and low-flow-rate desorption conditions to increase the concentration of the desorbed analyte in the carrier gas. As a result, it can provide high sensitivity with short sampling times. This device was tested with both EI and CI ion sources. Using 3-second sampling times, the preconcentrator enhanced EI signals by over 500-fold compared with direct sample introduction. The preconcentrator also improved the CI signal 18-fold.

A preconcentration factor or "gain" can be defined as the ratio of the fractional molecular concentration $f_d$ of a trace analyte in the desorption carrier gas to its concentration $f_s$ in the sample gas ($G = f_d / f_s$). The gain can also be expressed in terms of the adsorption and desorption flow conditions by noting that the number of analyte molecules desorbed from an ideal preconcentrator equals the number of analyte molecules adsorbed from the sample gas. The number $N$ of analyte molecules adsorbed on the sorbent is

$$N = f_s n_s W_s t_s$$  \hspace{1cm} (1)

where $n_s$ and $W_s$ are the number density (in cm$^{-3}$) and volume flow rate (cm$^3$ s$^{-1}$) of the sample gas entering the preconcentrator and $t_s$ is the sampling time. The number of analyte molecules desorbed from the sorbent is

$$N = f_d n_d W_d t_d$$  \hspace{1cm} (2)

where $n_d$ and $W_d$ refer to the carrier gas leaving the preconcentrator during the time $t_d$ required for desorption. Combining Eqs. (1) and (2) yields an expression for the preconcentration gain $G$

$$G = \frac{f_d}{f_s} = \frac{n_s}{n_d} \frac{W_s}{W_d} \frac{t_s}{t_d} = \frac{Q_s}{Q_d} \frac{t_s}{t_d}$$  \hspace{1cm} (3)

where $Q$, the mass flow rate in units of molecules per second, is the product of the number density and the volume flow rate.

Eq. (3) shows that the preconcentration gain factor is proportional to gas flow rate during the sampling period and the sampling time, as is commonly recognized. Eq. (3) also illustrates the importance of the desorption conditions.

In viscous flow, the mass flow rate $Q$ through the sorbent is proportional to the product of the average pressure in the sorbent and the pressure difference across the sorbent. Therefore, we can write

$$G = \frac{f_d}{f_s} = \frac{Q_s}{Q_d} \frac{t_s}{t_d} = \frac{<p>}{<p_d>} \frac{\Delta P_s}{\Delta P_d} \frac{t_s}{t_d}$$  \hspace{1cm} (4)

where $\Delta P = (p_f - p_0)$ is the pressure difference between the ends of the sorbent tube and $<p> = (p_0 + p_f)/2$ is the average pressure in the tube.
Eq. (4) shows that reducing both the pressure of the desorption gas and the pressure drop across the sorbent tube leads to enhancements in the concentration of the analyte in the carrier gas. The high-speed, high-gain preconcentrator described here uses low-pressure and low-flow-rate desorption conditions to produce high concentration gains without long sampling times.

This preconcentration concept was tested with a mass spectrometer equipped with an electron-impact ionization source. Gains of greater than 500 were observed with approximately equal sampling and desorption times (3 seconds). The mass flow rate during sampling Q_s was approximately 150 sccm from an atmospheric pressure sample (p_s = 370 torr and Δp_s = 670 torr), while the desorption mass flow rate Q_d was approximately 0.2 sccm (p_d = 19 torr and Δp_d = 21 torr). The gain was measured by comparing the ion signal produced by the preconcentrator and the signal generated from direct introduction of the sample at the same pressure in the ion source (2 x 10^-5 torr). The total preconcentrator cycle time, including the time required to cool the sorbent, was less than 35 seconds.

The same preconcentrator was applied to chemical ionization source using 3-second sampling and desorption times. This configuration produced gains of approximately 18 compared with direct sample introduction at the same source pressure. The difference in gain between the CI and EI sources results from the difference in desorption flow rates required by the two sources. As noted above, the EI source operated with desorption mass flow rates Q_d of about 0.2 sccm, while mass flow rates Q_d of about 3.7 sccm (p_d = 70 torr and Δp_d = 100 torr) were needed to produce high enough pressures in the ion source (approximately 0.5 torr) for effective chemical ionization.

Reducing the gas throughput of CI sources and low-pressure discharge sources, by reducing their leak rates, can reduce the required desorption gas flow rate Q_d and produce higher preconcentration gains. However, the residence time of the analyte gas in the source, which is determined by the ratio of the source volume and the volume flow rate, must be kept small compared to the desorption time. Otherwise, the advantages of rapid desorption times are lost. This limitation requires careful design of these sources to fully exploit this new low-pressure, low-flow-rate preconcentrator.

We expect that this preconcentrator will enable mass spectrometers with traditional electron-impact ionization sources to detect contaminants at concentrations below 1 part per billion in real time. With proper design of the CI and discharge sources, this preconcentration approach may push the real-time detection limits of these ionization sources into the part per quadrillion range.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics
Evaluation of a Time-of-Flight Mass Spectrometer (TOF-MS) as a Multi-purpose Detector for Environmental Monitoring

Paul Farrow, James Kyranos and Peter Ralbovsky, Jim Valentine
Arthur D. Little, Inc., Cambridge, MA 02140.

Continuous monitoring of potentially hazardous compounds in the environment has become increasingly important in the last decade. In some cases rapid on-site analysis is a viable alternative by the use of "mobile" laboratories. However for some applications and circumstances, to send out a mobile laboratory is impractical, e.g. space station, submarines, rocket launch pads. Conventional GC-MS systems can be expensive and difficult to maintain over extended periods of time (several years of continuous operation is often necessary). A potential solution is the development of a rugged, durable, multi-purpose detector for permanent monitoring. The development of a TOF-MS has been considered for this application.

A standard CVC (CVC Rochester, NY) MA-3 TOF was used for this development program to investigate the feasibility of TOF-MS. The inlet system was from Brunfeldt Company (Bartlesville, TX) and modified for our application. A strip chart recorder and PC-based data system were used to collect data (data acquisition system developed at Arthur D. Little).

Two aspects of the design are discussed in this paper along with data collected from the development instrument:

- Effect of low ionization energy on spectra
- Resolution of Instrument related to acquisition rate

Effect of low ionization energy on spectra

Determining the presence of low molecular weight volatile species in the presence of an air background were investigated without the use of chromatographic separation. By the use of low ionization energies (10-15eV), we were able to eliminate oxygen and nitrogen backgrounds from the spectra.

Hydrazine, an analyte of interest and the same molecular weight as nitrogen was introduced directly into the MS source. The spectra taken at 70eV (Figure 1), shows contribution from air masking the hydrazine. However, by dropping the ionization energy to 10eV, we were able to eliminate the air, and obtain a representation spectra of hydrazine (Figure 2) that can be used for qualitative determination.

Resolution of Instrument related to acquisition rate

The design of a data acquisition system is controlled by the amount of power available, physical size and application. As a result of understanding the application, the rate of data acquisition can be greatly reduced, thus reducing the complexity of the hardware involved. For this particular system, we investigated the trade-off between acquisition "bin size" and mass resolution. Figure 3 shows that at a 10ns "bin size," m/z 28 and 32 are well resolved. Even at 200ns, there is sufficient resolution between the two masses. The saving in power by using 200ns versus 10ns is very important when considering space station applications, where power is very limited.

To date, the TOF-MS has demonstrated adequate sensitivity and selectivity for certain analytes of interest. The data system requirements for the acquisition rate will be dependent on the specific application and the need to have unit mass resolution or not. From the data collected on hydrazines, it is apparent that operating at low ionization energies, thus eliminating the air background, a decreased resolution will be sufficient.

USE OF A TAGA 6000E MS/MS ON AN AIRBORNE MONITORING PLATFORM TO MEASURE SPECIES OF INTEREST IN GLOBAL CLIMATE CHANGE

D. V. Kenny, C. W. Spicer, L. E. Slivon
BATTLELLE
505 King Avenue
Columbus, Ohio 43201-2693

INTRODUCTION

The increased interest in conditions affecting global climate change has made it necessary to incorporate airborne monitoring platforms to obtain data aloft. Most instruments carried aloft can obtain real-time data, but only on a limited number of species (e.g., NO, NO\textsubscript{2}, \textit{O}_3, etc.). To obtain data on more complex species, air samples have been collected in canisters or on sorbent media and analyzed later. These limitations inhibit the assessment of 3-dimensional spatial variations in atmospheric concentrations for complex compounds of interest. To obtain spatial concentration data on more complex species in real-time, a feasibility study was conducted to evaluate the potential of atmospheric pressure chemical ionization (APCI) tandem mass spectrometry for continuous monitoring of compounds of interest in global climate change.

TECHNICAL APPROACH

A Sciex TAGA 6000E tandem mass spectrometer with an APCI source was used for this feasibility study. The TAGA was installed in Battelle's Douglas DC-3 aircraft for these flights. Minor modifications were made to the aircraft to supply power to the TAGA, as well as to shock mount the instrument to the floor of the aircraft. These were the only modifications that were required. Sample air was provided from a positive pressure sampling port located near the front of the aircraft ahead of the engine exhaust. A split in the sample line allowed control of the air flow to the TAGA.

Test flights were made in the central Ohio area by slowly spiralling down from 10,000 feet to 2,400 feet. This altitude window allowed us to sample above, as well as within the mixing layer of the atmosphere. Compounds continuously monitored were acetone, formic acid, acetic acid, peroxycetyl nitrate (PAN), NO\textsubscript{2}, and SO\textsubscript{2}. Multiple reaction monitoring was performed in positive or negative ion modes to maximize sensitivity for the compounds of interest.

In addition to the vertical profile experiments, monitoring was conducted while circling a trash burning power plant to identify plume boundaries and compounds in the plume.

RESULTS

Figures 1 and 2 are examples of the vertical profiles for acetone and SO\textsubscript{2}. Acetone concentrations ranged from 0.5 ppbv to 2.75 ppbv, formic acid concentrations ranged from 1.0 ppbv to 5.0 ppbv, acetic acid concentrations ranged from 0.2 ppbv to 0.7 ppbv, PAN concentrations ranged from 0.1 ppbv to 0.5 ppbv, NO\textsubscript{2} concentrations ranged from 5.0 ppbv to 13 ppbv, and SO\textsubscript{2} concentrations ranged from 2.5 ppbv to 28 ppbv. Concentration ranges for all of the species monitored are typical of the atmospheric concentrations in the central Ohio area.
CONCLUSIONS

We have successfully demonstrated the capability of real-time MS/MS monitoring of atmospheric species on an airborne monitoring platform. This capability opens new techniques that the atmospheric scientist can utilize in the study of global climate change, model verification, and pollution detection and quantification. Future experiments are scheduled to monitor species along the eastern seaboard between Washington, DC and Cape Hatteras, NC in the fall of 1991.

Identification of a Corrosive Agent in an Industrial Process:
Mass Spectrometry As Part of a Multi-Technique Problem Solving Effort

During the operation of a process column, catastrophic corrosion began to occur in the reboiler. This system which involved an aqueous methyl diethanolamine (MDEA) solution did not typically give corrosion rates even approaching the several hundred mils per year rate observed in this system. The rate of corrosion grew as the process solution aged, suggesting that some reaction product of the amine or other substance which built up in the system was to blame for the corrosion. Deposits of black material were found in the system which were identified by X-ray diffraction and Energy Dispersive X-ray Fluorescence as iron sulfide. NMR and FTIR analysis revealed traces of materials not found in virgin amine solution which could be oxidation products of the amine, but no specific identification could be made with these techniques. Analyses typically used to evaluate the amine solution in the production plant did not show any abnormal results which could account for the corrosivity. Cyclic voltammetry helped characterize the corrosion, but without a suspect corrosive agent, could not provide an identification of the culprit.

The literature suggested that a three step mechanism might be active in the corrosive process. The first step involved acidic attack on the materials of construction, carbon steel in this case. Acids are certainly present in the system in the form of so-called heat stable salts of the amine. Various acids such as formic, acetic and thiocyanic are known to be present and form salts with the amine. The concentration of these salts tends to increase because heat does not regenerate the amine from them. The second step is said to involve chelation of the dissolved iron so that it can be transported to a region where the third step becomes operative. In the third step, the iron is precipitated by sulfide freeing the chelating agent to tie up and transport more iron so that it can also be precipitated. Iron sulfide was already shown to be forming in the system in copious amounts. Thus, the corrosive agent might be some chelating agent unique to this process which is as yet unidentified.

In order to obtain a more specific identification of the corrosive agent GC/MS analyses were conducted. A number of materials were identified. Figure 1 shows a typical result. Some substances which were thought to be possible corrosive agents were not found either in the GC/MS runs or direct-probe MS runs. One relatively large impurity peak was observed by GC/MS and remained to be identified. (Figure 1 "145 m/z") As will be seen this material proved to be the chelating agent suggested by the three step mechanism.
EI-MS (Hewlett-Packard 5985B GC/MS/DS) indicated that the compound potentially had molecular weight of 145 Da, contained nitrogen, and probably a primary alcohol, similar to MDEA. Isobutane CI confirmed the 145 Da molecular weight. GC/FTIR/MS (Hewlett-Packard 5890A GC/5965A FTIR/5970B MS) indicated that the compound had a carbonyl band at 1781 cm⁻¹. This suggested that the compound was a carboxylic acid. Accurate mass measurements (VG 70-SE) showed that the compound had the empirical formula C₆H₁₁NO₃. GC/MS/MS (Finnigan TSQ-70) experiments showed that the fragmentation sequence was unremarkable being sequentially stepwise down from m/z 145. (145-114-86-56-42) The presence of six carbon atoms in the compound was surprising in that MDEA has only five carbons.

Brainstorming of possible structures suggested that a lactone containing nitrogen might be possible. Lactones and carboxylic acids both turn out to have carbonyl bands near 1780 cm⁻¹ in the vapor-phase. The specific compound 4-hydroxyethyl morpholin-2-one can be envisioned to form by cyclodehydration of N,N-bis-hydroxyethyl glycine, otherwise known as bicine. Bicine is very similar to compounds expected from oxidation of the MDEA except for the extra carbon. The literature indicated that bicine is a strong chelator of ferric ion. Evidently, the bicine was reacting in the GC injector to produce the lactone. (Figure 2) Synthesis of bicine revealed that it gives the lactone seen in the GC analysis. The lactone so produced has the same EI spectrum as the unknown. Direct-probe MS analysis of bicine gave spectra that were mixtures of spectra of the lactone and bicine.

The origin of bicine was the next question. Two mechanisms have been proposed as possible explanations for the formation of bicine from MDEA. The first involves disproportionation of the ammonium ion of MDEA to give various mixed amines including N-methyl ethanolamine, N,N-dimethyl ethanolamine, diethanolamine and triethanolamine. Triethanolamine was shown to oxidize in air to bicine. The other mechanism uses formaldehyde and cyanide ion both present in the system to produce the nitrile analog of bicine which is hydrolyzed to bicine.

The identification of bicine as the cause for the corrosion has led to a number of approaches for eliminating the problem. Several of these are being investigated presently.

GAS CHROMATOGRAPHY/MASS SPECTROMETRY (GC/MS) FOR REACTIVE ORGANIC COMPOUNDS

Q. G. Grindstaff

Plant Laboratory
Oak Ridge Y-12 Plant*
Martin Marietta Energy Systems, Inc.
Oak Ridge, Tennessee 37831-8189

INTRODUCTION

Reactive chemical compounds present many problems for analysis by gas chromatography (GC) and gas chromatography/mass spectrometry (GC/MS). These problems extend from the failure to detect these compounds at low levels to rapid decrease of the response factors, which are used for quantitation, of these compounds with time. Quantitative methods such as EPA Methods 525 and 625 require very precise reproducibility of response factors for many very reactive compounds at low concentration levels. Most GC/MS systems presently used for analysis of these methods can only meet the QC/QA requirements for a short time, especially for Method 525. An enhanced GC/MS system has been developed at the Oak Ridge Y-12 Plant. The system allows for the analysis of reactive compounds like those of EPA Method 525 and 625 at concentration levels much less than those required by Method 525.

EXPERIMENTAL

The experiments were performed on a Kratos MS-50 mass spectrometer equipped with the Enhanced GC/MS System. A Restek Rtx-5, 30 meter, 0.32 mm ID, 1.0 μm df column was used. The mass spectrometer was scanned at 0.5 sec/dec from 35-600 amu.

RESULTS AND CONCLUSIONS

Figure 1 shows the results of a 1 ng per component injection on the system after the system had been in maintenance-free service for 1 year. The results show excellent sensitivity of the Enhanced System for the highly reactive phenols of EPA Methods 525 and 625 when compared to the internal standards that are also injected at a 1 ng concentration level. The internal standards used were 1,4-dichlorobenzene-D4, naphthalene-D8, acenaphthene-D10, phenanthrene-D10. All of the phenols have excellent peak shapes. Table 1 shows the effect on performance of a year's operation on the Enhanced System. Even after this time, the data show no reduction in response to the phenols. The May 1990 data represent the average over 14 days, while the April 1991 data represent a single analysis. The Enhanced System has proven to prevent column bleed from reaching the mass spectrometer ion source. This reduction of bleed is so great that no background subtraction is required, even when 100 pg levels of the phenols are analyzed. The Enhanced System has proven its ability to greatly improve identification of compounds with very low response factors at concentration levels of less than 100 pg. The system has been able to get perfect identification on compounds, such as pentachlorophenol and 2,4-dinitrophenol at a concentration less than 100 pg.

A COMPARISON OF VARIOUS GC/MS INTERFACES FOR THE ANALYSIS OF VOLATILE ORGANIC COMPOUNDS

Linda C. Doherty and Douglas E. McIntyre, Scientific Instruments Division, Hewlett-Packard Co., 1601 California Ave. Palo Alto, CA 94304

EPA Method 524.2 is the capillary gas chromatography/mass spectrometry (GC/MS) method for the analysis of volatile organic compounds in drinking water. This method specifies full scan data acquisition and special MS tuning to meet p-bromofluorobenzene (BFB) ion ratio criteria. Because this method requires much lower detection limits than the "600 series" counterpart (EPA Method 624), the HP 5971A benchtop mass spectrometer and MS Engine were evaluated for the low-level volatile organic analysis (VOA) in drinking water.

Method 524.2 allowed for the use of 0.75, 0.53 (known as megabore) and 0.32 mm inner diameter (ID) columns. This study was conducted to evaluate different instrumental configurations necessary to implement 0.53 mm and 0.32 mm ID columns in both singly and differentially pumped mass spectrometers. Three MS configurations: megabore/jet, megabore direct and capillary direct were used. The HP 5971A Mass Selective Detector (MSD) required a jet separator to compensate for the high flow rates of the 0.53 mm ID column (8-15 ml/min). With the differentially pump MS Engine, the 0.53 mm ID column was interfaced directly. The 0.32 mm ID column was interfaced directly to the HP 5971A source but required cryofocussing. The MSD results obtained from the 0.53 mm ID column with a jet and the 0.32 mm ID column with a capillary direct interface were compared.

Figure 1 shows chromatograms from each of the three configurations. Twenty-five milliliter samples were analyzed in each configuration. Because of the large amount of CO\textsubscript{2} transferred from the trap to the column (from the charcoal), each chromatogram was either background subtracted or the chromatogram from mass 48-260 amu extracted. Comparing the HP 5971A with the 75 m, 0.53 mm ID column and the 50 m, 0.32 mm ID column the run times are similar. The absolute counts (y-axis) for the capillary direct configuration are about two times higher showing better transfer of sample from the purge and trap to the mass spectrometer.

The results of this study showed that the longer 0.53 mm ID columns (>50 m) eliminated the need for cryogen. The GC oven could be started at 35 °C and the light gases would still be chromatographed. Cryogenic conditions were necessary when the 0.32 mm ID column was installed because the low GC flow rate required long desorb times. The sub-ambient temperatures kept the sample in a tight slug which was essential for proper chromatographic peak shape.

The SGE metal jet was well suited for 0.53 mm ID columns and the HP 5971A. It eliminated the need for make-up gas (necessary with the glass jet). MS Engine, the differentially pumped mass spectrometer was able to accommodate high flow rates (10 ml/min) without a jet separator.

The capillary direct interface with cryofocussing allowed for low level calibrations at concentrations five times lower (0.04 ppb instead of 0.2 ppb) than the 0.53 mm ID column with the metal jet. The initial cost of the capillary direct configuration was less than the jet configuration. However, maintenance costs of the LN\textsubscript{2} cooled capillary configuration were much higher. The jet configuration was easier to install and better tolerated water carry-over from the purge and trap.

By demonstrating that all three configurations are amenable to volatile analysis, the choice of set-up will be dependent on the sensitivity required. The 0.53 mm ID columns will have much higher capacity (>200 ng on column). The 0.32 mm ID columns are more useful at lower concentrations (<200 ng). Thus, the 0.32 mm ID columns are most useful for high sensitivity analysis, where the 0.53 mm ID columns can be used for the analysis of drinking water and waste water.
Figure 1. Chromatograms for 1 ppb (25 ng) purged standards.
"DETERMINATION OF OFF-ODORS AND OTHER VOLATILE ORGANICS IN FOOD PACKAGING FILMS BY DIRECT THERMAL ANALYSIS-GC-MS" Thomas G. Hartman, Joseph Lech and Robert T. Rosen; Center for Advanced Food Technology, Cook College, Rutgers University, New Brunswick, New Jersey 08903

This investigation was conducted to determine the compounds responsible for an off-odor in a polypropylene food packaging film manufactured from a recycled resin feedstock. The off-odor was not present in films made under identical conditions using virgin resin. Therefore, it was our intention to obtain a profile of the volatile organic compounds from both film samples and look for differences which may be the cause of the off-odor complaint. A Scientific Instrument Services (SIS) model TD-1 Short Path Thermal Desorber accessory combined with GC-MS was used for the direct thermal analysis of the food grade polypropylene packaging films. Films were placed directly in the desorption apparatus and heated (100°C, 10 min.) to outgas volatile and semi-volatile compounds from the polymer films. The desorbed compounds were then separated and identified by GC-MS. Compounds causing an off-odor in the recycled polypropylene film were easily identified by comparing chromatograms from good and bad films. Both films were found to contain over 175 volatile organic compounds. However, the film made from recycled resin was found to contain a cluster of approximately 25 peaks in the low boiling region of its gas chromatogram which were absent in the film made from virgin resin (Fig. 1,2). These peaks were identified as a mixture of C-7 to C-9 aliphatic and olefinic hydrocarbons with branched, linear and cyclic species present. Perhaps even more significant from a sensory viewpoint was the presence of N,N-dimethylformamide. The aromatic compound toluene was also detected. Thus based on this data it was judged that these compounds were the cause of the off-odor in the recycled films. Additional compounds which were found in both films included a range of phthalate ester plasticizers (Fig. 3), phenolic antioxidants such as butylatedhydroxytoluene (BHT) and 2,6-di-t-butylphenol (Fig. 4), paraffinic hydrocarbons used as mold release agents (Fig. 5) and a series of sesquiterpenoid compounds such as α-copaenes and α & β-ylangenes which may be fragrance compounds or UV-stabilizers.

Plastic films made for food packaging applications are primarily composed of high molecular weight polymers which are hence nonvolatile at temperatures below those which induce pyrolysis reactions. However, a multitude of low molecular weight volatile compounds are added to films as manufacturing aids and to impart functional properties into the products. Plasticizers and elastomers are used to promote flexibility and inhibit brittleness. Common plasticizers and elastomers include phthalates, adipates, other esters of dicarboxylic acids and fatty acid amide derivatives. Antioxidants are added to prevent oxidation of the film itself as well as to protect the foods stored within the films. Hindered phenols such as BHT, BHA, TBHQ and di-t-butylphenols are commonly employed for this purpose. Ultraviolet (UV) stabilizers are added to prevent "yellowing" of the films upon exposure to light. Compounds such as diphenylketones and various methoxylated derivatives are commonly used for this purpose. During the manufacture of these films various processing aids are employed. These include accelerators and cross-linking agents to promote polymerization and polymer strength and mold release agents such as paraffinic hydrocarbons or organosilicones which are used to prevent sticking to the rollers as the films are extruded. Still other additives may be added to prevent static build-up and fragrance compounds may be used to mask resulting off-odors in the films. Indeed, in some heavily plasticized films the total volatile organic fraction can be as high as 40 % w/w. Given the plethora of volatile organic compounds which are present in food packaging films it is not surprising that they readily migrate into foods stored therein often causing off-odors. In addition, there is presently much concern for the potential health risks associated with consuming food products with high levels of packaging borne migrants. The problems have recently become exacerbated by the increased use of packaging films as food wraps during microwave cooking. For these reasons it is obvious why there is a need for analytical methodology to study the volatile organic composition of packaging films. These investigations serve to define the additive composition of particular films and to assess the potential for migration of these species into foods. In addition this methodology is useful for general QA/QC testing, packaging compatibility studies or for comparing films from different vendors.
We acknowledge the Center for Advanced Food Technology (CAFT) Mass Spectrometry facility for providing analytical support. CAFT is an initiative of the New Jersey Commission on Science and Technology. This is NJAES publication number S-10569-1-91.

LOW PICOGRAM DETECTION IN THE FULL SCAN MODE
WITH THE HP 5970 MSD MASS SPECTROMETER

Charles A. Koch* and Julius Peret‡

*Hewlett Packard Co., 1421 South Manhattan Avenue, Fullerton, California 92631
‡Phrasor Scientific Inc., 1536 Highland Avenue, Duarte, California 91010

The Hewlett Packard 5970 mass selective detector (MSD) demonstrates ample sensitivity for environmental waste analysis, but the lower limits of detection required for drinking water warrants improved sensitivity. Low picogram quantities can now be detected in the full scan mode by a modification to the detector. The quality control requirements of organic gas chromatography/mass spectrometry environmental analysis as found in the Federal Register¹ and also the U.S. EPA contract Lab program² can still be met. There is a 30 fold increase or more in absolute signal, which brings the MSD down into the picogram range of detection for full scan data acquisition, and much lower for selected ion monitoring. The improved sensitivity comes from a high energy dynode (HED), which has been described elsewhere³,⁴ to increase high mass signals that arise mostly from fast atom bombardment or liquid chromatography/mass spectrometry techniques. A conventional MSD detects positive ions by the production of secondary electrons released when incident ions impact the electron multiplier surface, while the HED uses post-acceleration of the positive incident ions to increase the sensitivity. The background subtracted mass spectrum of a 100 picogram injection of indeno(1,2,3-cd)pyrene made with an HED voltage of 5,000 volts, an electron multiplier voltage of 1800 volts, and a one microliter injection volume is shown in Figure 1. The MSD scanned at one cycle per second from 45 to 475 amu. A commercial environmental lab has placed the HED in an MSD for the analysis of volatile organic samples, and the quality control requirements in references 1 and 2 were satisfied, such as the twelve hour shift criteria and compound recoveries. The main benefit of the HED is increased sensitivity and lowered detection limits.

**Figure 1.** The background subtracted mass spectrum of 100 pg of indeno(1,2,3-cd)pyrene.

Investigation into losses of dimethylphthalate from matrix and blank spikes in EPA Method 625 (extraction, GC/MS) analyses of wastewater in our laboratory pointed to base-catalyzed hydrolysis as the mechanism of loss. There is, in fact, a trend toward increasing $K_\text{OH}$ values for phthalate esters with decreasing alkyl group size and branching (1). EPA Method Study 30 (summarizing the results of a round-robin test of Method 625) suggests that hydrolysis of the lower molecular weight phthalate esters may occur during the base extraction, resulting in low recoveries. The report suggests that extraction be done as quickly as possible to minimize loss.

In an investigation of ways to improve the recovery for the phthalates in general, and DMPh in particular, we undertook several series of experiments. The first established the base pH-adjustment step as the point of loss. The others examined the effects of spiking concentration, pH, and delay time between basification and extraction on the observed recoveries of phthalate esters.

The purpose of the Series 1 experiments was to locate the point of loss for dimethylphthalate (DMPh) in Method 625 analyses. Experiments were set up to isolate the various parts of the extraction and extract concentration techniques used. In these experiments, DMPh was not detected (ND) at the method detection limit (MDL) of 4 µg/L in all the extracts for which the extracted water had been made basic. Recovery was greater than 95% for all the other samples. This strengthened the hypothesis that the cause of DMPh loss was base-catalyzed hydrolysis.

The purpose of the Series 2 experiments was to compare the effect of pH with that of spiking concentration. In these experiments, it was found that keeping the pH between 11.0 and 11.5 gave 30% recovery for DMPh, while adjusting to pH > 12 reduced its recovery to below the MDL. Detection at this MDL (4 µg/L) would be equivalent to 20% recovery. Samples for which the pH was between 11 and 11.5 were spiked at two concentrations, but recoveries for both were about 30%, suggesting that pH has a greater effect on DMPh loss than spiking concentration. Reproducibility between split duplicates was good.

The purpose of the Series 3 experiments was to compare the effects of pH on the recoveries of the six phthalates which are Method 625 analytes. The results are given in Figure 1. In these experiments, it was found that, while the greatest effect of pH is observed with DMPh, there is also a substantial effect on the recovery of butylbenzylphthalate (BuBzPh). Lesser effects were observed with diethylphthalate (DEPh) and dibutylphthalate (DBPh), while no effect was observed on the recoveries of dioctylphthalate (DOPh) and bis(2-ethylhexyl)phthalate (B2EHPh). The most dramatic change occurred between pH 11 and 11.5.

The purpose of the Series 4 experiments was to compare the effects of a time delay between pH adjustment and extraction on the recoveries of the same six phthalates. The results are given in Figure 2. In these experiments, it was found that reduction in recovery for DMPh and BuBzPh began within minutes of basification. Again, lesser effects were observed with DEPh and DBPh, and no effect was observed with DOPh and B2EHPh.
Examination of the results from these experiments suggests that for the best recoveries of phthalate esters from basic water extractions, the pH should be adjusted to just past pH 11 and the extractions should be performed within 15 minutes after the pH adjustment.

Figure 2. Extraction recoveries of Priority Pollutant phthalates from basic(pH=11.5) lab water versus time delay between pH adjustment and extraction.
Direct Thermal Analysis of Plastic Food Wraps Using the Short Path Thermal Desorption System

John J. Manura, Sandy Overton, Chris Baker
Scientific Instrument Services, Inc.
1027 Old York Road, Ringoes, NJ 08551

The purpose of this study is to determine the low level volatiles and semi-volatiles present on the surfaces of commercially available "microwave safe" plastic food wraps which have the potential to leach into food products during the microwave cooking process. The new "Short Path Thermal Desorption System" was utilized to permit the direct volatilization (sparging) of samples into the GC injection port without any prior solvent extraction or without the use of vapor traps. This technique permits the maximum sensitivity of analysis due to this direct injection technique with subsequent GC and GC/MS analysis.

The Scientific Instrument Services "Short Path Thermal Desorption System" was attached to the injection port of a H.P. 5971 GC/MSD. A J&W DB-5, .25mm x 25 meters, 0.25u film thickness capillary column was used for this study. The GC was used in the splitless mode at a flow rate of 0.5 ml/min.

Desorption Tube for Direct Thermal Analysis

Experimental

Three square inch samples of each of the four plastic food wraps was placed directly inside the 1/4" x 4" long GLT desorption tube. These tubes were then fitted to the Short Path Thermal Desorption System and fitted with a syringe needle. The sample was flushed with helium carrier gas and then autoinjected into the GC injection port. The heating blocks were heated to the sparging temperature indicated and closed around the desorption tube to ballistically heat the sample to the set temperature. This combination of heat and flow sparge any volatiles or semi-volatiles into the GC injection port were they are subsequently trapped in a narrow band at the front of the GC column which has been cryo-cooled to -40° C. The sample is collected for 10 minutes after which the GC is programmed at 10° per minute up to 280° C, to elute the products which are subsequently analyzed via the Mass Spectrometer.
Results and Discussion

Each of the four plastic food wraps produced its own distinctive pattern of peaks consisting of more than 100 peaks which vary in intensity from strong to very weak. Each of the chromatograms exhibit the total ion chromatogram for each of the four plastic food wraps.

Most of the peaks present exhibit 43, 57, and 71 masses which are indicative of the linear and branched paraffinic hydrocarbons which are commonly used as mold release agents during the manufacture of the plastic food wraps. These hydrocarbons and some of their corresponding alcohols comprise the bulk of the peaks detected.

In addition two major phthalates at 34.4 and 38.6 minutes were identified as diethyl phthalate and dibutyl phthalate in the Glad Wrap sample and several of the other plastic wraps.

Additional peaks present in the plastic food wrap samples were identified as BHT (Butylated Hydroxytoluene), a few cyclic hydrocarbons, and aromatics.

Conclusion

Utilizing the "Short Path Thermal Desorption System" it is possible to analyze plastic film samples, as well as other packaging materials, by sparging directly into the GC injection port, the volatiles eluted from the surfaces of these materials at elevated temperatures. This technique is unique in that it can be utilized to analyze the trace surface components and impurities present on these polymers which are not pyrolyzed or thermally affected at the relatively low temperatures used in this study. The amount of sample required for analysis is very small, and due to the direct injection and volatilization into the GC injection port, maximum sensitivity is attained via this technique. In addition labor time for sample prep is minimized and the use of solvents for extraction is eliminated with this technique.
Purge & Trap GC/MS Analyses of Volatile Organics in Imported Bottled Mineral and Spring Water

Thomas L. Barry & Glenn Petzinger
U.S. Food & Drug Admin., B'klyn N.Y., 11232

The consumption of bottled water in the U.S. from both domestic and imported sources has been steadily increasing. The most recent incident which received much publicity was the finding of benzene in Perrier Water.

In order to obtain information with regard to current Good Manufacturing Practices, current/proposed Quality Standards and food labeling requirements, the FDA surveyed domestic and imported bottled water, including mineral and spring water for various contaminants including Volatile Organics (VOC's).

FDA is proposing to adopt as quality standards for bottled water (1,2,3) the Maximum Contamination Level (MCL) that EPA has established for seven of the following VOC's in public drinking water (4,5):

- Benzene 5 ppb
- Vinyl Chloride 2 ppb
- Trichloroethylene 5 ppb
- Trichloroethane 200 ppb
- Dichloroethylene 7 ppb
- 1,2-dichloroethane 5 ppb
- Carbon Tetrachloride 5 ppb

The limit for total trihalomethanes is already established by FDA at 100 ppb (6).

EPA method 524.1 (7), a Purge & Trap GC/MS procedure employing a 6 ft. packed GC column was used for the analyses of the water samples.

Samples (25ml) were spiked at 4 ppb with an internal standard and at 5 ppb with surrogate recovery compounds.

AutoQuan* procedure TCA was used to quantitate the mass spec runs. Average response values obtained from a four point calibration curve (1,4,10, & 20, ppb) were written into the library and used for quantitation and for comparison to the 4 ppb daily standard to determine instrument acceptability.

Thirty nine (39) samples of imported bottled mineral and spring water from thirteen (13) countries, representing thirty two (32) different brands were analysed for VOC's.

Twenty three (23) samples contained no reportable levels of VOC's and sixteen (16) samples contained reportable levels of seven (7) different VOC's. All reportable VOC's were well below the proposed limits:

- Chloroform (5) T-11 ppb
- Bromodichloromethane (1) 2 ppb
- 1,1,1-Trichloroethane (2) T
- Tetrachloroethylene (1) T

Only analytes not common to the blanks were reported.

