One objective of this investigation is to determine the effect of collision energy on the types and relative abundances of sequence ions. Figure 1, the 10 eV SID spectrum of the singly charged peptide GYLTLYKYKASA, is an example the effect of collision energy on the relative abundance of sequence ions. The low mass fragment ions increase in abundance as the energy of the collision increases. The high mass fragment ions and the parent ion are barely present at 30 eV and 65 eV collision energy (data not shown). Reducing the SID collision energy to 10 eV produces a full series of b type ions in the spectrum.

The SID experiments were also performed on doubly-charged peptide ions. 30 eV SID of the doubly-charged peptide, angiotensin I, produced a series of a and b type sequence ions in the spectrum (data not shown). Also present in the spectrum of the doubly-charged parent, is a singly-charged ion corresponding to the intact peptide. Further experiments are required to determine the nominal mass of this ion. SID spectra of the doubly-charged peptide Substance P illustrates the effect of collision energy on the abundance and type of fragment ions (data not shown). At low collision energies, 15 eV, ions of type b are present; as the collision energy increases ions of type a become more abundant.

Another goal of this study is to determine if side-chain specific ions of type d and w are detected in SID spectra of peptides. Figure 2 shows the 500-1050 m/z range of the 60 eV SID spectrum of the peptide Substance P. Side-chains specific ions, labelled d₃ and d₆, correspond to the loss of a glutamine side chain.

The electrospray ionization source used in this investigation was adapted from Chait and coworkers and Knapp and coworkers (3,4). A 40 eV surface-induced dissociation spectrum of the doubly-charged ion derived from des Arg¹ Bradykinin is shown in Figure 3. A series of y type ions is present in the spectrum.

SUMMARY
* High average internal energy deposition is apparent from the extent of fragmentation of the peptide ions investigated.
* The types and relative abundances of sequence ions from both singly- and doubly-charged parent ions are dependent on the ion structure and the SID collision energy.
* Ions of type d and w are detected in the SID spectra.

As part of the development of an organic ion microprobe, to be used for imaging of particular organic compounds in biological tissue, various methods of quadrupole-based tandem mass spectrometry (MS/MS) have been investigated. High transmission efficiency is essential for the success of the organic ion microprobe, due to expected low analyte concentrations in biological tissue and the potential for sample damage from prolonged exposure to the primary ion beam. MS/MS is necessary for organic ion imaging because of the complex nature of the biological matrices. The goal of these studies was to optimize the efficiency of daughter ion production and transmission by first determining daughter ion properties and then designing ion optics based on those properties. The properties of main interest are daughter ion kinetic energy and angular distribution.

Surface induced dissociation (SID) as a means of MS/MS has several potentially attractive features over gas-phase collisional activation dissociation (CAD) commonly used with the triple quadrupoles. One advantage is the reduction in gas load and therefore pumping requirements. A more subtle advantage is mitigation of the ion optical depth-of-field problem inherent in gas phase collisions—daughter ions originate from a planar surface of well defined potential. To design and construct an efficient lens system to collect and transport daughter ions into the second stage of mass analysis, however, it is essential to know the kinetic energy and angular distributions of the daughter ions.

A retarding grid analyzer was used for these measurements, because retarding analyzers do not exhibit ion optical discrimination, as does an electrostatic sector. A lens system was constructed to direct the parent ion beam exiting the first quadrupole into the collision surface in a controllable manner. The system consisted of an acceleration lens, which was used to vary the collision energy, and tandem sets of x,y deflection plates which were used to vary the collision angle, while keeping the ion beam very near the mean spectrometer ion axis at the plane of collision. Daughter ions should exhibit energy distributions peaked at lower energies than the parent ions, due to the reduction in mass upon fragmentation, as well as the conversion of kinetic energy to internal energy in the fragmentation process. Since there is no mass analysis with this type of analyzer, however, energy distributions of inelastically scattered parent ions can obscure the interpretation of the results.

Collisions of acetone molecular ions (m/z 58) ions with: (1) a microchannel plate; (2) a small stainless steel tube; and (3) a stainless steel mesh (50% transmission) were studied. Microchannel plates have been demonstrated as effective fragmentation surfaces at higher energies (1), and collisions with stainless steel surfaces have been used in quadrupole-based systems (2), and in a Fourier-transform mass spectrometer (3). We found, however, that only by severely attenuating the total transmitted ion current, were we able to observe energy distributions that differed from that of the parent ion beam very near the mean spectrometer ion axis at the plane of collision. Daughter ions should exhibit energy distributions peaked at lower energies than the parent ions, due to the reduction in mass upon fragmentation, as well as the conversion of kinetic energy to internal energy in the fragmentation process. Since there is no mass analysis with this type of analyzer, however, energy distributions of inelastically scattered parent ions can obscure the interpretation of the results.

These results led us to conclude that SID was not an acceptable means MS/MS for our microprobe.

Subsequently, we installed a triple quadrupole system; preliminary measurements indicate that transmission (25% in mass selected mode for both quadrupoles with unit mass resolution) and fragmentation efficiencies (20% of...
transmitted parent beam with modest gas pressure) are much higher than for our SID system. Our secondary ion source injects a tightly focused and centered beam into the first quadrupole [4], which we believe contributes to our high efficiency. We previously demonstrated [5] that if a tightly focused beam enters a quadrupole mass analyzer on axis, the exiting beam also has a small circular cross section. Consequently, the beam remains well defined throughout the triple quadrupole system, enhancing transmission. Beam blow up from scattering in the middle "collision cell" quadrupole is suppressed by keeping ions very close to the mean ion axis.

Figure 1. Retarding-grid spectra for (a) parent ion beam and (b) ions following glancing collisions in a microchannel plate (x 100). The integrated intensity shown in both plots represents the intensity of all ions having kinetic energy sufficient to be transmitted through the grid, held at the potential indicated by the abscissa. Differentiation of retarding grid spectrum, shown only in (a) gives the kinetic energy distribution normal to the grid plane.

SURFACE-INDUCED DISSOCIATION AT SELF-ASSEMBLED MONOLAYER ORGANIC SURFACES

D.E. Riederer, R.K. Julian, Jr., B.E. Winger, M.N. Eberlin and R.G. Cooks, Department of Chemistry, Purdue University, West Lafayette, IN 47907

C.E.D. Chidsey, AT&T Bell Labs, Murray Hill, NJ 07974

Surface induced dissociation (SID) has proven to be an effective means for depositing large amounts of internal energy into polyatomic ions. The internal energy distribution is usually quite narrow and the amount of energy deposited increases rapidly over collision energies ranging from 0 to a few hundred eV. A major competitive channel to SID is charge exchange (neutralization) with the target. This limits the efficiency of surface induced collisional activation.

We have recently studied the effect of thiol-bound alkyl monolayer target surfaces on SID efficiency and internal energy deposition using a BEEQ hybrid instrument. The three targets used were (i) fluorinated and (ii) deuterated thiol-bound alkyl monolayers on gold and (iii) untreated stainless steel.

SID efficiency refers to the total fragment ion current divided by the total parent ion current colliding with the target. Experiments performed thus far have shown that the SID efficiency on alkyl monolayer surfaces is significantly higher than on stainless steel. Figures 2 and 3 show the relative SID efficiency for benzene and limonene on each target. In experiments where benzene was used, the efficiency of the fluorinated surface was 3 times greater than that of stainless steel. In the case of limonene, the fluorinated surface provided a ten fold increase. The deuterated surface was also more efficient than stainless steel, although not to the same extent as fluorinated surface. We attribute these results to the fact that less neutralization occurs at the alkyl-monolayer covered surfaces; the fluorinated surface having the best SID efficiency due to its high ionization potential.

In addition to yielding different SID efficiencies the surfaces give different SID mass spectra. These differences are due to both ion surface reactive collisions and differing internal energy deposition. Figure 4 provides a comparison of the fluorinated and stainless steel surfaces. At the low collisions energies studied, the fluorinated surface produces more lower mass fragments and hence appears to deposit more internal energy than the stainless steel surface. The 15eV spectrum of limonene on the fluorinated surface in Figure 4a resembles the 25eV SID spectrum on stainless steel in Figure 5.

INTRODUCTION

The extensive work of R.G. Cooks and coworkers in the area of polyatomic ion surface collisions has led to our interest in the use of surface-induced dissociation (SID) as a tool to probe the structure of large ions (e.g. clusters and peptides). In SID, mass-selected parent ions are activated and fragmented by collisions with a surface; a significant fraction of the lab frame collision energy (10-20%) is converted to internal energy. Thus, SID may represent a relatively simple way to activate large ions in instruments that operate at relatively low voltages. A factor that will affect applications of SID is sensitivity. One parameter that affects sensitivity is the fragmentation efficiency (sum of the daughter ion abundances divided by the mass-selected transmitted parent ion abundance). Several processes fundamental to ion-surface collisions affect the efficiency, including: the extent of elastic scattering and inelastic scattering, and the amount of reactive scattering. The relative amounts of elastic and inelastic scattering may be influenced by energetic, chemical and instrumental factors. Reactive scattering includes charge reduction, ion-surface reactions, and reactive sputtering, and will be affected by the chemistry of the ion and the nature of the surface. We have undertaken a comparison of fragmentation yields in SID on different instrumental designs, as well as a comparison of some the chemical properties that may affect fragmentation yields in SID.

EXPERIMENTAL

Two of the designs were implemented on a commercial triple quadrupole instrument (Finnigan TSQ-70). The first of these designs is an in-line device (consisting of a flat plate acting as an off-axis surface and a slanted deflector to force ions into the surface) which replaced the collision quadrupole of the TSQ-70 and has been described previously. The second device was a modification of a design based on a deflection cone and cylinder, as published by Cooks and coworkers. This device was made small enough to fit between the first analyzer quadrupole and the collision quadrupole in the TSQ-70. The third instrumental design was a tandem quadrupole SID instrument at Virginia Commonwealth University, which has been described previously. Efficiencies were calculated based on the definition: Efficiency = ∑F/P0, where ∑F is the sum of the fragment ion abundances and P0 was the transmitted parent ion abundance. The transmission measurements were made by adjusting the surface and lens potentials such that the maximum amount of parent ion signal was generated.