The limit of quantitation was 1 ppb.
Values below 0.5 ppb are reported as None Detected.
Values between 0.5-1 ppb are reported as a Trace (T)
The 6 ft. 1% SP-1000 Carbopack B GC column provided good separation for all compounds of interest. Toluene (#28) was separated from Toluene-d<sub>s</sub> (#27 sur), 1,2-dichloroethane (#12) was separated from 1,2-dichloroethane-d<sub>s</sub> (#11 sur).

In peaks #19, 20, 21, 22, Benzene and dibromochloromethane were separated while 1,1,2-trichloroethane and dichloropropane were not completely separated, however, this did not present a problem in the analyses.

The average recovery for Toluene-d<sub>s</sub> (sur) over a three month period was 101% with a range of 85 to 116%. The average recovery for 1,2-dichloroethane-d<sub>s</sub> (sur) was 95% with a range of 81 to 114%.

Exploration of Ion-Molecule Reactions for Distinguishing Isomers of Polychlorodibenzo-p-dioxins

Stephen Chan and Christie G. Enke
Department of Chemistry, Michigan State University, East Lansing, MI 48824

Polychlorodibenzo-p-dioxins (PCDDs) have been known for their environmental hazard for decades. With the exception of the octachloro congeners, all the very toxic PCDD congeners have chlorine substitution at the 2, 3, 7 and 8 positions. In particular, much attention is focused on 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) because of its extreme toxicity. For many years, GC/MS has been a standard method for analyzing TCDDs in environmental samples. However, isomers of TCDD often give identical or very similar mass spectra when traditional mass spectrometric techniques are used. By inducing collisionally activated dissociation (CAD) on [M]+ and [M]- ions of TCDDs, tandem mass spectrometry (MS/MS) has been shown to reduce inferences in complex environmental samples (1,2). The CAD technique did not offer isomer-specific identification for 2,3,7,8-TCDD because the fragmentation patterns of most TCDD isomers are very similar. In order to improve the specificity for analyzing PCDD isomers, we have explored the options of employing ion-molecule reactions occurring in the second quadrupole of a triple quadrupole mass spectrometer to distinguish the more toxic PCDD isomers from the less toxic ones.

All the reactant ions are produced in the ion source using ammonia chemical ionization (CI). Under the CI conditions, all the congeners with four chlorines or less give the [M-1]- ion as the predominant product with the exception of 1,2,3,4-TCDD which gives mostly the [M]- ion. The lower acidity of 1,2,3,4-TCDD is primarily due to the lack of the electron-withdrawing effect of having a Cl adjacent to H. Increasing the number of chlorines from four to five also decreases the acidity of PCDDs. No [M-1]- ion is found for the PCDD congeners with five chlorines or more. The electron capture product, [M]- ion, is the main product for the PCDD congeners.

The selection of the [M-1]- ion as the reactant for ion-molecule reactions can reduce interferences from compounds with relatively low acidity. We have studied hydrogen/deuterium (H/D) exchange reactions between DsO and [M-1]- ions of PCDDs with 4 chlorines or less. With the exception of 1,3,6,8-TCDD, exchange products are observed from all the isomers selected for this study. In the case of TCDD isomers, 2,3,7,8-TCDD can be distinguished from 1,2,3,4-, 1,3,6,8-, 1,2,7,8-, and 1,3,7,8-TCDD by its formation of only one exchange product (Figure 1). The exchange reactions are not observed for the [M]- ions of the higher chlorinated PCDDs. We believe that the lone-pair electrons on the [M-1]- ion are important to initiate an H/D exchange reaction.

Alcohol molecules are also useful for identifying 2,3,7,8-TCDD from the other isomers. When the alcohol neutral molecules react with the [M]+ ions of PCDDs, ion-molecule adduct complexes are formed. The reactivity increases from methanol to isopropanol; but it decreases dramatically to a very low level when isobutanol is used as a reagent. For the four alcohols used, the reactivity of 2,3,7,8-TCDD is consistently the lowest among the five selected TCDD isomers. The [M]+ ion of 2,3-dichlorodibenzo-p-dioxin (DCDD) also exhibits lower reactivity compared to the other isomers of DCDDs. Since the most probable charge site for the anion of 2,3-DCDD is the same as the one on 2,3,7,8-TCDD, we conclude that a charge site located adjacent to an oxygen atom of a PCDD anion is an unfavorable site for the formation of an adduct complex. The unique chemical characteristics of the [M]+ ion of 2,3,7,8-TCDD have been well demonstrated by our studies. These results encourage the continued search for better isomer-specific ion-molecule reactions.

COMPARISON OF POINT AND NON-POINT SOURCES OF PCDD AND PCDF TO SEDIMENTS AND FISH FROM THE HOUSATONIC RIVER AS DETERMINED BY GC/HRMS.

Brian D. Eitzer, The Connecticut Agricultural Experiment Station, P.O. Box 1106, 123 Huntington St., New Haven, CT 06504.

Polychlorinated dibenzo-p-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF) are highly toxic classes of compounds produced during combustion and as a by-product of various manufacturing processes. The combustion sources result in atmospheric transport and deposition creating a non-point source to the environment, while the by-products are often discharged with wastewater creating point sources.

The Housatonic River flows through a series of impoundments in Southwestern Massachusetts and Western Connecticut into Long Island Sound. Much of the river is contaminated with polychlorinated biphenyls (PCB) at concentrations up to 60 ppm. The PCB were from a point source and PCDF are known contaminants in PCB. There are also several paper mills which discharge into the river. Thus sediments and fish from this river offer a unique opportunity to compare the environmental importance of PCDD and PCDF from these point sources with atmospheric input from the industrial Northeast.

Sediment and fish samples were taken from the impoundments of the river (from upstream to downstream respectively) at Center Pond (C), Woods Pond (W), Rising Pond (R), Falls Village Dam (F), Bulls Bridge Dam (B), Upper Lake Lillinonah (U), Lower Lake Lillinonah (L), and Lake Zoar (Z). Comparison samples were taken from the Shepaug River (R) (a Housatonic tributary) and West Side Pond (P) (a small isolated lake in the same region).

Samples were analyzed via a semi-automated modification of EPA method 8290 utilizing gas chromatography/high resolution mass spectrometry in the electron impact mode. Ions were selected for monitoring at mass resolution of 10,000 to minimize contribution to the ion channel for PCB remaining in the sample after clean-up.

Concentrations of the dioxins and furans ranged from 24 ppb PCDD and 44 ppb PCDF in Woods Pond to 110 ppt PCDD and 44 ppt PCDF in Center Pond. The concentrations of PCDD/F normalized to the organic carbon in the sediment is shown in Figure 1. Note the large jump for Woods Pond (just beyond the point PCB source) and a smaller jump for Lake Lillinonah (after a non-point input from the industrial area around Danbury).

Figure 2 is a principal components plot of the congener profile normalized to the total PCDD/F concentration for that sample. The first two factors are plotted. Note how the profile shifts for the Woods Pond samples and then gradually returns to "normal" as sample sites move down stream. These results show that the effect of a point source can be seen in sediments taken from an industrial area with a non-point or atmospheric profile.
Figure 1. Average total concentrations normalized to organic carbon for each site.

THE DETERMINATION OF COPLANAR PCBs, PCDDs, AND PCDFs IN MOTHER'S MILK BY HIGH RESOLUTION GAS CHROMATOGRAPHY/HIGH RESOLUTION MASS SPECTROMETRY

K.R. Thornburg, K.E. Boggess, and J.S. Stanley
Midwest Research Institute, Kansas City, MO 64110

INTRODUCTION

Polychlorinated biphenyls (PCBs) have been identified in virtually every part of the global ecosystem, including human and animal tissues, milk, sediment, and numerous other matrices. Because of the chemical and physical stability of PCBs, they tend to bioaccumulate in nature. Toxicological investigations of PCBs are complicated by the potential for exposure to up to 209 isomers. However, selected coplanar PCBs, particularly 3,3',4,4'-tetrachlorobiphenyl (IUPAC #77), 3,3',4,4',5-pentachlorobiphenyl (IUPAC #126), and 3,3',4,4',5,5'-hexachlorobiphenyl (IUPAC #169) have been found to elicit toxic responses similar to 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD). As a result, there is an interest in developing information on human body burdens of these compounds in addition to that of the 2,3,7,8-substituted polychlorinated dibenzo-p-dioxins (PCDDs) and dibenzofurans (PCDFs).

The coplanar PCB isomers are typically observed in human tissue at much lower concentrations than other PCB isomers. Therefore, accurate quantification of the coplanar PCBs is very difficult by standard GC/ECD methods. It is possible, however, to separate the coplanar isomers from the non-coplanar PCBs through the use of carbon adsorbents. This procedure isolates the coplanar PCBs, PCDFs, and PCDDs, in the same carbon column fraction so that they may be determined in a single HRGC/HRMS analysis.

EXPERIMENTAL

A quality control mother's milk pool was prepared from volunteers in the Kansas City area. Milk samples from five mothers were composited and homogenized with mechanical mixing. Approximately 50 grams of milk was fortified with nine $^{13}$C$_{12}$-labeled 2,3,7,8-substituted PCDD/Fs, and three $^{13}$C$_{12}$-labeled coplanar PCBs as internal standards for the determination of PCDD/Fs and coplanar PCBs, respectively. The fortified milk samples were then mixed with an aqueous solution of sodium oxalate, ethyl ether and ethanol, and extracted with hexane for 30 min. The hexane extract was recovered and concentrated to a constant weight for the determination of extractable lipid. The lipid residue was diluted in hexane and subjected to an acid silica gel slurry and neutral/acid silica gel chromatography column. The subsequent column chromatography cleanup steps included neutral alumina and Carbopack C/Celite. The extract was then concentrated, fortified with recovery internal standard, and concentrated further to a final volume of 5 µL.

The HRGC/HRMS analysis of the mother's milk extracts were conducted on a 60 meter DB-5 capillary column coupled directly to a VG70S high resolution mass spectrometer operated in the selected ion monitoring mode. Several modifications to existing methodologies were made to allow simultaneous detection and quantification of the coplanar PCBs along with the PCDDs and PCDFs. One modification was necessary to resolve hexachlorobiphenyl isomer 169 from 1,2,3,7,8-PeCDF. These two compounds coelute and require a mass resolution of approximately 50,000 to separate their isobars at m/z 358, 360, and 362. The M+4 peak of 1,2,3,7,8-PeCDD can be totally obscured in the case where the PCB
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

isomer 169 is present in higher concentrations than the dioxin congener. In order to avoid overlap of the responses of these compounds it is necessary to choose alternate ions for PeCDD from those suggested in the standard methods. Monitoring m/z 354 and 356 (M+ and M+2 respectively) for PeCDD instead of m/z 356 and 358 (M+2 and M+4) eliminates all overlap of hexachlorobiphenyl isomer 169 with 1,2,3,7,8-PeCDD.

Another modification to existing methods involves monitoring 12 additional ions necessary to determine the PCBs and the corresponding 13C-PCB internal standards. The PCB isomer 77 masses are monitored in a separate group which is inserted into the normal experiment before the TCDD/TCDF ion group. The PCB isomer 126 masses are added to the TCDD/TCDF ion group. The addition of four extra masses into this group does not compromise the sensitivity TCDD and TCDF. PCB isomer 169 masses are monitored during the elution of the PeCDDs and PeCDFs. Again, the addition of these extra masses does not affect the overall sensitivity.

RESULTS

The procedure outlined above yields accurate and precise data for the determination of PCDDs, PCDFs, and coplanar PCBs in mother's milk at the low parts per trillion level. The internal standard recoveries ranged from 65 to 82% for 13C-labeled PCDD/Fs and from 64 to 72% for 23PCBs. Accuracy ranged from 93 to 111% for PCDD/Fs and 73 to 96% for PCBs in fortified milk samples. Replicate analysis of control milk samples yielded percent standard deviations of 5 to 21% for PCDD/Fs and 10 to 31% for coplanar PCBs. These data are well within the performance criteria specified in most PCDD/F methods.

Introduction

Environmental samples suspected of containing polychlorinated biphenyls (PCB) and analyzed by EPA Method 8080 frequently contain non-PCB components, such as phthalates, PAH's, or organochlorine pesticides. The presence of these interferences can often obscure the GC/ECD patterns and cause problems in differentiating the Aroclor types by visual inspection. Since Method 8080 requires the identification of Aroclor types in order to trace the sources of PCB occurrences, NICI detection was used to provide additional parameters for discriminating PCB congeners from interferences. In this study, a pattern recognition method has been developed to classify the types of Aroclors for environmental samples. A computer program written in BASIC has been implemented to facilitate Aroclor classification using the NICI ion abundance measurement for PCB congeners.

Experimental

NICI spectra for PCB samples in this study were obtained with a Hewlett-Packard 5985B GC/MS system equipped for EI and CI operation. Samples were introduced via a 30 m x 0.25 mm DB-5 fused silica column with helium as carrier gas. The column temperature was programmed from 130°C to 180°C at 5°C/min, then increased to 250°C at 2°C/min. The flow rate of reagent gas (methane), introduced through a heated transfer line, was regulated to maintain a source pressure of 0.4 torr. The ion source temperature was 100°C. The electron energy was set at 200 volts and the emission current at 300 uA. Nine Aroclor standards, including 1016, 1221, 1232, 1242, 1248, 1254, 1260, 1262, and 1268, were analyzed for a concentration range of 0.2 to 100 ppm. Using selective ion display, the ion abundances of the prominent peak in the chlorine cluster were measured for eight homologs \((\text{Cl}_2-\text{Cl}_6)\) within the PCB retention window for each
standard. These NICI measurements on Aroclor standards were used as training data set to develop classification methods for environmental samples. PCB contaminated oil or soil samples were either extracted or diluted with hexane and analyzed in the same manner as the standards.

Results and Discussion

The relative ion abundances (RIAs), defined as the abundance of each homolog with respect to the sum of all homologs, were calculated for eight selective ions (m/z 221, 256, 292, 326, 360, 394, 430, and 464). The distances between Aroclor classes are measured in a 7-dimensional simplex space defined by the RIAs. We used the Mahalanobis distance function to measure separation between centroids of the Aroclor classes. Aroclor classification uses the smallest number of RIAs. The number of RIAs was selected by (1) ordering from largest to smallest the distance ratios of "between class" to "within class" for each RIA, and (2) the accumulative minimum distance among all the classes.

We developed linear discriminant functions (LDFs) to classify samples into the nine Aroclors based on 74 samples in the Aroclor training set. The first step of a sequential classification method calculated LDFs using six RIAs for ions m/z 430, 464, 394, 326, 256, and 360 to identify Aroclors 1016, 1268, and remaining Aroclors. Additional classification was necessary for samples classified as remaining Aroclors. Updated LDFs identified Aroclors 1221, 1232, 1242, 1248, 1254, 1260, and 1262. These updated LDFs used different set of RIAs (for ions m/z 430, 394, 326, 292, and 360) for classification variables and a different covariance matrix than those in the first step.

This sequential classification method classified all Aroclors in the training set correctly. A set of 15 environmental samples with known Aroclor types were also correctly classified.

2ASCl Corporation, 6201 Congdon Boulevard, Duluth, MN 55804

Analytical procedures and a quality assurance plan have been developed for the determination of coplanar polychlorinated biphenyls (PCBs) #77 (3,3',4,4'-tetrachloro-), #105 (2,3,3',4,4'-pentachloro-), #126 (3,3',4,4',5-pentachloro-) and #169 (3,3',4,4',5,5'-hexachloro-) in biological tissue at target level of quantification of 5 pg/g. The methodology is based upon isotope dilution HRGC/HRMS and is both analogous to and compatible with rigorous protocols developed for PCDD/PCDF determinations (1) as well as other environmental contaminants such as PCBs and pesticides (2).

The protocol for the isolation of coplanar PCBs was based upon chromatography on carbon (AMOCO PX-21) which has been suspended upon silica gel, however the exact procedure was determined by the analyte list. For instance if PCDD/PCDF were the only other analytes to be quantified, then soxhlet extraction and sample cleanup on a sulfuric acid/silica gel column was used, but if pesticides and PCBs were to be analyzed then soxhlet extraction and sample cleanup by gel permeation chromatography and micro-silica gel chromatography was used. In each case, extracts (0.5 mL in isoctane) were transferred to a 500 mm X 5 mm column containing 350 mg of carbon on silica gel (100 mg/g) with three 0.5 mL portions of hexane and eluted with an additional 18 mL hexane to remove non-coplanar PCB and pesticides. The column was then washed with 22.5 mL methylene chloride/benzene (1:1, v:v) to obtain coplanar PCBs. Finally, the column was eluted with 25 mL toluene in a reverse flow direction to obtain PCDD/PCDFs.

Analysis is accomplished using HRGC (30m X0.25 mm DB-5) and HRMS (R=5000) operating in the MID mode. Quantification of PCBs #77, #126, and #169 are relative to 13C12 analog internal standards. Quantification of PCB #105 is relative to PCB 13C12 #126. Rigorous QA/QC criteria which include GC elution time, signal to noise ratios, and ion abundance ratios have been established to assure...
high quality data (3). QA/QC criteria for the performance of the instrument follows that established for PCDD/PCDF determinations.

An analysis of composites of fish from the Great Lakes and Atlantic bottlenose dolphins from the U.S. east coast has been completed. The concentration of analytes in Lake Ontario lake trout, for instance, were; 22.5, 486, 6.96, and 0.62 ng/g lipid for PCB # 77 #105, #126, and #169 respectively. The mean concentrations for five dolphins were lower; 0.68, 251, 0.60, 0.27 pg/g lipid for the same PCBs. The observation of low coplanar PCB concentrations is consistent with data that show the concentration of other coplanar analytes such as PCDD and PCDF are also very low when compared to fish. Relative to total PCB concentrations, coplanar PCB in dolphin samples comprise a much smaller proportion than in fish. The reason for the differences is yet unknown, but may be due to differences and physical/chemical properties of individual PCBs, which results in different PCB compositions to which the animals are exposed, and/or to differences in metabolic capabilities. The capacity for biotransformation of PCBs has been found to increase in the order fish, open water cetaceans, harbor porpoises and seals.

A new herbicide F 6285 was placed in a 0.5 N solution of NaOH. The resulting product was extracted and submitted for NMR and MS analysis.

Low resolution (RP • 1,000) El mass spectral data determined the mass of the product to be m/z 320 (FIGURE 1). The isotope distribution indicated that 2 Cl's and 1 S were present. The mass of the parent herbicide was known to be 386 u, therefore some base breakdown had occurred and structural identification was necessary to determine a mechanism for this new product.

High resolution (RP = 10,000) El peak matching data determined the elemental composition to be C10 H10 N4O2SCl2. The results are below:

Measured Mass 319.99011
Theoretical Mass 319.99957
Difference (u) 0.00044
Difference (ppm) 1.4

The Proton NMR results indicated that two labile protons could be present in the base breakdown product. See FIGURE 2 (bottom).

Proton NMR spectra of F6285 base breakdown product before (bottom) and after the addition of deuterated pyridine (top).
To ascertain the number of labile protons an aliquot of CD₃OD (0.25 ml) was added to the sample and a low resolution EI mass spectrum was obtained (FIGURE 3). The results indicated that only one labile proton was indeed present in our base breakdown product.

To cross-check our conclusion that there is only one labile proton present in our base breakdown product, an aliquot of deuterated pyridine was added to the CDC₁₃ solution and a second proton NMR spectrum was obtained. We had suspected that some of the peak broadening (8.5 and 6.9 ppm) in the original NMR data was due to a small amount of HCl present in our CDC₁₃ solvent. Because of our relatively small amount of material (~2 mg) the peak broadening due to the HCl was evident.

The results are observed in FIGURE 2 (top) The peak at 8.5 ppm was sharpened and the peak at 6.9 ppm disappeared. The peak at 6.9 ppm was concluded to be the labile proton, and the structure and subsequent mechanism for the base breakdown product is shown in FIGURE 4.

**Proposed mechanism for the base breakdown product of F6285.**
LC/MS AS A COST EFFECTIVE METHOD FOR MULTIRESIDUE ANALYSIS OF HERBICIDES AND METABOLITES IN CROPS, SOIL, AND WATER

Lamaat M. Shalaby

INTRODUCTION

The demands for analytical methods to detect residues of crop protection chemicals in our environment stressed the need for multiresidue techniques. Thermospray LC/MS offers both the liquid chromatographic separation needed for thermally labile pesticides, high sensitivity, and mass selectivity required for trace level multiresidue analysis. In our recent applications, we used the technique as a stand-alone, primary method for multiresidue analysis of thermally labile sulfonylurea herbicides and metabolites in crops, soil, and water (1, 2). Using the mass spectrometer in the selected ion mode offers a universal selective detection which minimizes the need for sample clean-up and simplifies method development. Simple sample preparation will increase sample throughput which saves time and minimizes solvent waste. In addition, it will improve recovery by reducing analyte losses during the clean-up steps. Using the mass spectrometer for detection offers a build-in structure confirmation of the target compounds which eliminate the chance for false positive. This report describes the application of LC/MS for residue analysis of three sulfonylurea herbicides, sulfometuron methyl, the active ingredient of the noncrop land herbicide OUST and chlorsulfuron, the active ingredient of the cereal herbicide GLEAN and bensulfuron methyl, the active ingredient of the rice herbicide LONDAX in soil down to 50 ppb. In addition, the report includes residue methods for three sulfonylureas in wheat grain at 50 ppb level and another method for the analysis of sulfometuron methyl and metabolite in water at lower levels.

EQUIPMENT

The HPLC system consisted of a VARIAN model 5560 liquid chromatograph equipped with a constant-flow pump, a variable wavelength detector (VARIAN, Instrument Group, Walnut Creek, CA), and an Alltech Spherisorb ODS column, 4.6 mm i.d. x 25 cm (Alltech/Applied Science, IL). The mass spectrometer was a Finnigan model TSQ70 triple stage quadrupole instrument with the ICIS data system. The LC/MS interface was a Finnigan TSP2 thermospray with discharge electrode and filament ionization (Finnigan MAT, San Jose, CA). The liquid chromatographic conditions were optimized to separate the herbicide using gradient elution system of acetonitrile in 0.1M acetic acid. A simple extraction procedure was used to extract the herbicides from crops and soil without further clean-up. A typical sample preparation includes extracting a 10 gm sample three times with 10 mL aliquots of 80% acetonitrile in water followed by filtration.

Extract aliquots were concentrated 5/1 prior to the LC/MS analysis. The thermospray LC/MS interface temperature and mass ions were selected to maximize sensitivity and selectivity. The ammonium acetate solution required for thermospray ionization was added post column to maintain the chromatographic separation of sulfonylureas.

RESULTS AND DISCUSSION

An LC/MS reconstructed ion chromatogram for a standard mixture of sulfometuron methyl, chlorsulfuron and bensulfuron standards (0.1μg/mL) is presented in Figure 1. The
Figure indicates a stable ion signal and good chromatographic separation. A detection limit of 0.01 µg/mL is easily obtainable due to the good signal-to-noise ratio. Figure 2 represents the LC/MS total ion chromatogram of a 0.05 ppm fortified soil extract. The chromatogram shows no interference from the soil matrix at the retention time of the three sulfonylureas. The recovery of the three sulfonylureas in soil was determined by comparing the amount detected by LC/MS in the final extract of the fortified samples to the original fortification level. The recoveries were between 88-115% for the three compounds, sulfometuron methyl, chlorsulfuron, bensulfuron methyl at levels of 0.050 - 0.200 ppm in soil and were 75-95% in wheat grain at levels of 0.050 - 0.500 ppm.

LITERATURE CITED

A COMPARISON OF LOW RESOLUTION AND HIGH RESOLUTION MASS SPECTROMETRIC TECHNIQUES FOR THE DETERMINATION OF N-NITROSODIMETHYLAMINE IN ENVIRONMENTAL SAMPLES

Ontario Ministry of the Environment, Rexdale, Ontario, Canada M9W 5L1

The Ontario Ministry of the Environment analyzes N-nitrosodimethylamine (NDMA) in a variety of aqueous matrices including raw and treated drinking water, surface water, groundwater, sewage treatment plant influent and effluent, industrial effluent and impinger water. The analysis of NDMA in matrices that vary widely in composition requires a protocol that is selective as well as sensitive. The protocol must also be simple and rugged in order to maintain a high level of productivity.

The sample preparation procedure (1) consists of an extraction step (with dichloromethane) combined with acid/base partitioning to remove basic and acidic components respectively followed by concentration of the extract containing the remaining neutrals. Quantitation was performed by a standard isotope dilution technique using $d_6$-NDMA.

Analysis by GC/LRMS consisted of monitoring the quantitation ion at m/z 74 and the qualifying ion at m/z 42 on a VG Trio-2 using a 30m DB-1701 column. The ions monitored for the $d_6$-NDMA were m/z 46 and m/z 80.

Analysis by GC/HRMS consisted of single ion monitoring at 7,000 RP on a VG ZAB-2F using a 30m DB-1701 column. The ions monitored were m/z 74.0480 for NDMA, m/z 80.0857 for $d_6$-NDMA and m/z 68.9952 for PFTBA (lockmass).

Drinking water samples were analyzed by GC/LRMS and GC/HRMS (1). Although these samples are considered to be relatively clean, their chromatograms showed interfering peaks and the 42:74 ion ratio varied widely. The acceptable window for this ion ratio was set at +/- 20% of the value obtained from a calibration standard run on the same day. It was shown that the presence of chemical interferences made the 42:74 ion ratio criterion unreliable and that analysis by GC/HRMS was preferable.

Other aqueous matrices were analyzed using the same sample preparation protocol. These included sewage treatment plant (STP) influent and effluent, groundwater and industrial effluent. For samples containing high concentrations of NDMA, smaller aliquots were taken and diluted accordingly with HPLC-grade water so that the ratio of NDMA:$d_6$-NDMA would be close to 1:1. The sample extracts were analyzed by GC/LRMS and GC/HRMS. The results are shown in Table 1.

These data also show that the 42:74 ion ratio criterion is unreliable and that interferences are present at m/z 74 as well as at m/z 42. It is also possible to have interferences with the $d_6$-NDMA at m/z 80.

i=interference (incorrect ion ratio)
ND=not detected (no peak)

In subsequent studies of these interferences, another groundwater sample was analyzed by full scan GC/MS. Chlorobenzene and ethylbenzene were found to coelute with the NDMA on a DB-1701 column. M/p-xylene and o-xylene elute 0.2 min and 0.8 min respectively after the NDMA. These interferences are compounds that have minor ions in common with NDMA but are present in much higher concentrations. Chlorobenzene and ethylbenzene have a minor ion at m/z 74 but no ion at m/z 42. Their presence will affect the 42:74 ion ratio as well as the quantitation. Interferences having ions at m/z 42 only will affect the 42:74 ion ratio but not the quantitation. On a DB-5 column, toluene coelutes with NDMA.

Another sample contained N,N-dimethylformamide (DMF) which elutes after NDMA. If present in sufficient quantities, the M+1 (m/z 74) of DMF will interfere with NDMA.

The chemical interferences that have been identified in these samples will adversely affect the analyses of NDMA if they are done by GC/LRMS with the present level of sample cleanup. Further cleanup steps would be necessary if analysis of the underivatized NDMA by GC/LRMS is to become a reliable alternative to GC/HRMS. However, this would also adversely affect productivity.

These results demonstrate the superior selectivity of HRMS over LRMS. With GC/HRMS on a ZAB-2F, a method detection limit of 5 ppt at 7,000 RP can be obtained on a 1 L water sample. The instrument detection limit is <1 ppt.

INTRODUCTION

The fungus, Fusarium moniliforme, can cause leukoencephalomalacia (LEM) in horses (1) and has been shown to be a rat carcinogen (2). Fumonisin B₁ is a member of a family of mycotoxins recently isolated from cultures of the fungus F. moniliforme. Gelderblom et al. (3) have shown that Fumonisin B₁ displays toxic effects when given to rats. Marasas et al. (4) induced LEM in horses by intravenous injections of Fumonisin B₁. These reports suggest that Fumonisin B₁ could be the toxic component of F. moniliforme. Currently, HPLC with fluorescence detection is one of the most promising techniques being developed for the routine determination of Fumonisin B₁ (5). Mass spectrometry (MS) is also being investigated for use in the characterization of Fumonisin B₁. Both Bezuidenhout et al. (6) and Plattner et al. (7) have described the identification of Fumonisin B₁ using various techniques including liquid SIMS.

We have investigated the utility of thermospray mass spectrometry (TSM), fast atom bombardment mass spectrometry (FABMS), and electrospray MS (ESMS) for the analysis of Fumonisin B₁. In addition, we have analyzed two different standards of Fumonisin B₁ as well as a corn culture extract which contained Fumonisin B₁. This report describes the results of our efforts, showing that ESMS as well as FABMS and FABMS/MS provide useful data for the characterization of Fumonisin B₁.

EXPERIMENTAL SAMPLES

Two standards of Fumonisin B₁ were obtained from two different sources: Sigma and South Africa. The Sigma (Sigma Chemical Co., St. Louis, MO) standard was dissolved in 50/50 acetonitrile/water to give a solution that was nominally 100 µg/ml. The South African standard was received as a solution from Misty Conder (Arkansas Livestock and Poultry Commission) and was approximately 5 µg/ml in 50/50 acetonitrile/water. In addition, a purified extract from a corn culture containing Fumonisin B₁ was obtained from Ron Plattner (USDA/ARS, Peoria, IL); the concentration of this extract was adjusted to approximately 500 µg/ml in 50/50 acetonitrile/water.

THERMOSPRAY

The TS mass spectra were obtained using a Finnigan MAT TSQ 70 triple quadrupole mass spectrometer equipped with a Finnigan TS interface and source. Analyses were performed in the positive ion, discharge-off and filament-off mode. Flow injection analyses were performed using an Isco model LC-5000 syringe pump connected to a Rheodyne 7125 injector equipped with a 20 µl sample loop. The mobile phase was 0.1 M ammonium acetate in water pumped at 1.25 ml/min. Typically, the vaporizer was set to 90 °C and the block was set to 220 °C. The mass spectrometer was scanned from m/z 200 to m/z 800 at a rate of 1 sec/scan.

ELECTROSPRAY

The electrospray mass spectra were obtained using a Delsi/Nermag R3010 triple quadrupole mass spectrometer equipped with a Delsi/Nermag electrospray interface and source. The samples were pumped into the source at a flow rate of 1 µl/min. The mass spectrometer was scanned from m/z 100 to m/z 1000 at a rate of 4 sec/scan.

FAB

The FAB mass spectra were obtained using a Finnigan MAT TSQ 70 triple quadrupole mass spectrometer equipped with a Finnigan FAB source and an Ion Tech fast atom gun. Xenon was utilized in the primary atom beam at energies of 8 to 10 KeV. Thioglycerol was used as the matrix. Typically, 1 µl of sample was applied to the FAB probe tip after the matrix was applied, and the mass spectrometer was scanned from m/z 200 to m/z 800 at a rate of 1 sec/scan.

FABMS/MS analyses were performed by using the same conditions, but with argon set to about 0.5 mtorr as the collision gas and a collision energy of either 30 or 50 eV. To obtain daughter ion spectra, MS1 was set to pass the selected parent ion while MS2 was operated under full scanning conditions.
RESULTS AND DISCUSSION

Under TSMS conditions, Fumonisin B₁ gave an [MH]⁺ ion at m/z 722, but the signal was very weak and the relative intensity of the [MH]⁺ ion was less than 10%. Multiple fragment ions were also observed by TSMS.

Using ESMS, each standard showed a strong [MH]⁺ ion at m/z 722 as the base peak in the mass spectrum. Figure 1 shows the ES mass spectrum of the Sigma standard; the peak at m/z 744 is the [MNa]⁺ ion, and the peak at m/z 760 is the [MK]⁺ ion. The ES mass spectrum for the South African standard was similar to the one shown in Figure 1, except that in addition to the ions described for Figure 1, the mass spectrum included peaks at m/z 766 and m/z 788, corresponding to the [M + 2Na - H]⁺ ion and the [M + 3Na - 2H]⁺ ion, respectively.

FABMS provided strong [MH]⁺ ions at m/z 722 for each of the two standards. Figure 2 shows the FAB mass spectrum for the Sigma standard. The FAB mass spectrum obtained from the analysis of the corn extract sample also showed a base peak at m/z 722 indicating that Fumonisin B₁ was a major component in the sample. In addition, a new peak at m/z 564 was observed; the m/z 564 peak was assumed to be due to some unknown impurity in this sample. FABMS/MS analysis of the standards and sample was also performed. CAD of the [MH]⁺ ions for Fumonisin B₁ yielded daughter ions attributed to side chain cleavage and water losses. Similar results were obtained from the CAD analyses of the two standards and the corn extract sample. CAD of the m/z 564 ion from the corn extract sample provided data that suggest that the impurity which yields the m/z 564 ion has a structure in which one of the side chain groups in the Fumonisin B₁ molecule is replaced by a H atom.

CONCLUSIONS

While TSMS was not found to be suitable for the analysis of submicrogram quantities of Fumonisin B₁, both FABMS and ESMS provided useful data for nanogram quantities of this compound. In addition, FABMS/MS was found to be useful for the confirmation of Fumonisin B₁ in a corn culture extract. FABMS/MS was also utilized for characterizing an impurity in the corn extract sample.

A CONCISE METHOD FOR THE DETERMINATION OF PESTICIDES AND THEIR METABOLITES IN GROUNDWATER.

D. L. Swackhamer, M. Rahi, K. Schatz, L. Herschberger, S. Ugargol, R. Pearson, S. Larson, D. Pilger, S. Pitschka, Division of Environmental and Occupational Health, School of Public Health, University of Minnesota, Box 197 UMHC, Minneapolis, MN 55455. T. Klaseus and B. Wheeler, Minnesota Department of Health, 925 Delaware Street SE, Minneapolis, MN 55459

The wide use of pesticides in agriculture, their persistence at trace levels in the environment and the concern over their health risk effects have prompted an interest in the development of multi-residue analytical methods. The objective of this study was to develop a single and concise method to survey groundwater contamination in selected agricultural areas of the state of Minnesota. The study includes atrazine, alachlor, fonofos, phorate, chlorpyrifos, terbufos, carbofuran and most of their known degradation products.

A study comparing solid phase extraction (SPE) to liquid-liquid extraction indicated neither of the methods was suitable for good recoveries of all compounds under investigation. Fig. 1. shows recoveries for the phosphate residues.

It has also been shown that atrazine is better recovered by solid phase extraction while its degradation products de-ethylatrazine and de-isopropylatrazine are obtained in higher recovery by liquid-liquid extraction. Therefore, triplicate samples of groundwater were collected. One sample was pumped through a C-18 SPE cartridge, eluted first with ethyl acetate followed by a second elution with acidified methanol to recover hydroxyatrazine. The ethyl acetate extracts were concentrated under nitrogen to 0.2 mL, spiked with internal standard solution and analyzed. The second sample was subjected to liquid-liquid extraction using dichloromethane. The extracts were solvent exchanged to ethyl acetate and concentrated to 0.2 mL, spiked with the same internal standard solution and analyzed. Carbofuran and its degradation products, and de-methoxymethylhydroxyalachlor were measured in the third sample by derivatizing another SPE extract with trifluoroacetic acid anhydride to yield stable compounds suitable for GCMS analysis.

Analyses were performed on a Hewlett-Packard (HP) 5890 A gas chromatograph equipped with a 30 m x 0.25 mm DB-5 (J+W Scientific) capillary column coupled to an HP 5988 mass spectrometer in El mode. Injections of 1 μL were made by an HP 7673A automatic sampler. Separation was accomplished by a multistep temperature program. Two ions from each compound were selectively monitored over the appropriate retention window. The most abundant ion for each analyte was used.
for quantitation and the second most abundant for confirmation as shown in Fig. 2. Quantitation was done by the internal standard method using the Aquarius subroutine of the Hewlett-Packard RTE-A data system. The relative response factors were linear from 0.1 to 10 ng injected. Confirmation of the presence of any analyte was based on the relative retention time, the presence of the confirmation ion and the ratio of the abundances of the confirmation to quantitation ions. The detection limit of these compounds range from 10 to 100 pg injected. Carbofuran and its degradation products were screened for their presence in SPE extracts by qualitatively monitoring for the phenolic compounds, which are formed in the injection port. When a presence of these compounds was indicated, quantitation was done from an injection of the derivatized extract. The dual extraction methods of SPE and liquid-liquid extraction ensured an acceptable recovery for all the analytes under study. This study offers a concise method for the analysis of a wide variety of the most commonly used pesticides at trace level.

Fig. 2 GCMS/SIM chromatogram of 1 μL injection of a standard mixture containing between .50 and 10 ng of each compound. The quantitation and the confirmation ions (m/z) are as follows.

Quantitative Analysis of LAS Using Continuous-Flow FAB Tandem Mass Spectrometry

Anthony J. Borgerding and Ronald A. Hites
School of Public and Environmental Affairs and Department of Chemistry
Indiana University, Bloomington, Indiana 47405

Introduction. Linear alkylbenzenesulfonates (LAS), the most common commercial
surfactants, are introduced into the environment at rates of approximately
300,000 tons/year. Clearly, understanding the environmental fates of these
compounds is important. LAS have been measured using liquid chromatography and
GC-MS after one or more derivitization steps (1-2). Our laboratory is using
continuous-flow fast-atom bombardment (CFFAB) tandem mass spectrometry to give
quantitative and qualitative information on LAS occurring in environmental
samples.

In the study of alkylbenzenesulfonates by CFFAB tandem-quadrupole mass spectrom-
etry, only one daughter ion was found containing an intact benzenesulfonate
moiety. This daughter ion is at m/z 183 for linear alkylbenzenesulfonates and
at m/z 197 for alkylbenzenesulfonates containing branched alkyl chains. See
Figure 1 for spectra and proposed fragmentation schemes.

We have developed a method for the analysis of LAS which takes advantage of this
behavior. By scanning the parent ions of the ethylene substituted benzenesulfo-
nate ion at m/z 183, LAS are selectively identified. Because of this selectivi-
ty, sample preparation is reduced to concentration of the analyte in liquid
samples, and extraction from solid samples followed by concentration of the
extract. In addition, since we use flow injection introduction of the sample to
the mass spectrometer, analysis times are reduced to as low as 2 minutes, allow-
ing much quicker throughput than chromatographic methods.

Experimental. For all experiments, a flow injection system was utilized,
consisting of an Isco μ-LC 500 syringe pump and a Valco CI4W injection valve
with a 0.5 μl injection volume. A mixture of 50% methanol, 45% water, 5% gly-
cerol was pumped at a flow rate of 5 μl/min into a VG Trio 3 triple quadrupole
mass spectrometer. The probe tip was held at 50 °C. Argon was used as the
collision cell gas at a pressure of 2.7 mtorr as measured by a Baratron capaci-
tance manometer, while the collision energy of the cell was set to 20 eV. The
commercial FAB source and continuous-flow FAB interface were modified slightly
to improve performance: A small cup was soldered to the source heating block
which allowed a sorbent pad to be placed beneath the probe tip and absorb excess
liquid and prevent sudden evaporation. In addition, new probe tips were made
which included a 1/16" diameter frit and a 0.5 mm deep notch to control the
stability and direction of the liquid flow across the tip.

Water samples were passed through a 0.5 μm filter and concentrated by pumping
them through a 4.6 mm X 25 cm column packed with Bondesil preparative grade SAX
material. LAS were eluted with 0.2 M HCl in methanol, and concentrated to 1 ml.
LAS in a sample from a primary treatment tank in an activated sludge treatment
plant were determined by filtering the sample, removing the analyte from the
solid material by sonication in methanol, filtering the solids again, and con-
centrating the supernatant to 1 ml by evaporation.

Results. The CFFAB parent-ion method gives consistent results over a wide range
of concentrations, as indicated in Figure 2. Response to LAS is linear over a
range from 10 ng to 1000 ng (Figure 3). Figure 4 shows the parent-ion spectrum
of an equimolar mixture of C₁₀ to C₁₂ LAS homologues, indicating that the system
response to each of these homologues is equal. Therefore, each LAS homologue in
a sample can be determined by integrating the signals of the parent ion corre-
sponding to LAS with a given chain length.
The method was applied to the analysis of LAS in an activated sludge treatment plant. Samples were taken from the plant influent, the primary treatment tank, and the river into which the effluent from the plant flows. Figure 5 shows the parent-ion spectrum of the primary treatment sample, indicating the presence of C_{10} to C_{13} LAS homologues. Figure 6 shows the total concentration of LAS at each location as well as the concentrations of the individual homologues. Concentrations were determined against an external calibration curve. Each of these analyses was done in duplicate; the total analysis time was 18 minutes.

Reduction of Azo Dyes to Aromatic Amines for Monitoring Dyes in Waste Streams

J. Keever, R. Straub, and *R. D. Voyksner
Analytical and Chemical Sciences, Research Triangle Institute
P. O. Box 12194, Research Triangle Park, NC 27709 USA
H. S. Freeman, College of Textiles
North Carolina State University, Box 8302
Raleigh, NC 27695 USA

The limited availability of suitable analytical methods for the analysis of a wide variety of azo dyes hinders the ability to regulate their emission into the environment. Development of analytical methods for dyes is difficult due to the nonvolatility and thermal lability of dyes, the complexity of dye mixtures, and the variety of dye types (e.g., acids, solvents, disperses, etc.). The reduction of azo dyes to aromatic amines greatly simplifies the analytical problem since most of the aromatic amines (originating from all dye types) can be measured by one analytical technique. While reduction of azo dyes in solvent has been reported (1), the success of reduction of dyes in waste samples has been limited.

Three chemical procedures were evaluated for the reduction of azo dyes. The first reduction agent, tin chloride (SnCl₂), is important in the reduction cleavage of azo linkages in the presence of other easily reduced groups, such as a nitro group. The second method which involves sodium dithionate (Na₂S₂O₄) has been used to effect the reductive cleavage of water soluble azo dyes for decolorizing used dye baths. The third chemical procedure involved the in situ catalytic reduction of the azo dyes by hydrogen (H₂) in the presence of palladium (Pd) under the elevated temperature of a gas chromatographic injector.

The results observed from the reduction cleavage reaction of azo dyes are presented in Table 1. It was observed that the chemical reduction methods resulted in nearly 100% reduction of the azo bond to form the characteristic amines. Overall, the tin chloride method was a more powerful reducing agent, yielding a greater number of products. The in situ reduction of the azo dyes with H₂/Pd resulted in the formation of products consistent with the SnCl₂ and Na₂S₂O₄ reduction of the azo dyes, plus additional reduction products not previously observed.

These three reduction methods were evaluated on a dye containing wastewater sample. The dye was extracted with methylene chloride before undergoing reduction. Particle beam high performance liquid chromatography/mass spectrometry (HPLC/MS) analysis of the SnCl₂ and Na₂S₂O₄ reduced wastewater extracts indicated the presence of reduced, but unidentified compounds. Gas chromatography/mass spectrometry analysis of the wastewater using H₂/Pd produced reduction products consistent with azo dye structures. Table 2 shows a brief list of the HPLC/MS and GC/MS results.

Reduction methods permitted the detection of dyes that could yield aromatic amines under anaerobic degradation conditions that otherwise were not detected using standard MS techniques such as GC/MS or particle beam - HPLC/MS. While the identity of the dye could not always be postulated, their reduction products (aromatic amines) provided means to measure and possibly regulate azo dye wastes.

This work was supported in part by EPA Contract Number 68-02-4544.

Mass Spectral Identification of Compounds Present in Toxic Fractions of a Dye Manufacturing Effluent

Catherine M. Clarkin, M. Judith Charles, and Francis A. DiCiano
Department of Environmental Sciences and Engineering, School of Public Health, University of North Carolina, Chapel Hill, NC 27599-7400

INTRODUCTION

In response to the Water Quality Act of 1987 many state regulatory agencies require industries and municipalities to perform biomonitoring tests to determine the toxicity of their effluent to aquatic biota. Accordingly, the US Environmental Protection Agency has developed a Toxicity Identification Evaluation (TIE) protocol to guide the identification of toxicants in industrial and municipal effluent. This protocol is a series of fractionation procedures used to separate toxic and nontoxic components. Toxicity of the fractions is determined using acute tests with Ceriodaphnia dubia as the test organism. In this study we present a case history that uses the TIE protocol to identify/characterize the aquatic toxicity of effluents from a dye industry. The suspected contributors to effluent toxicity were chloride, which results from the use of sodium chloride to precipitate dyes, and some portion of the high organic content. Dyes, unreacted dye precursors, dye intermediates, surfactants, or byproducts from biological treatment were possible sources of the organic toxicity in the effluent.

METHODS

Toxicity testing of whole effluent samples and chemical fractions were performed using Ceriodaphnia dubia, an invertebrate, as the test species. Acute toxicity tests were performed, with lethality as the end point. Toxicity was measured in terms of an IC\textsubscript{50} or an ET\textsubscript{50}. The concentration at which 50% of exposed organisms die within a specified amount of time (in this case, 48 hours) is an IC\textsubscript{50} (g/L) and the time it takes for 50% of exposed organisms to die at a given concentration is an ET\textsubscript{50} (hours).

Samples of the effluent from the industrial waste treatment facility at the dye manufacturing plant were collected on January 9, 1990 (Sample 1), April 9, 1990 (Sample 2), and July 31, 1990 (Sample 3). The procedures outlined in the EPA TIE Phase I and II documents were followed in the examination of the three samples. The EPA TIE Phase I procedures are used to characterize effluent toxicity as metals, volatile compounds, nonpolar organic compounds, particulates, oxidants, or ammonia. Those tests that were successful in reducing toxicity pointed to specific classes of chemicals as causative agents.

To determine the contribution and identity of the nonpolar compounds to effluent toxicity, EPA TIE Phase II procedures were followed. Solid phase extraction (SPE) with a C\textsubscript{18} stationary phase and reverse phase HPLC fractionation were used to separate toxic and nontoxic chemicals in the effluent samples. Methanol, the solvent used in the fractionation procedures, is not toxic to C. dubia at or below 1.5%. Controls were taken through the fractionation procedures in order to account for artifactual toxicity introduced by the methods.

High-resolution gas chromatography/mass spectrometry (HRGC/MS) was used to identify components of the final toxic fractions from the Phase II procedures. The gas chromatographic conditions were an initial temperature of 50°C for 1 minute, followed by a temperature increase to 125°C at a rate of 5°C/min, the rate then was increased to 10°C/min and the temperature was brought to 300°C and held for 10 minutes. The GC column was a J&W Scientific DBS column, 30 m, 0.25 mm i.d., 0.25 μm film. A Hewlett Packard Model 5890 Series II gas chromatograph was interfaced with a VG model 70-250SBQ double-focusing mass spectrometer. Interpretation of electron ionization (EI) mass spectra provided information about the unknown components of the toxic fractions. Chemical ionization (CI) using methane, isobutane, or ammonia as the reagent gas was useful in verifying the molecular ions of some of the compounds identified by EI/MS. Accurate mass measurements from GC separation of toxic fractions of Samples 1 and 3 were performed. Identifications were verified by standards obtained from Aldrich Chemical Company or by finding matching spectra in the National Institute of Standards and Technology computer library of the Eight Peak Index of Mass Spectra.

RESULTS AND DISCUSSION

The C\textsubscript{18} SPE column was effective in removing a portion of the effluent toxicity from all three samples. Metals, oxidants, ammonia, particulates, and polar organic compounds were not the cause of the remaining toxicity. Measurement of the concentration of chloride in the whole effluent and comparison of the resulting toxicity to the measured toxicity of chloride...
showed that the toxicity that could not be extracted by the C<sub>18</sub> SPE column resulted from chloride. The concentration of chloride in both Samples 2 and 3 was 4.6 g/L. Chloride accounted for approximately 1/3 of the toxicity in Sample 2 and 1/2 of the toxicity in Sample 3. The remaining toxicity was caused by nonpolar organic compounds which could be fractionated by C<sub>18</sub> SPE and HPLC.

The compounds identified in toxic fractions where of three types: azo dyes, non-dye aromatics, and compounds related to 2,4,7,9-tetramethyl-5-decyne-4,7-diol (TMDD). Standards of some of the identified chemicals were tested for toxicity to <i>C. dubia</i>. The largest peak in the toxic fractions of the effluent samples was TMDD. Isomers and byproducts of TMDD were also identified in the fractions. A spectrum of TMDD is presented in Figure 1. The molecular ion of this compound is not observed due to the facile loss of a butyl group. 2,4,7,9-tetramethyl-5-decyne-4,7-diol is a component of Surfynol 104E, which is used at the plant to control foaming and to neutralize soda ash.

Twelve small azo dyes, with molecular weights less than 250 amu, were identified in the toxic fractions, only two of which were found in more than one fraction. Azo dye spectra were easily recognizable due to their consistent fragmentation patterns. As illustrated by the EI spectrum of 4-phenylazophenol in Figure 2, a fairly strong molecular ion is observed for azo dyes. The molecular ion initially loses a phenyl group and its substituents to form [M-PhX]<sup>-</sup>. This is followed by the loss of the azo group (N=N) to form the base peak. Subsequently the substituents of the remaining phenyl group are lost to form a peak at m/z=77 or m/z=76 for [C<sub>6</sub>H<sub>4</sub>]<sup>-</sup> or [C<sub>6</sub>H<sub>5</sub>]<sup>-</sup>, respectively.

**CONCLUSIONS**

Effluent acute aquatic toxicity was determined to be caused by chloride and nonpolar organics. No organic component of the three effluent samples was found to be solely responsible for organic toxicity, rather toxicity was thought to result from the interaction of several toxic chemicals present in low concentrations. The presence of azo dyes could be easily determined by GC/MS, due to their characteristic fragmentation pattern produced by electron ionization.

ANALYSIS OF CHELATORS AND CHELATOR FRAGMENTS IN MIXED HAZARDOUS WASTES BY DERIVATIZATION GC/MS

R.B. Lucke, J.A. Campbell, K.L. McKeeta, and S.A. Clauss

Advanced Organic-Analytical Methods Development Group, Pacific Northwest Laboratory, Richland, WA 99352

INTRODUCTION

Permanent waste disposal technologies for mixed hazardous wastes are currently being developed for implementation in the near future. The characterization of mixed hazardous waste is one criterion that needs to be addressed before the waste can be permanently disposed. Since chelators and their degradation products are often major constituents in mixed hazardous waste and their analysis is not amenable to gas chromatography (GC) without prior derivatization, alternative analysis methods need to be utilized. Previously, we have examined and reported on derivatization of chelators in mixed hazardous waste by methylation with BF₃/methanol followed by GC and gas chromatography/mass spectrometry (GC/MS).¹² The BF₃/methanol derivatization may not be applicable to all chelators, and therefore alternative methods such as silylation, diazomethane, and butyl esterification need to be compared. In this study, we derivatized ethylenediaminetetraacetic acid (EDTA), hydroxyethylethylenediaminetriacetic acid (HEDTA), ethylenediaminetriacetic acid (ED₃A), and iminodiacetic acid (IDA), with subsequent GC/MS analysis.

EXPERIMENTAL

Methylation by diazomethane, silylation by BSTFA, butyl esterification by butanol/HCl, and methylation by BF₃/methanol were achieved for chelator standards obtained from Aldrich and independent sources. GC/MS analysis was obtained on a Hewlett Packard HP 5988 GC/MS system. A fused silica DB5, 30 m x 0.25 mm i.d. (0.25-µm film thickness) column was used in the splitless injection mode. The oven program consisted of 40°C for 1 min followed by 8°C/min to 300°C. The mass spectrometer was scanned from 40-600 amu with 70-eV electron impact ionization.

RESULTS / CONCLUSIONS

Diazomethane methylation: This reaction occurs at ambient temperature and is a slow reaction for chelators; often it will take several hours to complete the reaction. The mass spectrum of IDA, when derivatized with excess diazomethane, shows a peak at m/z 175; however, the methyl ester has a molecular weight of 161. These results indicate an example of multiple methylation that often takes place with the use of diazomethane.⁴ For ED₃A and HEDTA, a lactam and lactone were observed.

BSTFA silylation: The parent ion typically fragments severely for chelators, which can make mass spectral interpretation difficult at times. Silylation occurs at the carboxylic acid groups and the hydroxy groups of chelators.

BF₃/methanol methylation: Chelators were methylated at the carboxylic site and not at the hydroxy sites. For ED₃A (MW 234) derivatized with boron trifluoride/methanol, one observes a peak at m/z 244 in the mass spectrum, which indicates the formation of a lactam. HEDTA, derivatized with boron trifluoride/methanol, is identified by the formation of a lactone at m/z 288. BF₃/methanol requires heating the sample to 100°C, which has the potential to thermally degrade the component of interest.

MULTISPECTRAL IDENTIFICATION OF CHLOROALKYL PHOSPHATE FIRE RETARDANTS IN AN INDUSTRIAL EFFLUENT

Introduction

Under the Clean Water Act Amendments of 1987, the U.S. Environmental Protection Agency continually reviews the occurrence of potentially harmful chemicals in industrial waste waters. Selected waste effluents are analyzed to identify chemicals that have not been identified previously either because they were not present or because improvements in identification methods permit their detection and identification for the first time. Recently, organic extracts of samples taken from several plants manufacturing organic chemicals were analyzed using multispectral identification techniques not generally applied previously. Among the plants sampled was a plant that manufactures fire retardants.

Alkyl, haloalkyl, and aryl phosphates have been widely used as flame retardants in a variety of products. The more common aryl phosphates are found in plasticizers, lubricants, and hydraulic fluid. The chloroalkyl phosphates have been used both in fabrics and in insulation materials. Many studies have been performed to determine the toxicity of these phosphates, as warranted by their widespread use in fabrics, plasticizers, hydraulic fluids, and lubricants. The results showed phosphates to be absorbed into the body and to be toxic to fish.

We identified 13 alkyl and chloroalkyl phosphates and also demonstrated how multispectral analysis can be used to identify organic compounds in environmental samples. Multispectral techniques--gas chromatography coupled with high and low resolution electron-impact mass spectrometry (GC/EI-MS), high and low resolution chemical ionization mass spectrometry (GC/CI-MS), and Fourier transform infrared spectroscopy (GC/FT-IR)--provided structural information that permitted the identification of these alkyl phosphates.

Experimental

Samples were collected from the effluent of a plant that manufactures fire retardant chemicals and were extracted according to EPA Method 1625C. GC/MS analyses were performed on a VG 70-SEQ high resolution hybrid mass spectrometer, equipped with the VAX-based OPUS data system and a Hewlett Packard Model 5890A gas chromatograph. The GC/FT-IR analyses were performed using a Digilab Model FTS-60 FT-IR spectrometer equipped with a Digilab Model 3200 FT-IR workstation and a Hewlett Packard Model 5890 gas chromatograph with a cool on-column injector.

Results and Discussion

The conventional method for identifying organic compounds found in the environment -- low resolution EI-MS with library database matching -- was only partially beneficial to the identification of the phosphates found in this industrial effluent. Only 4 of the 13 phosphates gave good library database matches. Therefore, techniques other than conventional low resolution EI-MS with database matching were required. One example of how we used multispectral techniques to identify these compounds was the identification of bis(2-chloroethyl)-2-(2-chloroethoxy)ethyl phosphate (Compound 8); its low resolution mass spectrum exhibited many of the same ions seen in the mass spectrum of tris(2-chloroethyl)phosphate (Compound 4), indicating that it was a phosphate with a similar structure. However, this compound showed a molecular weight of 328 by CI-MS. It was found by high resolution CI to contain an additional oxygen atom and to have an empirical formula of C₈H₁₅O₃Cl₂P. There are 3 primary scissions evident from the EI spectrum for Compound 8: the loss of Cl, CH₂Cl, and OC₂H₄Cl.
Infrared spectroscopy provided the remaining necessary pieces of information. The additional oxygen atom would most likely be present as an ether, a carbonyl, or an alcohol functionality. There was no indication in the infrared spectrum of either C=O or O-H stretching peaks (both of which are easily detected in the infrared at about 1650-1850 cm\(^{-1}\) and 3500-3700 cm\(^{-1}\), respectively). Unlike OH and C=O, ether linkages, which absorb at about 1100 cm\(^{-1}\), cannot always be unequivocally assigned due to absorbances of many other vibrations in this region. Also in comparing the IR spectrum of Compound 8 to that of Compound 4, we observed a shoulder on the intense P-O-C stretching peak at about 1135 cm\(^{-1}\) for Compound 8, which is not present in the spectrum of Compound 4. This indicates the presence of an ether linkage in the structure of Compound 8. However, in light of the empirical formula provided by high resolution MS, the most conclusive evidence for an ether linkage in this structure is the absence of OH and C=O IR absorbances. The high resolution MS and infrared data, coupled with the similarity of the low resolution mass spectrum and IR spectrum to that of tris(2-chloroethyl)phosphate, indicate Compound 8 is bis(2-chloroethyl)-2-(2-chloroethoxy)ethyl phosphate.

The 13 identified compounds were dimethylmethyl phosphonate, trimethyl phosphate, triethyl phosphate, tris(2-chloroethyl)phosphate, tris(1-chloro-2-propyl)phosphate, bis(1-chloro-2-propyl)(3-chloro-1-propyl)phosphate, bis(3-chloro-1-propyl)(1-chloro-2-propyl)phosphate, bis(2-chloroethyl)-2-(2-chloroethoxy)ethyl phosphate, bis(1-chloro-2-propyl)-3-(3-chloropropoxy)propyl phosphate, (1-chloro-2-propyl)(3-chloro-1-propyl)-3-(3-chloropropoxy)propyl phosphate, (1,3-dichloro-2-propyl)phosphate, bis(1,3-dichloro-2-propyl)(2,3-dichloro-1-propyl)phosphate, and 1,2-bis[bis(2-chloroethyl)-phosphato]ethane.
CHEMICAL IONIZATION MASS SPECTROMETRY OF O-ETHYL S-[2-DIMETHYLAMINOETHYL] METHYLPHOSPHONOTHIOATE AND ITS DEGRADATION PRODUCTS
Dennis Rohrbaugh, U.S. Army Chemical RD&E Center, APG, MD 21010-5423

Recent multinational interest in chemical weapon treaty verification has renewed interest in the detection of chemical warfare agents and their degradation products, particularly organophosphorus compounds. Many of these compounds are difficult to analyze by conventional electron ionization methods because extensive fragmentation results in little or no molecular ion information. In addition, compounds containing the dialkylaminoethyl group have similar EI spectra which are difficult to distinguish. In this study we apply capillary GC/MS using methane as the reagent gas to detect and identify 18 products resulting from the degradation of O-ethyl S-[2-dimethylaminoethyl] methylphosphonothioate. This technique provides the valuable molecular ion and fragmentation information necessary to identify these compounds.

Spectra were obtained on a Finnigan 5100 GC/MS equipped with a fused silica 15m x 0.25mm id SE-54 capillary column. Injection temp was 200°C and the oven was programmed from 60°C to 260°C at 10°C/min. CI reagent gas was methane (0.6 Torr). The mass range was scanned from 58 to 450 amu at 1 scan/sec. A comparison of EI and CI spectra for the phosphonothioate in Figure 1 illustrates the usefulness of CI for identification of these compounds. Fragmentation structures are shown in Figure 2.

Products were identified for storage under both inert and atmospheric conditions. The total ion chromatogram obtained for the sample under an inert atmosphere (nitrogen) is shown in Figure 3. The identification of each of the 18 compounds and relative quantities detected under both storage conditions are listed in Table 1. Under inert storage conditions degradation occurs primarily to a mixture of pyrophosphonates, thiolamines and phosphonothiolates containing 1, 2 and 3 sulfur atoms. Exposure to the atmosphere results in considerable oxidation to disulfides.

725
ANALYSIS OF SAMPLES FOR CHEMICAL WARFARE AGENTS: CANADIAN CONTRIBUTION TO A UNITED NATIONS VERIFICATION EXERCISE

* Paul A. D’Agostino and Lionel R. Provost, Defence Research Establishment Suffield, P.O. Box 4000, Medicine Hat, Alberta, Canada, T1A 8K6.

The possible entry into force of a Chemical Weapons Convention (CWC) has prompted many countries to consider the difficulties involved in ensuring compliance by all participating nations. Compliance monitoring will be required in the verification of alleged use, the storage and destruction of chemical weapons stocks and to ensure that industrial sites are not illegally producing chemical warfare agents. The United Nations Conference on Disarmament, realizing that these scenarios would require the development and use of analytical techniques to ensure compliance, formed a multinational Technical Group on Instrumentation to address the analytical challenges confronting signatory nations. Nations involved in the Technical Group on Instrumentation recently participated in a round robin analytical exercise designed to evaluate the capabilities and analytical approaches of the laboratories. Samples, taken from the feedstock, product and waste streams within a chemical industry utilizing compounds that would be scheduled by a CWC, were circulated to sixteen National Laboratories for analysis. Participating laboratories were asked to document their methods and report the presence of chemical warfare agents, their degradation products or other scheduled compounds. Canada participated in this and a prior exercise (1) and utilized in-house methods for sample clean-up and capillary column GC-MS analysis (2,3).

Twenty-nine cotton swab, Tenax, XAD resin, charcoal, aqueous and blank samples were received by the participating laboratories following inspection of an industrial plant. The samples were extracted with 1 to 10 mL dichloromethane (cotton swabs and charcoal samples) or hexane (Tenax and XAD resin samples) in an ultrasonic bath for 2 to 5 minutes. Aqueous samples were extracted with 2 x 1 mL hexane. Sample extracts were screened by capillary column GC-FID and GC-FPD (phosphorus mode) and scheduled compounds were confirmed by capillary column GC-MS under the following electron impact (El) and ammonia chemical ionization (CI) conditions:

**GC**: 15 m x 0.32 mm ID DB-1701; 40°C (2 min) 10°C/min 280°C (4 min); on-column injection at 40°C.
**MS**: VG 70/70E; 6 kV; 500 to 40 u (0.75 sec/decade; 0.25 sec interScan delay); El (70 eV, 200°C, 100 µA, 10³ Torr); CI (50 eV, 110-130°C, 500 µA, 2x10⁻² Torr NH₃).

Degradation products, due to hydrolysis of scheduled organophosphorus compounds, were confirmed following trimethylsilylation (TMS) of the actual sample medium or extracts of the samples. Analysis of the provided samples clearly indicated that the site was producing the organophosphorus pesticide, Dichlorvos. Table I lists the compounds, including those scheduled under the proposed CWC, found in the provided samples. Four of the scheduled compounds, trimethyl phosphate, dimethyl phosphate, dimethyl methylphosphonate and methylyphosphonic acid, would be expected at an industrial plant producing Dichlorvos. Dioctyl methylphosphonate, a scheduled compound, could not be explained at a Dichlorvos production site and its presence would create concern for a CWC Inspectorate. Figure 1 illustrates the GC-MS chromatogram of the hexane extract of an aqueous sample. Dioctyl methylphosphonates were tentatively identified in this extract and several other sample extracts by interpretation of the acquired El and ammonia CI data (Figure 2). The El mass spectra of all the dioctyl methylphosphonates exhibited a base ion at m/z 97 due to [(HO)₂P(CH₂)₁₂]⁻ and an ion at m/z 209 due to (M+H)⁺. Molecular ion information, critical to structural assignment, was absent in the El mass spectrum, but was evident during ammonia CI analysis. The CI mass spectra of the dioctyl methylphosphonates were dominated by (M+H)⁺ and (M+NH₄⁺) ions at m/z 321 and 338 respectively. CI fragmentation ions due to loss of C₆H₄OH from the pseudo-molecular were observed at m/z 209 and 226. Tentative identification of dioctyl methylphosphonates was confirmed by synthesis of several isomers.

Canada identified more than 20 compounds in the samples, including 5 compounds scheduled under the proposed CWC. Thirteen of the 16 participating National Laboratories (including Canada) identified the presence of the organophosphorus pesticide, Dichlorvos, and detected the scheduled compounds, trimethyl phosphate, dimethyl phosphate and dimethyl methylphosphonate. Nine of the 16 laboratories (including Canada) identified the scheduled degradation product, methylyphosphonic acid. These organophosphorus compounds could not be explained at a Dichlorvos plant and would not raise compliance monitoring concerns under the proposed CWC. Only 5 of the 16 participating National Laboratories (including Canada) identified the presence of dioctyl methylphosphonates. These scheduled compounds would not be associated with Dichlorvos production and would not raise compliance monitoring concerns under the proposed CWC. Two of these 5 laboratories also detected traces of octyl methylyphosphonofluoridate.

EVALUATION OF AIR CLEANER EFFICIENCY WITH AN APCI MASS SPECTROMETER

P.R. Nelson and S.B. Sears
R.J. Reynolds Tobacco Company
Bowman Gray Technical Center
Winston-Salem, NC 27102 USA

Some have suggested that exposure to environmental tobacco smoke (ETS) in occupational environments should be limited. One way to minimize the impact of ETS on indoor air quality would be the use of effective air cleaners. The results reported here are a subset of a larger experiment to gauge the effectiveness of one prototype and two commercial air cleaners. ETS was generated in an 18-m³ controlled environment test chamber. A SCIEX® TAGA® 6000 mass spectrometer was used to monitor the air concentrations of nicotine, pyridine, picoline, ethylpyridine, and ethenylpyridine in real time. Experimental data were analyzed to determine whether use of the air cleaners resulted in significant reductions of these analytes in the chamber and to determine the effective clean air delivery rate (CADR) of each air cleaner.

The chamber, analyzers, calibration, and data analysis have been described elsewhere. Temperature and relative humidity were controlled at 22°C and 50%. The chamber was ventilated at a rate of 6 air changes per hour. Five runs were performed with each air cleaner and ETS. The following air cleaners were evaluated: OZNI-commercial ozone/negative ion generator, unit was adjusted so that ozone concentrations in the chamber did not exceed 50 ppm (half of ozone TLV); ESP-commercial electrostatic precipitator with minimal charcoal filtration; COMB-prototype unit with physical filtration, UV ozone generation, and charcoal filtration. Environmental tobacco smoke was initially generated by sequentially machine smoking two pairs of University of Kentucky 1R4F reference cigarettes. Then, individual cigarettes were sequentially machine smoked until the end of the experiment. The smoking was preceded by a twelve-minute background determination.

The average real-time pyridine concentration in the chamber during each test is depicted in Figure 1. Similar response was observed for each substituted pyridine measured. Concentrations appear to be the highest with the OZNI cleaner on. This may be due to the formation of nicotine pyrolysis products in the ozone generation discharge. Although the ESP was highly efficient at removing particles, it was not designed for the effective removal of vapor phase compounds. The COMB air cleaner typically removed =50% of the target compounds. This was probably due to the adsorption of gas phase components onto the charcoal bed.

A one-way ANOVA was performed on results for each analyte by air cleaner type. Following ANOVA, a Bonferroni-adjusted multiple comparison test was performed to determine whether differences among air cleaners were significant at the p<.05 level. For the removal of pyridine, picoline, and ethenylpyridine: Neither OZNI nor ESP significantly reduced chamber concentrations; concentrations were significantly higher for OZNI compared to ESP; and COMB significantly reduced concentrations of these compounds in the chamber. For the removal of ethylpyridine: no significant differences were observed between the no air cleaner, OZNI, or ESP conditions; COMB significantly reduced concentrations of this compound relative to the other air cleaners and the no air cleaner condition. For the removal of nicotine: there was no significant difference in concentrations with the OZNI and no air cleaner conditions; concentrations were not significantly different with the OZNI, ESP, or COMB air cleaners in operation; both the ESP and COMB air cleaners significantly reduced nicotine concentrations relative to the no air cleaner condition.
CADR is the equivalent volume of fresh air provided by an air cleaner per unit time. An air cleaner with a given CADR has the same effect on contaminant concentration as diluting the contaminant by ventilation with fresh air. The CADR is useful for comparing the suitability of different air cleaners for removing indoor air contaminants. The greater the CADR, the more effective the air cleaner is. Unfortunately, all compounds in indoor air may not be removed with the same efficiency by an air cleaner. It then becomes important to know the CADR of the air cleaner with respect to particular compounds of interest.

Air cleaner rate constants were determined from "concentration vs. time data" by application of a simple mathematical model of chamber dynamics. The model assumes a first-order removal mechanism and a zero-order (constant) generation rate. It was assumed that effective equilibrium had been reached during the final 10 minutes of each run. CADR's were subsequently calculated from the model. The table below shows airflows and CADR's for each compound measured with the TAGA®. Negative numbers correspond to elevated concentrations relative to the no air cleaner condition.

Conclusions

Real-time data obtained with the TAGA® can be used to determine decay kinetics of compounds in indoor air. Air cleaners designed for the removal of particles from indoor air may be less effective at removing gas phase compounds. Ideally, an air cleaner should combine methods for the removal of both gaseous and particulate phase compounds.

THERMAL STUDY OF SOLANESOL BY ON-LINE THERMOGRAVIMETRY/ GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Henry L. Chung*, John C. Aldridge, and Michael W. Ogden
R. J. Reynolds Tobacco Company, Bowman Gray Technical Center, Winston-Salem, NC 27102

Solanesol (3,7,11,15,19,23,27,31,35-nonamethyl-2,6,10,14,18,22,26,30,34-hexatriacontanonaene-l-ol) is the most abundant terpenoid in tobacco and is a major component of the lipid fraction. Lipid constituents of tobacco or their thermal degradation products are related to the flavor and aroma of tobacco smoke.