RESULTS AND DISCUSSION

Table 1 shows a comparison of efficiency data obtained on the three different experimental designs for benzene, pyridine and the tetramethylammonium ion. The results indicate that the highest efficiencies were obtained on the 90° tandem quadrupole at VCU. Efficiencies were found to be considerably lower for the slant plate device at NRL, and further efforts were not made with this device. The energy deposition properties of the different designs were found to be very similar (as determined by comparisons of the collision energy dependent fragmentation of the thermometer molecule W(CO)6 on all three instruments). Thus, the differences in efficiency are thought to be related to ion optics. One possibility is that the collection optics are better in the 90° design, or there are systematic underestimations of the parent ion transmission for the 90° instrument.

Table 1. SID efficiencies for three compounds on three experimental designs.
The results also suggest that there are significant variations fragmentation efficiency with chemical structure. Table 2 summarizes SID efficiencies for various compounds as obtained on the in-line (cone-cylinder) device at NRL. Efficiencies range from 0.2% for benzene to nearly 10% for some tetraalkylammonium ions. The results also directly compare the efficiencies for some similar odd and even electron ions. In general, the SID efficiencies are higher for even-electron ions. This effect may arise because the even electron ions have lower electron affinities, and therefore are less easily neutralized. As shown by the Wysocki group and the Cooks group, modification of the surface work function with bound organic monolayers also affects efficiency, and may be related to neutralization effects. At present, the significant differences between the efficiencies at 30 eV and 50 eV are unexplained. However, they may be the result of focussing problems with the in-line device as the collision energy increases.

Table 2. A comparison of SID efficiencies for various compounds on the in-line device at NRL.

An example of the effect of surface neutralization is observed in the SID spectrum of C₆₀ (Figure 1). The singly charged fragment does not dissociate at collision energies of up to 130 eV, while the doubly charged ion does fragment at 130 V (260 eV). However, the only fragments observed are singly charged ions, as a result of the charge reduction process. Similar effects most likely play an important role in all SID efficiencies.

Surface-Induced Dissociation by FTMS: An Internal Energy Deposition Study

*John A. Castoro, Paul Rucker and Charles L. Wilkins

Department of Chemistry, University of California, Riverside Riverside, CA 92521

Introduction
Surface-induced dissociation (SID) first introduced by Cooks in 1985, is a promising new technique for ion activation in connection with structural analysis studies. A limitation to collision induced dissociation (CID), is that the yield of the daughter ions decreases as the parent mass increases. This is a result of increasing mismatch in parent and target masses and the greater number of vibrational modes available in a larger molecule, resulting in enhanced internal energy distribution, instead of dissociation. Therefore, using a technique such as SID, no additional gas load is used, and a higher percentage of translational energy is converted into internal energy, due to the relatively infinite mass target.

This paper reports the first step in the characterization of SID by FTMS by a comparison study of the internal energy deposition in iron pentacarbonyl for both SID and CID by FTMS.

Mass Spectrometer: Electron ionization (El) SID experiments of iron pentacarbonyl were performed with a FTMS-1000, upgraded with a standard Extrel FTMS-2000 dual cell (4.76cm cubic cell) and operated at a magnetic field strength of 2.9T.

Procedure: Ions were formed in the source cell transferred to the analyzer cell through the 2mm conductance limit. After transferring ions to the analyzer side, lower mass ions were ejected by multiple ejection sweeps. The cyclotron radius of the chosen parent ion was excited by an attenuated on-resonance cyclotron frequency. After this tickle event a +25V pulse was applied by the analyzer trap plate, repelling the positively trapped ions causing them to strike the conductance limit and fragment. The duration of this event was set to 1.5 times the calculated flight time for the parent ion, from the center of the cell to the conductance limit.

Results and Discussion
To characterize the internal energy depositing by SID by FTMS, the much studied compound, iron pentacarbonyl was chosen. The critical energies necessary for the loss of each successive carbonyl group were used to estimate the internal energy distribution. A relatively recently developed method for estimating the internal energy distribution was used. The relative abundance of a fragment is divided by the known critical energy interval. The energy deposition can be therefore estimated by the daughter ion spectrum. The relative abundance of these fragment ions at various SID energies resulted in the internal energy distribution, shown in Figures 1 and 2.

The SID of Fe(CO)5+ by FTMS is compared with SID with a triple quadrupole and with CID by FTMS. The quadrupole spectrum at 60 eV has an internal energy deposition of 6.6 eV or 11%, while the FTMS spectrum of 64 eV has an average internal energy deposition of 2.5 eV or 3.8%. The percent energy deposition difference, being due to the angle of incidence of the collision, since SID by FTMS is at a grazing angle, while the quadrupole has more of a near-normal angle of incidence. Both methods do show an advantage of SID to CID, which is a narrow energy deposition range. Collision induced dissociation of Fe(CO)5+ with Helium, has a broader energy deposition range, but more importantly, the percentage energy deposition with increased collisional energy decreases much more rapidly.
Conclusion

It has been shown that SID by FTMS converts a relatively high percentage of translational energy into internal energy. The limitation of the translational energy being a function of the cell dimensions and magnetic field strength, as in CID. The increased conversion efficiency of translational energy to internal energy makes SID more useful for fragmenting higher mass ions. Future work will be implementing SID to higher mass compounds and studying its applicability to complex structure analysis problems.

As a result of the known inefficiency of collision-induced dissociation for structural analysis of molecules with masses in excess of a few thousand, even when high energy CID is employed, it is of interest to develop alternative strategies for ion activation. This paper describes recent studies intended to evaluate the relative merits of two alternatives, surface-induced dissociation and photodissociation. Results of comparative studies of SID and PD for a laser-desorbed porphyrin and metalloporphyrin are discussed. Relative dissociation efficiencies are calculated from daughter ion spectra obtained using various SID energies and PD wavelengths and time durations. In addition, results from the combined use of PD and SID for MS/MS/MS studies are presented.

Experiments were performed using a 7 T Nicolet FTMS-2000 mass spectrometer. CO2 laser desorption experiments were performed using a Tachisto 215 pulsed CO2 laser. A Lambda Physik EMG 201-MSC excimer laser was used to pump a Lambda Physik FL-2001 dye laser for ultraviolet and visible photodissociation experiments. The dye laser was operated from 568 nm to 605 nm in the visible region (rhodamine 6G) and from 368 nm to 402 nm in the ultraviolet/visible region (QUI).

Samples of tetra(4-pyridyl)-porphyrin (TPyP) and tetraphenylporphyrin iron chloride (TPP FeCl) were dissolved in dichloromethane and portions of each solution were spotted onto a stainless steel probe tip and the solvent evaporated. Each spectrum resulted from the addition of four co-added transients from separate laser desorption events.

**TPyP studies**

Figure 1 contains the photodissociation spectra for TPyP [M]+ ions with m/z 618 at both a) 388 nm and b) 575 nm. Photodissociation at 388 nm results in more extensive fragmentation of the porphyrin, especially in the pyridyl ligands, as might be expected for higher energy photon activation (3.19 eV at 388 nm compared to 2.16 eV at 575 nm). Note that the dye laser was fired for 1 second to obtain the spectrum in a) and for 60 seconds to obtain the spectrum in b). The relative dissociation efficiencies were dependent upon both the wavelength employed and the length of irradiation time. Dissociation efficiency vs. irradiation time was plotted for photodissociation at ultraviolet (390 nm) and visible (581 nm) wavelengths. Relative efficiency values were obtained by dividing the sum of the daughter ion abundances by the initial parent ion abundance. The graphs indicate that efficiency generally increases with increasing irradiation time up to a point, and then levels off as time is increased further. SID for this same compound is shown in Figure 2 at four different collision energies. The abundances of daughter ions increases as a function of increasing SID energy. The dissociation efficiencies vs. collision energy were graphed for TPyP parent ions and the efficiency Increases up to a point and then decreases. LD/PD/PD and LD/PD/SID experiments were performed for TPyP. After isolation of molecular ions and photodissociation at 581 nm, the daughter ions with m/z 540 were subjected to either SID or a second stage of photodissociation at 581 nm. Photodissociation did not produce any granddaughter ions, while SID produced granddaughter ions resulting from loss of a second pyridyl ligand from the m/z 540 ions.

**TPP FeCl studies**

Photodissociation of TPP FeCl [M-Cl]+ ions using ultraviolet and visible radiation results in the production of abundant daughter ions resulting from loss of C6H5 and 2(C6H5) ligands. As observed with the previous sample, in order to obtain comparable photodissociation efficiencies at these two wavelengths, considerably longer irradiation times in the visible region are required than in the ultraviolet region. The ultraviolet and visible photodissociation efficiencies calculated for various irradiation times were graphed and the efficiencies appear to increase with increasing irradiation time and then level off, similar to the earlier TPyP results. Although the efficiencies tend to increase with time, these daughter ions...
ion spectra are not always better for structural analysis purposes. Frequently more non-specific fragment ions are produced at the expense of daughter ions more indicative of ion structure. SID dissociation efficiencies of [M-Cl]+ ions were calculated and plotted from spectra obtained at four different collision energies and are similar to those obtained for TPyP. In Figure 3a, parent [M-Cl]+ ions are photodissociated with 388 nm radiation and the daughter ions with m/z 512 subjected to either b) SID or c) 388 nm photodissociation. Photodissociation produces only one major type of fragment ion (m/z 485 corresponding to loss of C2H3) while SID results in the generation of more types of fragment ions corresponding to successive losses of hydrocarbons (probably resulting from fragmentation of the residual phenyl rings).

In conclusion, PD efficiencies were higher than dissociation efficiencies obtained by SID. PD could be performed at various wavelengths and the efficiency manipulated as a function of irradiation time. Longer times tended to produce more types of fragment ions and in greater abundances. However, in some cases, longer irradiation times also resulted in the production of new fragment ions, at the expense of other fragment ions, which were not necessarily as useful for structural analysis. SID has the advantage that it does not depend upon the absorption characteristics of the parent ion. Although efficiencies are much less, it is the technique of choice for cases where the absorbance of the ion limits the utility of PD.
A New "in-line" Surface Induced Dissociation (SID) for Hybrid Tandem Mass Spectrometers

F. Theobald and H. Budzikiewicz, Inst. for Organic Chemistry, University of Cologne, Greinstr. 4, W-5000 Köln 41, Germany.
E. Schroeder, Finnigan MAT GmbH, Barkhausenstr. 2, W-2800 Bremen 14, Germany

In tandem mass spectrometry a new and very promising technique for activating mass selected ions is based on the collision of the precursor ion beam with a solid surface. Up to now, most surface induced dissociation (SID) experiments reported in the literature have been performed with an angular arrangement of the MS analyzer [1]. Instruments of this type cannot be obtained commercially and an adaption of commercial mass spectrometers requires a fundamental modification of their geometry.