An on-line thermogravimetry/gas chromatography/mass spectrometry (TG/GC/MS) system was designed, constructed and used to study the stability, weight loss, and the thermal degradation products of solanesol. The system permits evolution of thermal degradation products of solanesol by the TG, separation of the volatile thermal degradation products by the GC, and identification of the volatiles by the MS. The on-line TG/GC/MS system employed a Du Pont 951 thermogravimetric analyzer equipped with a 9000 thermal analysis system interfaced to a Hewlett-Packard 5890 GC/5970 MSD system. The TG/GC interface consisted of a heated transfer line, an adsorbent trap packed with Tenax and a six-way valve. Solanesol was heated and purged with air at a flow rate of 30 ml/min during the heating and purging process. The TG temperature was programmed from 50°C to 900°C at 10°C/min. The volatile compounds generated in the TG were swept into the adsorbent trap. The purge gas, after passing through the trap at room temperature, was vented to the atmosphere. After the heating and purging process, the trap was rapidly heated to 200°C and the volatile compounds in the trap were swept into the GC/MS system by helium at a flow rate of 35 ml/min. The volatile compounds were separated by GC. A 60 m X 0.25 mm ID DB-1701 (0.25 μm film thickness) fused silica capillary column was used for compound separation. The GC injector temperature was 250°C. Helium was used as the carrier gas. The column head pressure was 25 psi. The column temperature was held at 35°C for 5 minutes and then programmed to 220°C at 3°C/min. An open-split GC/MS interface was used with the temperature set at 275°C. The mass spectrometer was operated at 70 eV in the EI mode. The ion source temperature was maintained at 250°C. The mass range was scanned from 29-500 amu. The volatile compounds were identified by mass spectra. The thermogram of solanesol depicted a curve with two plateaus showing sample weight loss as a function of increasing temperature. The first decomposition occurred over a temperature range of 237°C-389°C with a total weight loss of 87% and a maximum decomposition rate at 320°C. The second degradation occurred between 389°C-496°C, and involved a further 13% weight loss with a slower decomposition rate. Solanesol decomposition was complete at 496°C. Thus, a temperature profile of stability and weight loss from solanesol could be obtained. The total ion chromatogram showed that a great number of compounds were thermally degraded from solanesol under the condition studied. The volatile degradation products were identified as aliphatic ketones, furan derivatives, aliphatic hydrocarbons, aromatic hydrocarbons, ethanone derivatives, aliphatic aldehydes, aliphatic alcohols, 2-cyclopenten-1-one derivatives, 2-cyclohexen-1-one derivatives, and phenol derivatives. Compounds known to contribute to the flavor and aroma of tobacco smoke are identified as acetic acid, acetoin, limonene, linalool oxide, nonanal, 2-methylbenzaldehyde, 2,6-dimethyl phenol, citral, farnesal, farnesol, and methyl oleate.
Removal of Salt Interference from FAB Spectra

*M. W. Collins and J.L. Occolowitz, Eli Lilly & Co., Indianapolis, IN 46254

Introduction

Although the presence of salts is sometimes helpful in identifying molecular species in FAB mass spectra, their presence can often be deleterious. Cationization of matrix peaks adds to the chemical noise in spectra and this may completely mask less intense analyte peaks. Also, cationization spreads the analyte signal amongst a number of cationized species. Furthermore, large salt concentrations can completely suppress analyte ionization. This poster deals with the limitation of salts in the FAB experiment by revealing a method of sample washing for the removal of the water soluble impurities. We modified the method used by Beavis and Chait\textsuperscript{1} to remove salt interference from matrix-assisted laser desorption samples. Our method involves a fast, cold, aqueous extraction of the sample on the FAB target before the addition of matrix.

Wash Method

The sample is dissolved in a high vapor pressure solvent, typically methanol containing 0.1\% TFA, to achieve a concentration of about 1mM. A few uL of the solution is applied to the FAB probe with a gold tip and the solvent is allowed to evaporate. The probe tip is then immersed in an ice water bath (distilled water) for 1 - 5 seconds depending on the degree of salt contamination. The water remaining on the probe after withdrawal from the ice bath is removed by placing the probe in the insertion lock of the mass spectrometer and allowing the water to be pumped away. After taking the probe back out of the insertion lock, about 1 uL of the appropriate matrix is applied to the dried sample. The sample is now ready for analysis.

FABMS

FAB mass spectra were measured on a VG ZAB2-SE mass spectrometer using a cesium ion gun (12 kV) to provide energetic particles for desorption. Data acquisition was accomplished by the OPUS data system (version 1.5f). Instrument parameters were held constant, eg. multiplier gain, during experiments so that the only variable was the washing step.

Results and Discussion

Fig. 1a. shows the FAB spectrum of the products of reaction of the antibiotic daptomycin, MW 1619, with aqueous methanolic sodium cyanoborohydride. The submitter of the sample had previously attempted to desalt it. Daptomycin is an N-acylated peptide antibiotic containing a macrocyclic lactone. On the basis of the data in Fig. 2a. the submitter concluded that the ion at m/z 1642 was due to hydrolysis of the lactone ring and the concomitant reduction of two sites within the molecule (1619 + 18 + 2x2). Some of the peaks at lower mass were assigned to expected peptide bond cleavages of the new protonated molecule.

Fig. 1b. shows the FAB spectrum of the washed sample. It was now clear that two products had resulted from the reaction, unreacted daptomycin (MH+ = 1620) and a compound with MW 1651. The compound of MW 1651 was probably due to the addition of a mole of methanol, presumably through the methanolysis of the lactone. The peaks at m/z 563 + n(58) in spectrum 1a. were due to the antifoam agent polypropylene glycol, which was coincidently removed with the salts during washing.

The concentration of salt impurity in a sample can influence the washing time needed for optimum results. Fig 2a. shows the FAB spectrum of a peptide submitted to our laboratory. The data indicate a MW of approximately 6581 d. while a peak m/z 3294.3 could be interpreted as arising from a doubly-charged molecule with MW 6586.6 d. The spectrum of the sample obtained after a 2 sec. wash in Fig. 2b. A series of peaks spaced approximately 22 d. in the region of m/z 6500 indicate a MW of 6475.3 d., although a less well-defined peak at 6450.5 d. might suggest that 6476.3 d. is MNa+ rather than MH+. Washing the sample for 4 sec. removed this ambiguity. The spectrum of this washed sample, Fig. 2c., shows no evidence of cationization and clearly indicates a MW of 6475.3 d. measured from MH+ and 6477.0 d. measured from MH2++.
Conclusion

The washing technique is very useful although it is simple in theory and easy in practice. While probably not applicable to all classes of compounds, it can solve the difficult problem of water-soluble contaminants in FAB samples, especially with large biomolecules and mixtures.

As far as characterization of this technique, we have found that washing samples result in negligible losses of ion signal for many samples. In some cases where the ion signal is spread over the protonated molecule and sodium adduct ions, washing proved to increase absolute intensity of the protonated molecule.

Also, washing times for samples depend on the degree of salt contamination. In most cases washing for 1-2 sec. is all that is needed. However, some samples with unusually large amounts of salt may take on the order of 5 sec. for the salt impurities to be fully dissolved into the cold water.

Characterization of Organic Constituents of Produced Water and Marine Sediments Using GC/MS

Ronald B. Kelley¹, A. Daniel Jones¹, and A. Russel Flegel²

²Institute of Marine Sciences
University of California, Santa Cruz, CA 95064

Primary source water pollutants can have direct effects on aquatic populations. Produced water, the crude oil recovery processed aqueous effluent from offshore reservoirs, is usually piped directly into the ocean some distance from land.

Objectives

Biomarker analysis is widely used by the petroleum industry to study geochemical events leading to petroleum formation, but these techniques have not been brought to bear to determine sources of pollutants. It has been difficult to distinguish hydrocarbon pollutants that occur as a result of human activity from those that are due to natural forces such as oil seeps. Fortunately, the source of crude oil and the extent of its degradation can be determined from fingerprints of biomarker compounds, and GC/MS is the best method available for the task.

GC/MS Results

This project aims to develop and apply GC/MS analytical methods to quantify organic molecular indicators (biomarkers) of the amount of crude oil pollution, its sources, and the extent to which these pollutants have been weathered by environmental forces. The techniques we are developing will be applied to analyze for biomarker compounds in produced water, sediments, and biota to distinguish pollution from discharges of produced water versus discharges from other sources of petroleum products. The total ion chromatograms (TIC) (Figures 1 and 2) for the offshore crude oil/sea water emulsion and the west district sediment sample, down current from the produced water effluent pipe. The crude oil shows the characteristic n-alkane series while the sediment sample displays a weathered unresolved hydrocarbon pattern.

Figure 3 shows the reconstructed ion chromatograms (RIC) of the produced water effluent for the characteristic ion of triaromatic steranes, a major biomarker constituent of California source crudes (1). The pattern is identical to the source crude and similar to the sediment sample. Natural petroleum seeps in the Santa Barbara Channel have contributed to the observed biomarker pattern similarly.

The results indicate that the efficacy of current petroleum extraction methods, especially removal of branched chain and aromatic compounds, from the crude oil/sea water emulsion is suspect.

Acknowledgement

This work has been supported by the University of California Toxic Substances Teaching and Research Program in Coastal Toxicology.

DISTRIBUTION OF PETROLEUM PRODUCTS WITH RESPECT TO BOATING ACTIVITY IN A RESERVOIR

Trina A. Mastran, Daniel L. Gallagher, Thomas J. Grizzard, Andrea M. Dietrich
Environmental Engineering and Environmental Sciences Division
Virginia Tech, Blacksburg, VA 24061-0246

INTRODUCTION
The Occoquan Reservoir, located in Northern Virginia near Washington, D.C., serves as a water supply and recreational facility. The reservoir currently has three marinas—Bull Run, Fountainhead and Lake Ridge—and restricts the use of motor boats to engines of less than 10 HP. There is some concern that boating activity may contribute raw and combusted petroleum chemicals to the reservoir water and sediment.

This research was conducted to determine: 1) the concentrations of polycyclic aromatic hydrocarbons (PAHs) in water and sediment samples; 2) if the presence of PAHs is related to boating activity. Water and sediment samples were collected from sites in the reservoir and local tributaries during a time of high boating activity in June (2034 boats launched at Fountainhead) and during a time of low boating activity in October (653 boats launched at Fountainhead).

METHODS
Samples were obtained from thirty-two sites in the Occoquan Reservoir in June, 1990 and thirty-three sites in October, 1990. Sites were selected to represent areas of both high and low boating activity. Approximately one third of the sites were located near marinas, and the remaining sites were located in non-marina areas throughout the reservoir and tributaries.

For water samples, grab sampling from a motor boat was employed. Water samples were obtained in a Kemmerer sampler, and samples were stored in amber glass bottles. The water samples were extracted according to EPA Method 3510 (in SW-846). This involved liquid-liquid extraction of a one liter sample with methylene chloride, then concentrating the extract to one milliliter in a K-D apparatus. The extract was analyzed by GC/MS (EPA Method 8270 in SW-846).

Grab sampling from a motor boat with an Eckman dredge was employed for soil samples, and samples were stored in amber glass bottles. The soil samples were extracted according to EPA Method 3540. A ten gram sample was soxhlet extracted with 50/50 hexane/acetone, then concentrated and solvent exchanged to hexane only in a K-D. The hexane extract was applied to an alumina column; an aliphatic fraction was eluted with 15 ml of hexane, then the PAH fraction was eluted with 100 ml of methylene chloride. The PAH fraction was concentrated to 1 ml and analyzed by GC/MS (EPA Method 8270).

A Hewlett-Packard 5790 MSD coupled to a Hewlett-Packard 5890 Series II GC was used for analysis. A 30 meter DB-5 column was used, and the temperature program was from 40-320 °C. Full scanning from m/z 50-550 was utilized. A five point calibration curve and single ion quantitation were used for quantitative analysis. Benzo(a)anthracene, anthracene, and chrysene were not resolved under the conditions utilized.

RESULTS
The average concentrations of PAHs found in the water samples for marina and non-marina sites during June, 1990 are listed in Table 1. No PAHs were detected in water samples obtained from the October 1990 sampling trip.

Average concentrations of PAHs in the sediment samples taken from the three different marinas located on the Occoquan Reservoir are listed in Table 2.

ND = not detected

**DISCUSSION**

Boating activity on the reservoir appears to result in increased petroleum contamination of the reservoir water. During the period of high boating activity in June 1990, sub ug/L quantities of fluorene, naphthalene, and pyrene were detected in the water samples taken from areas where the marinas are located, while no PAHs were detected in corresponding non-marina areas during the same time period. Additionally, samples taken in October, 1990 during a period of low boating activity showed no detectable levels of PAHs in the water. PAHs were detected in the sediment samples taken at the marina sites, further suggesting that boating activity is related to PAH occurrence in the Occoquan Reservoir. To conclusively evaluate the effect of boating on PAHs in the sediment, it would be necessary to compare sediment samples from both marina and non-marina areas.
Determination of Aqueous Cyanide by Purge and Trap Gas Chromatography/Mass Spectrometry

G. F. Moler
Organic Section, Public Health Laboratories
Arkansas Department of Health; Little Rock, Arkansas 72205

Preliminary experiments were conducted to ascertain the feasibility of analyzing water and blood samples for cyanide by purge and trap gas chromatography/mass spectrometry.

**Equipment:** A Tekmar LSC-2 purge and trap apparatus was interfaced with a H-P 5890A gas chromatograph, containing a Restek 502.2 volatiles fused silica capillary column. The effluent of the column was fed into a Nermag R10-10H quadrupole mass spectrometer. The mass spectrometer was operated in full-scan mode (m/z=20 to m/z=150).

**Procedure:** Refer to Figure 1. Blood was diluted 1/10 with 0.001 N NaOH, and 4 drops Antifcam-A were added; the solution was shaken vigorously. At this stage, it was treated as per water: 5 mL were added to a gas-tight syringe containing a small stir bar. An internal standard was added and the solution was stirred for one minute. Then bleach and HCl were added to the syringe and the mixture was stirred again one minute. The sample was then placed into a 5-mL sparger, purged for fifteen minutes, and the vapor analyzed for cyanogen chloride by gas chromatography/mass spectrometry. (This method will be referred to as CN-Cl P&T GC/MS.)

**Variation of reaction pH:** Figure 2 shows recovery of cyanogen chloride vs. the pH of the bleach/HCl reaction mixture.

**Variation of bleach concentration:** Figure 3 illustrates recovery of cyanogen chloride vs. the reaction bleach concentration.

**Linearity:** Figure 4 shows the ion chromatogram peak area at m/z=61 ([13CHN]) divided by the ion chromatogram peak area at m/z=62 ([12CHN]) vs. HCN concentration, using [13CHN] as an internal standard.

**Reproducibility:** On seven consecutive days, HCN at 50 ppb (ug/L) was analyzed by CN-Cl P&T GC/MS, using [13CHN] as an internal standard. Figure 5 shows the ion chromatogram peak area at m/z=61 ([13CHN]) divided by the ion chromatogram peak area at m/z=62 ([12CHN]).

**Detection limits:** The full-scan (from m/z=20 to m/z=150) detection limit was approximately 5 ppb HCN. The selected ion monitoring (SIM) detection limit was approximately 0.5 ppb. Both detection limits were based on a signal-to-noise ratio of at least three-to-one for each peak at m/z=61 and at m/z=63.

**Metal complexes:** Cyanide complexes of gold, cobalt, iron, mercury, copper, silver, and zinc were dissolved in 0.001 N NaOH, and analyzed by CN-Cl P&T GC/MS. HCN recoveries were 0 % for complexes of gold and cobalt; 0.14 % for the complex of iron; 83 % for the complex of mercury; 100 % for the complex of copper; 125 % for the complex of silver; and 185 % for the complex of zinc.

**HCN:** The detection limit for purged HCN (no Cl2) was about 500 ppb. Low-level HCN analysis by this method was thus not feasible.

**CN-Br:** The detection limit for HCN was about 300 ppb when CN-Br was generated by HBr and Br2. Low-level HCN analysis by this method was thus not feasible.

**Interferences:** In addition to thiocyanate, methanol when present in the sparger can generate an ion chromatogram peak at m/z=63 at the same retention time as CN-Cl. Vinyl chloride interferes with the use of [13CHN] as an internal standard.

**Blood:** Whole blood was spiked at 500 ppb HCN. Recovery was 99 %.

MASS SPECTROMETRIC ANALYSIS OF SAMPLES FROM AN 1864 MILITARY ENCAMPMENT

Kenneth L. Busch, David E. Bostwick, and Sarah J. Shealy, School of Chemistry & Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332, and Christopher T. Espenshade, Brockington and Associates, 2853 Henderson Mill Road, Atlanta, GA 30341

Introduction: In September of 1864, the 32nd U.S. Colored Infantry spent about one month at Camp Baird (located on Hilton Head Island, SC, site 38BU79/1151) constructing earthworks for an adjacent fort. As part of the environmental impact study for a proposed golf course and housing development at the site, archaeological excavations were completed near the supposed tent of the regimental surgeon.

Sample A -- Prepared as a diethyl ether extract of tan crystals, and run by direct-insertion probe introduction with El and then with positive ion ammonia and isobutane chemical ionization. The total-ion-current trace showed no strong peaks. A weak peak desorbed at a high temperature gives a mass spectrum with a characteristic isotopic signature at m/z 133, 135, and 137 that matches the envelope predicted for ZnCl2. Zinc chloride can vaporize from the probe at the indicated temperature.

Sample B -- Prepared as a diethyl ether extract of a yellow/green powder, and analyzed by direct-insertion probe introduction with electron ionization. Sulfur vaporized from the direct-insertion probe at a relatively low temperature, consistent with the behavior of pure sulfur. This was confirmed by a search of the spectral library that gave an excellent match to molecular sulfur. Positive ion ammonia and isobutane chemical ionization confirmed the presence of elemental sulfur in this sample. No other significant peaks were noted. GC/MS analysis of an aliquot of the same ether extract (programmed to 250 degrees) showed only a few small peaks that could not be identified.

Sample C -- Prepared as a diethyl ether extract of a black/red chunky solid, and analyzed by direct-insertion probe introduction with El and positive ion ammonia and isobutane Cl. The total-ion-current trace showed no strong peaks with the exception of a peak vaporized at about 240 degrees. This compound searched through the library of electron ionization mass spectra as a phthalate ester, a common plasticizer in plastic bags such as used to store the sample removed from the site. At a temperature of about 400 degrees, higher mass ions in the range of 300 to 500 amu were observed. Reconstructed ion chromatograms show the reproducible desorption of this ion series at higher probe temperatures. Interestingly, these ions provide a good library match to safflower oil. While the identification is not confirmed as that particular oil, the spectral signature is consistent with that of a naturally derived plant oil. Neither ammonia nor isobutane chemical ionization mass spectrometry (using the same temperature program from the probe) could provide supporting evidence for the presence of this natural oil. Positive ion fast atom bombardment (FAB) mass spectra in a meta-nitrobenzyl alcohol matrix does give some high mass peaks separate from matrix background, suggesting the presence of high mass organic acids, but the spectrum could not be uniquely identified.

Sample D -- This sample was prepared as a diethyl ether extract of a brown amorphous mass, and analyzed by direct-insertion probe El and positive ion ammonia and isobutane Cl. The total-ion-current trace with electron ionization showed several moderately strong peaks for compounds that vaporized from the probe at about 225 and 400 degrees. The first peak produced an electron ionization mass spectrum that matched the library search as octadecanoic acid. The second peak produced an electron ionization mass spectrum that matched as an ester of octadecenoic acid. The presence of the higher mass ions in the latter mass spectrum is significant. Although the match to any one of the compounds shown in the library is not good, the similarity in compound class for all of the compounds listed shows that a mixture of related compounds is vaporizing at the same time from the direct desorption probe. These compounds are characteristic of extracts from a number of plant products, the exact nature of the preparation cannot be determined. Both ammonia and isobutane positive ion chemical ionization produce total ion current traces similar to that measured for electron ionization, and evidence for the same classes of compounds vaporizing from the probe. Positive ion FAB mass spectra (meta-nitrobenzyl alcohol matrix) confirms the presence of such high mass compounds.

Sample E -- Prepared as a diethyl ether extract of a dark brown amorphous mass still in the original ceramic container, and analyzed by direct-insertion probe El. Several peaks were observed.
in the trace of total ion current as samples evaporated from the probe. Again, these compounds provide electron ionization mass spectra that are matched by the computer library with C14, C16, and C18 acids and their derivatives. Positive ion isobutane chemical ionization mass spectra confirm the mass spectra and the classes of compounds observed. A close similarity in the desorption profile and the mass spectra to those observed for Sample D is observed.

Sample F – This sample is a bottle filled with a clear liquid with a flocculated precipitant. The condition of the stopper suggests that the seal was intact. Several samples were derived, including a diethyl ether extract of the supernatant (F1), an ether extract of the precipitate (F2), and an ether extract from the cap itself (F3). EI mass spectra were recorded from a temperature-programmed direct insertion probe run for each. GC/MS analyses were similarly completed; in one case, a silylation was performed using BFTBA to increase the volatility of any components present and allow their passage through the GC column. Finally, FAB analyses with both dithiothreitol/dithioerythritol and m-nitrobenzyl alcohol liquid solvents were completed.

For F1, the probe electron ionization run shows only a small peak vaporizing at a temperature of about 400 degrees. Since most of the peaks in the mass spectrum are also present in the mass spectrum of a compound that vaporizes much earlier, and identified as a plasticizer, the identity of the latter peak cannot be established. An ion at m/z 149 normally indicates the presence of a phthalate plasticizer. However, an analysis of the ether blank was performed separately to confirm that we have not introduced such a contaminant in sample preparation. For F2, the EI mass spectra from the precipitant are very similar to those recorded from the liquid solution, as are the electron ionization mass spectra recorded for sample F3. Sample F1 was silanized and the GC/MS analysis completed. Library search of the EI mass spectra give indication for silylated hydrocarbons derived from the column packing. Significantly, the trimethylsilyl derivative of arsenous acid is indicated.

Discussion: The results obtained from the mass spectrometric analyses must be considered in view of the drugs likely to be present in the samples. Robertson and Damann have authored monographs that describe the pharmacopoeia of the times. The list of tinctures, extracts, and derivatives is extensive, and includes quinine, ethers, chloroform, morphine derivatives, and opium preparations (opium in one form or the other was used to treat almost every infirmity or condition).

Zinc chloride, zinc acetate and zinc sulfate are all listed as standard issue for physicians. Sample A was identified as zinc chloride (butter of zinc). This compound was usually issued as a solution, and was used as a disinfectant, a deodorant, and embalming preservative. Similar uses are noted for zinc acetate and sulfate. The original status of the sample at the site (whether in a bottle or not) was not noted. Sample B was determined to contain sulfur. Sulfur was issued to physicians by the pound; it was used as a scabicide (often mixed with lime), an antiseptic, and in ointments used to treat parasites. Sample E was thought to be the ubiquitous blue mass when first submitted to the laboratory. Blue mass contains 32-34% elemental mercury, along with powdered licorice, powdered rose leaves, and honey. Blue mass and calomel were widely used cathartics, diuretics, and antiseptics. They were consumed internally and applied externally. Systemic mercury poisoning often resulted; however, such was the medicine of the time, and it is instructive to note that mercury ointments were used as topical treatments for syphilis as late as the 1940s. However, examination by FAB, EI, or CI did not provide any evidence for the presence of mercury in this sample. We cored the sample to test whether mercury was still present in the unexposed core of the sample; this sample did not show the presence of mercury. The same sort of porcelain apothecary jar usually used to hold blue mass was also widely used to contain cerates, a mixture of bland fats and oils used as a salve to promote healing. Without a standard composition for such a sample, we can only suggest that this is the composition. In any case, the initial characterization of the sample as blue mass was incorrect. Sample F provided spectral evidence for the presence of arsenous acid, provided at the time to be used in the cauterization of wounds. For samples C and D, the presence of any particular compound could not be unequivocally established. Safflower oil was listed as a possible compound for sample C, and long chain fatty acids for sample D. We have insufficient experience to identify these samples further. Physicians of the time were equipped with extracts of a large number of plants. Without standards, more accurate determinations could not be made.
Results of experiments in our laboratory have shown that benzene is metabolized by animals in part to an intermediate which binds to cysteine groups in hemoglobin to form the adduct S-phenylcysteine (SPC). These results suggested that SPC in hemoglobin may be an effective biological marker for exposure to benzene. However, we could not detect SPC in the globin of humans occupationally exposed to benzene concentrations as high as 28 ppm for 8 h/day, 5 days/wk. As an alternative biomarker for humans, we examined the binding of benzene to cysteine groups of a different blood protein, albumin. To facilitate the process, a new method for the precipitative isolation of albumin from plasma was developed (Fig. 1). The isolated albumin was analyzed for SPC by isotope dilution gas chromatography/mass spectroscopy. We used this approach to measure SPC in the albumin of F344/N rats exposed by gavage to 0 - 10,000 μmoles/kg benzene. Amounts of albumin-associated SPC increased rapidly as a function of dose, followed by a leveling off in the amount of SPC seen at higher doses. Levels of SPC were measured in humans occupationally exposed to average concentrations of 0, 4.4, 8.4, and 23.1 ppm benzene 8 hr/day, 5 day/wk. Of nine controls, seven had levels of SPC below the limit of detection (0.1 pm SPC/mg albumin). SPC-albumin adducts increased in the blood of exposed groups in a linear fashion relative to exposure concentration, although only the highest dose group possessed levels statistically different from controls (Fig. 2). Current research focuses on the occurrence and extent of SPC in individuals with no known exposure to benzene, and in cigarette smokers, since exposure to cigarette smoke is the most common mode of benzene exposure in the United States. SPC in albumin may prove to be useful biomarker of benzene exposure. (Research sponsored by the U.S. DOE/OHER under Contract No. DE-AC04-76EV01013.)

ARSENIC METABOLITE ANALYSIS BY MASS SPECTROMETRY

Patrick R. Jones¹, Mark S. Smith² and Donald Y. Shirachi², ¹Chemistry Department, ²Department of Physiology and Pharmacology, University of the Pacific, Stockton, CA 95211.

Introduction. Arsenic is found widely distributed in the atmosphere and on the earth's crust as well as in the aquatic environment. The mechanisms of arsenic toxicity are related to the oxidation state of the compound. It is generally accepted that trivalent arsenic (As(III)) exerts its toxic effects by reacting with thiol groups which are often important parts of active centers for many enzymes. Pentavalent arsenic (As(V)) can substitute for inorganic phosphate due to a similarity in structure. Apparently two major mechanisms are involved in the detoxification of inorganic arsenic by mammals. These involve methylation and protein binding (1). Biomethylation appears to be the predominant path for detoxification of inorganic arsenic in both mammals and other organisms. Biomethylation of inorganic arsenic by mammals leads to the production of methylarsenic acid (MA) and dimethylarsenic acid (DMA) which are mainly excreted in the urine. A need exists to be able to separate out the various arsenic species due to their different toxicities. At the present time, separation by ion-exchange HPLC and quantification by either atomic emission or absorption spectrometry appears to show the most promise. The use of HPLC procedures allows the separation and purification of most compounds from a complex mixture. Analysis by mass spectrometry can provide immediate structural and molecular weight information. The objectives of the present study were to: (a) develop a simple, reproducible method for the structural analysis of reduced metabolites of alkylarsines utilizing mass spectrometry (MS), and (b) develop procedures to minimize possible molecular rearrangement of alkylarsines generated from aqueous mixtures of organic arsines.

Materials and methods. Highest grades available of sodium arsenite (NaAsO₂, As(III)), sodium arsenate (Na₂H₂AsO₄·7H₂O, As(V)), sodium methylarsonate (CH₃NaH₂AsO₄) and dimethylarsinate ((CH₃)₂NaAsO₂) were used. Stock solutions of the arsenic standards were prepared weekly in deionized water (1 mg/ml) and kept refrigerated until use. Sodium borohydride (NaBH₄, 98%) was purchased from Mallinckrodt. Working standards were diluted from stock solutions with deionized water and prepared on the day of analysis.

Animals and liver cytosol preparation. Male Wistar rats (250-300g) were sacrificed by decapitation and livers were immediately removed and rinsed in ice cold 0.32M sucrose in 50mM HEPES buffer pH 7.40, blotted dry on filter paper and weighed. A 50% homogenate was then prepared (40g/80ml buffer) in the above buffer using a Potter-Elvenhjelm homogenizer (Teflon pestle). The cytosol was then prepared by ultracentrifugation of the homogenate at 100,000 x g for 75 min at 4°C in a Beckman Model L3-40 ultracentrifuge (50.2TI rotor). The supernatant was then pipetted off and kept on ice for preparation of the standard incubation mixture (SIM).

Preparation of SIM. The SIM was prepared with 1 ml of 0.32M sucrose in 50mM HEPES buffer, pH 7.4, 0.75 ml of a methyl-cobalamin solution (10mM final concentration in SIM), 0.25 ml of 10mM As(V), and 0.5 ml of cytosol. The mixture was incubated for 60 min in a water bath at 37°C in open glass tubes. The reaction was stopped by the addition of 0.5 ml 15%(w/v) trichloroacetic acid. The supernatant was then pipetted off and kept on ice for preparation of the standard incubation mixture (SIM).

Hydride generation and analysis of arsines. As(III) and DMA were reduced with 5% NaBH₄ in 0.1N NaOH in a pH 4.0 solution following deoxygenation with N₂ gas. Aqueous samples of As(V) and MA were analyzed by first acidifying the samples in 3M H₂SO₄ followed by reduction with NaBH₄ as described by Lakso et al. (2). The volatile arsines were collected in a glass expansion chamber attached to an arsine generator. The expansion chamber was then disconnected from the generator and connected to a glass "U"-trap. The arsine gas was then slowly bled into the liquid nitrogen cooled trap that was being pumped out under vacuum and trapped. The cryogenic trap was then removed and the arsines volatilized at their boiling points and were pumped by vacuum into the MS for analysis. The instrument used was a UTI Model 100B quadrupole mass spectrometer that was part of a Varian CVA-1 vapor analysis apparatus. The mass spectrometer
was run at an electron energy of 70eV. Mass spectra were recorded with a Gould Brush 220 recorder system.

**Cation-exchange chromatography.** Arsenic metabolites in the SIM were first separated by cation-exchange chromatography according to the method of Tarn et al. (3).

**Results.** Reaction rates for arsine generation were monitored qualitatively with the use of mercuric chloride-saturated filter paper disks (Gutzeit test for arsine). Peak arsine formation was seen at 45 sec from the start of NaBH₄ addition. When As(III) and As(V) were reduced with 5% NaBH₄, the spectra showed peaks at 75, 76, 77 and 78 m/z corresponding to arsine (AsH₃). With MA, reduction peaks were observed at 75, 76, 77, 78, 90 and 92 m/z indicating masses for arsine and methylarsine (CH₃AsH₂). When DMA was reduced with 5% NaBH₄, masses were observed for arsine and methyarsine. However, when 3% NaBH₄ was used, in addition to those masses observed above, masses at 105 and 106 were seen indicating dimethylarsine. Under our experimental conditions, mass spectra generated from As(V) and MA were observed only at pH 1 but not at pH 4. Mass spectra generated from DMA occurred only at pH 4 but not at pH 1 but spectra from As(III) were observed at both pH 1 and pH 4. The approximate lower limits of detection for MA and DMA was 500ng and 1ug for As(III) and As(V). Preliminary in-vitro biomethylation experiments utilizing separation by cation-exchange chromatography prior to hydride generation (5% NaBH₄) showed spectra for arsine and methyarsine at pH 1 and 4 in fractions that did not elute for MA and DMA.

**Discussion.** Although AsH₃ from As(III) could be generated from both pH 1 and 4, AsH₃ from As(V) was only found when the reduction occurred at pH 1, not at 4. MA and DMA generated arsine and methyl- and dimethylarsine at pH 1 and 4 respectively, supporting the suggestion by Aggett and Aspell (4) that arsines can be selectively generated from a complex mixture by changing the pH. Procedures such as the use of glass beads or silanized glass wool that are used in the "U"-trap to increase the recovery when measuring arsine gases with atomic absorption spectrophotometry or a DC discharge cell (5,6,7) were not effective in our system which uses MS for detection. We were unable to observe any spectra with the use of our "U"-trap half-packed with glass beads. Furthermore, using 0.4% silanized glass wool in the trap resulted in the absence of spectra for arsine and the spectra were greatly suppressed for methyarsine. The design of our system does not utilize any trapping material in the "U"-tube and places a fiber plug between the generator and the gas expansion chamber to break-up aerosol and thus decreased the amount of water vapor which decreased the suppression of the arsine mass spectra. The lack of dimethylarsine peaks between 100-110 m/z with 5% NaBH₄ may be explained by possible arsine molecular rearrangements as noted by others (8). This observation appears to be dependent on the initial NaBH₄ concentration because when a 3% solution was used we were able to detect the spectra for dimethylarsine. The results of the in-vitro biomethylation experiments using rat liver cytosolic fractions and As(V) showed mass spectra for methyarsine with 5% NaBH₄. These fractions did not contain MA or DMA, thus suggesting that the methyarsine detected by MS was generated from some other unknown methylated arsenic metabolite. This would also suggest the possibility that the methyl- and dimethylarsine observed in other studies not utilizing chromatographic techniques prior to hydride generation could result in other interpretations of their data. Further work is necessary in order to unequivocally identify our unknown methylated arsenic metabolite.

Exposure to naphthalene is a potential health hazard for cigarette smokers and industrial workers. Naphthalene exerts species and organ specific toxicity that is not yet fully understood. The goal of this study is to help us understand naphthalene's potential toxicity to humans, and the toxicity of polyaromatic hydrocarbons in general. The metabolites of naphthalene used in these experiments can serve as simple models that will help us learn more about the reactivity of electrophilic metabolites of polyaromatic hydrocarbons toward nucleophilic macromolecules such as proteins. In addition to studying the reactivity, the characterization of the products formed will provide important information towards understanding the mechanism of toxicity that polyaromatic hydrocarbons undergo.

Two of the reactive metabolites studied here are aromatic quinones. Therapeutic drugs and some pesticides contain quinones, but quinones are widely distributed in nature and are found in higher plants, fungi, bacteria, and throughout the animal kingdom as well. Quinones can exhibit toxicity by forming covalent adducts or by redox cycling. The two quinones included in these experiments may also serve as models that will further the knowledge of how this important class of compounds reacts towards protein nucleophiles.

The present work has investigated the reactions of three metabolites of naphthalene (1,2-naphthoquinone, 1,4-naphthoquinone, and racemic 1,2-naphthalene oxide) with model compounds N-acetylcysteine, α-N-acetyllysine, Lys-Tyr-Lys, and Lys-Cys-Thr-Cys-Cys-Ala. Aqueous solutions (pH = 7.4) of these reactants were incubated for 24 hours on a shaking water bath at 37°C. The mixtures were then lyophilized.

The crude reaction mixtures, and HPLC fractions of the adducts formed from incubations of the naphthalene metabolites with model peptides, were analyzed by static FAB in positive ion mode. In all instances, the sulfhydryl (cysteinyl) and amino (lysinyl) groups reacted in a similar fashion resulting in Michael addition products that are further oxidized to yield the quinone adduct (rather than the hydroquinone adduct). Schiff base adducts are only seen in minor amounts. Especially interesting were the spectra obtained from the adducted peptides.

In the case of the mono-adduct tri peptide of Lys-Tyr-Lys, tandem mass spectrometry was performed on the parent ion which consisted of the Lys\textsubscript{1}-adduct and the Lys\textsubscript{3}-adduct. Figure 1 shows the daughter ion spectrum obtained by collisionally activated dissociation of the [M+H]\textsuperscript{+} m/z = 595, with the especially relevant daughter ion peaks annotated.

The spectrum provided conclusive evidence that the quinone is binding to either the alpha position on the N-terminal lysine or at the epsilon position of the C-terminal lysine.

Incubation of Lys-Cys-Thr-Cys-Cys-Ala with naphthoquinone produced a mixture of products ranging from the mono-adduct through to the tetra-adduct and these are evident in the spectrum shown in figure 2. In addition to forming multiple adducts, the products are in various oxidation states as shown by the multiplicity of the peaks. The adducts detected here may be in the quinone or the hydroquinone form, or a combination of the two where more than one modification has occurred. The excess unreacted quinone oxidized the sulfhydryl groups on the cysteine to form a disulfide linkage.
The results indicate that the quinones form Michael adducts even with amino groups. Sequence information that indicates the position of the adduct within the peptide is obtained from daughter ion spectra. In addition, the bound quinone may be inducing oxidation to occur elsewhere within the peptide.

Leukotrienes and hydroxyeicosatetraenoic acids (HETEs) are metabolites of arachidonic acid. The more common members of the leukotriene family of compounds are formed in vivo by a cascade of reactions initiated by a lipooxygenase-catalyzed oxygenation of arachidonic acid. All six possible hydroperoxide (HPETEs) that could result from such a reaction are formed in one cell type or another. After the initial oxygenation, the HPETEs can undergo several different transformations. The HPETEs are often reduced to hydroxy derivative (HETEs) or are dehydrated to the initial members (LTA4s) of the leukotriene family. Subsequent hydrolysis to LTB4 or reaction with glutathione leads to the other leukotrienes. Many of these various derivatives are known to be involved in a multitude of physiological processes, including hypersensitivity reactions and inflammation. As part of our continuing interest in the FAB/MS/MS analysis of biomolecules, we have investigated the collisional activation decomposition of these compounds using coaxial continuous flow FAB (1,2).

Coaxial continuous flow FAB has proven to be a useful technique for the acquisition of MS/MS spectra (3,4). The coaxial CF-FAB interface uses a pair of coaxial fused silica capillary columns to independently deliver the column analytes and the FAB matrix to the FAB probe tip (1,2). This design is advantageous since the chromatography is not affected by the matrix and one gains independent optimization of the composition and flow rates of the analytes and the FAB matrix. In addition, the coaxial CF-FAB interface allows for increased sensitivity over other CF-FAB Interfaces due to the ability of the a nanoscale capillary LC system to deliver a high concentration of analyte in a short time period. This advantage makes this interface very useful for the acquisition of MS/MS spectra. The MS/MS spectra of a variety of compounds have been acquired by delivering a constant flux of analyte into the mass spectrometer (3,4). This constant flux of analyte is advantageous for the acquisition of CAD spectra that are otherwise cumbersome. We demonstrate the use of this constant flux of analyte with the acquisition of the MS/MS spectra of a variety of leukotrienes and HETEs.

The leukotrienes and HETEs were desorbed by FAB as negative ions and then collisionally activated. CAD spectra of the (M - H)- ions of these derivatives of arachidonic acid reveal that structurally informative fragmentations occur. These fragment ions can be used to locate the position of hydroxy groups on the fatty acid chain. In addition, the position and type of the cysteine moiety of the leukotrienes can be determined. As an example, the MS/MS spectrum of LTC4 is shown in Figure 1. The fragmentations observed for high energy collisions are different than those observed by Gaskell and coworkers (5) for low energy collisions. Upon low energy collisional activation, LTC4 fragments to give an abundant ion of m/z 306. Increased fragmentations involving extensive H-transfers around the S of the cysteine moiety are observed at high collision energies. For example, the LTC4 fragment ions of m/z 306 observed in low energy collisions shifts to m/z 305 at high collision energies.

Upon collisional activation, the HETEs fragment to give an abundant loss of water. The MS/MS spectrum of the (M - H)- ion of 12(S)-HETE is shown in Figure 2. In addition, fragmentations on either side of the substituted carbon are particularly facile. These fragmentations are especially useful for the determination of the location of the hydroxy substituents.

The epoxyeicosatrienoic acids (EETs) are biologically active eicosanoids derived from arachidonic acid and a cytochrome P450 mono-oxygenase (1). Insertion of an oxygen atom into one of the four double bonds in arachidonic acid produces four regioisomers of EET: 5,6-, 8,9-, 11,12-, or 14,15-EET. Detection of EETs in biological systems is difficult mainly because of the rapid metabolism of these compounds to dihydroxy fatty acids, glutathione conjugates, or reincorporation into cellular lipids. The strongest evidence that the EETs are endogenously formed is the discovery of 14,15- and 8,9-EETs in urine (2). In kidney and liver as much as 80% of the EETs were found incorporated into phospholipids (3–5). In order to investigate the physiological significance of the EETs or the EET-phospholipids, adequate analytical methods are required for direct structural characterization of these labile molecules.

Analysis of EETs has mostly been done by GC/MS of the free EET after phospholipase A2 treatment of the phospholipids (4). In this work we show that fast atom bombardment ionization and tandem mass spectrometry can be used to directly analyze the different isomers of EET incorporated into phospholipids from biological sources (6).

### METHODS

**Incorporation of EETs into mast cells** - Virally-transformed murine bone marrow-derived mast cells kept in tissue culture were harvested (1.6–2.6 × 10^8 cells) by centrifugation at 50×g for 15 min at room temperature, washed then resuspended in Hank’s balanced salt solution to 0.7 × 10^7 cells/ml. Individual EETs were dissolved in 5mg/ml fatty acid free bovine serum albumin (BSA) and then added to cells to give final concentrations of 1μM EET and 0.05mg/ml BSA. Incubations proceeded at 37 °C for 2 hours. Incubations were stopped by centrifugation and washing the cells to remove any unincorporated EET. EETs (5,6-, 8,9-, 11,12-, and 14,15-EET) were obtained from Cayman Chemical, Ann Arbor, MI.

**Isolation** - Phospholipids were extracted from the cells using CH₃0H/CHC1₃/H₂O (1:1:1) according to the method of Bligh and Dyer (7). The phospholipids were then separated according to polar head groups by normal phase HPLC, using a Lichrosorb column (4.6x 250mm, 3μm, Phenomenex, Torrence, CA). The mobile phase consisted of a gradient of 53% solvent A(hexane/isopropanol; 30/40; v/v) held for 6 min then programmed to 100% solvent B (hexane/isopropanol/H₂O; 30/40/7; v/v/v) over 20 minutes. Individual molecular species within each phospholipid class were separated using reverse phase HPLC with an Ultrasphere ODS column (4.6x 250mm, 5 μm; Beckman, San Ramon, CA). Mobile phase consisted of CH₃OH/H₂O/CH₃CN (90:5.7/2.5; v/v/v) containing 1mM NH₄OOCFCF₃.

**Mass Spectrometry** - Collisionally induced dissociation mass spectra of isolated EET-phospholipids and authentic unesterified EETs were obtained from 20–100 ng of material, using negative FAB ionization and a triple quadrupole mass spectrometer (Finnigan TSQ70B, San Jose, CA). Diethanolamine was used as the FAB liquid matrix. The fast atom gun was operated at 1mA with xenon accelerated to 6 kV. Argon (0.5 mtorr) was the collision gas. The collision offset energy (E₀ab) was 30 eV. The electron multiplier conversion dynode was maintained at 12 kV.

### RESULTS

**Negative ion FAB** collisionally induced dissociation mass spectra of the [M-H]⁻ ion from 16:1p/EET GPE (1-O-hexadec-1'-enyl, 2-O-epoxyeicosatrienoyl-glycerophosphoethanolamine) molecular species isolated from mast cells that were incubated with either 14,15-EET, 11,12-EET, 8,9-EET, or 5,6-EET as well as the negative FAB CID mass spectra of the [M-H]⁻ ion from unesterified 14,15-, 11,12-, and 8,9- and 5,6-EET are shown in Table 1. Different low mass fragment ions were observed in the CID mass spectra of each of the four 16:1p/EET GPE molecular species. CID mass spectra of the four isomeric EETs, in unesterified form, were taken to test the origin of these low mass ions. The same low mass fragments that were observed upon CID of the EET-containing phospholipid molecular species were observed in the CID spectra of the corresponding unesterified EETs. Possible mechanisms for some representative fragmentations are shown in figure 1.

### CONCLUSIONS

Collisionally induced dissociation of EET-containing phospholipid molecular species yields low mass ions that are indicative of the specific regioisomer of the esterified EET substituent. Negative FAB and CID are useful for...
identifying EET-containing phospholipid molecular species isolated from biological sources at the 100 ng level. The EET-specific ions from EET-phospholipids probably arise from secondary fragmentations of the EET carboxylate anion (m/z 319) that is produced upon CID of the phospholipid [M-H]⁺ ion. Some collisionally induced dissociations of the EET ion appear to arise by charge-driven mechanisms that may involve the transfer of allylic or bis-allylic protons to the carboxyl moiety leaving an anionic site on the hydrocarbon chain.

ANALYSIS BY FOUR SECTOR TANDEM MASS SPECTROMETRY OF COMPLEX MIXTURES OF PHOSPHATIDYLCHOLINES

Duncan K. Bryant, Ronald C. Orlando, and Catherine Fenselau

Department of Chemistry and Biochemistry, University of Maryland Baltimore County, Baltimore, Maryland 21228

Glycero-type phospholipids, along with protein, are the main constituents of biomembranes. The most abundant glycero-type phospholipid in mammalian cell membranes is phosphatidylcholine which can account for up to 49.5% of the total phospholipid content and up to 30% of the total lipid content in cells. Acyl chain length can vary from 10 to 24 carbons and up to 6 unsaturations per acyl group have been reported.

Fast atom bombardment (FAB) ionization has proven to be the optimal technique for mass spectral analysis of choline-containing phospholipids (1-4). Using a JEOL HX110/HX110 four sector tandem mass spectrometer we have examined the phosphatidylcholine content of a purified preparation of the human immunodeficiency virus (HIV-1), the etiologic agent of AIDS. In the positive ion mode, molecular ion stability is enhanced by the presence of the tetraalkylated ammonium cation, while in the negative ion mode formation of a phosphoryl anion contributes to the stability of the negatively charged fragments. Figure 1 shows the negative-ion FABMS spectrum of the phosphatidylcholine content of the HIV-1/MN virus. When combined with tandem mass spectrometry, not only can complex mixtures be analyzed, but much structural information can be obtained. Positive ion FABMS/MS can be used to identify the polar head group. Negative ion FABMS/MS is useful in elucidating the structure and position of the acyl groups. Figure 2 shows the negative-ion FABMS/MS spectrum of the ions weighing 742 from the viral phosphatidylcholine mixture; it can be seen that two phosphatidylcholines occur at this mass in the mixture. The four sector instrument used here provides high energy collisions, unit resolution in both MS-1 and MS-2, while maintaining good ion transmission and provides the capability to perform MS/MS/MS experiments (5) (Figure 3). The higher resolution of mass selection for a four sector mass spectrometer compared to a two sector instrument is essential for studying phospholipids, many of which differ by only two mass units.

An approximate quantitation of the fatty acid content of the phosphatidylcholines present in the HIV-1 viral preparation was obtained by measuring the relative peak heights of the phosphatidylcholine protonated molecules in FABMS AND FABMS/MS. An array of fatty acids is revealed that is consistent with that found in human blood cells. This work has been submitted to Analytical Chemistry and is in press.

Charge Remote Fragmentation during FAB-CAD-MS/MS of Triphenylphosphonium Derivatives of Carboxylic Acids.

Yoon-Seok Chang and J. Throck Watson, Dept. of Biochemistry, Michigan State University, East Lansing, MI 48824.

Recently, a simple chemical method has been developed in this laboratory, which permits the triphenylphosphonium (TPP) moiety to be selectively attached to the C-terminus of peptides, thus localizing a positive charge at that site (1). EDC [ethyl-3-(3-dimethylaminopropyl)-carbodiimide] activates the carboxylic acid group, allowing it to be coupled to the amino group of the AETPP (aminoethyl-TPP) reagent. The derivative significantly enhances the efficiency of FAB ionization by increasing the surface activity of the analyte and controls the fragmentation pattern by a remote charge fragmentation process (2). This method has now been extended to various fatty acids.

![Chemical structure](https://example.com/structure.png)

FAB-CAD-MS/MS of these fixed-charge AETPP derivatives of carboxylic acids show typical charge remote fragmentation as shown with metal ion adducts by Gross et al. (3). The fragmentations observed involve the parallel losses of C\(_n\)H\(_{2n+2}\) elements beginning at the alkyl terminus (Figure 1). The AETPP derivatives of tested fatty acids produce diagnostic fragments for locating a variety of structural modifications. For example, methyl branch positions in 4,8,12-trimethyloctadecanoic acid are easily recognized from the FAB-CAD-B/E linked scan spectrum of the M\(^+\) ion of the AETPP derivative (Figure 2). Iso and anteiso branched fatty acids also are easily distinguished by this characteristic fragmentation pattern (Figures 3 & 4).

In comparison to the metal cationized fatty acids, the detection limits for the analytes can be reduced substantially upon preparation of the AETPP derivative. This could be due in part to the fact that the AETPP ions are shifted up in mass by 288 u into a region where the chemical noise is lower and the ion current is concentrated principally in fixed-charge molecular ions of AETPP derivatives. Moreover, the covalently-bonded charged moiety generally allows better control of fragmentation than does the adduct with a metallic cation. The application of this procedure to other acids, including prostaglandins and thromboxanes with comparison of their mechanism of fragmentation to that of metallic cation adducts are currently under investigation.

ANALYSIS OF STEROLS IN FUNGI BY TANDEM MASS SPECTROMETRY

*Kate R. Noon, Mark J. Cole, and Christie G. Enke
Department of Chemistry, Michigan State University
East Lansing, Michigan 48824

Most fungi have been found to produce sterols in a variety of forms [1]. Tabulation of the content and distribution of the individual sterols present in different fungi may constitute a useful method for fungi identification. Tandem mass spectrometry has the potential to identify various types of sterols in complex mixtures without the use of derivitization.

Samples of crude lipid extracts were introduced directly into the ion source of a triple quadrupole mass spectrometer via a direct exposure probe. Three structural features were studied: $\Delta^5$, $\Delta^{5,22}$, and $\Delta^{5,7}$. Characteristic daughter ions were found for these specific structural features using four sterol standards as examples. The $\Delta^5$ sterols (cholesterol, sitosterol) produced two characteristic daughter ions of m/z 231, and m/z 178, the $\Delta^{5,22}$ sterol (stigmasterol) produced two characteristic daughter ions of m/z 273, and m/z 271, and the $\Delta^{5,7}$ sterol (ergosterol) produced one characteristic daughter ion of m/z 253. The daughter spectrum of the cholesterol molecular ion is shown in Figure 1.

Feature-selective parent scans were then developed for these characteristic fragmentations, and their usefulness confirmed using the sterol standards. Examples of two of these scans are shown in Figure 2. In the first example, a parent scan of m/z 231 for cholesterol, a $\Delta^5$ sterol, produced a peak at m/z 386, which represents the molecular ion of cholesterol. In the second example, a parent scan of m/z 271 for stigmasterol, a $\Delta^{5,22}$ sterol, produced a peak at m/z 412, which represents its molecular ion. Similar results were obtained for ergosterol and sitosterol.

Next, these feature selective parent scans were applied to the crude lipid extracts of four fungi samples. A number of peaks were detected in each sample that represented the molecular ions of different sterols containing the specific structural features for which the samples were being analyzed. Examples of these scans are shown in Figure 3. Variations in these distributions of sterols may provide a basis for detecting, characterizing, and identifying fungi.

Glycosaminoglycans (GAGs) are sulfated, linear polysaccharides found in mammalian tissues. These compounds exhibit a variety of biological properties and can be altered in disease states [2]. The presence of a certain type of GAG or the identification of one with a particular disaccharide composition might give valuable information about the nature of the biological process in which the GAG is involved. To study the structure of GAGs we rely on polysaccharide lyases to break them down into smaller oligosaccharides.

Recent work in our laboratory, with the underivatized sodium salts of sulfated oligosaccharides obtained from heparin, demonstrated that negative ion fast atom bombardment (FAB) mass spectrometry analysis, using the matrix triethanolamine, is useful for both molecular weight and sequence determination [3]. In addition to the loss of NaSO$_3^{-}$ ($+H^+$) ions, first reported by Reinhold and Carr using the matrix triglycerol [4], there was glycosidic cleavage which gave the corresponding sugar sequence. These full scan spectra can be used to determine which sugar ring contains sulfate groups but can not specifically pinpoint the sulfate substitution on the ring.

Our current work focuses on the sulfated disaccharides derived from chondroitin/dermatan sulfate polysaccharides. Exhaustive treatment of these chondroitin sulfates with chondroitin AC and ABC lyases [5] affords a mixture of unsaturated disaccharides having structures 1-8 shown in Figure 1.

In this paper, the collision induced dissociation (CID) spectra for three monosulfated chondroitin sulfates is presented (Figure 1; compounds 2, 3, and 4). These disaccharides produce abundant molecular ions of the type $[M - Na^+]^-$ ($m/z$ 460) and $[M - 2Na^+ + H^+]^-$ ($m/z$ 458) [6], where M is the fully sodiated neutral compound. All negative ion FAB-tandem mass spectrometric analyses were performed using a VG ZAB-HF mass spectrometer in the mass analyzed ion kinetic energy (MIKE) mode. In general helium was used as the collision gas at an analyzer pressure of ca. $5 \times 10^{-9}$ mBar (normal operating pressure ca. $5 \times 10^{-5}$ mBar).

The CID-MIKE spectra arising from the $[M - Na^+]^-$ molecular ion at m/z 460 is unique for each of the three compounds analyzed. That is, the CID-MIKE spectrum of the 2S sulfated compound has a fragment ion at m/z 277 corresponding to the portion of the sugar possessing the sulfate, which is not observed in the CID-MIKE spectra of the 4S or 6S compounds. This is not surprising since the sulfate groups are located on different rings of the disaccharide. Differentiation between the 4S and 6S disaccharides is achieved due to structurally significant fragment ions observed in each spectrum. Most notably are two small fragments containing the sulfate group arising from ring cleavage at m/z 153 for the 4S compound and m/z 139 for the 6S compound. The CID-MIKE spectra arising from the $[M - 2Na^+ + H^+]^-$ molecular ion at m/z 458 also allows for the differentiation between the 2S, 4S, and 6S sulfated disaccharides. Although the same fragment ions are observed in the MIKE spectra of 4S and 6S, differentiation between them is possible due to ion intensity differences. For example, ions at m/z 282 and 300 arise from glycosidic cleavage with and without loss of water and are observed as abundant fragment ions in the MIKE spectra of 4S and 6S. In the CID-MIKE spectrum of 4S, the product ion at m/z 300 is the base fragment ion; loss of water from 300 is a minor fragment ion. For the 6S compound, the product ion at m/z 282 is the base fragment ion observed suggesting that it is formed due to direct bond cleavage.

Figure 2. CID-MIKE spectra of \([M - \text{Na}^+](m/z \ 480)\) and \([M - 2\text{Na}^+ + \text{H}^+]\) (m/z 458) for disaccharides 2S, 4S, and 6S.

LOW-MASS IONS PRODUCED FROM PEPTIDES BY HIGH-ENERGY COLLISION-INDUCED DISSOCIATION IN TANDEM MASS SPECTROMETRY.

Mass Spectrometry Facility, Dept. of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143-0446.

High-energy tandem CID mass spectrometry provides a rapid and sensitive means of determining or verifying the amino acid sequences of peptides [1, 2]. Interpretation of a peptide MS/MS spectra relies mainly on the sequence-specific ions present. However, it is important to study all of the ions present in CID spectra, both because of their potential usefulness for interpretation and also as a means of uncovering previously uncharacterized fragmentation modes. The low mass region of peptide CID spectra contains peaks due to immonium and related ions as well as acyl and immonium dipeptide ions [2, 3]. We studied a large number of spectra, concentrating on the mass range 60-300, with a view to eventually incorporating this information into a "second-generation" computer-based scheme for interpretation of peptide CID spectra.

EXPERIMENTAL

MS/MS experiments were carried out on a Kratos Concept IIHH 4-sector instrument of EEBB geometry [4], equipped with an LS1MS source and a multichannel array detector capable of acquiring data simultaneously over a 4% mass window. Precursor ions were generated with an 18 keV Cs+

RESULTS AND DISCUSSION

IImmonium ions. Immonium ions for most of the common amino acids and for many modified residues are prominent in high-energy CID mass spectra [2, 3]. The usefulness for interpretation purposes of the immonium and related ions varies a great deal for different amino acid residues. For example, the cluster of ions produced by Arg is usually unmistakable as the characteristic ions from His, Leu/Ile, Phe, Tyr and Trp. On the other hand, the immonium ions of a few residues, such as Asp and Glu, are sometimes weak or absent. In some cases interferences can occur; for example, proline produces a strong ion at m/z 70, but Arg also generates a strong ion at the same mass. Similarly, the mass 87 ion of Asn is also masked if Arg is present.

Figure 1 shows the low mass region of the tandem CID spectrum of the peptide Ac-Gly-Ile-Gln-Glu-Leu-Tyr-Gly-Ala-Ser-NH2. The spectrum indicates that the peptide must contain He or Leu, Gin or Lys, and Tyr, and that Arg, His, Phe, Pro and Trp must be absent. The spectrum also gives strong evidence that Ser, Glu and Ac-Gly (or Val) are present and that Asn, Cys, Met and Thr are probably absent.

Modified amino acids. The immonium ions produced by modified amino acid residues nearly always produce peaks at the expected mass, namely 27 Da less than the modified residue mass. Acetylated N-terminal residues usually give rise to both acetylated and non-acetylated immonium ion peaks. Residues at the C-terminus of a peptide which have a modified carboxyl group (esters, for example) show only the normal immonium ion. Hexyl esters of aspartate, glutamate and carboxymethylcysteine give the expected immonium ions both with and without the modifying groups. Table 1 is a list of a number of modified residues and the masses of the characteristic positive ion high-energy CID peaks observed when these residues are present.

Dipeptide ions. The peptide CID spectra in Fig. 1 contains several examples of ions related to two adjacent residues in the original peptide. These ions are either internal acyl ions (designated by the dipeptide single-letter code) or immonium ions (designated by the dipeptide single-letter code -28) [5]. Dipeptide ions are often abundant when one of the residues gives rise to a strong immonium ion of its own, and/or when cleavage at one of the residues is favored, such as at the N-terminal side of Pro or Gly. Peaks corresponding to immonium or acyl dipeptide ions for the last two residues in a peptide are rarely or never observed. Dipeptide ion peaks can be particularly useful in interpretation of CID spectra. It is frequently the case that two satisfactory interpretations of a spectrum of an unknown peptide differ by a dipeptide inversion, for example, TATWFSR or TTAWFSR.

INTRODUCTION

A four sector mass spectrometer of BBEB geometry has recently been installed in our laboratory. The instrument was purchased primarily for the characterisation of advanced materials and associated formulations using the technique of FD-MS-MS. However, the problems associated with the combination of field desorption with tandem mass spectrometry (relatively weak ion currents and ion beams which can have a tendency to be somewhat transient in nature) have meant that this potentially powerful combination has not enjoyed the success that might otherwise have been the case. Consequently, there has been little applications data published in this area and so, as a way of comparing the performance of our system with other instrumentation of its type, we have evaluated the performance of the system using LSIMS in the peptide analysis area. A series of peptides have been examined on our four sector system (the VG ZAB-T) and compared with data obtained on a Kratos four sector mass spectrometer (Concept IIHH). The instruments were, as far as is practically possible, tuned in a consistent, reproducible manner to allow a sensible comparison of the resulting product ion spectra to be undertaken. Product ion spectra which compare and contrast the resulting data which have been obtained for Bradykinin are compared in this poster.

EXPERIMENTAL

The two four sector mass spectrometers utilised in this study were the VG ZAB-T and the Kratos Concept IIHH and these were prepared for operation in product ion mode by firstly tuning the instruments using CsI analysed in LSIMS mode. The tuning procedure used was carried out in as systematic a way as possible and the following tuning protocol was used:

(a) Select m/z 1692 peak of CsI using MS1
(b) Attenuate the beam with collision gas (25% transmission for Ar, 30% transmission for He)
(c) Tune to obtain optimum intensity for parent ion and a range of fragment ions

This procedure was followed using an 8kV source accelerating voltage and with the collision cell floated at 4kV (ie 4kV collision energy). Having obtained CsI product ion data, then the peptide Bradykinin was analysed in LSIMS mode using 4kV collisions and the Ar/He attenuation conditions indicated above.

RESULTS AND DISCUSSION

(a) CsI data

Table 1 provides a comparison of the product ion intensities obtained for product ions produced by high energy (4kV) CID of m/z 1692 of CsI.

These data, which show similar product ion yields at m/z 912, do begin to show interesting differences in terms of the relative ion intensities at m/z 133/393.

(b) Bradykinin

The product ion data obtained on the VG and Kratos instruments for Bradykinin appear to show some interesting differences (in terms of the overall appearance of the spectra) in the product ion spectra observed. Table 2 is a comparison of the relative product ion yields which were observed during the analysis of Bradykinin by LSIMS-MS-MS (normalised to the most intense product ion in the three ions considered here).

*BP indicates the base peak in the three product ions considered here.

Table 2 highlights a number of issues which merit comment. The two sets of data, despite the systematic approach to the experiments undertaken, are quite different. Of particular interest is the much higher yield of product ions observed in the Concept spectra at low (<m/z 150) mass. It is not clear at this point as to the reasons for this difference but it is presumably caused by a complex combination of collision cell design, extraction focus conditions, etc. Both sets of data do allow sequence specific information to be generated, and further work is necessary to determine if other sets of collision conditions on the two instruments are more appropriate to this type of analysis.

The initial conclusions from this work, in terms of the type of product ion spectra generated, have given us much confidence regarding the quality of data which we might expect to generate using the FD-MS-MS technique. This work has now begun in our laboratory and is the subject of other presentations at the 1991 ASMS conference.
An important advantage of tandem mass spectrometry (MS/MS) is its ability to isolate an ion from a complex mixture and subsequently obtain its collisionally activated spectrum. In this way, mixture components can be analyzed directly and their chemical structures can be elucidated without interferences. Comparison of an unknown spectrum with a library of known spectra is considered to be an effective method to identify chemical structures. The technique is simple, reliable, and relatively fast as compared to other computer-automated methods such as pattern recognition and heuristic interpretation. The successful operation of a library system depends on the quality of the comparison parameters used in the search, on the choice of standard conditions for spectral acquisition and on the degree of control of the experimental parameters affecting the reproducibility of the spectra. Moreover, the ability to reproduce similar enough spectra enabling the use of a common library, with mass spectrometers in different laboratories, is very important for the success of the technique.

In our laboratory, we have examined high energy (KeV) CAD processes and created a library of MIKES/CA spectra using the energy centroid, peak area, and peak width as parameters for structure identification purposes. Since several experimental factors such as collision gas, beam attenuation, collision energy, instrument geometry and others can affect the efficiency of the MS/MS library search we have undertaken a systematic study of the optimal experimental conditions under which the system would give reliable results. The instruments used in this study for the acquisition of MIKES/CA spectra were a Kratos MS50-TC triple sector mass spectrometer of EBE geometry, and a VG Autospec-C hybrid mass spectrometer of EBEqQ geometry. In chemical ionization the reactant gas was isobutane, and samples were introduced via a direct insertion probe. Samples in the FAB ionization mode were dissolved in glycerol, and were bombarded with a 14KeV caesium ion beam. Treatment and comparison of energy spectra were performed using an automated MIKES/CA data system (1). Instrumental conditions for the use of the library were calibrated using n-decane in El, glycerol in CI and FAB/LSIMS, and ethylene glycol in thermospray. The specific conditions of the El source for accumulation of kinetic energy MS/MS spectra are: 70eV electron energy, 200° C source temperature, and \(10^{-6}\)Torr source pressure. The ion repeller voltage was optimized for maximum ion extraction. Precursor ion selection is preferred to be conducted under high mass resolution conditions to eliminate isobaric ion contributions in mixture analysis. In the activation step, helium has been chosen as the appropriate target gas due to minimization of scattering and charge exchange effects, and production of good ion intensities. The standard collision energy of 8keV was selected for maximum sensitivity and convenience. However, the range 4000-8000 keV is acceptable for use of the library. The energy resolution interval =500-800 has been selected as the optimal resolution range for acceptable peak separation and maximum sensitivity.

The reproducibility of MIKES/CA spectra, examined using n-decane as a reference compound, was found to be within acceptable limits identification. Reproducibility for consecutive scans ranged between ±0.9% and ±2.9% of fragment ion abundances. Errors in the encoding of weak peaks were reduced using spectral averaging techniques and appropriate digital filter methods. Spectra obtained for an energy resolution interval = 600-2700 (13eV-3eV main beam width at 10% height) were found to be similar and showed a decrease in S/N at higher resolutions. Experiments conducted on different days were found to produce spectra with reproducibility errors for the various ion abundances within the ±0.5% and ±2.4% range.

The dependence of fragmentation patterns on the target gas pressure has been examined using several compounds of common organic chemical classes. Fragmentation patterns can change drastically within the 0%-30% beam attenuation interval (FIGURE 1, FIGURE 2) and small pressure changes can produce considerably different spectra. Beam attenuations higher than 70% although they usually produce extensive fragmentation, are associated with weaker MIKES/CA spectra, due to the increased probability of scattering, and the other competing collisional processes. Therefore, a 50% main beam attenuation has been chosen as a representative value in the generally accepted beam attenuation interval 30%-70% where fragmentation patterns are relatively stable and sufficient fragments are present allowing good fingerprinting.

A good overall similarity between spectra was obtained with two tandem mass spectrometers of similar geometry under the established experimental conditions for several classes of chemical compounds. As an example, the data presented in Figure 3 indicate that the spectra generated by different mass spectrometers are fairly similar despite instrumental differences. Thus, a general application of the MS/MS search approach is possible, using a common data base of MIKES/CA spectra for comparison and identification of
spectra acquired with different mass spectrometers.

In the process of evaluation of the search approach, several dipeptides were used to investigate the effect of the ionization method on the fragmentation pattern of the MS/MS spectra. As an example, the CI and FAB mass spectra of the MH⁺ ion (m/z 189) of the Glycyl-L-Leucine dipeptide, are considered. The CI and FAB MS/MS spectra of the m/z 189 protonated dipeptide shown in Figure 4, are very similar. The CI and FAB MIKES/CA spectra of at least 14 other dipeptides have been acquired and found to be identical within experimental reproducibility limits. This observation indicates that under the employed conditions, the CI and FAB ionization sources can lead to the formation of the same precursor ion structure (or a mixture of structures). An important implication of ionization method-independent MS/MS spectra of protonated species is the fact that a wider choice of ionization sources can be used without the need of multiple data bases.

REFERENCES

Four-sector tandem mass spectrometry is proving extremely useful for providing sequence information for peptides. Daughter spectra of large numbers of peptides may be generated in a relatively short time-frame. However, efficient interpretation of the data from high energy collisions remains one of the obstacles to rapid sequencing by mass spectrometry, due mainly to the complexity of the fragmentations. We have developed a derivatization procedure that produces simplified, predictable fragmentation of ions produced by FAB to permit more rapid and accurate data interpretation.

A fixed positive charge is attached to the peptide by (a) acylation with iodoacetic anhydride at pH 6, which selectively modifies the N-terminal α-amino group (1), and (b) subsequent addition of a dimethylalkyl amine at pH 8 to form a quaternary ammonium group. The first step exploits the pKa differences between the α-amino group and any lysine side-chain ε-amino groups. The second step yields improved spectra over previous derivatives (2) in which step (b) was addition of thiocholine. The quaternary ammonium derivatives have also been prepared by Vath and Biemann using gas-phase methodology (3). A related approach, developed by Wanger et al., utilizes an ethyltriphenylphosphonium moiety to direct fragmentation (4).

The derivatives in this study are prepared as follows: 0.1-2 nmol of peptide is dissolved in 12 µl of 0.3 M 2-[N-morpholino] ethanesulfonic acid (MES), pH 6. The solution is cooled to 0°C and 5 µl of 0.01 M iodoacetic anhydride in dry THF is added. The solution is vortexed, maintained at 0°C for 5 min, and then allowed to return to ambient temperature. To the iodoacylpeptide is added 5 µl of either 12.5% trimethylamine, 0.5 M dimethylhexylamine, or 0.5 M dimethyloctylamine. The solution is vortexed and heated to 37°C for 2 hrs. The derivatized peptide is purified by reversed-phase HPLC. Mass spectra were obtained with a JEOL JMS-HX110HF/HX110HF tandem mass spectrometer using a 3-inch JEOL array detector (9.5% simultaneous mass range). Peptide ions were produced by 10 keV Cs⁺ primary ions, using m-nitrobenzyl alcohol or monothioglycerol as the matrix, and accelerated to 10 keV. The collision gas was helium, and the collision cell was operated at 6 kV.

The amine alkyl chain length was varied from C1 to C8 for the hexapeptide FGAKQA. Dimethyloctylamine was found to produce the best parent ion signals due to its higher surface activity in the matrix. The simplification of the daughter spectrum of the derivatized peptide is evident by comparing Fig. 1, the daughter spectrum of 100 pmol of an undervatized tryptic fragment (T4) from recombinant human growth hormone, with Fig. 2, the corresponding dimethyloctylaminoacetyl (DMOA-Ac) peptide (40 pmol). The sequence of the peptide is LHQLAFDTYQEFEEAYIPK. The spectrum of the undervatized peptide exhibits partial series of aₙ, bₙ, cₙ, dₙ, eₙ, fₙ, gₙ, hₙ, and m+n+1 ions, plus numerous internal fragments at low mass. The determination of the sequence from this spectrum alone would be difficult. In contrast, the spectrum in Fig. 2 shows a complete set of aₙ ions from which the entire sequence of this 19-residue peptide can be derived. Moreover, a strong series of dₙ ions is observed which permits distinction between Ile and Leu residues and also provide additional confirmation of the sequence. A minor cₙ ion series is also observed, but few bₙ ions are found. By limiting the fragmentations primarily to three ion series, the peaks observed are stronger than those from the undervatized peptide because the available daughter ion current is distributed among fewer masses.

In summary, this derivatization procedure (a) enhances interpretation of CAD spectra by yielding simpler fragmentation, (b) enhances signal strength by concentrating the parent ion abundance in fewer fragmentation pathways, (c) permits distinction of Ile and Leu by exhibiting abundant dₙ ions, and (d) lowers the necessary daughter ion resolution by producing fewer, well separated peaks.
FAST ATOM BOMBARDMENT AND TANDEM MASS SPECTROMETRY OF QUATERNARY PYRIDINIUM SALT-TYPE TRYPTOPHAN DERIVATIVES

Laszlo Prokai1, K. Prokai-Tatrai2, E. Pop3, N. Bodor1, J. Lango4, and J. Roboz;4
1Center for Drug Discovery and 2Department of Pharmacology and Therapeutics, University of Florida, Gainesville, FL 32610; 3Pharmatec, Inc., Alachua, FL 32615; 4Mount Sinai School of Medicine, New York, N.Y. 10029.

Fast atom bombardment (FAB) and liquid secondary-ion mass spectrometry (LSIM) provide routine means of efficiently sampling quaternary salt-type compounds for subsequent mass analysis. Optimally, these desorption ionization techniques generate intact ionic species (the molecular cation in positive-ion mode) as well as structure-related fragment ions from the sample dissolved in a suitable liquid matrix upon the impact of the keV-energy atom/ion beam. The desorption of closed-shell quaternary ions is of special interest, since usually no apparent chemical interaction leading to proton/cation attachment from the constituents of the matrix can be observed. FAB and LSIMS may not actually be referred as "soft" ionization techniques, since abundant fragment ions analogous to those observed in EI or CI mass spectra are commonly formed. Fragmentation pathways for the FAB technique can also be elucidated with the same rigor as the EI/CI processes.