We wish to present here an "in-line" SID cell allowing the use of conventional hybrid MS/MS systems. The cell is placed between the deceleration lenses of MS1 and the RF-only quadrupole of MS2. It consists of a metal tubing which houses an insulated electrode (Fig. 1). A variable electrical potential (deflection voltage) can be applied to this electrode which causes a deflection of the ion beam traversing the cell tubing. The deflected ions collide with the metall surface of the latter. The fragment ions thus generated are collected by ion optical lenses, and the resulting daughter ion spectrum is recorded by MS2. When a OV potential is applied to this electrode the mass spectrometer can be used for conventional low energy gas collision experiments.

The varying amounts of energy transferred by collision result in an array of activated ions, which can be described by a distribution function. The relative fragment ion abundances of model substances can be used as an indicator for the band width, and the mean of the distribution curve provided the fragment ions are formed in a linear reaction sequence and their appearance energies are known [2].

Experiments with tetraethyl silane indicated a high mean energy of the activated precursor ions upon in-line SID. The spectrum obtained with a collision energy of 100 eV corresponding to mean energy of 10.5 eV is reported in Fig. 2. A comparison of the fragmentation pattern obtained in this way with those in the EI- and the low energy gas collision spectra demonstrated the narrow energy band width and the comparatively high mean energies of the ions activated by SID.

The internal energies and the collision energies show an approximately linear correlation. The efficiency of the energy transformation could be shown to be 10-11 of the kinetic laboratory energy between 20 and 200 eV.

The activation efficiency with respect to fragment 'formation' (fragmentation efficiency) has been defined as the ratio of the total of the fragment ion intensities after the ion beam deflection (IF), and the precursor ion intensities before activation (IP). SID efficiency = IF/IP. The fragmentation efficiency (example tetraethyl silane) depends strongly on the focusing of the ion beam (voltages of the ion optical lenses). For determination of the fragmentation efficiency the focusing was adjusted for maximal IF in SID experiments and for maximal IP without deflection. Values between 4 and 8 % were obtained. The potential of the technique is demonstrated for peptides up to mass 1300 u (Fig. 3). With a collision energy of 25 eV a pronounced fragment formation and a good resolution of fragment ions was achieved. Peptides yield structure specific fragment ions of the A, B, C+2 and Y+2 series. In addition, larger fragments of the inner part of the peptide chains and ions corresponding to the various amino acids can be observed.

THE FORMATION OF AMMONIUM IONS BY SURFACE IONIZATION
OF TETRAALKYL AMMONIUM SALTS

Institute of Physical Chemistry, University of Bonn
Wegelerstr. 12, D-5300 Bonn 1, FRG

INTRODUCTION

Surface ionization (SI) on oxide-free metal surfaces is a very selective ionization technique for the detection of quaternary salts from mixtures. At filament temperatures < 1000 K SI mass spectra show only the intact cation whereas higher filament temperatures induce fragmentation of the cation. NH₄⁺ ions were abundantly formed by SI of tetrabutyl, tetrapropyl and tetraethyl ammonium salts at elevated filament temperatures [1]. These ions are not present in the CID spectra of the cations of these salts. This prompted us to elucidate the origin of the ammonium ions.

EXPERIMENTAL

The ion source employed is shown in Fig. 1. The salt was evaporated from the sample holder and ionized on a platinum wire heated to temperatures between 900 and 1750 K.

RESULTS

Fig. 2 shows the SI spectrum of tetrabutyl ammonium iodide at a filament temperature of 1600 K. For this temperature the SI spectrum is similar to that obtained by CID of Bu₄N⁺ [2] with the exception of the abundant NH₄⁺ signal (m/z=18) in the SI spectrum. CID MS/MS/MS studies of the fragmentation behaviour of the primary decomposition products of Bu₄N⁺ reveal the fragmentation step 188 → 130 and are in support of a further step 130 → 74, again by loss of butene, while the tendency of Bu₃NH⁺ (m/z=186) to form iminium ions is low. No ions of the ammonium type were observed in the fragmentation of Bu₃N=CH-Prop⁺ (m/z=184) [2].

In order to elucidate the fragmentation pathway leading to the NH₄⁺ ion SI spectra of Bu₄NI were recorded at filament temperatures between 1100 and 1700 K. Fig. 3 shows the temperature dependence of the relative abundances of the fragment ions Bu₃NH⁺(m/z=186), Bu₂NH₂⁺(130), BuNH₃⁺(74) and NH₄⁺(18) which differ by the loss of one to three butene molecules from the intact cation.

DISCUSSION AND CONCLUSIONS

The intensity profiles of Fig. 3 show the typical shape expected for subsequent monomolecular decomposition reactions thus providing evidence for the formation of NH₄⁺ in SI by successive loss of alkenes from the intact cation. The occurrence of this multistep process in SI can be explained by the trapping of ions in a two-dimensional potential well on the filament surface arising from the image force on the ions, and the permanent heating of the ions during their lifetime \( \tau \) in the trap. For Bu₄N⁺ the depth of the well is about 0.7 eV at a distance of about 0.5 nm. Under the assumption of thermal equilibrium \( \tau \) can be estimated to about \( 10^{-8} \) to \( 10^{-9} \) s in the temperature range used in SI.

A NOVEL COLLISION CELL FOR HIGH RESOLUTION ENERGY LOSS ION MOLECULE COLLISION PROCESSES

A Gareth Brenton and Christopher S Enos
Mass Spectrometry Research Unit, University of Swansea, Swansea SA2 8PP, U.K.

The study of ion molecule collisions (at kilovolt energies) has proved a difficult technique in providing clear spectroscopic information on ions and neutral species, primarily because of the very high energy resolutions that would be required [1] and also that the collision process tends to smear spectra, for several reasons. The technique that we are interested in is where the electronic and vibrational spectra of ionic species can be obtained by monitoring directly the energy loss of an ion in a fast (500-10000 eV) collision process. It is initially assumed that the excitation energy can be directly measured from the loss of translational energy of the fast ion species however energy may also be taken up by the target [2]. In addition the ion may be scattered through an angle which might affect the energy measurement by the analysing sector. We have designed a collision cell which allows the energy given to the target in a collision process to be measured in coincidence with the energy loss (gain) of the fast ion species. This modified collision cell is being fitted to an ultra high resolution energy loss tandem mass spectrometer [3]. The consequences of this design will be that the energy distribution imparted to the target during collision can be deconvoluted, either at a later stage or immediately by simultaneous energy analysis of the scattered target gas molecule. This will enable spectra free from target effects to be obtained reflecting the structure of the ion alone and will allow considerably higher spectral resolutions to be obtained. Reactions that are particularly suited to this technique are when the collision results in the target gas being ionized or gaining a charge by charge exchange or electron capture or if an electron is stripped off the fast ion or target species.

Figure 1 shows a schematic diagram of the collision cell and its location in the energy loss mass spectrometer. Several types of energy analysers could be chosen and used for energy analysis of the ionized target species. A cylindrical electrostatic analyser is shown, which is suitable for ions but for electrons a hemispherical analyser would be preferable or a simpler arrangement of a parallel plate analyser would also work effectively for both electrons and ions. The ion optics of the collision cell are a derivation of the electron source design of Pierce [4] and are shown in Figure 2 schematically, the cell was also modelled using the SIMION [5] programme which allowed some further optimisation. Figure 2 shows a plan view of the cell for a given set of potentials applied to the cell repeller and side beam shaping electrodes. The purposes of these side electrodes is to shape the potential distribution within the cell so that an equipotential is formed along the path (XX') of the ion beam. Thus any target molecules that are ionized (or electrons ejected) will be formed at a given potential and will be capable of being refocussed on the entrance slit of the auxiliary energy analyser. Use of coincidence counting techniques allows the energy imparted to the target to be measured and correlated to the energy loss of the fast ion. The method by which this is achieved is illustrated in Figure 3 whereby a delay is set between the arrival of the target species (at detector D1) and the fast ion species (at detector D2). The efficiency of coincidence counting is less efficient than that for a single channel and is the product of the efficiencies for detecting the target species multiplied by that for the fast ion species.

Figure 4 illustrates for charge stripping how the deconvolution of the energy spread imparted to the electron during the collision process can lead to a significant improvement to the charge stripping spectrum. However in this case it does not account for the energy given to the target so is only a partial solution. For reactions involving charge transfer then monitoring the ionized target together with the fast ion fully describes the partitioning of energy in the reaction. Currently although the energy resolution of the current instrument is ca. 0.015 eV for a 3000 eV ion beam, the achievable product ion energy resolution is generally around a factor 1.5 to 10 worse. This new collision cell design shows promise to solve this deficiency of Translational Energy Spectroscopy (TES).

INTRODUCTION

There has been increasing interest in the use of metal ion attachment as a means for directing fragmentation of large molecules. Recent work by several groups has shown that specific interactions between metal ions and biopolymers are important in fragmentation processes. These studies have suggested that cation attachment may lower activation energies and enhance certain fragmentation processes. Recently, Lattimer and coworkers have reported the fragmentation of synthetic polymers with attached protons and sodium ions at relatively high energies (> 50 eV). They reported fragmentation processes that appeared to be both charge initiated and charge-remote. Lattimer's work suggested that specific metal ion dependent fragmentation processes might be observed. Energy resolved collision-induced dissociation (CID) at relatively low energies (0-200 eV) may prove useful in the elucidation of such processes. In this study we report the low-energy fragmentation of protonated and cationized poly(ethylene glycols). To determine the effect of the cation species, we have studied lithium, sodium and potassium adducts.

EXPERIMENTAL

Low-energy collision-induced dissociation tandem mass spectra were obtained on a Finnigan TSQ-70 (0-200 eV) or a ZAB-2FQ reverse geometry hybrid instrument (BEqQ; 0-500 eV). MIKE spectra of unimolecular decomposition products were obtained on the ZAB and were obtained by scanning the electric sector for decompositions between the magnet and ESA (FFR2). Unimolecular decompositions in FFR3 of the hybrid were obtained by mass-selecting a parent in the double focussing mode and scanning the quadrupole for decomposition products. Low-energy CID was carried out with Xe (at near single collision conditions) or Ar (both single or multiple collision conditions as indicated).

The polyethylene glycols (PEGs) used in these studies were obtained from Baker Chemical and had estimated number average molecular weights ($M_n$) of 400, 600 and 1000. Ions were formed by fast-atom bombardment of neat polyethylene glycols (PEGs), or the PEGs mixed with alkali halide salts. Parent ions were selected with unit resolution unless indicated otherwise.