We have recently synthesized [1,2] quaternary pyridinium salt-type derivatives of tryptophan (α-amino-1-indolepropionic acid) in which the structure of the organic cation varies with respect to both the substituents and the distance of the quaternary nitrogen from the indole/carboxyl portion. In structure 1, the α-amino group of the parent compound is transformed into the quaternary nitrogen of the pyridinium cation. Structure 2 represents derivative in which trigonellyl, a pyridinium-type acyl group, is used to attach the charged portion to tryptophan esters. Compound 3 is also an amide; the quaternary nitrogen is, however, separated from the acyl carbonyl by -CH2-"spacer." The localization of the charge on a particular structure has especial significance for the mechanistic interpretation of fragmentation pathways of organic ions. Unlike large, highly functionalized molecules where the site of the positive charge arising from proton or cation attachment may not be clear, the title structures provide unambiguously localized charge—the quaternary nitrogen. In this presentation, we elucidate fragmentation processes of these pyridinium ions occurring under FAB conditions. Accurate mass measurement, isotope labeling, and tandem mass spectrometry have been used to gain insight into the origin and possible structure of the ions of interest.

FAB mass spectra were recorded on a MS80RFA/DS90 instrument (Kratos Analytical, Manchester, U.K.). The FAB gun, an Ion Tech Ltd. (Teddington, Middlesex, U.K.) FAB11NF saddle-field source, was operated with research-grade xenon at 8 keV beam energy and 1 mA current. Sample introduction was accomplished via placing 1-5 µg of analyte onto the copper probe tip, and then mixing with 1-2 µL of liquid matrix (glycerol or thioglycerol). CID and tandem mass spectrometry studies were carried out on a Trio-3 (VG Instruments, Manchester, U.K.) triple quadrupole instrument. The samples were dissolved in glycerol, and FAB experiments were performed with a xenon gun operated at 8 kV and 2 mA. All MS/MS experiments (daughter and parent ion scans) were recorded using nitrogen as collision gas at a pressure of 2-6 millitorr in the RF-only quadrupole. Collision energy was 5-15 eV, adjusted to give maximum intensities for the particular transitions studied.

For the pyridinium ions involved in our study, the FAB ions obtainable from ion source reactions and the CID experiments have revealed complex, structure-dependent fragmentation patterns. A variety of cleavage reactions apparently independent of the localized charge and frequently taking place at charge remote sites of the structure have been identified even under experimental conditions that favor reactions with low energy barrier. Though the extent of such reactions may be largely dependent on the arrangement of the functional groups within the ions involved, certain uniformity of the governing principles of fragmentation has been demonstrated by keeping portions of the structure, intact. Remarkably, ions with new charge sites formed during the homolytic cleavage reaction may dominate as product species in the respective mass spectra over the ones that retain the pyridinium structure. Further studies are to reveal mechanistic details on the underlying processes, and to extend our knowledge on the chemistry of these closed-shell ions. The following fragmentation pathways have been elucidated for the selected quaternary pyridinium salt-type tryptophan derivatives:

INVESTIGATION OF CONFORMATIONAL EFFECTS ON FRAGMENTATION OF N-PROTECTED TRIPEPTIDES BY MS/MS

Brenda L. Schwartz, Bruce W. Erickson, Maurice M. Bursey, University of North Carolina, Department of Chemistry, Chapel Hill, NC 27599

INTRODUCTION

Determination of conformation of peptides by mass spectrometry has become important for the prediction of secondary structure of oligopeptides. To explore the relationship between intramolecular hydrogen bonding caused by side chain interactions and intensity of products formed, two N-protected tripeptides, N-Cbz-Gly-Leu-Arg-NH₂ and N-Cbz-Gly-Pro-Arg-NH₂ were studied using LSIMS MS/MS on a hybrid tandem mass spectrometer. The differential loss of benzyl alcohol (106 u) from the protonated molecular ion of the two peptides and the formation of significant other products were studied under unimolecular decomposition and CAD conditions as a function of collision energy and gas pressure.

RESULTS AND DISCUSSION

MS/MS relative ion intensities were found to differ dramatically from conventional MS-I full scan results. For example, contrary to full scan data, the [MH - 108]+ ion at m/z 354 in the MS/MS spectra of Cbz-Gly-Pro-Arg-NH₂ is an intense product ion, often the most intense observed, under all collision energies and gas pressures investigated, having abundances ranging from 7 to 17%; however, the corresponding ion for Cbz-Gly-Leu-Arg-NH₂ at m/z 370 never reaches intensities greater than 4% relative to the sum of all products (Figure 1). The intensities of these ions, as well as other high mass products, decreases at the Eolation approaches 50 eV, with a corresponding increase in intensity of lower mass ions, such as m/z 70, 86 and 91, under CAD conditions, with the effect being more pronounced at higher Ar pressures (Table 1). Another major difference in the MS/MS behavior of the two peptides is that higher intensity lower mass fragment ions are observed only from the leucine peptide (Figure 2). Higher collision energies and gas pressures are required to induce the production of lower mass fragments for the proline peptide, suggesting that the extended time in the MS/MS experiments versus the time in the source allows the proline peptide to assume a more stable conformation through intermolecular hydrogen bonding between side chains because of the nature of the proline ring.

EXPERIMENTAL

Cbz-Gly-Leu-Arg-NH₂ and Cbz-Gly-Pro-Arg-NH₂ were synthesized by reacting Cbz-Gly-Leu-OH and Cbz-Gly-Pro-OH, respectively, with H-Arg-NH₂ using DCC as a coupling reagent. The peptides were purified by HPLC and dissolved in methanol.

LSIMS mass spectra were obtained on a VG 70-250 SEQ instrument (EBQQ), 8kV in MS-I. A cesium ion gun was operated at 25 kV (1.5 uA emission), with glycerol matrix and 5-µl sample volumes. Product ion spectra were acquired in the multi-channel analysis (MCA) mode by scanning from m/z 50 to 500 with the accumulation of 15 scans. Four collision energies were chosen ranging from 10 to 50 eV with low pressure CAD conditions at Ar pressures of 10⁻⁷-10⁻⁶ mbar (primary beam attenuation by 10%) and high pressure CAD conditions at 5 X 10⁻⁵ mbar (by 90%).

* Base Peak
Many aromatic molecules have strong absorption bands in the UV which are rather broad at room temperature; the ionization potentials for many such polyatomics are also often less than 9 eV. Therefore, they can be ionized with high efficiency by resonance enhanced two-photon ionization (R2PI) using the frequency-quadrupled output of the Nd:YAG laser at 266 nm (4.7 eV). Ionization selectivity for polyatomics is necessarily limited when fixed-wavelength R2PI is used, however. Although improvements in ionization selectivity can be achieved through the use of tunable UV laser radiation, limitations exist on the optical selectivity of tunable R2PI attainable at room temperature due to the thermal population of excited rovibronic states. Moreover, in some situations such as rapid screening of complex mixtures for compound class, it may be advantageous to use a relatively nonselective ionization method in conjunction with another technique which enhances the analytical specificity. Because the degree of fragmentation accompanying R2PI is a function of laser power, mass spectrometric analysis of such fragments also can often improve the specificity of the overall analysis. However, in the case of organic mixture analysis, the complexity of R2PI/fragmentation mass spectra may compromise compound identification. MS/MS can also enhance the specificity of analysis over that provided by a single stage of mass spectrometry. Although R2PI/fragmentation and MS/MS can yield complementary data, situations may often occur in which the spectra reveal no unique structural information. Nevertheless, the combination of R2PI and MS/MS can still provide an advantage over the use of R2PI alone.
R2PI/fragmentation mass spectra obtained in the ITMS for ethylbenzene, propylbenzene, N,N-dimethylaniline, and N-ethylaniline are shown in Figures 1-4, respectively. The R2PI-MS/MS spectra for each of the sample compounds contain major product ions corresponding to those major fragment ions seen in the R2PI/fragmentation spectra. On the basis of the above results, combining MS/MS with R2PI appears to provide little advantage over the use of R2PI alone for the analysis of pure compounds. However, the effectiveness of R2PI-MS/MS compared with R2PI/fragmentation for mixture analysis can be demonstrated using a mixture of the above compounds.

The molecular ion signals at m/z values 106 and 120 in Figure 5a, obtained using unfocused laser radiation, indicate the presence of ethylbenzene and propylbenzene, respectively. However, the m/z 121 ion signal could be due to either N,N-dimethylaniline, N-ethylaniline, or both compounds. Although the increase in the m/z 120 signal in Figure 5b, acquired using focused laser radiation, suggests that N,N-dimethylaniline is present, such an effect could be attributed to propylbenzene. In any case, the presence of N-ethylaniline cannot be confirmed because its major fragment ion at m/z 106 coincides with the molecular ion of ethylbenzene. Therefore, the origin of the ion signal at m/z 121 can not be confirmed. Thus, despite the fact that individual R2PI/fragmentation mass spectra for the components comprising a sample are unique, mixture analysis can be problematic when fragment ions are indistinguishable from molecular ions.

Tandem mass spectrometry in conjunction with R2PI can enhance specificity in such circumstances. An MS/MS spectrum (Figure 6) of the m/z 121 molecular ion from the same mixture was obtained using unfocused laser radiation and the same CID parameters previously used for pure component spectra. As seen in the spectrum, the major product ions are at m/z values 106 and 120. Comparison with pure component MS/MS spectra reveals that the m/z 106 and 120 product ions correspond to the N-ethylaniline (M-CH₃)* and N,N-dimethylaniline (M-H)* ions, respectively. Given this MS/MS structural information and the molecular ion data obtained from the low power R2PI mass spectrum (Figure 5a), it can then be deduced that the sample is comprised of all four components. Given any combination of mixtures generated from the same suite of compounds, similar reasoning could be used to deduce the composition.
APPLICATION OF SUBSTRUCTURE IDENTIFICATION RULES TO MS\textsuperscript{n} SPECTRA OBTAINED ON AN ION TRAP MASS SPECTROMETER

K.J. Hart, Scott A. McLuckey and Gary L. Glish
Oak Ridge National Laboratory, P.O. Box 2008
Oak Ridge, TN 37919-6365

Empirically derived rules have been generated by the MAPS software for use in identifying molecular structures in unknown compounds from MS/MS spectra [1]. The rules were based on a training set of CID product spectra obtained on a triple quadrupole mass spectrometer (TQMS) under single collision conditions. The TQMS was used for acquisition of the training set MS/MS spectra because the instrument was capable of rapidly acquiring the CID reference spectra. The ion trap mass spectrometer (ITMS), however, has the advantage of better sensitivity and CID efficiency compared to the TQMS. Therefore, a study of the applicability of rules generated from the TQMS reference spectra to MS/MS and MS\textsuperscript{n} spectra acquired on the ITMS was performed.

The MAPS rule for the phenothiazine substructure was used as a model for this study. In particular, the CID products obtained for the m/z 198 ion (the intact phenothiazine ring) were investigated. The CID products observed in the single collision TQMS spectrum (1% threshold) are m/z 197 (loss of H), m/z 171 (loss of HCN), and m/z 154 (loss of CS). The m/z 45 (HCS+), m/z 166 (C12H8N+), and m/z 127 (C10H7+) ions were also observed in this spectrum upon the use of a blowup factor. The MAPS rule generated using multiple collision CID spectra included m/z 197, m/z 171, m/z 166, m/z 154, m/z 128, m/z 127 and m/z 45 (using the 1% threshold). The ITMS MS/MS spectrum of the m/z 198 ion derived from phenothiazine is shown in Figure 1. Note that the spectrum shown was acquired with a q value of 0.45, a value chosen to maximize CID efficiency (approx. 100%). This q value was too high to observe the m/z 45 product ion. A separate spectrum was taken using a q value of 0.18. The m/z 45 was not observed for the m/z 198 precursor ion of phenothiazine or any of the eight other standards listed in Table 1. This ion is actually the most abundant CID product ion in the multiple collision TQMS spectrum. The m/z 166 CID product ion was also missing from two of the nine phenothiazine standards.

Application of the single collision MAPS rules to the nine phenothiazine standards yielded nine identifications of the presence of the phenothiazine substructure while only seven identifications were made using the multiple collision rule. The difference in these results was the missing m/z 166 and m/z 45 product ions in the ITMS spectra (MAPS rules do not utilize relative intensities, just the presence of specified spectral features). Ion activation in the ion trap proceeds by successive collisions with relatively small increments of energy deposition compared to the TQMS experiment. Thus, xenon was added to the He buffer gas (approximately 1:1 for a total pressure of 1.2 x 10\textsuperscript{-4} torr) in an effort to increase the energy deposited per collision in the ITMS. The MS/MS spectra obtained with (top) and without (bottom) resonant excitation are shown in Figure 2. The ions observed in the bottom spectrum appear because of incomplete isolation of the m/z 198 precursor ion (done to maximize m/z 198 signal before resonant excitation). The top spectrum of Figure 2 represents the largest m/z 45 signal observed (approximately 3% of the base peak m/z 198 and approximately 0.8% of the original m/z 198 abundance). Increasing tickle time or tickle voltage leads to decreasing m/z 45 signal probably due to ejection of the precursor ion before dissociation can occur. The 5 x 10\textsuperscript{-5} torr pressure of xenon was also optimal to observe the 198 -> 45 CID reaction.

773
Since the q parameter is such a critical parameter in CID by resonant excitation in the ITMS, another ion
activation method such as photodissociation, which does not lose efficiency as the q parameter decreases (for
values set to store the product ions), may yield better results. The challenge in utilizing photodissociation in the
ion trap lies in dissociating the selected ion without ionizing neutral molecules.

AN APPROACH FOR THE DESIGN OF MS\textsuperscript{n} EXPERIMENTS ON A MULTISECTOR HYBRID SPECTROMETER OF EBEqQ GEOMETRY.

Yves Mouget, T. Davies, M. Baker and Michel J. Bertrand
Regional Center for Mass Spectrometry,
Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7.

 Since the accelerating voltage was first scanned to analyse metastable ions, a great deal of work has gone into the study of fragments formed in field free regions. MS\textsuperscript{3} type scans, performed on an instrument with three mass analysers of BEqQ geometry, have been shown to exhibit a distinct improvement in selectivity over the more common MS\textsuperscript{2} type scans (1). Using a four sector instrument (ZAB-4F), MS\textsuperscript{4} and MS\textsuperscript{5} type experiments were not only proven feasible, but also useful in the structural elucidation of biopolymers (2). The development of more complex multisector mass spectrometers with high performance computer systems enables tandem mass spectrometry experiments to be conducted more easily and more reliably, opening the door to a multitude of possible MS\textsuperscript{n} scans, some involving several consecutive fragmentations (n=3,4,5). A new nomenclature, first introduced to describe the MS\textsuperscript{3} type scans, allows all the scans theoretically possible on an instrument to be easily defined according to the function of the scan rather than the scanning method. These scanning modes increase exponentially with the number of analysers in a given system. Since programming all the scans would be a near impossible task, considering that scans with a functional relation between two masses can be individually tailored, a new approach is suggested that allows the user to program any desired linked scan. The concept of this approach is to translate scan equations, typed by the user into the computer, into the correct commands to execute the scan through the use of software controlled DACs. Examples are given to show the feasibility and the flexibility of this approach for multisector mass spectrometers.

Until recently, typical linked scans (B/E, B\textsuperscript{2}/E, neutral loss) were available on most magnetic sector mass spectrometers only as pre-programmed functions. While for linked scans pre-programmed functions simplify the work involved in performing such scans, they limit the user by not allowing him to investigate special cases, which require the design of customized experiments. The scan modes which are possible on an instrument can be obtained by consideration of the fundamental scans, the functional, and total scans that can be conducted on a four sector spectrometer. As theoretically calculated by Cooks et al., the total number of scans for a four sector geometry is 74 scan modes, if all MS\textsuperscript{n} (n=0-4) experiments are considered. To allow the design of all possible MS\textsuperscript{n} experiments on the instrument and in keeping with the modern trend of user friendly programs and menu-type displays, the new approach was developed based on the use of a graphical matrix. The concept of this matrix is applicable to an instrument of any geometry. In this case, a VG Autospec-Q double focussing instrument of EBEqQ geometry was used. The instrument comprises two collision cells, located in FF1, FF3 and the rf-only quadrupole, and since the three sectors, the two quadrupoles, and the accelerating voltage are each controled by their individual DACs, it is thus well suited to the development of such a matrix.

The approach considers linked scans as equations in which each sector involved is represented as a variable in the mathematical equation. As seen below, the matrix consists of two main sections: the top row is used to select which sector should scan or not scan, and the lower grid is used to enter the equation that describes the relationship between two sectors (Figure 1). The two sectors linked by the relationship are selected according to the intersection of their respective row and column. By first selecting the sectors involved in the scan, the user can enter an equation that describes the link between the sectors. An interpreter will evaluate the equation and determine whether it is mathematically correct. Existing menus can be used to enter the missing values, necessary to calculate the scan parameters, such as the accelerating voltage, the mass range of the scan, the mass of the parent, daughter or neutral fragment, and other instrument parameters. For example, in order to set a B/E linked scan experiment, E1, M, and E2 would be set to the scan mode and E1 and E2 would be linked together and to the magnet as indicated in the matrix in Figure 1 by the relations R1, R2 and R3, which are defined as shown. In those relations, m represents the parent mass and M the field corresponding to the daughter ions. As a comparative test, a daughter ion scan of m/z 122\textsuperscript{+} in ethylbenzoate was conducted using conventional software and using the "link-matrix". The results obtained with the "link-matrix" are shown in Figure 2, and are comparable to those obtained with pre-programmed functions for the same scan.

One of the experimental limitations of MS\textsuperscript{n} experiments is the sensitivity with which these experiments can be conducted, if several fragmentations are involved. In order to investigate this aspect, MS\textsuperscript{5} type experiments were conducted to evaluate the practicality of the approach.
In these experiments the daughter ion spectra of m/z 77⁺ in the spectrum of ethylbenzoate were obtained by scanning the last analyser (Q). The parent ion was selected by increasing the number of fragmentations after the source leading to its formation from the molecular ion of ethylbenzoate. The results obtained in MS⁴ and MS⁵ experiments are shown in Figures 3 and 4. It can be observed that the S/N ratios are quite acceptable for this type of experiments. The acquisition times, that range from 150 to 600 seconds compare well with published data, in which the times ranged from 30 minutes to 3 hours for similar experiments. Thus, the use of more recent computerized data acquisition modes makes these experiments feasible, and the results demonstrate the possibility of performing multiple fragmentation experiments in a reasonable amount of time. Therefore, it would appear that the approach which is presented is worth pursuing to explore the types of MSⁿ that can be conducted on this instrument or other types of multisection spectrometers.

Although not all 74 different scans theoretically possible on the EBEqQ geometry will have analytical applications, the instrument is shown capable of performing even the ones involving multiple fragmentations. Therefore, if the matrix can correctly interpret scan equations for customized experiments, and providing the equations are correct from the point of view of a linked scan, then the instrument should execute the instructions and produce a spectrum. This new approach effectively allows the user to design an experiment for a particular application. The greatest advantage of the "link-matrix" is its versatility, especially when performing scans with a functional relation between masses.

REFERENCES
The development of techniques allowing the introduction of liquid samples has considerably increased the range of compounds that can be analysed by mass spectrometry. Although substantial efforts have been devoted to developing interfaces in order to couple liquid chromatography to mass spectrometry, there are several other applications that can benefit from such liquid introduction techniques. Among these applications that require continuous introduction of the sample, the identification of organic compounds by techniques of MS or MS/MS and real time monitoring of chemical reactions occurring in solution can be taken as examples. A survey of the existing liquid introduction systems shows that DLI systems using a simple capillary to transfer the liquid sample into the ion source of the mass spectrometer are the most appealing. These systems are inexpensive, simple, and can be easily adapted to most magnetic sector and quadrupole mass spectrometers. Examination of the actual configuration of most GC/MS systems using direct coupling immediately leads to the conclusion that they could be used for capillary DLI interfaces with thermal nebulization. In this perspective the feasibility of using the direct coupling GC/MS interface of a magnetic sector mass spectrometer to introduce liquid samples was evaluated.

The instruments used in this study were a VG TRIO-1 quadrupole mass spectrometer equipped with differential pumping and a VG-AutoSpec-Q magnetic-sector hybrid mass spectrometer of EBEqQ geometry. The TRIO-1 was slightly modified by the addition of a high vacuum gauge and the source was slightly altered to increase its pumping speed and sensitivity. The VG-AutoSpec-Q was used without modification. The DLI experiments were done by directly introducing a 50 μm I.D. fused-silica transfer capillary into the EI/CI source of either mass spectrometers. On both instruments, the transfer capillary was introduced by the GC oven through the conventional GC/MS Interface where it replaced the GC capillary column and was adjusted into the ion source exactly like the GC column. The capillary was directly connected at the other end to a microinj ector valve (60nL) through which the solution containing the sample was introduced. The transfer capillary was heated over the length of the interface and maintained at the optimal temperature on both spectrometers using the standard GC/MS interface heaters. The chemical ionization source was operated using the DLI mobile phase as a reagent gas.

The temperature of the interface is an important factor that influence the performance of the DLI systems using capillary thermal nebulisers. Since the temperature of the capillary governs the rate and stability of vaporisation of the mobile phase, the effect of interface temperature was studied in relation to the stability of the systems. In the range of 180-220 °C the interface showed excellent stability in the order of few percent. This can be seen by examination of the TIC shown on Figure 1. Outside this range partial to severe instability was encountered on both sides of this temperature range. Another Important factor that affects the stability and the operating conditions is the flow rate. Its value has to be such that the thermal input through the interface is sufficient to vaporize the mobile phase while the pressure within the chemical ionization source is adequate to maintain ionization and sensitivity. The range of flows corresponding to stable operating conditions found over six months of operation is between 0.5 to 1.6 μL/min on the Autospec-Q and between 0.5 to 2.0 μL/min on the TRIO-1. With these flows, the major ion in the plasma at the lower pressures (<4×10^-5 torr) corresponds to protonated acetonitrile at m/z 42, while the protonated dimer at m/z 83 is small. As the pressure is increased, the intensity of the dimer increases and it becomes the most important ion. Ions corresponding to H2O+ and HgO+ at m/z 18 and 19 have weaker intensities than those related to acetonitrile.

Inter instrument variation between a magnetic sector and a quadrupole mass spectrometer can be evaluated by comparison of the spectrum of ibuprofen obtained on both instruments (Fig.2). The results indicate that the interfaces performs similarly on different types of instruments. The reproducibility for the Autospec-Q can be observed on Figure 3 where several injections of ibuprofen have been made consecutively. This simple, transportable DLI interface can be used advantageously not only for LC/MS (1) analysis but also for MS and MS/MS experiments. The stability of the system facilitates exact mass measurement experiments using the continuous introduction of reference compound with the analyte of interest or by allowing the introduction of the analyte by injection in the mobile phase. Exact mass measurements can be done with an accuracy of 10 ppm with the present system. Since the system offers good operating stability and can produce stable and persistant ion beams it also allows tandem mass spectrometry experiments to be performed at low levels of concentrations. Figure 4 shows the CA spectrum of ibuprofen (1.5 ng/sec) and the signal to noise ratio (S/N) is excellent for a single scan (Fig. 4a). It can be increased by spectral averaging procedure (Fig. 4b) due to the persistant ion beam allowing experiments to be conducted in the picogram range.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics
This persistence of the ion beam can also be used advantageously for complex MS^n experiments. MIKES/CA spectra obtained in FF3 for the ion at m/z 161 of ibuprofen selected in the ion source (MS^2), and after dissociation in FF1 (MS^3) were compared and the spectra obtained in both experiment showed good similarity indicating that the DLI system can be helpful for that type of analysis, that are difficult to conduct easily using conventional direct insertion probes.

The simple DLI system, using a conventional direct GC/MS interface, described in this study can be very useful to interface capillary liquid chromatography and can also be used as an independent introduction system for specialized MS or MS/MS mass spectral analysis requiring persistent ion beams. The system is simple, easy to operate, offers good stability when operated under optimum conditions and is easily transportable from one instrument to another. It should easily be installed in any laboratory using a GC/MS instrument.

The free-jet, molecular-beam mass spectrometer at SERI has been recently coupled with an Extrel triple quadrupole mass analyzer. This unique instrument (a schematic is shown in Figure 1) enables us to identify the structure of various pyrolysis products from several energy-related processes currently under study by SERI researchers. Among these projects are solar detoxification of hazardous waste, biomass characterization, zeolite upgrading of pyrolysis oils from biomass and municipal solid waste (MSW), and pyrolysis of cellulose, paper and MSW.

A brief description of the above instrument is given here. Samples are extracted through the orifice, undergoing an adiabatic, free-jet expansion to form a molecular beam. This beam is then extracted through a skimmer and a collimating orifice into the ionization region where samples are ionized via electron impact. Only positive ions are focussed and passed to the triple quadrupole mass analyzer. Collision-induced dissociation of the desired parent ion selected from the first quadrupole (Q1) takes place in the second quadrupole (Q2). Argon is used as the collision gas. The resulting fragment ions are then filtered by the third quadrupole (Q3) and detected by an electron multiplier.

Collision-induced dissociation (CID) studies of the usually complex mixtures provide important structural information about the gaseous products formed from precursor materials either by direct pyrolysis or in the presence of catalysts. They are also helpful to the understanding of mechanisms of reactions taking place in these thermal processes. For example, Figure 2 compares the CID mass spectrum for daughter ions of the m/z 106 parent that is produced in small abundance from high temperature (700°C) oxidation of chloronaphthalene, a model hazardous chemical, with that of benzaldehyde. Similar studies have positively identified the following products from this process: 1,4-naphthadione, 1,3-indandione, indenone, and their chlorine derivatives. Additional examples are identification of methyl chloride as a pyrolysis product from MSW, acetone from both MSW and wood and 2,6-dimethylphenol from poly[2,6-dimethyl-p-phenyleneoxide].

We have also applied multivariate analysis to the CID spectra to deconvolute the relative amounts of components that contribute to the same parent ions. Figures 3 to 5 show one such example. In the mass spectrum of cellulose and paper pyrolysis, an abundant peak at m/z 60 is observed. CID studies of this m/z 60 ion as well as m/z 60 ions from three pure compounds, acetic acid (HAc), hydroxyacetaldehyde (HAA) and levoglucosan (LEVO), were undertaken. The factor diagram is shown in Figure 3, in which scores of factors 2 and 3 are displayed. It indicates that this m/z 60 peak is well represented as a mixture of these three pure compounds with almost unique daughter ions at m/z 45 (HCO2*), 30 (H2CO*) and 32 (CH2O*), respectively. The relative amounts of the three components deconvoluted from factor analysis for the four paper samples tested are given in Figure 4. CID mass spectra of m/z 60 ions from the three pure compounds and a paper sample are compared in Figure 5.

REAL TIME DETECTION OF HF AND HCl IN AMBIENT AIR USING A MOBILE APCI/MS/MS SYSTEM

G.B. De Brou, N.S. Karellas, J.V. Merrill, and *A. Ng
Air Resources Branch, Ontario Ministry of the Environment
880 Bay Street, Toronto, Ontario M5S 1Z8, Canada

Hydrogen fluoride (HF) and hydrogen chloride (HCl) are colourless and corrosive gases, highly irritating and toxic, even at low concentrations. Both gases are widely used in industry and are known to be byproducts of large-scale municipal waste incineration processes. HF is also used in the manufacturing of chlorofluorocarbons (CFCs), aluminum production and uranium processing. Commercial detectors lack the capabilities for sub ppb sensitivity and real time detection. Thus, a method was developed to identify and quantify ambient HF and HCl present at sub ppb levels in a complex chemical matrix.

This method involved the real time analysis of ambient air with an atmospheric pressure chemical ionization tandem mass spectrometer (APCI/MS/MS, TAGA 6000). The ion chemistry under APCI conditions is dominated by dissociative attachment reactions:

\[ R^- + XH \rightarrow X^- + HR \]

where R refers to OH, SO₂ or CO₃, and X refers to F or Cl. Other reactions observed in an APCI source lead to the formation of adduct ions:

\[ YZ^- + XH \rightarrow YZ^- \cdot HX \]

where YZ may be OH, O₂ or NO₂. The X⁻ ion may arise from a variety of F⁻ or Cl⁻-containing compounds so that F⁻ or Cl⁻ is only a good identifier of HF or HCl in the absence of other fluorinated or chlorinated species.

A background-subtracted single mass spectrum of HCl obtained by admitting trace amount of gaseous HCl to the TAGA APCI source is shown in Figure 1. The anions at masses (M-1),

![Figure 1: Single Mass Spectrum of HCl](image)

![Figure 2: Daughter Ion Spectrum of O₂⁻•HF](image)
(M+17), (M+32), (M+46) and (M+61) amu are produced by HCl deprotonation, and clustering with OH\(^-\), O\(_2\)\(^-\), NO\(_2\)\(^-\) and HCO\(_2\)\(^-\). In the tandem mass spectrometer major adduct parent ions, O\(_2\)\(^-\)-HX and OH\(^-\)-HX, are selected by the first quadrupole (Q1). These adduct ions then collide with argon gas in the second quadrupole (Q2, RF only) undergoing collision activated dissociation (CAD) to form daughter ions which are mass analyzed by the third quadrupole (Q3). Each compound has its distinct daughter ion spectrum. Figures 2 and 3 are examples of daughter ion spectra of O\(_2\)\(^-\)-HF and O\(_2\)\(^-\)-H\(^3\)Cl. These established spectra are used to identify HF or HCl in a complex matrix including other fluorinated or chlorinated compounds. The natural abundance of \(^3\)Cl and \(^37\)Cl isotopes can also be used for further confirmation of HCl.

Calibrations are performed by monitoring the real time response of the TAGA to known gas phase concentrations of the compound. The parent/daughter ion pairs, mainly O\(_2\)\(^-\)-HX/O\(_2\)\(^-\), O\(_2\)\(^-\)-HX/X\(^-\) and OH\(^-\)-HX/X\(^-\), are selected to monitor the hydrogen halides. An example of a HF calibration is shown in Figure 4: parent/daughter ion pairs of 52/32, 52/19 and 37/19 were calibrated at five different concentrations. Since HF reacts with glass and silica, the glass sampling system was silanized to lessen wall effects of the air inlet system.

The standard monitoring period for air quantity data is thirty minutes with instantaneous measurements acquired every five seconds. All monitoring data are correlated with meteorological information, which is also recorded by the mobile unit. This method had been field tested downwind of municipal waste incinerators. Real time detection limits were in the range of 0.2 to 0.5 \(\mu g/m^3\).

TANDEM MS ANALYSES OF ATRAZINE WITH PCI, NCI AND FAB IONIZATION

H.Y. Tong, K. Caldwell, S.J. Monson, M.L. Gross and R. Spalding, (1) Midwest Center for Mass Spectrometry, (2) Water Center, University of Nebraska, Lincoln, NE 68588

Atrazine is one of the most widely used herbicides in the United States and has caused great environmental concern. A study of atrazine fragmentation by tandem mass spectrometric techniques may facilitate our understanding of the degradation processes of atrazine in the environment. Also, the current GC/MS method of atrazine analysis which uses EI ionization has limited sensitivity because of thermal decomposition and extensive fragmentation of atrazine under the GC/MS conditions. These problems may be avoided by using direct probe tandem MS and a softer ionization technique. Specificity is provided by using two-stage mass selection.

Tandem MS analyses of atrazine were performed on a Kratos MS-50 Triple Analyzer (EBE configuration, Manchester, UK) with PCI, NCI and FAB ionization techniques. The mass resolution of MS-I (BE) and MS-II (E) were about 3000 and 100 respectively. An Ion Tech saddle-field atom gun was used to produce 6 - 8 keV Ar for FAB ionization. CH₄ (ca. 0.1 torr in the source) was the reagent gas for Cl ionization. Glycerol and a mixture of dithiothreitol and dithioerythritol (DT) were used as matrices in the FAB experiment. The atrazine standard was purchased from AccuStandard (New Haven, CT). Helium was used as the collision gas to reduce the parent ion beam by 50%.

The high-energy CAD spectra of major ions produced in the three soft ionization methods mentioned above, show different pathways of fragmentation. Selected spectra are shown in Figure 1. For example, under the CH₄-NCI conditions used, the C-Cl bond of the atrazine radical anion, M⁻ (m/z 215), is weakened and loss of HCl is favored (see spectrum A); cleavage of C-Cl is not significant in the EI spectrum of atrazine. However, spectrum B indicates a stronger C-Cl bond in the [M - 1] anion formed under the same CH₄-NCI conditions. As reported previously (1), the H at the amino site is very active. Most likely, an elimination of H at the amino site promotes the cleavage of -CH₃ and makes the C-Cl bond less vulnerable.

The [M + 1] anion is also abundant in the NCI spectrum, but actually contains two components; one is the 37Cl isotopic ion of [M - H]⁺, and the other is [M + H]⁺. This is indicated by the two ions of m/z 179 and 181 observed in spectrum C.

The CAD spectra of the protonated molecular ion of atrazine, generated by using CH₄-PCI and FAB ionization, show an HCl loss of very low abundance at m/z 180. In general, when a halogen is attached to an aromatic nucleus, a significant signal of [M + H - Cl]⁺ ion would be anticipated. This suggests that the proton may not incorporate at the Cl site. A further study of ion m/z 180 by MS/MS/MS reveals a consecutive elimination of mass 42 (C₃H₆ and/or C₂H₄N) from m/z 180. This information regarding the fragmentation pathways of atrazine implies that the degradation processes of atrazine may be different depending on the environmental conditions.

In the FAB spectrum of atrazine in a DT matrix (Figure 2A), another abundant ion of m/z 182 is present in addition to [M + 1]. Measurement of the accurate mass of this ion has allowed an elemental composition to be assigned which corresponds formally to substitution of the Cl on the triazine ring with H, followed by protonation. Such beam induced halogen substitution reactions have been reported previously (2-4). In references 2-4 a free radical mechanism was used to account for the Cl substitution. An alternative reduction mechanism is presented in reference 4.

Experimental evidence exists which indicates that the ring stabilized free radical R₁₉₀ produced from homolytic cleavage of the C-Cl bond participates in reactions with matrix derived radical species under FAB conditions (5). For example, the ion seen at m/z 334 in a DT matrix can be accounted for by considering that the R₁₉₀ radical couples with a DT - H₋ RISS radical to produce a species with a mass of 333, which is protonated to give the ion at m/z 334. This mechanism is supported by the accurate mass and the MS/MS spectrum of m/z 334. The He CAD spectrum of m/z 182 is shown in Figure 2B.

In our preliminary FAB analyses, a nanogram quantity of atrazine provided satisfactory CAD spectra for the ions at m/z 216 and 182, indicating that a detection limit of low ppt levels of atrazine in environmental samples may be achieved by using direct probe FAB MS/MS technique. Peak profile monitoring using a DT matrix results in an acceptable signal from 20 pg of atrazine mixed with the matrix on the probe tip (5).

APPLICATION OF LIQUID SIMS MS/MS TO THE ANALYSIS OF SULFONATED AZO DYES

Susan D. Richardson, John M. McGuire, Alfred D. Thruston, Jr., and George L. Baughman
U.S. Environmental Protection Agency, Athens, GA 30613

Introduction

Sulfonated azo dyes are among the most important and widely used textile dyes. The most recent available figures indicate that each year the textile industry uses approximately 57 million pounds of acid and direct azo dyes—most of which are sulfonated compounds [1]. It has been estimated that 15% of the total dye produced is lost in the manufacturing and application process, with most of the dye being discharged in the effluent of textile mills [2]. Because recent laboratory studies have shown that both the intact azo dye molecule and the aromatic amine metabolites cause cancer in test animals [3,4], sulfonated azo dyes have become a concern of the U.S. Environmental Protection Agency. Currently, methods are being sought to better characterize and identify these azo dyes and their transformation products, in order to predict their transport and transformation in receiving waters.

Due to their involatility, sulfonated azo dyes have required techniques other than conventional EI mass spectrometry for their analysis. LC/MS [5-6] has been useful for providing molecular weight information; FAB mass spectrometry [7] and LC/MS/MS [8-9] have provided some structural information, such as ions due to the sulfonate moiety and due to cleavage at the azo linkage. In an attempt to obtain further structural information to better characterize sulfonated azo dyes, we have undertaken a systematic study of eight monosulfonated and disulfonated azo dyes using negative ion liquid SIMS-tandem mass spectrometry. In addition to obtaining the common "azo cleavage" ions [7] (formed by cleavage of the C-N bond on either side of the azo linkage and by cleavage of the N=N bond of the azo linkage) and $SO_3^-$ ions, we obtained many other structurally characteristic ions, previously unreported for sulfonated azo dyes.

Experimental

Azo dyes were supplied by the U.S. Environmental Protection Agency's Risk Reduction Engineering Laboratory, Cincinnati, OH, which had obtained the active colorants from the Ecological and Toxicological Association of Dyestuffs Manufacturers (ETAD). The colorants had been prepared synthetically and were successively precipitated to remove impurities. In each case, reverse phase high performance liquid chromatography (HPLC) showed the dyes to have only one major component. Liquid SIMS MS/MS experiments were performed on a VG 70-SEQ hybrid mass spectrometer. The cesium gun was operated at 1.2 $\mu$A and 15 kV. (M-Na)$^+$ parent ions were selected (at a resolution of 1000 and at 8 kV accelerating voltage) using the EB section of the instrument, and then were collisionally activated in the first (rf-only) quadrupole region, using argon as the collision gas. The parent ion beam was attenuated by 50%. Collision energies (in the laboratory frame of reference) were optimized for each compound, and they ranged from 110 to 150 eV. Daughter-ion scans were recorded at unit resolution using the multichannel acquisition (MCA) mode; 5 scans were accumulated at a scan rate of 6 s for the mass range 40 to 800 Da. Glycerol was used as the mass calibrant, and 3-nitrobenzyl alcohol was used as the matrix.

Results and Discussion

In addition to eliminating interfering matrix ions, liquid SIMS MS/MS produced a greater variety of fragment ions than have previously been reported for sulfonated azo dyes. The following types of ions were observed: azo cleavage ions, $SO_3^-$ and $HSO_3^-$ ions, and ions believed to be due to loss of $SO_2$, $SO_2$, $SO$, $N_2$, $CO$, and aromatic substituents $NO_2$, $HNO_2$, $NHCOCH_3$, $COCH_2$, and $COCH_3$. Figure 1 shows an example of one of the collisional activation (CA) product ion spectra obtained, and Scheme I displays the possible pathways for the formation of product ions. Many of the product ions observed were azo cleavage ions. All of these azo-type fragments that were formed directly from the (M-Na)$^+$ parent ion contained at least one sulfonate group as part of their structure; these ions are listed.
in Table 1. To date, azo cleavage fragment ions that have been observed for sulfonated azo dyes (in the negative ion mode) have contained at least one sulfonate moiety. We observed many azo cleavage product ions that did not contain sulfonate groups. These ions are listed in Table 2. Many of these ions were the result of subsequent loss of SO$_2$ or SO$_3$ from an azo cleavage ion. The fragmentation observed should aid future identifications of sulfonated azo dyes. In addition, losses of SO$_2$ were detected for all eight dyes studied, and this mass difference of 64 Da may be a useful diagnostic tool for screening sulfonated azo dyes in complex environmental mixtures.

EFFECTS OF IONIZATION METHOD ON COLLISION-INDUCED DISSOCIATION MASS SPECTRA OF NONIONIC SURFACTANT MATERIALS

Henry T. Kalinoski * and Leonard O. Hargiss
Unilever Research U.S., Inc. 45 River Road Edgewater, NJ 07020

The methods used to form parent ions for low energy (electron-volt) collision-induced dissociation (CID) mass spectra may influence the appearance of the daughter ion mass spectra (1). This may allow additional structural information to be obtained through low energy CID. Further, one ionization method may be preferred for acquisition of structural information for a particular class of compounds. Fast atom bombardment (FAB) ionization is often chosen for mixtures of low volatility, polar compounds but FAB is not necessarily the best or only ionization method available. With appropriate introduction methods, chemical ionization (CI) or thermospray could provide alternative methods for particular compound classes.

One such class of compounds are the nonionic surfactants, ethoxylated or propoxylated ethers of long-chain aliphatic alcohols or alkyl-substituted phenols. Other, more polar, functionalized molecules have also been employed as surfactant hydrophobes. These commercially important materials are produced and used as complex mixtures, characterization of which requires information on number of components present, length and composition of hydrophobe, and type and extent of alkoxylation. Low-energy CID following direct supercritical fluid injection and positive CI (SFI/CI) indicated different types of daughter ions are produced from different surfactant types (2). Diagnostic fragment ions were produced and structural information was available for some hydrophobe types.

In the current work, tandem quadrupole CID/MS/MS spectra were produced following FAB, thermospray and desorption chemical ionization (DCI). Results were combined with those from the SFI/CI study and compared to determine the extent to which ionization mechanism influences the type and amount of fragment ions produced. A single mass spectrometer with variable ion sources was employed. Six different types of commercial nonionic surfactant mixtures were analyzed in an effort to produce ions diagnostic of hydrophobe structure. Information to determine the mechanisms of ion decomposition was also sought. Results were to be used to define the most appropriate combination of introduction and ionization techniques for rapid structural characterization of nonionic surfactant mixtures.

Results indicated qualitative differences are apparent in the daughter ion spectra produced. These differences are noted without regard to the type of nonionic surfactant mixture studied. The use of different ionization methods does not appear to lead to different types of ions for the surfactants studied but to the increase of one type of fragment ion over other ions in the spectrum.

Fast atom bombardment (FAB) ionization appears to be the most energetic mechanism compared with SFI/CI, DCI or thermospray. FAB ionization prior to CID leads to more abundant fragment ions at lower collision energies than for the other methods. This may be due, in part, to the lack of collisional cooling in the lower pressure FAB source, as compared with the CI or thermospray sources. This higher energy ionization may also be responsible for the difficulty in producing protonated molecules for the nonionic surfactants used in this study. The addition of
alkali metal salts results in production of more abundant parent species in FAB, but these are more difficult to dissociate under low energy CID conditions (3,4).

Chemical ionization following supercritical fluid injection appears slightly more energetic than either DCI or thermospray. Reasons for this are not readily apparent, but the differences appear very slight. Thermospray ionization appears to be the least energetic approach of those studied but again only by a small amount. This may be influenced by the production of ammonium adduct ions in thermospray, with some energy in CID dissipated through loss of the solvated ammonia molecule. Future efforts will address production and CID analysis of protonated molecules in thermospray.

Although FAB is more energetic than other approaches, it still does not allow complete hydrophobe characterization of all nonionic surfactant types. Difficulty in producing ions for CID is one limitation, along with the apparent energy limitation of the tandem quadrupole system. Other approaches using supercritical fluid injection/CI may be useful, such as charge-exchange (CE) ionization and CID of CE-produced fragment ions. Further work is underway to address these issues.

Proposed ether-cleavage mechanism to explain formation of protonated poly(ethylene glycol) ions and loss of hydrophobe as an alkene.
TANDEM QUADRUPOLE CID OF ORGANOMETALLIC IONS PRODUCED DURING FAB STUDIES OF PALLADIUM-MEDIATED C-NUCLEOSIDE SYNTHESIS REACTIONS

Henry T. Kalinoski
Unilever Research U.S., Inc. 45 River Road Edgewater, NJ 07020

Carbon-carbon bond formation in organic synthesis can be accomplished through use of palladium (II) salts in a mechanism, known as the Heck reaction (1), involving a reactive arylpalladium species and a carbon-carbon double bond. A version of this reaction, with the C-C double bond present in a cyclic enol-ether or glycal, has been extensively studied as a route for C-nucleoside synthesis (2). This route is believed to involve four distinct organometallic reaction steps: (a) transmetalation from an arylmercury salt to form the organopalladium reagent (R-Pd), (b) π-complex formation between the palladium and glycal double bond, (c) π-complex collapse and formation of a σ-adduct, and (d) σ-adduct decomposition to products. Isolation and characterization of each of the organopalladium intermediates of this reaction has been difficult due to their highly reactive nature.

Fast atom bombardment (FAB) ionization provides a means to study species in liquid solution using mass spectrometry and has been used to study solutions of organopalladium reagents (3,4). The study of C-nucleoside synthesis via organopalladium reactants using FAB/MS (3) gave strong evidence to verify the structure of the reactive arylpalladium intermediate, R-Pd. There was some ambiguity, however, regarding the structures of some of the metal-containing ions produced in that study. The relationships between the solution chemistry of the species and gas-phase ions and between ions and reaction products was not directly apparent.

The present work extends the previous effort (3) by studying some of the FAB-produced ions using tandem quadrupole mass spectrometry. The aim was to produce structurally significant fragment ions to ascertain details of the metal-glycal bonding in the reactive intermediates. Ions produced in collision-induced dissociation (CID) may also reveal details of the decomposition mechanisms of metal-containing intermediates to known reaction products.

Tandem quadrupole mass spectrometry, in conjunction with fast atom bombardment (FAB) ionization, increases the amount of information available for
reactive organometallic reagents in solution. Collision-induced dissociation in the low energy (electron-volt) regime is capable of producing metal-containing fragment ions characteristic of structures of organometallic reaction intermediates. Preliminary identification of some of these fragment ions supports the proposed structures of selected reactive intermediates in the palladium-mediated synthesis of C-nucleosides.

The results of the FAB/MS/MS study of the palladium-mediated reaction of pyrimidinedionyl mercury with triacetylglucal indicate that conditions used in the current study do not completely correspond with conditions used in a previous, more limited effort (3). Many of the same intermediate and product-related ions found in the earlier work were detected in the present study. The extent of fragmentation, for both organic and organometallic ions, in the single quadrupole FAB/MS in the current work suggest that FAB mass spectrometry conditions were more energetic than used in the previous study. The high energy present in the FAB/MS appears to favor the production of certain products from this reaction.

Although not completely clear from the data, the analytical conditions appear to favor the detection of one form of the principal organometallic intermediate over the other possibility. The more stable σ-bonded adduct appears responsible for the m/z 517 glycal-palladium-pyrimidinedione ion. An ion corresponding to the reactive pyrimidinedione-palladium reagent (PyPd, m/z 245) was not found. This condition complicates the analysis of the reaction mixtures, as it is not clear to what extent the analytical method or conditions dictate which ions will be formed.

Further work is underway to more fully duplicate the analytical conditions used in the previous work. It remains to be determined if and how the design and operation of the tandem quadrupole mass spectrometer may be directing the preference for one bonding form of the organometallic intermediates. Other reactions and analytical conditions are also being explored.

EPIMER DISTINCTION AND STRUCTURAL EFFECTS ON GAS-PHASE ACIDITIES OF ALCOHOLS MEASURED USING THE KINETIC METHOD

T. K. MAJUMDAR* F. CLAIRET*, J.-C. TABET* AND R. G. COOKS*

*Purdue University, Dept. of Chemistry, West Lafayette, IN 47907, USA.
*Laboratoire de Chimie Organique Structurale, Université Pierre et Marie Curie, Paris, France.

The kinetic method is used to estimate gas-phase acidities ($\Delta G^{\circ}_{\text{acid}}$) of two sets of epimeric methylcyclohexanols. Metastable decomposition of proton-bound dimers of alcohols formed by negative chemical ionization in a Finnigan TSQ 4500 mass spectrometer is used. MS/MS product spectra of the proton-bound dimers of epimers of 4-methylcyclohexanol and 3-pentanol (Fig. 1) clearly show differences in gas-phase acidities of the epimers. Structures and $\Delta G^{\circ}_{\text{acid}}$ values of the four isomers a-d of methylcyclohexanol as calculated using a calibration curve (Fig. 2) are shown in Scheme 1. Comparing these $\Delta G^{\circ}_{\text{acid}}$ values for the two sets of epimers a vs. b and c vs. d, it is clear that in both cases the cis-isomers have lower gas-phase acidity values than their corresponding trans-isomers as a result of destabilization of the alkoxide anions due to 1,3 diaxial interactions between the axial hydrogens and the oxygen atom. Location of the methyl group in the 2-position of the cyclohexanol ring lowers the $\Delta G^{\circ}_{\text{acid}}$ values due to destabilization of the alkoxide anion by gauche interactions of the 2-methyl group.

![Figure 1: MS/MS product spectra of the proton-bound dimers of 3-pentanol and cis-4-methylcyclohexanol (a) and trans-4-methylcyclohexanol (b).](image)

![Scheme 1.](image)
Effective temperatures for metastable dissociation of proton-bound dimers of various alcohols are calculated from the slopes of the calibration curves and summarized in Table 1. It is evident from Table 1 that for homogenous proton-bound dimers, alkyl substitution at the carbon atom having the hydroxyl-group has a great influence on the effective temperature. The extent of change depends on the number of substituted alkyl groups; the largest effect being observed during the first alkyl substitution and the effect decreases for second and third substitutions. For the heterogenous proton-bound dimer systems, dissociation of primary alkoxide anions proton-bound to secondary alkoxide anions shows the largest effective temperature of 550K whereas secondary/tertiary systems show an effective temperature of 340K (Table 1). An increase in effective temperature is also observed when the experiment is done under CID condition compared to that observed under metastable condition. Similar results were reported for experiments performed at different target (argon) pressures and collision energy. The increase in effective temperature is due to the increase in internal energy of the ion as a result of increasing collision pressure or collision energy. The highest temperature in Table 1 is shown by the proton-bound dimers of the mixed system, primary and secondary alcohol. This is a case where two different functional groups are attached to a proton by weak hydrogen-bonds. In such a situation the frequencies of vibration of the hydrogen bonds in the proton-bound dimer will be different. As a result the effective temperature needs to be corrected for frequency factors. Similar results were reported in case of formate/acetate systems where the alpha-carbon atoms were different and difference in slopes of the calibration curves were observed.

THE CHARACTERISATION OF SUBSTITUTED TRIPHENYLENE COMPOUNDS
BY FIELD DESORPTION - MASS SPECTROSCOPY

K Rollins, J H Scrivens, M J Taylor, A Thorne and R C K Jennings
ICI Wilton Materials Research Centre
Wilton, Cleveland, TS6 8JE England

INTRODUCTION

Field Desorption - Mass Spectrometry (FD-MS) is used in our laboratory as a lead characterisation tool in the analysis of complex mixtures of industrial significance. We have recently studied a selection of substituted triphenylene compounds of structure:

where R may be either -O,CPhOC,H_{2n+1} (Ph = 1,4-Substituted phenyl group) or -OC,H_{2n+1}. These materials have been analysed using both FD-MS and FD-MS-MS methodology and this combination of techniques has provided information unobtainable other techniques.

RESULTS AND DISCUSSION

(a) Triphenylene Esters

An example of the type of FD-MS spectrum obtained for this compound class is shown below for the C_{20} ester.

The fragment at m/z 401 represents cleavage at the carbonyl bond and provides good diagnostic information regarding the alkyl chain feedstock used in the synthesis of these materials. This extent of fragmentation is somewhat unusual in FD data and appears not to be as might be expected, thermal in nature but occurs as a result of a combination of complex field-induced mechanisms.

(b) Triphenylene Ethers

The second class of triphenylene compounds included in this study were ethers of alkyl chain length C_{8} to C_{12}. The type of FD-MS spectrum obtained for this compound class (for the C_{8} ether) is shown below.
It is immediately interesting to note the lack of fragmentation observed in this spectrum when compared to the ester data. Also of interest is to note the occurrence of peaks corresponding not only to the expected molecular ion (at m/z 744) but also a peak at m/z 814 which is consistent with the presence of an additional alkyl group in the molecule. The origin of this 'additional' peak is further discussed in the tandem mass spectrometry section of this poster.

(c) FD-MS-MS

FD spectra are generally dominated by molecular ion species and as such are ideally suited for analysis by tandem mass spectrometric methods.

One of the unresolved issues connected with the analysis of the triphenylene ether compounds concerned the nature of the peaks occurring at masses greater than the expected molecular weight and FD-MS-MS has been used to further investigate this issue. The spectrum shown below is the product ion spectrum obtained by subjecting the C₅ molecular ion (m/z 744) to high energy (4kV) CID using He as the collision gas.

The m/z 744 product ion spectrum demonstrates losses of side chain moieties together with associated losses of oxygenated side chain moieties for the more intense product ions. This still leaves unresolved the nature of the extra alkyl substitution occurring at m/z 814 for the C₅ ether. The product ion spectrum obtained for this ion is characterised by a high yield of product ions consistent with the intact, fully substituted C₅ triphenylene ether. This indicates that the m/z 814 product is related to the fully substituted ether molecule and is not an experimental artefact.

ACKNOWLEDGEMENT

The authors thank R Vickers, VG Analytical Ltd for his assistance in obtaining the high energy CID MS-MS data.
TANDEM MASS SPECTROMETRIC STUDIES OF UNUSUAL EI FRAGMENTATION PATHWAYS OF 5-NITROOCTAETHYLPORPHYRIN AND ITS DIVALENT METAL COMPLEXES

INTRODUCTION

Porphyrins chelate with virtually all metallic elements. The chelated ion can have a strong influence on the spectroscopic properties of the complex.

In the EIMS analysis of octaethylporphyrin (OEP) and its metal complexes, $\beta$-cleavage of the peripheral ethyl groups is the predominant mode of fragmentation. In studies performed by Beato et al., it was determined that insertion of a metal into the free-base OEP markedly influenced $\beta$-cleavage intensities. The influence of the metal was found to be important in determining the abundance of ions in the doubly charged region of the mass spectrum, whereas the singly charged region was relatively unaffected.

In our studies, the insertion of metals into 5-nitro-OEP was found to have a strong influence on the types of fragmentation encountered in the singly charged region of the mass spectrum. The divalent metal complexes studied include Co, Cu, Zn, Ni, Pd, Ag and Mg. The effect of the metals on the fragmentation pathways were significantly different for each of the metals studied.

Clezy et al. determined that the presence of a nitro group at one of the bridge carbons modified the normally encountered beta-cleavage of OEP. In our MS/MS studies of free-base 5-nitro-OEP, daughter spectra showed a significant $[M-17]^+$ peak due to loss of OH$^-$ as was reported by Clezy in his EIMS work. We have also found evidence for a novel ring fragmentation of 5-nitro-OEP not observed for OEP under EI conditions.

EXPERIMENTAL

All mass spectra presented here were obtained with a Finnigan MAT TSQ45 triple quadrupole mass spectrometer. Porphyrin samples were dissolved in dichloromethane and 1 $\mu$L aliquots of the solution were deposited onto a direct exposure probe (DEP) filament. The DEP was heated from 100 to 600 $^\circ$C at $600^\circ$C/min. The rapid rate of heating was found to reduce the amount of thermal elimination of NO$_2$ observed in EIMS.

The spectra were obtained under EI conditions. The filament emission current was maintained at 0.3 mA and the electron energy was 70 eV for all experiments. For the initial EIMS experiments quadrupole 1 (Q1) was scanned from 50 to 800 m/z in 0.8 s with Q2 and Q3 passing all masses. Tuning for MS/MS was achieved with Co(II) OEP in a capped aluminum solids probe vial heated to 275$^\circ$C. The MS/MS experiments were performed with a collision gas pressure of 1.6 mTorr argon and a collision energy of 24.8 eV.

A Finnigan MAT 95 high resolution mass spectrometer was used for determination of exact masses for fragment ions. The MAT 95 was tuned for a resolution of 7000. The high resolution data were used as an aid in determining the composition of certain fragment ions.

5-nitro-OEP was chosen for these studies because its spectroscopic properties have been extensively studied. Porphyrin compounds were synthesized according to literature procedures.

RESULTS

The fragmentation exhibited by 5-nitro-OEP was found to be different from the fragmentation of OEP. We have found that pyrrole ring cleavage occurs for 5-nitro-OEP under EI conditions. The daughter spectrum of $M^+$ is shown in Figure 1. The composition of the m/z 375 ion was confirmed by high resolution mass spectral data and is shown in Figure 2. Metallation of 5-nitro-OEP altered the fragmentation exhibited. Pyrrole ring cleavage was unobserved, but $[M-75]^+$ or $[M-86]^+$ ions appeared in daughter spectra of $M^+$ for all of the metal complexes studied. The
fragments associated with both of those ions are shown in Figure 3. Parent spectra for the [M-75]+ and [M-86]+ ions revealed that the fragmentation for both ions was concerted within the timescale of collision-induced dissociation.

Figure 4 displays a trend in the intensity of the [M-86]+ peak when plotted versus the number of d electrons of the inserted metal. The general trend is paralleled by the dependence of the metal-sensitive IR bands of OEP to the d electrons of the inserted metal.

CONCLUSIONS

The fragmentation of 5-nitro-OEP was found to be different from that of OEP. We have found evidence for pyrrole ring cleavage in 5-nitro-OEP. Oxygen migration seems to be an important part of the process. With metallation of 5-nitro-OEP, the modes of fragmentation are significantly altered. A peak at either [M-75]+ or [M-86]+ was the base peak in the daughter spectra of the M+ ions of all of the metallated species. The intensity of the [M-86]+ ion was found to increase as the number of d electrons of the inserted metal decreased. Similar trends were previously found for the metal-sensitive IR bands of OEP.

INTRODUCTION: Many unusual fragmentation and rearrangement reactions are observed in the mass spectra of organosilicon compounds. These reactions can make structural elucidation of some relatively simple organosilanes difficult based solely on EI MS data. A collisionally activated dissociation (CAD)/MS study was conducted to provide more information on the mass spectrometry of tetraethoxysilane (TEOS) and its carbon analog, tetraethoxymethane (TEOM). Utilizing the fragmentation mechanisms elucidated by this CAD study, an empirical system for the identification of unknown alkylalkoxysilanes in complex mixtures was developed.

EXPERIMENTAL: Electron impact (EI) mass spectra were acquired on a VG Trio 3 triple quadrupole mass spectrometer. Samples were ionized at 70 eV ionization energy with a source temperature of 200°C. Constant sample pressure was provided by injection of 1 to 2 uL of sample into the heated septum inlet. Argon was used as the collision gas for all CAD experiments. The pressure in the collision cell was varied from 0.05 to 2 mTorr, with 0.2 mTorr being optimal. Typical collision energies ranged from 0.1 to 20 eV (laboratory frame). GC/MS spectra were acquired on a VG 7070H sector mass spectrometer. All separations were made on a DB-5 0.25 mm ID column temperature programmed from 50 to 300°C.

RESULTS AND DISCUSSION: The EI spectrum of TEOS was extremely complicated compared to its carbon analog, TEOM (Figure 1). The fragmentation mechanisms of TEOS were elucidated using CAD experiments. Product and precursor scans indicated the ions; m/z 207 ([M-H]+), m/z 193 ([M-CH3]+) and m/z 179 ([M-C2H5]+) were precursors for three separate fragmentation pathways. The first fragmentation pathway was initiated by the loss of a hydrogen radical from the molecular ion to produce m/z 207 [M-H]+. The product ion spectrum of m/z 207 revealed a loss of 44 u to yield m/z 163 ([C2H5O)3Si]+ . Product scans of m/z 163 produced a series of ions resulting from consecutive losses of 28 u and 44u, consistent with the neutral losses of ethylene and acetaldehyde, respectively. The second pathway proceeded by the loss of a methyl radical from the molecular ion to produce m/z 193 ([C2H5O)3SiOCH2]+ . Product scans of m/z 193 indicated a neutral loss of 44 u (acetaldehyde) to m/z 149 (the base peak in the EI spectrum). There were no indications for the neutral loss of ethylene or the loss of -OCH₂ in this pathway. The third pathway was initiated by the loss of an ethyl radical from the molecular ion to produce m/z 179. Product ion scans of m/z 179 revealed two product ions, m/z 151 and 135 again proceeding via the elimination of ethylene and acetaldehyde, respectively. The carbon analog, TEOM, produced a simpler EI spectrum under identical MS conditions. No molecular ion was observed. Product scans of m/z 147 [M-45]+ indicated the ions m/z 119, 91, and 63 resulted from consecutive neutral losses of ethylene. The differences in complexity between the EI spectra of TEOS and TEOM were determined to result from the lack of an energetically favored pathway for the elimination of acetaldehyde from TEOM during fragmentation.
Based on the information obtained from the CAD study of TEOS, an empirical system was developed to identify unknown silanes resulting from the reactions of TEOS and metal alkyls. The compounds studied had a general formula:

$$(\text{EtO})_x\text{Si}(\text{R})_{4-x}$$

where R = ethyl, butyl, and chlorine.

The system is based on the presence or absence of three ions in the El spectrum of the unknown silane. The three ions of interest are $m/z$ 63 [H-Si-(OH)$_2$]$^+$, $m/z$ 75 [(H)$_2$Si-OEt]$^+$, and $m/z$ 79 [Si(OH)$_3$]$^+$. General formulas for the unknown silanes can be obtained by the following system:

<table>
<thead>
<tr>
<th>Present</th>
<th>Absent</th>
<th>Gen. Formula</th>
</tr>
</thead>
<tbody>
<tr>
<td>$m/z$ 75</td>
<td>(no m/z 63 or 79)</td>
<td>EtO-Si-(R)$_3$</td>
</tr>
<tr>
<td>$m/z$ 63 and 75</td>
<td>(no m/z 79)</td>
<td>(EtO)$_2$Si-(R)$_2$</td>
</tr>
<tr>
<td>$m/z$ 63 and 79</td>
<td>(no m/z 75)</td>
<td>(EtO)$_3$Si-R</td>
</tr>
</tbody>
</table>

After assignment of a general formula, the complete structure of the unknown silane can be elucidated by identifying ions resulting from neutral losses of alkenes.

Current research involves extending this system to larger, more complex alkylalkoxysilanes and mixed tetraalkoxysilanes.

Structural Analysis of Glycosphingolipids by Charge Exchange DCI / MS / MS
J. S. Duh1, V. N. Reinhold2, and G. R. Har1, 1Dept. of Chemistry, National Taiwan University, Taipei, Taiwan, R. O. C. 2Harvard School of Public Health, Boston, MA

In the analysis of permethylated glycosphingolipids with desorption chemical ionization (DCI) mass spectrometry, carbon dioxide/methanol has been reported to be a superior reagent gas than the most popular ammonia. In addition to the molecular ion and sugar sequence related fragment ions, fragment ion (F fragment) of high abundance resulting from the loss of long chain base were also observed[1]. These F fragment ions make it easy to establish the ceramide composition.

F fragment ion (or an β - cleavage ion) was first reported in the analysis of permethylated glycosphingolipids with DEI[2]. In the carbon dioxide/ methanol DCI system, it is believed that methanol was responsible for the production of protonated molecular ion whereas charge exchange between the sample molecule and the carbon dioxide radical cation was responsible for the formation of F fragment ions. In this report, charge exchange DCI with reagent gases of different recombination energy, alone and in combination with tandem mass spectrometry, were evaluated as a means of improving structural information of the glycosphingolipids.

Strong F fragment ion signals were recorded when helium, argon, nitrogen or carbon dioxide was used as the charge exchange reagent gas. These F fragment ions were either absent or present as very weak signal when ammonia or methane was used as the reagent gas. A typical charge exchange DCI mass spectrum of permethylated glycosphingolipids is shown in Fig. 1. The ion at m/z 734 is the F fragment ion. The protonated molecular ion observed in the charge exchange mass spectrum is probably due to the trace of water in the system.

Due to its low E\textsubscript{lab} value, triple quadrupole mass spectrometry is generally considered as a low energy CID instrument. Recently, several groups reported its limited CID capability for parent ion with mass to charge ratio above 800 amu. The daughter ion mass spectrum of permethylated glycosphingolipids is shown in Fig. 2. It is surprising to see that parent ion with mass to charge ratio of 1573 can be fragmented. These daughter ions are very useful in the assignment of the glycan sequence.

Although parent ion with mass to charge value over 1500 amu does fragment in the triple quadrupole mass spectrometry, unlike the high energy CID results reported by Costello[3], no ion related to ceramide composition was observed. Therefore, Ceramides ions, instead of molecular ions, were chosen as the precursor ion in the daughter ion analysis. Fig. 3 shows the daughter ion mass spectrum of ceramide ion with m/z value 578 from the permethylated N-stearoyldihydrolactocerebroside. Two major fragmentation pathways were observed. The signals at m/z 312, m/z 280 represented the long chain base ion, and the loss of methanol from the long chain base respectively. Thus, the sphingoid moiety can be assigned as dihydrospingosine. The signal at m/z 298 is the fatty acid fragment ion representing a palmitamide residue. It is interesting to see that only long chain base ions were observed (Fig. 4) when the long chain base is a sphingosine or a eicosasphingosine residue. The fragmentation mechanism which might be related to the double bond in the long chain base is currently under Investigation.

Collision Induced Dissociation of Group IIIA Dimethyl Cations via Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

Stephan B.H. Bach and Stephen W. McElvany
Chemistry Division/Code 6110
Naval Research Laboratory, Washington, D.C. 20375-5000

The goal of metalorganic chemical vapor deposition (MOCVD) is to deposit a metal atom to a surface without contaminating the deposition surface. This technique has become a leading contender in the fabrication of sophisticated heterojunction devices. The reactions that take the metal from the gas phase metal-organic compound to the bare metal play an important role in determining the impurities found within the materials produced by this method. These reactions are also important in determining the deposition rates of the semiconductor materials. An understanding of the ion chemistry of these compounds may also open a new avenue to getting the metal to the deposition surface in a reproducible way, while being able to monitor and reduce the amount of contamination.

Various methods have been investigated with the goal of improving the deposition of these semiconductor materials on various types of surfaces. The traditional method of thermal decomposition of the precursors has given way to plasma stimulated MOCVD, electron cyclotron resonance plasma excited MOCVD, and laser-induced photochemistry in the MOCVD process. These new methods open up the very real possibility of ion/molecule chemistry becoming directly involved in the MOCVD process and therefore influencing the purity and the characteristics of the deposition surface and the rates at which these surfaces are deposited.

The experiments were performed with a Fourier transform ion cyclotron mass spectrometer (FT-MS). The experimental apparatus consists of an Extrel FTMS-1000 data system, a 3 Tesla superconducting magnet and a vacuum system with a 1 x 1 x 2 (z-axis) inch cell made of stainless steel plates, except for the trapping plates which are composed of 90% transparent nickel mesh. The metal alkyls (M(CH$_3$)$_2$) were maintained at static pressures ranging from $0.5 \text{ to } 2.0 \times 10^{-4}$ torr and ionized via electron impact (EI). Molecular ions were observed for these compounds with increasing difficulty as one goes down the group from aluminum to indium. The reactant gases were added to give total pressures of between $3.0 \times 10^{-8}$ to $1.1 \times 10^{-7}$ torr. The reaction gases (O$_2$, H$_2$, NH$_3$) were used without further purification the H$_2$O and D$_2$O samples were freeze-pumped-thawed several times. The purities of these compounds were verified using EI.

The electron impact experiments were carried out on the TMM neutrals by varying the beam voltage to increase the internal energy of the ionized species (DMM$^+$) to induce further fragmentation. The collision-induced dissociation experiments were carried out by setting a low amplitude single frequency pulse on the desired species for a variable length of time (0.06 to 3.0 msec). This translationally excites the cation of interest which then undergoes collisions with argon.

The TMI fragmented upon electron impact to give the DMI cation. No products were observed for reactions with water but the presence of a small amount of the adduct was detected for reactions with ammonia. The EI and CID experiments with DMI$^+$ gave similar results. In$^+$ was the major product at all energies. A small amount of the TMG molecular cation was observed. The TMG cation yielded DMG$^+$ under both EI and CID conditions. No products were observed for reactions with water. An adduct was observed for reactions with NH$_3$:

$$(\text{CH}_3)_2\text{Ga}^+ + \text{NH}_3 \rightarrow (\text{CH}_3)_2\text{GaNH}_3^+$$

The CID experiments with DMG$^+$ gave Ga$^+$ and CH$_3$Ga$^+$. The ratio of the fragments did vary with energy, giving a ratio of approximately 3:1 at the high-energy limit of the CID experiment. Using EI (variable beam voltage) on the TMG neutral to produce DMG$^+$ with excess internal energy yielded no fragments.

A substantial amount of TMA molecular cation was produced. The CID of TMA$^+$ yielded DMA$^+$, MMA$^+$, and Al$^+$ with a ratio of 10:1:1, respectively. The fragmentation pattern of DMA$^+$ did depend on the internal energy of the cation. DMA$^+$ collisional activation gave Al$^+$ and MMA$^+$ with ratio of 5:1, respectively. The reaction of DMA$^+$ with ammonia yielded a mono and a di adduct. At short reaction times DMA-NH$_3^+$ was observed which reacted at longer times to produce DMA-(NH$_3$)$_2^+$ as shown in Figure 1.
DMA undergoes a sequential substitution of methyl by OH as shown in Figure 2. This reaction most likely proceeds by:

$$\text{(CH}_3\text{)}_2\text{Al}^+ + \text{H}_2\text{O} \rightarrow \rightarrow \text{(CH}_3\text{)}\text{AlOH}^+ (m/z=59) + \text{CH}_4$$

$$\text{(CH}_3\text{)}\text{AlOH}^+ + \text{H}_2\text{O} \rightarrow \rightarrow \text{Al(OH)}_2^+ (m/z=61) + \text{CH}_4$$

Masses 59 and 61 underwent CID yielding A1OH* (m/z=44) and Al*. These results were verified by using D$_2$O which gave products at mass 60 and 63. Again these products underwent CID and yielded AlOD* (m/z=45) and Al* as fragments. Many adducts were produced when TMA/DMA cations were allowed to react with H$_2$O. These products progress to about m/z equal to 300. These products grow in as the reaction time is increased with the higher mass products growing in at longer reaction times. Peaks in a series are separated by two mass units: CH$_3$ being substituted by OH. The series seem to have a separation of 18 mass units: addition of H$_2$O. The series of peaks can also be seen as being separated by DMA units. Some of the more abundant products have been studied by CID. These experiments yielded a variety of products such as DMA*, Al*, as well as losses of (CH$_3$)$_x$ with x equal to 1-3.

The three members of Group IIIA TMM and DMM cations investigated in this work exhibited different CID behavior as well as different reactivities. The fragmentation pattern of the DMM cations was shown to vary with internal energy. This is true for DMA and DMG, but DMI essentially showed no energy dependence fragmenting directly to give the metal cation which indicates that DMI* fragments exclusively via ethane elimination. Ethane elimination may also occur in DMG* and DMA*, but to only a minor extent. None of the TMMs (neutral or ionic) or the DMM cations studied reacted with oxygen or with hydrogen, a commonly used carrier gas in MOCVD. The TMMs were found to adsorb readily to the stainless steel walls of the vacuum chamber. They were also found to desorb intact from the stainless steel. Both DMG* and DMA* readily formed adducts with ammonia. DMG* produced a mono adduct and DMA* produced both a mono and a di adduct. The observation of these adducts in the experiments lends weight (not mass) to the belief that adduct formation occurs in MOCVD reactors and that these species can be a cause of the impurities observed in semiconductor materials. Direct evidence for this type of adduct formation has recently been reported by Piccos and Ault for the formation of a neutral trimethylgallium:arsine adduct.