RESULTS AND DISCUSSION

Unimolecular decomposition spectra and low-energy CID spectra of protonated PEGs formed by FAB show that there are two major ion series formed by dissociation. As proposed by Lattimer, these series could arise from a charge-initiated mechanism, as suggested in the scheme presented below. The unimolecular decomposition spectrum is very sensitive to the flight time. The B series of ions result from loss of (mx44)+18 and predominate at longer flight times. CID of the protonated species tends only to shift the B series to lower molecular weights.

![Chemical structure](image)

The results are considerably different with alkali ion adducts of the PEGs. Figure 1 shows the low-energy CID spectrum of [HO(CH₂CH₂O)₄H + Na]⁺. Two series of ions are observed with 10 eV collisions, corresponding to the scheme below. An unusual feature of the spectrum is the enhanced abundance of the ion corresponding to the neutral loss of 150 amu (HO(CH₂CH₂O)₄OH). This enhanced loss of 150 amu is observed with higher molecular weight PEGs in both unimolecular and CID spectra. This result suggests that specific ion-oligomer interactions may be involved in the fragmentation process, as this enhanced loss is not observed with protonated molecules.

Figure 2 shows the 150 eV CID spectrum (Xe collision gas) of the same Na adduct. The spectrum shows...
considerably more fragmentation. At least 4 additional types of fragmentation are observed, as depicted in the schemes below. The C series of ions has been identified by Lattimer et al. in previous studies, and they have postulated that it arises from a charge remote process involving 1,4 hydrogen elimination. The complementary ion (D) has the same mass as the B series above, however. The ion series labelled E, F and G all arise from heterolytic bond cleavages and most likely form distonic radical cations. They do not appear in the spectra of protonated PEGs. This suggests that the alkali ions lower the activation barriers for fragmentation, possibly through specific ion-PEG interactions. The fact that similar types of processes are observed with Li$^+$ and K$^+$ adducts supports the idea that ions lower the activation energies for these processes. It should be noted, however, that the preferential loss of 150 amu is not observed with Li$^+$ and K$^+$ adducts, suggesting that there are interactions that are specific to a particular species of ions as well.

A BEAM DYNAMICS STUDY OF THE ROLE OF INTERNAL AND KINETIC ENERGY ON
COLLISION-INDUCED DISSOCIATION OF LOW ENERGY IONS

Anil K. Shukla and Jean H. Futrell
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716

Recent studies of collision-induced dissociation (CID) of polyatomic ions at low collision energies have demonstrated that kinetic as well as internal energy of the ion play a very important role in determining the dynamics and mechanisms of collisional activation and subsequent dissociation [1-3]. Using a crossed supersonic beam tandem mass spectrometer, we have demonstrated backward and superelastic scattering processes, incomplete energy randomization after collisional activation as well as initial preparation by electron ionization and change from vibrational to electronic excitation of the ion on collision. These studies also provided a strong correlation of the CID behavior with the photoelectron spectrum of the molecule.

We have extended our CID studies to benzene ion whose photoelectron spectrum shows similar characteristics of large energy gaps between photoelectron bands as in acetone and nitromethane molecules. Also, many studies [4,5], on the fragmentation of the benzene ion have suggested that its dissociations to C_4H_4^+ and C_3H_3^+ occur from a different state than the dissociations to C_6H_6^+ and C_6H_4^+. An excited electronic state or an isomeric structure may be involved for these dissociation processes. However, a recent study by Baer et al. [6] showed that the dissociation of benzene ion proceeds from the ground state in agreement with the statistical theories. Another interesting feature in benzene ion dissociation process is the kinetic shift; thermochemical threshold for C_4H_4^+ is 13.85 eV, however, experimentally measured threshold is 14.30 eV.

Figures 1 and 2 show velocity contour maps for the dissociation of benzene ion to C_4H_4^+ at 69.5 and 10.1 eV collision energies, respectively. Intensity maximum for 69.5 eV CID is located in the forward scattering region at 7 deg. (CM) corresponding to the energy transfer of -7 eV. At 10.1 eV collision energy, however, the contour map shows the occurrence of a very complex CID process. Three intensity maxima in backward, forward and superelastic forward scattering regions are observed. As collision energy is reduced further, intensity peaks in backward and forward scattering regions are still present but only a tail extending to backward superelastic region is observed. It may be due to large energy requirement for this dissociation channel.

Integration of Figure 2 over all scattering angles gives the relative translational energy distribution (P(T) diagram) shows a very broad energy distribution with probability maxima corresponding to the energy transfer from kinetic to internal and internal to kinetic of -4.7 eV. This energy transfer from kinetic to internal energy corresponds to the excitation of ground state benzene ions to third electronic band. Similarly the excess kinetic energy gained by the dissociating benzene ion corresponds to the release of excess electronic energy via de-excitation of benzene ions in the seventh electronic band to the third electronic band. These latter ions have sufficient internal energy to dissociate from that surface. Further experiments are in progress to understand the complex dissociation mechanisms of benzene molecular ions to C_4H_4^+ and C_3H_3^+.

Examination of Ortho Effects in the Collisionally Activated Dissociation of Closed Shell Disubstituted Aromatic Ions. Tracy Donovan and Jennifer Brodbelt, University of Texas, Austin, TX 78712-1167.

Functional group interactions classified as "ortho effects" have been characterized for many disubstituted open shell aromatic ions. These effects are manifested as specific dissociation pathways that are observed for ortho substituted aromatic compounds that are not observed for the other isomers. Such effects have been reported for a variety of aromatic compounds, including methoxybenzaldehyde, acetophenones, nitrophenol, phenylacetylenes, phenyl sulfides, benzoic acids and many more complex aromatic species. The importance of ortho effects in influencing the reactive and dissociative behavior of closed shell aromatic ions has not been extensively examined.

We have studied the reactive and dissociative behaviors of the ortho, meta and para isomers of five disubstituted aromatic compounds containing various combinations of electron-releasing and electron-withdrawing substituents: methoxyacetophenone, hydroxyacetophenone, anisaldehyde, methoxy phenol, and hydroxybenzaldehyde. The results for methoxyacetophenone, anisaldehyde, and methoxyphenol are reported. The two main objectives were to compare the dissociative behavior of various closed shell ions generated via ion/molecule reactions of the p-, m-, and o-isomers, and to elucidate the mechanisms for the unusual ortho effects. The ions of interest were generated by proton transfer from dimethyl ether, or by methylene substitution or methyl addition from ion/molecule reactions with dimethyl ether or ethylene oxide. The structures and dissociative pathways of the ions were characterized by low-energy collisionally activated dissociation in a quadrupole ion trap and a triple quadrupole mass spectrometer and by comparison to the behavior of model ions. The CAD spectra of related monosubstituted aromatic ions were also acquired. These latter spectra served as a basis to determine which of the substituents in the disubstituted aromatics had the dominant role in directing reactive and dissociative pathways.

**Methoxyacetophenone.** The methoxyacetophenone isomers contain an electron-withdrawing acetyl substituent and a moderately electron-releasing methoxy substituent. The CAD spectra of the open shell radical cations, M+-, of o-, m-, and p-methoxyacetophenone generated by electron ionization are qualitatively similar, all showing extensive loss of methyl radical and formation of a variety of aromatic-type ions (C6H5*, C7H7+). However, the CAD spectra of isomeric closed-shell (M + H)+ methoxyacetophenone ions show several striking differences (Figure 1). The protonated meta and para isomers both dissociate via loss of methane and via formation of acetyl cation (formation of m/z 135 and formation of m/z 43 respectively), which is more similar to the behavior of protonated acetophenone than protonated anisole. These processes are not the most significant ones observed for the ortho isomer. Instead, the ortho isomer produces m/z 133 via dehydration, and m/z 105, the most abundant fragment ion.

The unusual ion of nominal mass-to-charge 105 in the CAD spectrum of protonated o-methoxyacetophenone could presumably be C6H5H+ (an alkyl aromatic ion) or C7H5O+ (an aromatic carbonyl ion). Sequential collisional activation experiments in the quadrupole ion trap were performed to determine the structural composition and mechanism of formation of the ion at m/z 105. First the protonated o-methoxyacetophenone ion at m/z 151 was isolated and collisionally activated. Using a second stage of selected ion isolation, the daughter at m/z 105 was chosen and all other ions were ejected from the trap. Then m/z 105 was excited at its resonant frequency to induce dissociation. The major dissociation routes are by dehydrogenation (formation of m/z 103) and loss of 26 amu (formation of m/z 79).

The identity of the m/z 105 ion was elucidated by comparison of CAD spectra of model ions generated from o-xylene, (M - H)+ or C6H5+, and benzaldehyde, (M - H)+ or C7H5O+. The o-xylene ion dissociates predominantly via loss of H2 and C2H2, whereas the benzaldehyde ion dissociates via loss of CO only. The CAD spectrum of the o-xylene ion closely resembles that observed for the m/z 105 generated from o-methoxyacetophenone, and therefore the composition of this ion is assigned as C6H5H+. This composition is somewhat surprising because it must involve extensive rearrangement of the protonated o-methoxyacetophenone in order to transfer both methyl groups to the ring. Sequential activation experiments show that it is likely that the ion of m/z 105 results from sequential dehydration then decarbonylation of the ion of m/z 151, and that the ion of m/z 133 is a direct precursor to m/z 105.
A mechanism for this process is suggested in Scheme 1. Under the near equilibrium conditions during ionization, the thermochemically favored \((M + H)^+\) ion is formed, with the proton localized at the most basic site (the carbonyl oxygen). Upon collisional activation, the proton re-locates at the ortho-methoxy substituent and the methyl group transfers to the aromatic ring. This is followed by elimination of H\(_2\)O via a four-membered-ring transition state. Subsequently, the positively-charged aromatic ring is stabilized by another methyl transfer from the acetyl substituent, and then CO is expelled. The resulting product is a dialkyl aromatic ion.