Oxygen incorporation into TMA-produced semiconductors is most likely due to residual water in the deposition lines and not due to residual oxygen.

Addition of Ammonia to Dimethylaluminum

$$P = 3 \times 10^{-8} \text{ Torr (Ammonia)}$$

Sequential Substitution (OH for Methyl)

$$P = 2 \times 10^{-5} \text{ Torr (Water)}$$

ENERGIES OF TRIPLET ELECTRONIC STATES OF THE \textit{N}_2\textit{O}^{2+} ION

Frank M Harris*, Colin J Reid*, James A Ballantine and David E Party

*Mass Spectrometry Research Unit, **ECSC Mass Spectrometry Centre, †Department of Chemistry, University College of Swansea, Singleton Park, Swansea, SA2 8PP, UK.

INTRODUCTION
The energies of electronic states of \textit{N}_2\textit{O}^{2+} have previously been measured by Auger-electron (AE) spectroscopy [1], double-charge-transfer (DCT) spectroscopy [2,3] and photolon-photolon coincidence (PIPICO) spectrometry [3,4]. In addition, these energies have been calculated [1,3,5] by several procedures. The AE spectroscopy and DCT spectroscopy (in which \textit{H}^+ was the projectile ion) experiments [1-3] gave information on energies of \textit{singlet} electronic states of \textit{N}_2\textit{O}^{2+}. The PIPICO experiment [3], however, allowed the energy of the lowest triplet state to be determined; this energy was particularly important since it was taken as the reference point for the computed energies [3].

The purpose of the present investigation was to obtain information on \textit{triplet}-state energies of \textit{N}_2\textit{O}^{2+} using a modified form of DCT spectroscopy. A high-velocity, singly charged positive ion is converted in DCT spectroscopy to a negative ion in a double-electron-capture (DEC) reaction with the molecule under investigation. There is now considerable evidence [6] that the total spin of reacting and resulting particles is conserved in such reactions. For a closed-shell species such as \textit{N}_2\textit{O}, the molecule is in a singlet state. Using a ground-state singlet projectile ion such as \textit{H}^+ gives rise to reactions which populate singlet states of the dication, since \textit{H}^+ ions which reach the detector must be in the relatively long-lived \textit{\Sigma}_0^+ singlet state. However, using ground-state triplet projectile ions, such as \textit{OH}^+ and \textit{F}^+, leads to the population of triplet states of the dication since \textit{OH}^+ and \textit{F}^+ have only singlet bound states. Thus, the present DCT spectroscopy study of \textit{N}_2\textit{O} was carried out with \textit{OH}^+ and \textit{F}^+ projectile ions in order to determine double-ionization energies to triplet states of \textit{N}_2\textit{O}^{2+}. In addition, the double-ionization energies to ground triplet and singlet states of the dication have been calculated using Møller-Plesset perturbation theory with split-valence basis sets.

EXPERIMENTAL PROCEDURE
The experiments were carried out on a VG ZAB-E spectrometer. The \textit{OH}^+ and \textit{F}^+ ions were generated by dissociative electron ionization of \textit{H}_2\textit{O} and \textit{CF}_4, respectively, and were accelerated to either 6 or 8 keV. After mass selection, they interacted with \textit{N}_2\textit{O} molecules contained in the second field-free region collision-gas cell. \textit{OH}^- or \textit{F}^- ions were transmitted to the detector by re-arranging the polarities of the voltages normally applied to the plates of the electric sector. DCT spectra were obtained by scanning these voltages.

If the projectile ion is denoted by \textit{A}^+, the DEC reaction can be represented by

\[ \textit{A}^+ + \textit{N}_2\textit{O} \rightarrow \textit{A}^- + \textit{N}_2\textit{O}^{2+} \quad \ldots(1) \]

Since the energy, \( I_2(\textit{N}_2\textit{O}) \), required to doubly ionize \textit{N}_2\textit{O} is greater than the energy \( E(\textit{A}^+ \rightarrow \textit{A}^-) \) made available from charge inversion of \textit{A}^+, the energy to drive reaction (1) must come from the translational energy \( E_0 \) of \textit{A}^+.

If the translational energy of \textit{A}^+ is \( E_1 \), then

\[ E_0 - E_1 = I_2(\textit{N}_2\textit{O}) - E(\textit{A}^+ \rightarrow \textit{A}^-) \quad \ldots(2) \]

If various states of \textit{N}_2\textit{O}^{2+} are populated, various values of \( E_1 \) result, each corresponding to a peak in the DCT spectrum.

The energy-loss scale was calibrated by carrying out a DCT spectroscopy experiment with argon atoms in the cell. If the translational energy of the \textit{A}^- ions formed in DEC reactions with \textit{Ar} is \( E_{\textit{A}^-} \), then

\[ E_0 - E_{\textit{A}^-} = I_2(\textit{N}_2\textit{O}) - E(\textit{A}^+ \rightarrow \textit{A}^-) \quad \ldots(3) \]

and

\[ E_{\textit{A}^-} - E_1 = I_2(\textit{N}_2\textit{O}) - I_2(\textit{Ar}) \quad \ldots(4) \]

In practice, \( E_{\textit{A}^-} \) and \( E_1 \) are measured and \( I_2(\textit{N}_2\textit{O}) \) is calculated using Eq. (4) since \( I_2(\textit{Ar}) \) is known.

THEORETICAL PROCEDURE
The double-ionization energies calculated in the present investigation are the differences between the total energy of the ground state of the singlet \textit{N}_2\textit{O} molecule and those of the singlet and triplet...
dication. They were calculated using the GAUSSIAN86 ab initio programme package. The geometry used for the dication was the equilibrium geometry of neutral N$_2$O. This is in keeping with the assumption that no significant geometry change occurs during the DEC reaction as the high-velocity projectile ion collides with an N$_2$O molecule. A standard basis of atom-centred one-electron functions of split-valence type, 3-21G, was employed which has the flexibility to describe changes in valence shells on ionization while offering acceptable computational economy. Second order Møller-Plesset perturbation theory corrections to Hartree-Fock energies were calculated (with core orbitals frozen).

RESULTS AND DISCUSSION

The DCT spectra showed five peaks identifiable as due to DEC reactions. From the translational energies corresponding to their maxima, five double-ionization energies were determined. The lowest, which corresponds to the ground triplet state of N$_2$O$^{2+}$, is 35.7 ± 0.4 eV which agrees with the value of 36.0 eV measured previously [3]. The value calculated in the present investigation for the double-ionization energy to the ground triplet state is 35.84 eV. The closeness of this to both the present and previously measured values confirms that the computational method used does for N$_2$O, as it did for CO$_2$, COS and CS$_2$ [7], accurately predict double-ionization energies to ground triplet states of the dication. The next highest double-ionization energy measured in the present investigation is 38.6 ± 0.4 eV. This is significantly higher than the previously measured ground singlet-state energy of 37.0 ± 0.2 eV [3] which has been calculated in the present investigation to be 37.09 eV.

The present data for the higher state energies, together with those calculated previously, are shown in Table 1. Where states with closely-lying computed energies are present, an average has been taken which is shown in the appropriate column. The experimental data have been positioned to correspond to those states having the most similar energies. It can be seen that the experimental data are not too different from those calculated by Price et al [3] and are in excellent agreement with those calculated by Connor et al [1]. This gives some confidence that triplet states were populated in the present DCT spectroscopy experiments and that, provided groups of calculated values similar to those shown in Table 1 are considered, calculated and experimental data are in excellent agreement.

**Investigation of Ligation Effects by Charge Stripping of FAB Produced Metal Ions**

Sæsl M. McCullough, A. Daniel Jones, and Carlito B. Lebrilla  
Department of Chemistry and Facility for Advanced Instrumentation, University of California, Davis, CA 95616

Formation of simple gas-phase metal-ligand complexes offers the opportunity to gain insight into the effects of ligation on the electronic energy levels of metal ions. The charge stripping (CS) of these complexes allows the determination of second ionization energies through the kinetic energy loss or $Q_{\text{min}}$, in the charge stripping process. These values, when compared with the second ionization energies of the corresponding bare metal ions, provide a measure of the degree of stabilization of a metal by a particular ligand.\(^1\)

We have used the combination of FAB/CS in a VG-ZAB 2F mass spectrometer to produce doubly charged metal and metal-ligand complexes of alkaline earth, transition and rare earth metals from their metal salts. Ions are selected with the magnetic sector, collided with $N_2$, and analyzed with the electrostatic analyzer. Values are obtained using the additive calibration method described by Beynon.

Table 1 shows a representative sample of the transition and lanthanide metals produced with this method. The $Q_{\text{min}}$ values obtained correspond well (within the experimental error of ±0.5 eV) to the literature values for second ionization energies. The charge stripping spectra of the bare metal ions (e.g. Co$^{2+}$, Figure 1a) contain a single peak with no high energy (lower $Q_{\text{min}}$) components representative of electronically excited ions.

The charge stripping of ligated metal ions (e.g. CoCl$^{2+}$, Figure 1b) produces similarly uncomplicated spectra. Ligation by either OH, O, or Cl increases the $Q_{\text{min}}$ values thereby making it more difficult to remove a second electron (Table 2). For example, the energy necessary to charge strip CoCl$^{+}$ is 0.9 eV greater than the corresponding value for Co$^{+}$. This is expected for electronegative ligands. There are clear variations when either the ligand or the metal is changed. A Cl ligand on Mg increases the $Q_{\text{min}}$ value from the bare to the ligated by 1.4 eV but the OH ligand produces only a corresponding value of 0.5 eV. Similarly an O ligand on V increases the $Q_{\text{min}}$ by 2.8 eV but produces a $\Delta Q_{\text{min}}$ of 5.1 eV for Ho. In general, we find that ligation affects the lanthanide metals the most. These results clearly illustrate that charge stripping can be used to determine the effects of ligation on the ionization potential of ligated metal ions.

The observed $Q_{\text{min}}$ values for the ligated metal ions may be used to estimate the bond dissociation energy of the ligated metal dication. Through the energy diagram shown (Figure 3) it is possible to obtain the dissociation energy if the corresponding energy for the monocation is known. Several bond energies of ligated metal ions have recently been obtained allowing us to determine the bond dissociation energy of CoOH$^{2+}$.\(^2\) As shown in the diagram, this complex dissociates to form a combination of Co$^{2+}$ + OH or Co$^+$ + OH$^+$. The pathways to form the metal dication is endothermic by 2.1±0.5 eV and the alternative pathway is exothermic by 2.2±0.5 eV.

PHOTODISSOCIATION PHOTOIONIZATION MASS SPECTROMETRY OF ALKENES
S.E. Van Bramer and M.V. Johnston

INTRODUCTION:
In Photodissociation Photoionization Mass Spectrometry (PDPI/MS) the analyte is first photodissociated to form neutral fragments. These neutral fragments are then photoionized with coherent vacuum ultraviolet radiation. Because fragmentation is the result of neutral photodissociation rather than ionic fragmentation, the resulting mass spectrum is much different than that observed with EI.

An important difference between neutral and ionic fragmentation is that rearrangement barriers are frequently much higher for neutrals. This means neutral isomers are less likely to rearrange to a common structure. As a result isomers with identical ionic fragmentation are often distinguishable with PDPI/MS.

EXPERIMENTAL:
An excimer laser (193 nm) is used for photodissociation. The resulting neutral fragments are then softly ionized with 10.5 eV coherent VUV radiation produced by frequency tripling the third harmonic of a Nd:YAG laser in a rare gas mixture. Alternatively the output of a Nd:YAG pumped dye laser is mixed with residual 1064 nm radiation to produce tunable UV radiation. This is then frequency tripled in rare gas mixtures to produce coherent VUV radiation from 121 to 129 nm (10.2 to 9.6 eV) which is used to softly ionize the neutral photodissociation products.

WAVELENGTH EFFECT:
One problem with PDPI/MS is that the ionization step can also induce fragmentation of the molecular ion, complicating the spectra. By careful selection of the photoionization wavelength it is possible to reduce this fragmentation, greatly simplifying the PDPI spectrum.

The photoionization step can also induce fragmentation of the neutral photodissociation products. The use of longer photoionization wavelengths also reduces this secondary fragmentation. Comparison of 118 and 128 nm PI and PDPI spectra shows how the use of longer wavelength PI simplifies the PDPI spectra.

FRAGMENTATION PATTERNS:

The PDPI/MS fragmentation of alkene isomers from C₂ to C₁₄, including dienes and branched alkenes, were studied with both 118 and 128 nm PI. Alkenes were chosen because they undergo rapid rearrangement after ionization, as a result their mass spectra are often identical. Unlike their conventional mass spectra the PDPI mass spectra of alkene isomers are very distinctive and the location of the double bond is readily determined. Previous photochemical studies indicated that 193 nm photodissociation would induce α-cleavage in alkenes. The resulting unsaturated allyl radical identifies the location of the double bond in the PDPI/MS. Apparently the saturated compliment undergoes further fragmentation to form the smaller radical species seen in PDPI/MS. The figure below shows the PDPI mass spectra (193 nm PD and 128 nm PI) for 1, 2, 3, and 4-Nonene. α-cleavage of 1-Nonene results in the fragment at m/z 41. α-Cleavage of 2-Nonene gives the peak at m/z 55. 3-Nonene has two α-cleavage sites, loss of C₄H₈ gives m/z 69 and a second cleavage, loss of CH₃, gives m/z 54. In 4-Nonene only cleavage at both α sites, m/z 54, is seen. The other alkene isomers studied undergo similar fragmentation.
Glycosphingolipids are important components of cell membranes. Their basic structure (1) comprises a carbohydrate group (R) attached to a ceramide residue. The ceramide group (R = H) is a long-chain sphingoid base, such as sphingosine (R' = CH=CH(CH2)3CH3) or sphingenine (R' = (CH2)4CH3), that is substituted at the amino group by a fatty acid (R'' = alkyl chain). If R were a monomer or polymer of a simple sugar, the molecule would be called a cerebroside. The structures of the carbohydrate group and the sphingoid and N-acyl chain can vary. Thus, easy but complete structural elucidation of ceramides and cerebrosides has traditionally been a challenge. Recently, however, fast atom bombardment (FAB) and collision-induced dissociation (CID) of (M + H)+ and (M - H)- ions has been shown to be an important avenue for their structure determination [1-3].

As an alternative to using CID of (M + H)+ and (M - H)- ions, we have been exploring the use of alkali metal ions as reagents to enhance structural determination by CID. Here, we show some results from applying CID of (M + Cat)+ ions, where Cat = alkali metal ion, to structure determination of ceramides and cerebrosides. All mass spectra were acquired by using a VG 70-S, forward geometry mass spectrometer. FAB matrices were 3-NBA and 3-NBA saturated with alkali iodides. CID occurred in the first field-free region, and CID spectra were acquired at 50% beam reduction with He. B/E linked scans were used to record the spectra.

Figure 1 shows CID spectra of (M + H)+, (M - H)-, and (M + Li)+ ions of a ceramide and a cerebroside.

![CID spectra of ceramides and cerebrosides](image)

Figure 1. CID spectra of (M + H)+, (M - H)-, and (M + Li)+ ions of N-oleyl sphingosine (A-C), and N-stearoyl dihydrolactocerebroside (D-F).
S and T ions in Figure 1C and 1F are analogous to those reported previously for \((M - H)^+\) ions [1]. CID of \((M + Li)^+\) ions gives complementary information to \((M + H)^+\) and \((M - H)^+\) ions, and more information about the structure of the \(N\)-acyl chain. Our detection limit for obtaining an interpretable CID spectrum of ceramides is 10 ng, which is comparable to that previously reported for \((M + H)^+\) ions [1].

Figure 2 shows CID spectra of \((M + Cat)^+\) ions, where Cat = alkali metal ion, of a ceramide. The spectra change in interesting ways with increasing size of alkali metal ion. The abundances of closed-shell ions, H, T, S, and V, decrease, while, abundances of open-shell ions, P, K, and \((T + 1)\), increase. For cerebrosides, somewhat similar chemistry occurs: Abundances of closed-shell ions, \(Y_0\), B, C, and S also decrease, while the abundance of the open-shell ion, \((J + 1)\), increases.

We do not entirely understand why the fragmentations change with increasing size of alkali metal ion. We hypothesize, however, that the changes may be a result of differences in multidentate metal ion binding to several binding sites.

REFERENCES
Reactions of ions and neutrals at keV collision energies have been extensively studied and attempts to understand the processes that occur have rely on several different types of measurements, e.g. energy loss accompanying ion-neutral collision, what fraction of the energy loss appears as internal energy to affect dissociation, the time-scale of the dissociation process, etc. An alternative method for probing the dynamics of collisional activation is to measure the neutrals formed by keV collisions. One of the questions that remain is the importance of endothermic charge exchange. A magnetic sector (EB)/reflectron time-of-flight instrument offers a unique opportunity for the study of the neutrals. The ability of the EB/reflectron time-of-flight to study neutrals is based on a detector situated behind the reflectron. Voltages may be placed on the reflectron such that only neutrals can reach the detector situated behind the reflectron.

Figure 1 shows the ion arrival time distribution of the mass-selected (M+H)' ion of sinapic acid on the detector position behind the reflectron (no voltage applied to the reflectron). Figure 1 also shows the arrival time distribution of the neutrals formed upon collisions with He (4 keV collision energy; 25% beam attenuation). It should be noted that the neutral abundance can not be accounted for by CID. The high abundance of neutrals can only be accounted for by neutralization of the ions by endothermic charge transfer reactions. This result indicates a significant portion of the collision energy is converted into internal energy of the collision gas, because the ionization potential for He is 24.6 eV.

A unique experiment to the magnetic sector(EB)/reflectron time-of-flight experiment is neutral-ion correlation. The experiment involves the use of a neutral detector to start the time of flight clock for ion detection. Since the start is caused by a neutral formed by an ion process, for example metastable decay, an ion that dissociates into daughter ions and daughter neutrals produces a signal for the daughter ions. Ions that lose their charge to the target gas, for example endothermic charge transfer, will produce a neutral signal without producing an ion signals. The correlation should therefore distinguish charge transfer neutrals from neutrals that produce fragment ions. Ideally, metastable spectra should give an ion for each neutral; however, the metastable spectra obtained by neutral-ion correlation experiments give only a small percentage of the numbers of ions for a particular starting neutral. For example, a metastable spectra was obtained with 100,000 neutral starts; however, only approximately 500 ion counts were observed. This poor collection efficiency of the daughter ions may be attributed to three factors.

1. Ions decaying in the reflectron will produce neutrals without a correlated ion (Flight time of ion and neutral will depend on the position of decomposition).
2. Ions can undergo collision with the background gas to produce a neutral without a correlated daughter ions.
3. Inefficient collection of ions by the short co-linear reflectron.

The effects of neutralization can be observed in the neutral-ion correlation experiment. The large number of uncorrelated neutrals produced by endothermic charge transfer limits the signal to noise ratio of the CID spectra by this method.

Fundamental Studies and Optimization of Anthracic Acid
as a Matrix for Protein Analysis by $^{252}$Cf-PDMS

Barbara Wolf* and Ronald D. Macfarlane

Department of Chemistry, Texas A & M University, College Station, TX 77843

We have recently introduced the use of small molecules as matrices in $^{252}$Cf plasma desorption mass spectrometry (PDMS)\textsuperscript{1} as an alternative to the commonly used polymeric matrices, such as nitrocellulose. One of the most interesting of the new matrices is anthracic acid (AA), which gives much sharper protein molecular ion peaks than are obtained with nitrocellulose. In addition, the background in the molecular ion region is reduced by over 50\% when anthracic acid is used as the matrix instead of nitrocellulose. We have pursued studies of the anthracic acid matrix to optimize the conditions for high molecular weight protein analysis. Further, fundamental studies have been done to increase knowledge concerning the desorption mechanisms in $^{252}$Cf-PDMS.

The optimization studies included determining the effect of protein solution and matrix parameters on the molecular ion yield of bovine insulin (SBI). In these studies, a cover glass was used to spread the SBI solutions over the electrosprayed substrates in order to ensure uniform coverage of small volumes over the surfaces. For each study, adsorption times were 5 minutes, following by rinsing of the targets with purified water and spinning dry at 10,000 RPM. In the first study, thicknesses of the AA substrate were varied by electrospraying different volumes of the solution (2 g/L in acetone). The thicknesses were determined by measuring the energy loss of alpha particles passing through the deposits. A plot of the results is shown in Fig. 1. Optimum SBI ion yield is obtained at an anthracic acid thickness of about 100 ng/cm$^2$. For the remaining studies, electrosprayed AA deposit thicknesses of 100 (±10) ng/cm$^2$ were used. The results of the SBI concentration studies are shown in Fig. 2. The volume of SBI solution applied for each target was 5 µL. The SBI yield increased strongly with the concentration of solution applied. The ratio of singly to doubly charged molecular ions increased with solution concentration as well. Studies in which the volume of SBI solution (10$^{-3}$ M) was varied from 1 to 5 µL showed no significant change in SBI intensities.

As part of the fundamental studies, a radio-assay using $^{14}$C-lysozyme revealed that about six times more protein is adsorbed onto a nitrocellulose (NC) matrix than an AA matrix prepared under the same conditions, though molecular ion yields from two such targets are similar. In another fundamental study, the fragmentation pattern of bradykinin (BRN) was studied for BRN adsorbed onto NC and AA. A plot of the intensities of some of the observed fragment ions relative to the BRN molecular ion is shown in Fig. 3. In general, fragment ion intensities are significantly decreased for the AA matrix, compared to the NC matrix. In addition, side chain fragmentation, such as the "d" series, are less sensitive to the substrate used, while the "a" series fragments are very much affected. Fig. 4 shows the axial kinetic energy (KE) distributions for BRN adsorbed onto AA and NC. These measurements were made using the method developed by Jacobs\textsuperscript{2}. The average axial KE is lower when AA is used (2.2 eV) than when NC is used (3.8 eV). The curves represent a maxwell-boltzmann fit to the data. Finally, angular correlation measurements were made for BRN/AA using the method developed by Mudgett\textsuperscript{3}. The angle of $^{252}$Cf fission fragment incidence was varied by varying the source to target distance and using an annular collimator over the target. Data was compared to computer simulations to determine the angle of emission and total (axial + radial) initial KE of ions. The total initial KE was found to be 4 keV for BRN/AA, and 10 keV for BRN/NC. For both targets, the angle of emission of BRN was determined to be 60° with respect to the incident fission fragments.

Are Large Highly Charged Polyatomic Ions Stable?

Alan L. Rockwood, Mark Busman, and Richard D. Smith,
Chemical Sciences Department
Pacific Northwest Laboratory,
P.O. Box 999, Richland, WA 99352

According to electrostatic theory, like charges repel each other. Therefore, placing many charges on a polyatomic ion tends to destabilize it. We have modeled the effect of coulombic energy on the dissociation of large highly charged polyatomic ions using a simple electrostatic contribution superimposed on a "typical" potential curve for dissociation of a chemical bond. The calculation was oriented toward biopolymer ions modeled as thin strings containing a set of evenly spaced elementary charges. The "chemical" part of the bonding model consisted of a Morse curve parameterized to give a 3.25 eV bond dissociation energy and a 400 mdyne/Å force constant. Based on the results from this model, many of the highly charged ions observed in electrospray ionization mass spectrometry (ESI-MS) are probably energetically unstable against dissociation into two or more charged fragment ions. For example, in our model an ion of 550 Å length containing 26 elementary charges should be unstable by almost 9 eV, yet the +26 charge state of myoglobin (estimated "extended" length ~550 Å) is readily observed in electrospray mass spectra. The fact that highly charged but undisassociated ions are often observed in ESI-MS might be attributable to the long-range nature of the coulomb interaction versus the short-range nature of "chemical bonding" interactions. Thus, coulombic repulsion is relatively inefficient in reducing the barrier to dissociation, even though the overall energy balance may favor dissociation, making the system "metastable". For example, in the system described above the energy barrier was lowered by only 0.32 eV even though the overall energy balance favors dissociation by almost 9 eV. The slight lowering of the dissociation barrier that does occur may, under certain circumstances, significantly alter (accelerate) the kinetics of dissociation. This may help explain certain recent findings concerning the thermally induced dissociation of highly charged biomolecular ions in which the more highly charged ions exhibited reduced stability.

The modeling studies show several trends: Coulombic energy lowers the dissociation energy with an approximately quadratic dependence on total charge, with an order of magnitude of ~10 eV for physically realistic systems. The barrier to dissociation is lowered quadratically with total charge. Barrier lowering may amount to as much as a few tenths eV in physically realistic cases. There is an increasing tendency for highly charged ions to fragment near the center of the polymer chain. (Simple RRKM arguments favor terminal fragmentation for uncharged systems.) Finally, if polymer chain length and charge are both increased so as to keep m/z constant, the amount of barrier lowering grows approximately logarithmically with the size of the system.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830. This research has been supported internally by the Molecular Sciences Research Center and the Environmental and Molecular Sciences Laboratory at Pacific Northwest Laboratory.
Figure 1. Potential energy curves for the dissociation of a string-like ion containing various numbers of charges. The curve labeled (13, 13, 550) for example, corresponds to an ion of 550 Å chain length and 26 total charges breaking into equal sized fragments with 13 charges each.

Figure 2. Energy barrier lowering as a function of charge state for a 550 Å long ion.

Figure 3. Dissociation energy as a function of charge state for a 550 Å long ion.
We have been working on a procedure for the characterization of unsaturated fatty ester moieties in the liposidomycin series of antibiotics, using an approach dependent entirely on mass spectrometry (1). After attempting several methods, we decided to opt for a recently established procedure, the charge-remote fragmentation of lithiated fatty acid cations as described by Adams, Gross, et al. (Refs 2-4). The adequacy of this procedure was easily confirmed on our instrument using low energy CID of a series of underivatized model fatty acids.

High resolution mass measurements proved that liposidomycin A contained two additional carbon atoms in the fatty side-chain as compared to liposidomycin B; NMR work done at RIKEN further suggested that the unsaturation occurs in the form of a CH₂-interrupted diene. Previous mass spectral work on the liposidomycins employed a strong acid FAB dopant in order to facilitate its degradation. In the present case, however, it was of utmost importance that this delicate functionality remain unrearranged throughout the experiments. Therefore, we endeavored to obtain structural information on the fatty acid moiety using the intact antibiotic in the positive-ion FAB, low energy CID of lithiated fatty acid fragments formed in the primary beam.

In Gross and Adams's original work, optimal conditions for many fatty acid charge-remote fragmentations (CRF) were obtained using meta-nitrobenzyl alcohol (3NBA): LiI. We found, however, that liposidomycin A performs poorly with this matrix, but that it does give good spectra from LiBr:glycerol.

We found that the abundances of free fatty acid fragments derived from intact compound were too low to permit detection of CRF, but that the abundance of the dehydrated fatty acid was sufficient to permit MS/MS of its lithiated cations. We were thus able to detect sufficient CRF to deduce the presence of 7,10-hexadecadienoic acid -- an unusual fatty acid -- in the liposidomycin A molecule. The double bond configurations remain as yet undetermined.
Instrumental conditions: VG 70 SEQ, primary beam generated by FAB (Xe), 8 kV; collision gas Kr (50% beam reduction) at collision energies ($E_{\text{lab}}$) of 10-75 eV.

LASER DESORPTION VERSUS FAST ATOM BOMBARDMENT: THE EFFECT OF ION GENERATION PROCESS ON SURFACTANT ANALYSIS RESULTS

The utility of Fast Atom Bombardment (FAB) mass spectrometry for the analysis of many ionic surfactants has been well documented over the years. Many commercially available surfactants are mixtures of several different components or oligomers of a specific surfactant. Hence determination of both the chemical composition and molecular weight distribution of the surfactant components are necessary. Component identification in surfactant mixtures can often be obtained by using FAB, however, the use of a liquid matrix often complicates the analysis and some surfactants are not amenable to analysis by FAB.

Laser Desorption (LD) mass spectrometry combined with Fourier transform mass spectrometry offers many advantages for surfactant analysis including the elimination of the liquid matrix, high sensitivity, laser desorption/postionization to obtain library-searchable EI mass spectra of surfactants, the high resolution measurement of the parent ions and the accurate mass measurement of parent and fragment ions.

This study was designed to: investigate the usefulness of LD/FTMS for cationic and anionic surfactant analysis, to compare FAB versus LD mass spectra for mixture analysis (component abundance profiles) and to show the effect of LD acquisition parameters (such as laser power and postionization) on surfactant analysis results.

The LD experiments were performed by using a 3T EXTREL FTMS-2000 mass spectrometer equipped with a high-power pulsed CO$_2$ (10.6 um) laser, to ablate and ionize the surfactants. The output energy of the laser was controlled by adjusting an aperture and was estimated to be on the order of 0.05 J per pulse for the laser desorption/ionization results. For LD/EI postionization experiments, the laser energy was adjusted below the laser ionization threshold to desorb/ablate surfactant molecules that were subsequently ionization by using electron ionization. The FAB experiments were performed by using a Kratos MS-50 HMTA mass spectrometer. Both commercial surfactant mixtures and reference standards were analyzed by both FAB and LD.

Positive- and negative-ion spectra of typical surfactants obtained under FAB and LD ionization are similar and illustrated by mass spectra of a dialkyldimethylquaternary amine salt (Figures 1a & 1b)

For certain surfactants the LD technique appears to yield higher molecular ion abundances by avoiding the use of a sample matrix. The FAB spectrum (Figure 2a) contains abundant low mass matrix ion (m/z 131, 185, etc.) while the LD spectrum (Figure 2b) is essentially only the molecular cation.

In these laser desorption/ionization experiments, molecular ion abundance is strongly dependent on the output power of the laser. In a preformed ion like the dialkyldimethylquaternary amine, higher laser power results in increased fragmentation (Figures 3a & 3b).
The results of these experiments suggest that FAB and LD ionization techniques yield similar positive- and negative-ion mass spectra of typical ionic surfactants. Additional experiments need to be conducted on laser desorbed ions including high resolution daughter ion measurements for composition determination, breakdown curves and energy variation.
INTRODUCTION

Cooks and coworkers have illustrated several processes that occur when mass-selected polyatomic ions collide with a surface. These include (i) elastic scattering, (ii) inelastic scattering (surface-induced dissociation; SID), (iii) charge exchange and (iv) chemical reaction. Chemical reaction at the surface, which occurs primarily for odd-electron ions, is illustrated by the ion of m/z 91 in the reported spectrum for benzene (m/z 78)\(^1\). The ion of m/z 91 has been proposed to correspond to addition of methyl followed by loss of H\(_2\).\(^1\) We report here the spectra that result when benzene, benzene-d\(_6\), pyridine, and pyridine-d\(_6\) collide with a surface in our 90° tandem quadrupole mass spectrometer. Comparison is made between gas-phase and surface reactions. The goal of the research is to determine the mechanism(s) of alkyl ion addition at the surface.

EXPERIMENTAL

The instrument used in this investigation consists of two Extrel 4000 amu quadrupoles arranged in a 90° geometry. For this investigation, ions were produced by electron ionization and chemical ionization. An ion of interest is mass-selected with the first quadrupole and allowed to collide with the surface. The potential differential between the ion formation region and the surface determines the kinetic energy of the ion/surface collision. Surfaces used in the investigation include bare metals with adventitious hydrocarbon adsorbates (from pump oil) and highly-ordered, self-assembled monolayer films of alkanethiols on gold. Product ions are analyzed by the second quadrupole and a conversion dynode electron multiplier is used for ion detection. A Teknivent Vector/Two data system is used to acquire and process the data.

RESULTS FOR BENZENE

The spectra that result when benzene and benzene-d\(_6\) are mass-selected and allowed to collide with a surface are shown below (Fig. 1 and 2). The spectral regions that correspond to alkyl ion addition are shown in greater detail in Fig. 3 and 4. Peaks corresponding to addition of 1-4 carbons upon ion/surface collision are evident in these spectra. The number of H (or H and D) in the reaction product ions varies with the collision energy (Fig. 3 and 4). Fig. 5 indicates that alkyl addition products dissociate by losses of combinations of H, D, and C to form lower mass product ions with varying numbers of H and D. These ions appear in the spectrum along with those ions that are direct dissociation products of C\(_6\)H\(_6\)\(^+\).

RESULTS FOR PYRIDINE

The spectra that result when pyridine and pyridine-d\(_6\) are mass-selected and allowed to collide with a surface indicate the presence of product ions corresponding to alkyl ion addition. The pyridine spectra show a greater relative abundance of the ion corresponding to addition of an intact methyl group than do the benzene spectra. This may result from the probability of pyridine to undergo methylation at nitrogen, whereas benzene must undergo methylation on the ring (with ring opening and H\(_2\) loss likely).

MECHANISM FOR ION/SURFACE REACTION

It has been proposed that benzene radical cation undergoes alkyl addition at the surface by the mechanism illustrated below.\(^2\) The mechanism is supported by the fact that benzene radical ions do not undergo alkyl ion addition when mass-selected and allowed to collide with alkanes in the second quadrupole of a triple quadrupole instrument.\(^3\) The low reactivity of benzene radical ions in gas-phase reactions has been noted by other workers.\(^3\)

The proposed first step in the ion/surface reaction of C\(_6\)H\(_6\)\(^+\) is neutralization by electron transfer from surface species to form neutral benzene and an ionized surface adsorbate. The resulting neutral benzene is then re-ionized by addition of a proton or an alkyl ion. This initially formed ion can then fragment by loss of H\(_2\) or by C\(_6\)H\(_6\) loss to form lower mass fragments. Our results for benzene-d\(_6\) are consistent with this mechanism. For example, the ion at m/z 91 for benzene shifts to m/z 98 and 97 for benzene-d\(_6\) (see Fig. 1 and 2). This can be envisioned as addition of CH\(_3\)\(^+\) followed by loss of HD or H\(_2\). Our results for gas-phase reactions of benzene support this mechanism and suggest that the mechanism shown earlier could be written more generally to include addition of R\(^+\) followed by loss of RH, where R represents an alkyl ion or H.

SURFACE-INDUCED DISSOCIATION OF SINGLY- AND MULTIPLY-PROTONATED PEPTIDE IONS

Amino acid sequence determination by tandem mass spectrometry is a rapidly expanding field. The majority of these investigations have been performed by low and high energy gas-phase collision-induced dissociation (CID). A new technique, surface-induced dissociation (SID), has been shown to deposit high average internal energies in a controllable manner (1). One goal of this investigation is to determine if the types and relative abundances of sequence ions from singly- and doubly-charged parent ions can be controlled by varying the collision energy in the surface-induced dissociation experiment. Another goal is to determine if side-chain specific ions of type d and w are detected in the SID spectra (2). These ions are generally detected in gas-phase collisional activation experiments performed in the high-energy regime (keV), but not in experiments performed at low laboratory collision energies.

The instrument used in this investigation consists of two Extrel 4000 amu quadrupoles arranged in a 90° geometry. For this investigation, ions were produced by Cs⁺ bombardment (LSIMS) or electrospray (see below).