Ortho effects play an important role in the collisionally activated dissociation of closed shell disubstituted aromatic ions. These effects are more dramatic in the dissociation of ions formed from ion/molecule reactions than in the dissociation of isomeric open shell radical cations generated by electron ionization. Moreover, the dissociative behavior of adduct ions, such as \((M + 15)^+\) and \((M + 13)^+\) ions generated by ion/molecule reactions with dimethyl ether or ethylene oxide, may demonstrate pronounced ortho effects even when such effects are not observed in the CAD spectra of the simple protonated ions. The dissociative processes of the disubstituted meta and para aromatic ions are often analogous to ones observed for monosubstituted aromatic ions. In general, for disubstituted aromatics containing both electron-withdrawing and electron-releasing substituents, the dissociative behavior of the \((M + H)^+\) and \((M + 15)^+\) ions of the meta and para isomers reflect the behavior observed for the corresponding monosubstituted aromatic ions containing electron-withdrawing substituents. Conversely, the \((M + 13)^+\) ions of those meta and para isomers dissociate via pathways observed for the monosubstituted aromatic ions containing electron-releasing substituents, such as methoxy or hydroxyl groups. Many of the dissociative mechanisms of the ortho isomers can be rationalized as involving proton transfer or cyclization between the adjacent functional groups. Because of the ortho effects, these latter mechanisms do not reflect the behavior observed for the monosubstituted aromatic ions.

![Scheme 1. Proposed Mechanism for Loss of H\(_2\)O and CO from Protonated o-Methoxyacetophenone](image)
Collisionally activated dissociation (CAD) is one of the most popular techniques in tandem mass spectrometry. However, the internal energy that can be deposited in an ion upon collision with a stationary target is limited by the ion center-of-mass kinetic energy \( T_{cm} \) which shows a hyperbolic decay with increasing ion mass. A rigorous treatment of the two-body collision kinematics based on König's theorem yields a three-term expression for \( T_{cm} \), where \( m_1, T_1, p_1, \) and \( m_2, T_2, p_2 \) are the mass, laboratory kinetic energy, and momentum vectors for the ion and the target, respectively. For stationary or thermal energy targets \( (T_2 = 0.038 \text{ eV}) \) the second term becomes negligible, while the third term only broadens the internal energy distribution. By contrast, for high kinetic energy targets, e.g. fast atoms produced by a FAB source, or keV ions or electrons produced by ion or electron guns, the collision kinematics depends on the particle masses and relative velocities.

According to (1) \( T_{cm} \) of slow (1-100 eV) analyte ions colliding with a fast target increases with the ion mass to reach the \( T_2 \) limit (Figure 1).

![Figure 1. Center-of-mass kinetic energy in collisions of 6 keV \(^{131}\text{Xe} \) atoms with 10 eV ions of mass \( m_1 \).](image-url)
This contrasts the decrease of $T_{\text{CM}}$ with increasing ion mass in collisions with stationary targets. In fast (keV) ion-fast target collisions $T_{\text{CM}}$ depends on the encounter orientation (head-on, perpendicular or chasing) due to a non-negligible momentum term in (1). However, at very high masses ($m > 100$ kDa) $T_{\text{CM}}$ converges to $T_2$, too (Figure 2). These features could make collisions with fast targets an attractive alternative to other ion-activation techniques. The technical aspects of the fast ion-fast target collisions will be discussed.

Figure 2. Center-of-mass kinetic energy in collisions of 6 keV $^{131}$Xe atoms with 8 keV ions of mass $m_1$. 
INTRODUCTION

Tandem mass spectrometry is a powerful tool for obtaining amino acid sequence information for peptide ions. Collisionally activated dissociation (CAD) is the most widely applied tool for peptide tandem mass spectrometry. Photodissociation (PD) has been studied by several investigators (1-6) as an alternate method for dissociating peptide ions. PD offers the advantage that the energy deposited into the parent ion is independent of the mass of the precursor, in contrast to CAD, in which energy deposited decreases with increasing precursor mass. However, efficient PD requires that the excitation wavelength is strongly absorbed by the peptide. The solution spectra of most peptides show a strong absorbance between 190 nm and 225 nm. Most previous studies of peptide PD have used 193 nm light from an excimer laser (1-5). In this study, we compare PD and CAD of a number of small peptides.

EXPERIMENTAL

These experiments were performed in a Fourier transform mass spectrometer equipped with a 4.4 cubic centimeter analyzer cell, IonSpec Omega data system and electromagnet operating at 1 Tesla. Peptide ions were formed by laser desorption/ionization of the neat sample. Since a single laser is utilized for these studies, 193 nm light from the ArF line of an excimer laser (Questek, Model 2110) is used for desorption/ionization as well as PD. The irradiance used for laser desorption and for PD is ca. 10^7 watts/cm^2. The peptide samples were prepared by electrospraying 100 - 200 microliters of a 10^{-3} M solution of the sample in methanol on a 75 nm thick Au/Pd (40:60) coated Macor probe. All CAD experiments were conducted in the low energy regime with Ar as the collision gas. The PD experiments used from 10-99 laser pulses.

RESULTS

The generation of sequence specific ions by PD and CAD have been studied for all the isomers of VPL and FGGF. The data obtained by each ion activation method provides sufficient fragmentation information to determine the amino acid sequence. Interestingly, the FGGF isomer requires approximately twice the number of PD pulses to obtain the same relative amount of fragmentation as the other two isomers. CAD experiments show that all three isomers fragment with the same efficiency. These results suggest that the FGGF isomer does not absorb energy as efficiently as its isomers. Condensed phase UV-VIS spectra have been measured, and appear identical for each isomer typically showing a broad absorption envelope from 190 - 230 nm. Molar absorbivities in solution are the same for the three isomers, within experimental error. In the gas phase the absorption bands are known to be more discrete thereby exposing holes in the absorption spectrum which may overlap with the PD wavelength. We have applied PD and CAD to tetra- and pentapeptides, and obtained adequate information to identify the amino acid sequence. We find that higher mass fragment ions tend to be produced more abundantly by CAD while lower mass ions tend to dominate the PD spectra.

We have performed matrix assisted laser desorption at 248 nm (KrF) for moderately sized peptides, gramicidin S and gramicidin D. Because of the mass of these peptides, the CAD technique does not impart enough energy for fragmentation in our instrument. PD at the wavelength of the desorption laser (248 nm) did not yield any daughter ions, as the peptides absorb weakly at this wavelength. Further studies of these middle sized molecules will require separate lasers for desorption and photodissociation. The application of the KrF line (222 nm) will be studied, as this wavelength is close to \lambda_{max} for most peptides.
Figure 1. Comparison of PD and CAD mass spectra for a tripeptide, tetrapeptide, and pentapeptide.
KINETICS and MECHANISM of the COLLISIONALLY-ACTIVATED DISSOCIATION of the ACETONE CATION

Richard I. Martinez and B. Gangull
National Institute of Standards and Technology (NIST)
Gaithersburg, MD 20899

Used NIST kinetics-based measurement protocol\(^1\) to study kinetics, energetics, and mechanism of collisionally-activated dissociation (CAD) of acetone cation (m/z 68) under single-collision conditions (Ar target)\(^8\) in NIST QqQ tandem mass spectrometry (MS/MS) instrument.\(^3\)

- Measured CAD breakdown curves; viz., the dynamically-correct (absolute), Instrument-Independent branching ratios (product distributions) of CAD fragment ions as function of center-of-mass collision energy \(E_{cm} = 1-60\) eV (Table 1 in ref. 2).
- Major fragment ions are MeCO\(^+\) (m/z 43; branching ratios of 0.96-0.60) and Me\(^+\) (m/z 16; branching ratios of 0.02-0.26) — see Table 1 and Fig. 1 in ref. 2.
- Ketene cation (m/z 42; branching ratios of 0.02-0.06) is minor fragment (Table 1 and Fig. 3 in ref. 2).
- For \(E_{cm} = 1-60\) eV, absolute total cross sections were 24 to 36 \(\text{Å}^2\).

Estimated average internal energy \(E_{int}\) of collisionally-activated acetone cation by normalization of our CAD data relative to corresponding PEPICO (photoelectron-photolysis-coincidence) breakdown graphs from refs. 4 and 6, and to internal energy deposition functions \(P(E)\) from ref. 6.

- \(E_{int}/E_{cm}\) vs. \(E_{cm}\) dependence observed in NIST QqQ instrument for 58—>43\(^+\) (thermodynamic threshold energy \(E_{thr} = 4.24\) eV) in good agreement with that derived from Fig. 8-12 of ref. 6 for 68—>43\(^+\) (\(E_{thr} = 0.82\) eV), with the plots shifted relative to each other by the difference in the respective \(E_{thr}\) (Table 2 and Fig. 2 in ref. 2).

Concordance of CAD and PEPICO data in Figs. 1 and 2 of ref. 2 is consistent with knowledge (from molecular beam studies\(^7\)\(^9\)) that: (a) CAD excitation mechanism follows electronic excitation ladder for acetone and nitromethane cations; (b) these cations have bands of electronically-isolated states which do not communicate efficiently with ground state (cf. photoelectron spectrum (PES) in ref. 10); (c) CAD of acetone and nitromethane cations violates fundamental principle of 'strong version' of quasi-equilibrium theory (QET) of mass spectra, which requires strong coupling of excited states to the ground state;\(^5\) and (d) there's an apparent correlation between extraordinarily efficient interconversion of electronic and translational energy effected by low-energy ion-neutral collisions\(^5\)\(^4\), and large gap (or 'window') in corresponding PES of more than 1 eV between the ground and excited states (first and higher ionization bands) (cf. PES of nitromethane and acetone\(^10\)).

- Indicates that dissociation occurs primarily from same electronic states in both CAD and PEPICO experiments.
- Indicates correspondence between PEPICO and CAD breakdown curves for systems which have isolated electronic states (as does the acetone cation).\(^5\)\(^7\)\(^9\)
- Suggests collisional activation in such non-QET systems may correspond to scattering angles which emphasize optically-allowed transitions accessed by photolization.

Rate of production vs. \(E_{int}\) of each CAD fragment ion is consistent with a reaction mechanism wherein \(E_{int}\) for each source reaction coincides with an ionization band in the photoelectron spectrum (PES) of MeCO\(^+\) (cf. ref. 10).\(^4\) For example, our CAD breakdown curves for 58—>43\(^+\) and 58—>15\(^+\) show complex, complementary energy dependences for production of MeCO\(^+\) and Me\(^+\). This is consistent with competition between three fast, primary (direct) reactions (viz., (1)-(3)), each of which exhibits non-QET behavior, and each of which opens sequentially at its respective \(E_{int}\).

\[
\begin{align*}
\text{MeCO}^+ & \rightarrow \text{MeCO}^+ + \text{Me} (X ^1A'') & \Delta H = 0.82 \text{ eV} & (1) \\
& \rightarrow \text{Me}^+ + \text{Me} + \text{CO} & \Delta H = 4.24 \text{ eV} & (2) \\
& \rightarrow \text{MeCO}^+ + \text{Me} (B, 1 ^1A') & \Delta H = 6.56 \text{ eV} & (3)
\end{align*}
\]
This proposed mechanism is consistent with refs. 6 and 7 if correspondence between the CAD and PEPICO data were due to having the endoergic reactions (2) and (3) proceed by pumping ground state ions to excited electronic states of Me$_2$CO$^+$, so that CAD occurs predominantly from these excited electronic states.

- For reaction (2), collisional activation of Me$_2$CO$^+$ involves direct electronic excitation from ground state of Me$_2$CO$^+$ (a) into C state of Me$_2$CO$^+$ (4th ionization band$^{10}$) and (b) into E state of Me$_2$CO$^+$ (6th ionization band$^{10}$).
- $\Delta E_{th}$ for (2) coincides with 4th ionization band$^{10}$.

- For reaction (3), CAD involves direct electronic excitation into G state of Me$_2$CO$^+$ (8th ionization band).
- $\Delta E_{th}$ for (3) coincides with 8th ionization band$^{10}$.

Other minor fragments observed are consistent with production via Me-C=O-Me (I)

\[
\begin{align*}
\text{Me}_2\text{CO}^+ & \rightarrow \text{MeCH}_2^+ + \text{HCO}^- & \Delta H = 2.36 \text{ eV} \quad (4) \\
& \rightarrow \text{HCO}^+ + \text{MeCH}_2^- & \Delta H = 2.32 \text{ eV} \quad (5) \\
& \rightarrow \text{CH}_2\text{H}^+ + \text{H}_2\text{CO} & \Delta H = 2.47 \text{ eV} \quad (6) \\
& \rightarrow \text{CH}_2\text{H}^+ + \text{MeO}^- & \Delta H = 4.24 \text{ eV} \quad (7) \\
& \rightarrow \text{CH}_2\text{H}^+ + \text{MeOH} & \Delta H = 4.22 \text{ eV} \quad (8) \\

& \rightarrow \text{CH}_2^+ + \text{MeCHO} & \Delta H = 5.18 \text{ eV} \quad (10) \\
& \rightarrow \text{H}_2\text{C} = \text{CH} = \text{O}^+ + \text{H} + \text{Me} & \Delta H = 5.43 \text{ eV} \quad (11) \\
& \rightarrow \text{CO}^+ + \text{H} + \text{CH}_2\text{H}^+ & \Delta H = 5.96 \text{ eV} \quad (12)
\end{align*}
\]

- $\Delta E_{th}$ for reactions (4)-(6) coincide with onset of 2nd ionization band$^{10}$ (A state).
- $\Delta E_{th}$ for reactions (7)-(9) coincide with onset of 4th ionization band$^{10}$ (C state).
- $\Delta E_{th}$ for reactions (10)-(12) coincide with onset of 6th ionization band$^{10}$ (E state).

This work further validates that NIST kinetics-based measurement protocol can provide dynamically-correct (i.e., instrument-independent) representation of CAD (and other ion-neutral interactions) under single-collision conditions in MS/MS instruments which use rf-only multipole collision cells.$^{10}$

REFERENCES

A well demonstrated advantage of neutralization-reionization mass spectrometry (NRMS) is to obtain isomerically characteristic mass spectra from hydrocarbons and other ions whose isomerizations are facile relative to their dissociations. Vertical charge exchange moves the analyte ion onto the neutral potential energy surface, where isomerization barriers can be higher relative to those for fragmentation. This NRMS capability has now been applied to the MS determination of deuterium position in hydrocarbons, specifically toluene and styrene, whose mass spectra show a high degree of hydrogen scrambling prior to ionic fragmentation.

The mass spectra of α- and ar-α-toluene from electron ionization and from collisionally activated dissociation are nearly identical because of the rapid equilibration of various isomeric C₆H₅· structures before dissociation. Neutralization of the toluene ions with metal vapors of low ionization potential (IP) yields toluene molecules whose internal energy content reflects the difference between the electron affinity of the toluene ion and the metal IP. As shown in the Figure, this should yield toluene with increasing internal energy as the metal vapor is changed from Hg to Na, K, and Cs. Because the rearrangement reaction is entropically unfavorable, increasing the internal energy of the toluene molecules decreases the degree of isomerization before dissociation, as shown by the increasing relative favorability for the loss of D vs. H from toluene-α. Angle-resolved NRMS, described in a separate abstract, should reduce further the scrambling accompanying Cs neutralization.

The isomerization of styrene is even more facile, with NRMS spectra using even Cs neutralization showing almost complete isotopic scrambling accompanying H/D loss from styrene-α and -γ. Although there is little difference between Na, K, or Cs neutralization, the higher energy losses of C₂H₂ and C₂H₃ are not accompanied by complete scrambling; for the d₁ compounds the losses are: C₂H₂ 32%, C₂HD 37%, and C₂D₂ 29%; C₂H₃ 37%, C₂H₂D + C₂HD 34%, and C₂D₃ 29%. Actually, the scrambling is not complete for these losses using CAD, but rearrangement is reduced by a further ~15% by NR for both C₂H₂ and C₂H₃ losses. Stepwise isomerization to cyclooctatetraene explains the favored losses of C₂H₂/C₂D₂ and C₂H₃/C₂D₃ from the d₁ and d₁ precursors.

Linked scanning of the final electrostatic and magnetic analyzers of the four-sector instrument made possible complete resolution of these peaks in the CAD and NR spectra. The m/z 80 and 82 peaks from the d₁ and d₁, precursors actually represent mixtures of C₂H₂D₃, C₂H₂D₂, and C₂H₂D, and C₂H₂D, respectively; the proportions of these in the respective CAD spectra were determined in an MS/MS/MS experiment in the four-sector EBEB instrument by dissociating these ions in the fourth field-free region followed by mass analysis in magnet-II.

USE OF A CONTINUOUS IONIZATION SOURCE WITH A DOUBLE FOCUSING
MAGNETIC SECTOR (EB)/REFLECTRON TIME-OF-FLIGHT
MASS SPECTROMETER
F. H. Strobel, K. Washburn, D. H. Russell
Department of Chemistry, Texas A&M University
College Station, TX 77843.

The standard mode of operation for time-of-flight instruments is to form ions by using a pulsed
ionization source, e.g., pulsed Cs+ ion source, pulsed laser (for multiphoton ionization or desorption), and,
assuming the ions are formed with a narrow distribution of kinetic energies, the mass resolution of the
time-of-flight measurement is limited by the temporal characteristics of the ionization pulse. Thus,
ionization pulse durations of 1-3 nanoseconds are required for high mass resolution measurements.
Although pulse widths of 1-10 nanosecond can be obtained by rastering a convention Cs+ ion gun across
a small slit, this mode of operation requires summing a large number of events (10^6 or greater) to obtain
a complete mass spectrum. The requirement of a large number of ionization events presents a major
obstacle to performing tandem mass spectrometry by using a pulsed ion source. For example, the
efficiency of collision-induced dissociation is quite low ranging from a few per cent to 0.1-0.5% for large
molecules. If we assume a collision-induced dissociation efficiency of 0.1%, then 10^6 primary ions yields
10 fragment ions. Because the number of reaction channels available to the collisionally activated ion
is quite large (say 10-15 structurally significant fragment ions are typical for relatively small peptides), it
may be necessary to accumulate data from 10^6-10^7 ionization events in order to collect a statistically
significant data set. If the repetition rate of the ionization source is 10 kHz a data set of 10^6 events can
be obtained in 100 seconds. However, as the ion yield or collision-induced dissociation efficiency
decreases, as is observed for increasing molecular weight, the number of events required to collect a
statistically significant data set also increases.

An alternative approach to performing measurements with a pulsed ion beam is to form large
numbers of ions per ionization pulse and collect the data by using a transient recorder. This is a common
mode of operation for matrix-assisted laser desorption where the yield of ions per laser pulse is high, e.g.,
10-100 ions are formed for each laser pulse. The limitation of this experiment is the high rate of sample
consumption and the inherent loss in sensitivity over single ion counting experiments. The sample
consumption rate does not effect acquisition of normal mass spectral data but this does pose a problem.
for signal-averaging. In addition, because the efficiency of the activation/dissociation process is low the transient recorder mode is less effective for acquisition of collision-induced dissociation and/or photodissociation data.

This paper describes a novel method of data acquisition for a magnetic sector(EB)/ reflectron time-of-flight mass spectrometer, which uses a continuous source. The method is based on the detection of a neutral to start the time-of-flight clock for the ion. Shown in Figure 1 is the metastable spectrum of Gly-Pro-Gly-Gly obtained with this method.

THEORETICAL INVESTIGATION OF THE STRUCTURES OF C5-C8 ALKANES AND ALKYL CATIONS
IN COLLISION ACTIVATION

Stillanos G. Roussis, Dennis R. Salahub, I. Papal, and Michel J. Bertrand

University of Montreal, Montreal, Canada, H3C 3J7

Computer-automated interpretation of mass spectra involves the correlation of an experimental mass spectrum to a chemical structure. In practice, MS interpretation programs generate a list of most probable structures which, in order to provide useful information, has to be evaluated according to the degree of consistency between the proposed structure and the unknown spectrum. The consistency test requires the prediction of appropriate spectral features for each candidate structure, and further classification according to best match results obtained by comparison with the experimental mass spectrum of the unknown structure. Rule-based mass spectrum prediction methods have been developed for candidate structure ranking, but those methods are of limited success and are based on ion fragmentation plausibilities and not on actual ion intensities. Fragmentation theories based on calculated charge densities and bond orders have been developed, which in some instances can successfully deduce the most likely fragmentation pattern of mass spectra. In a previous study (1), such an approach based on a simple forced oscillator model has been evaluated for the generation of synthetic tandem mass spectra, to be used for classification of the candidate structures proposed by an MS interpretation program.

Although the model was found capable of correlating structures to activation spectra its application involved knowledge of force constants and charge distributions evaluated from the neutral molecules. However, upon ionization those values can change and a better approximation is required in order to provide more reliable force constants and charge distributions for ionic structures. Therefore, the objective of the present work has been to apply MO quantum methods to representative ionic structures in order to obtain typical structural and spectroscopic data which will improve the performance of the model, and at the same time, serve as a test for the validity of the assumptions.

Linear alkanes have been chosen as the first representative class of compounds, due to the structural simplicity of their ions, and the relatively simple fragmentation patterns in their CA spectra. Theoretical investigation involved the use of the MINDO/3, MNDO, and AM1 hamiltonians of the MOPAC (2) semi-empirical quantum program, and of a density functional quantum method (LCGTO-DF) (3). CA spectra were obtained by high energy (8 KeV) collisions with helium in a floated collision cell (1 KeV) at a pressure consistent with single-collision conditions (=10% beam attenuation). Under the employed experimental conditions, the CA spectra are considered to represent characteristic information about the structure of the dissociating ionic species. The most abundant ion in the spectra of the open-shell alkanes is the \([M-29]^+\) ion formed by the preferential loss of \(C_2\text{H}_5\). The loss of 15 daltons (CH3) is small for heptane and octane but higher for hexane and pentane. The alkyl cations show a more complex behavior compared to the alkane chains with \(C_5\), \(C_7\), and \(C_9\) yielding the \([M-42]^+\) as the most abundant ion, and \(C_5\) the \([M-28]^+\). Unfloated collision cell experiments for the hexyl closed-shell cation have shown the \([M-26]^+\) as the most intense ion peak in the MIKES/CA spectrum. Floating of the collision cell separates ions formed by natural and collisionally activated processes and reduces mass discrimination effects.

Semi-empirical methods were preferred initially because the calculation time is considerably shorter compared to \textit{ab initio} quantum methods. It was, however, found that MNDO yielded carbon-carbon bonds which were rather questionably long (=2Å). Thus, the other MOPAC hamiltonians MINDO/3 and AM1 were used in order to compare the methods and draw further conclusions on the ionic structures. A force calculation was conducted without any symmetry constraint for full optimization of the ion geometry. Tables 1 and 2 give heats of formation for the alkane and alkyl structures obtained by the various semi-empirical methods, and errors as compared to experimental data. AM1 was found to produce the most accurate \(\Delta H_f\) values, however, similarly to MNDO, AM1 calculated rather long C-C bond lengths, and asymmetric structures for the ions (TABLE 3). MINDO/3 produced reasonable bond lengths and retained the symmetry. It is interesting to note the correlation of the longer C-C bonds of the optimized structures with the experimental data. A similar correlation appears to hold true for the closed-shell cations, however, a clear conclusion cannot be drawn from the obtained results. It has been necessary, therefore, to resort to a higher level of calculations, in order to obtain a better degree of confidence in the data of the ion structures.

The geometry of the neutral \(C_5\text{H}_{12}\) molecule and two states (I and II) of the \(C_5\text{H}_{12}^+\) cation has been optimized with the LCGTO-DF method (3). The population analysis of the molecular orbitals of \(C_5\text{H}_{12}\) shows that the CC(middle) bonding orbitals lie closer (0.3 and 0.4 eV) to the highest occupied molecular orbital (HOMO) than the CC(end) bonding orbitals (1.1 and 2.0 eV), indicating that ionization from the
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The former is preferred. The two ionic states of \( \text{C}_5\text{H}_{12}^+ \) (I and II) correspond to ionization from the HOMO (CH-bonding) and the HOMO-1 (CC(middle)-bonding) levels respectively. The structure \( \text{C}_5\text{H}_{12}^+ \) (II) (after geometry relaxation) is more stable with respect to \( \text{C}_5\text{H}_{12}^+ \) (I) by about 0.3 eV. Table 4 shows that the CC(middle) bond length (R2) is longer than the CC(end) distance (R1) for the (II) state. The same trend is observed for the corresponding bond orders (0.9 and 1.1 for the CC(middle) and CC(end) respectively) in agreement with the experimental results.

Structural and spectroscopic data of ionic structures, in this study, were found to differ depending on the method employed for the calculations. Although, some methods yielded acceptable thermodynamic data, they generated questionable geometries. Therefore, caution is required for acceptance of a given method, and comparison of values calculated by the various methods is necessary in order to obtain chemically reliable data which are to be used for the prediction of fragmentation patterns of ionic species.

CURIOUS KINETICS IN FRAGMENTATIONS OF N,N-DIMETHYLFORMAMIDE RADICAL CATIONS

Qinghong Ann and Jeanette Adams, Department of Chemistry, Emory University, Atlanta, GA 30322.

The neutral amide group has been a subject of many investigations because of its role as the peptide bond. Amides are fundamentally interesting because their lowest energy forms (planar) contain four delocalized \( \pi \) electrons in three \( \pi \) orbitals, analogous to the allyl anion [1]. \( N,N \)-Dimethylformamide (DMF) is particularly interesting because the HOMO of its planar form is the antisymmetric \( \pi \)-nonbonding orbital, which is followed in energy by the nonbonding oxygen lone pair [2]. Rotation about the C-N bond disrupts \( \pi \) delocalization and alters the orbital energies so that the HOMO now becomes the nitrogen lone pair orbital, which is of higher energy than the \( \pi \)-nonbonding orbital in the conjugated form [3].

Studies of gas-phase amide radical cations have primarily involved ion source decompositions of acetamide homologues [4]. Because there have been no studies of the formamide homologues, and because we are interested in the chemistry of the peptide bond [5], we began this study. All mass spectra shown here were acquired by using a VG 70-S, forward geometry mass spectrometer. Metastable ion and CID occurred in the first field-free region, and CID spectra were acquired at 50% main beam reduction with He. B/E scans were used to record the field-free region reactions.

Figure 1 shows 70-eV ion source (A, D), metastable ion (B, E), and CID (C, F) spectra of DMF and DMF-\( d_1 \) radical cations, respectively. The important observations are that DMF-\( d_1 \) undergoes a high-
energy rearrangement to give loss of HCO⁻, and three slow direct cleavages. The direct cleavages (with their average KERs [6]) are: loss of H⁻ (non-statistical, 0.19 eV); loss of CH₃⁻ (bimodal, 0.16 eV; and loss of DCO⁻ (statistical, 0.10 eV). We hypothesize that cleavage of the amide bond with loss of DCO⁻ occurs via a long-lived ion-dipole complex (Figure 2).

\[ C₂H₆N⁺ + DCO⁻ \]

Figure 2 (see text for details).

We have also begun to study other amide radical cations, and they also undergo some slow (metastable) direct cleavage reactions, none of which include cleavage of the amide bond. Both formamide and \( N \)-methylformamide lose H⁻; \( N,N \)-diethylformamide loses CH₃⁻. \( N,N \)-Dimethylacetamide undergoes no metastable decompositions, whereas \( N,N \)-diethylacetamide loses CH₃⁻; \( N,N \)-diisopropylacetamide loses C₂H₅⁻; and \( N \)-t-butylacetamide loses CH₃⁻.

We currently do not understand the chemistry of these interesting systems. Our on-going research includes obtaining evidence of the potential energy surfaces by modeling the KERDs by Phase-Space Theory and by evaluating the energies of the ionic structures by \textit{ab initio} calculations. We also plan to perform kinetic studies and model them by RRKM.

Single photon and Multiphoton Ionization of IR-Laserdesorbed Bio-Molecules

Institut für Physikalische und Theoretische Chemie, TU München, Lichtenbergstr. 4, D-8046 Garching, FRG.

Photoionization with lasers of different wavelength has resulted in a large number of applications in mass spectrometry. For ionizing molecules introduced into the gas phase two alternative methods can be applied. One possibility uses multiphoton [1] and the other single photon [2] absorption for ionization. While multiphoton ionization (MUPI) of laser desorbed biomolecules, like aminoacids or peptides, is a well tested technique, single photon ionization of IR-laser desorbed biomolecules is fairly new.

In this work we coupled the technique for generation of coherent 10.5 eV radiation (118 nm), which can be easily produced by frequency tripling the third harmonic of a Nd:YAG laser (355 nm) in a mixture of xenon and argon [3], to our Reflectron-Time-of-Flight (RETOF) mass spectrometer.

First mass spectrometric investigations show the application of single photon ionization to small CO2 laser desorbed peptides without chromophore groups. These molecules are not accessible by MUPI. All measured peptides give intensive ion signals with low noise. In every case the molecular ion can be observed but with intensities normally lower than 10%. Remarkable is the high intensity of the A1-fragment (Roepstorff-nomenclature [4]) which is often base peak.

The second measurements compare the two ionization techniques in combination with CO2 laser desorption of the aminoacid tryptophan and some tryptophan containing peptides. Overlapping in space and time of the VUV and UV foci and the separation of the third Nd:YAG harmonic were ensured. While the dipeptides Leu-Trp and Ala-Trp show nearly the same ionization pattern with single- and two photon absorption of the same energy, the mass spectra of tryptophan and the measured tri- and tetrapeptide are different. 10.5 eV single photon ionization of tryptophan gives the molecular ion and the methylindole fragment with a ratio of 1 : 2 whereas two photon ionization of the same energy produces only the methylindole fragment. We believe this may be due to a neutral dissociation after the absorption of one 236 nm photon.
More distinct differences exist in the spectra of Leu-Trp-Met and Leu-Trp-Met-Arg. In the first case single- and two photon ionization produce the molecular ion and a variety of different intense fragment ions. Multiphoton ionization of Leu-Trp-Met-Arg gives a nearly soft ionization. However, single photon ionization gives hard ionization with intense low mass fragment ions. We think this may be due to ionization of neutrals photoproduced during the desorption step as well as the large excess energy delivered to the molecular ion by the VUV-photon.

A Study of Peptide Fragmentation by Photon Induced Dissociation in a Magnetic Deflection Tandem Mass Spectrometer

R.S. Annan, J.A. Hill, H.J. Köchling, and K. Biemann
Department of Chemistry, MIT, Cambridge, MA, 02139 USA

We have previously demonstrated the feasibility of photon induced dissociation (PID) of relatively large peptides (500-2200) in a magnetic deflection high performance tandem mass spectrometer, operating in conjunction with a pulsed Cs ion gun, an excimer laser (400 Hz), and an integrating array detector. These promising but limited results prompted a more extensive study to evaluate the utility of lasers for both dissociation and ionization of peptides and proteins in a magnetic deflection mass spectrometer. We report here our most recent results using PID, at both 193 nm and 350 nm, as an alternative to CID. We also report our initial efforts at matrix assisted UV laser desorption.

EXPERIMENTAL

The PID experiments were carried out on a JEOL HX110/HX110 tandem mass spectrometer with a mass range of 14,500 at 10 kV accelerating potential. An excimer laser, operating at either 193 nm (ArF) or 350 nm (XeF), was used to photoexcite selected precursor ions in an excitation cell located in the interface between MS-1 and MS-2. The laser produces 12 ns pulses and was operated with a repetition rate of up to 400 Hz.

Photon Induced Dissociation To overcome the inherent difficulties associated with using a pulsed laser and a continuous beam ion source, the focusing lenses of a 25 kV Cs+ ion gun were interfaced with a square wave pulse generator. This pulsed source generates 5 µsec ion packets with a variable frequency. The precursor ions of interest are mass selected by MS-1 and transmitted into the photoexcitation interface. To improve the interaction cross section between the ions and the photons, the 10 kV ion packets are decelerated to 2 kV by a lens and the PID cell, which is floated at 8 kV. A pulse delay generator circuit linked to the Cs+ gun and the laser allows coordination of the arrival times of the ion packets and laser pulses. Because the velocity of the ion packets is inversely proportional to the square root of the mass of the ion, the timing is adjusted for each precursor ion mass. The laser beam is focused by a cylindrical lens resulting in a 25 x 0.5 mm profile which enters the PID cell through a quartz window, perpendicular to the ion beam. The energy of the laser can be varied reliably between 10 and 100 mJ per pulse.

After photon induced dissociation, the PID fragment ions are mass analysed by MS-2. Because the product ions are formed in a pulsed mode, the PID mass spectra are recorded using an integrating array detector. Integrations are varied between 0.1-10.0 sec.

The PID spectrum of peptides generated using a 193 nm laser source are in general, very similar to those generated with CID, at the same collision energy, using He as a collision gas. As was to be expected, the PID experiments performed using a 350 nm laser source were not effective until the peptides were derivatized with a chromophore which absorbs at 350 nm. The PID spectrum of the dinitrophenyl derivative (DNP) of PQGIAGQR shown in Figure 1 gave a complete set of C-terminal ions including abundant w7 ions. The most abundant ions were the w7 and the x7 which arise from cleavages adjacent to the DNP proline residue.

Figure 1
Matrix Assisted UV Laser Desorption. The laser desorption (LD) experiments were carried out using the FID cell as an ion source for MS-2. A small voltage was applied to the LD probe tip to act as a repeller. The instrument was operated at a resolution of 1000 and spectra were acquired using the array detector, either by jumping the magnet of MS-2 from m/z 200-4500 and connecting the segments to form a complete spectrum, or by setting the magnetic field so that the molecular ion of the protein falls at the array detector. Samples were dissolved in a saturated solution of dihydroxy benzoic acid (DHB), and 2-3 μl applied to the probe tip. Sinapinic acid was also evaluated as a matrix, but did not produce spectra beyond m/z 2000. The laser was operated at between 10 and 75 Hz at an energy of 20-200 mJ at the sample target, with the beam dimensions of approximately 25 mm x 0.5 mm at the plane of the target.

Figures 2a and 2b show the LD spectrum of the molecular ion region from 12 pmoles of Ubiquitin (M_r = 8564) and the molecular ion region for the doubly charged species from 4 pmoles of Myoglobin from horse skeletal muscle (M_r = 16,951) respectively. Both of these spectra show the presence of DHB photo adduct ions 136 u higher than the molecular ion. Figure 3 shows the full scan spectrum generated from approximately 32 pmoles of an unpurified chymotryptic digest of acetylated cytochrome C. This demonstrates that the ionization is not affected by either 2M urea or buffers.

The nature of the transition state for the decomposition reaction of alkyl phenyl ether ions to phenol molecular ion and the corresponding alkene has been the subject of a number of recent inquiries. Thermodynamic arguments and isotopic labeling results have been presented as support for the existence of an ion-neutral complex in the transition state rather than a cyclic McLafferty type intermediate.

The technique of time-resolved photodissociation spectroscopy is particularly useful in probing the kinetics of the transition state for decomposition with rate constants slower than $10^6$ sec$^{-1}$. The procedure involves comparing experimentally measured time-resolved data with theoretically generated RRKM fitted curves and from the RRKM plots extracting kinetic parameters such as the critical energy and entropy change at 1000 K.

Experiments were carried out on an ICR spectrometer with a one inch cubical cell, 1.4 T magnet and bridge detector. n-Propyl and i-propyl phenyl ether parent ions were produced by electron impact, allowed to cool for three seconds and then excited with laser light for 10 ns. Following a variable delay time during which decomposition proceeds the ICR detector sequence was initiated to yield the time-resolved spectrum. A Lumonics Nd:YAG laser was tuned to the 532 nm line to pump a dye laser producing 5 to 20 mJ 10 ns pulses at the desired wavelength of light between 727 and 650 nm.

Both isomers follow the generalized reaction below:

$$C_6H_5OR^+ \rightarrow C_6H_5OH^+ + R-H$$

RRKM fits for the n-propyl isomer yielded values of 1.24 eV for $E_0$ and -15 eu for.
$\Delta S_{1000}$ K. Results for the isopropyl isomer indicated that the decomposition was too fast on the ICR time scale for any kinetic parameters to be determined. Light intensity studies ruled out the possibility of any significant contribution from a two photon process. Figure 1 summarizes the thermodynamic data.

Previous work concluded that the n-propyl isomer rearranges to the isopropyl isomer as part of the decomposition mechanism. It is reasonable to expect that after this rearrangement the pathways for both isomers are identical. The striking difference between the decomposition rates for n-propyl and isopropyl isomers indicates that this rearrangement is the rate limiting step.

It is unclear whether the large negative entropy change for this reaction favors an ion-neutral complex for a concerted pathway. However, it is clear that the activated complex is tight.

KINETICS OF MULTIPHOTON PHOTODISSOCIATION OF IONS BY LOW-INTENSITY INFRARED LASER IRRADIATION

Robert C. Dunbar
Chemistry Department
Case Western Reserve University
Cleveland, OH 44106

Introduction

Ion dissociation by irradiation with a continuous, low-power infrared laser (cw IRMPD) is finding increasing use in ICR and QUISTOR ion traps. It is considered a very gentle dissociation technique, normally breaking only the weakest bond. We are trying to understand the kinetics of this process better through quantitative experiments, computer modelling, and theory.

We describe here the close analogy between cw IRMPD kinetics and thermal decompositions. The thermal analogy leads to Arrhenius activation energies for IRMPD; we discuss the relation between the activation energy and the dissociation energy of the ion. IRMPD data for n-butylbenzene ion and styrene ion are used to illustrate the application of these ideas.

Focus Question: A plot of dissociation rate versus laser intensity is intimately connected with the value of the dissociation energy (bond energy). How can we use these data to measure ion bond energies?

Computer Modelling

IRMPD was modelled by a computer simulation using a random walk on the energy axis. From these plots we calculate the predicted k_diss and induction time values as a function of laser intensity from 0 to 10 W.

The predicted results can be fitted to the experimental data to test the validity of the kinetic model assumed in the simulation, and to assign the temperatures for the thermal model.

Experimental Results

IRMPD of n-butylbenzene ions and styrene ions was studied in the FT-ICR instrument using a CO_2 laser at 940 cm^{-1}. A typical plot from the IonSpec data system is displayed, showing the decrease of parent ion and the increase of daughter ion, with dissociation commencing after an induction time. (Experimental data thanks to Guy Uechi and Rebecca Zaniewski.)
Thermal Picture of IRMPD

After the induction time, the laser-pumped ion population comes to a steady-state distribution. This distribution is closely approximated as a Boltzmann distribution truncated at the dissociation threshold $E_L$. The dissociation reaction occurs when an ion in the reactive zone ($E_f + \hbar \nu$ to $E_L$) absorbs one additional IR photon. This model leads to expressions for the activation energy, and to Tolman's theorem.

Activation Energies $E_a$: The activation energy defined by $E_a = R \frac{d \ln k_{diss}}{d (1/T)}$ is determined from the slope of the Arrhenius plot of $\ln k_{diss}$ vs. $1/T$, as shown in the figure. Values derived from the data are 0.32 eV (n-butylbenzene ion at 3.3 W), and 0.41 eV (styrene ion at 4 W).

The Arrhenius activation energies $E_a$ are much smaller than the dissociation thresholds $E_L$, which are 1.23 eV (n-butylbenzene ion) and 2.5 eV (styrene ion). We can understand this difference through Tolman's theorem (corrected for IRMPD) which says:

$$E_a = <E_{reacting}> - <E_{population}> + \text{small correction.}$$

Determining $E_L$ from plots of dissociation rate versus laser intensity: From rate versus intensity data alone, this is probably impossible. Using the induction time values to give additional information, as was done in the present study, this can be done through computer modelling. If independent ion thermometry information is available, an excellent determination of $E_L$ should be possible by a Tolman's theorem analysis of IRMPD data.

Conclusions

A satisfactory kinetic picture of cw IRMPD has been formulated, and its quantitative predictions calculated through computer modelling. The kinetics and the computer simulations are in excellent accord with experiment for n-butylbenzene ion and styrene ion.

The formulation of the kinetics using a thermal dissociation picture is successful, giving good agreement with the computer simulations and the n-butylbenzene ion results.

Determining threshold dissociation energies and ion bond strengths from IRMPD data is promising, but requires additional experimental information beyond the rate vs. intensity curve.
Introduction - A series of 9-Naphthyl Esters ranging from the Acetate (MW=186) to the Stearate (MW=410) have been studied using 10.5 eV photoionization and 266 nm multiphoton ionization. Ions were mass analyzed using a linear time-of-flight mass spectrometer and a microchannel plate detector. The basic fragmentation sequence for the esters is outlined in figure one. Primary and secondary fragmentation of the esters have been studied as a function of both molecular size and temperature.

Primary Fragmentation - Photoionization spectra for each of the esters were obtained using 10.5 eV radiation which was produced by frequency tripling 355 nm radiation in a Xe/Ar cell. The spectra show a parent ion and a primary fragment at M/Z 144. No secondary fragmentation was observed. A sample spectrum for 9-Naphthyl Myristate is shown in figure 2. The small amount of M/Z 115 present in the spectrum is the result of the absorption of residual 355 nm pump radiation in the source region. The 10.5 eV spectra were obtained at the same temperatures due to the rate dependence on temperature discussed below. Due to the varying volatilities two temperatures were used to obtain spectra for all of the esters. The spectra show a metastable tail on the high mass side of the M/Z 144 peak. Figure 3 shows the overlaid, normalized region around the metastable peak. By normalizing each of the spectra to the height of the promptly formed M/Z 144 ion, increases in the size of the metastable tail reflect a decrease in the ratio of prompt versus metastable ions (or $k_{\text{on}}$). The increase in the size of the metastable tail is roughly the same as the increase in the number of the vibrational degrees of freedom and thus only a weak function of size.

Figure 4 shows the temperature dependence of the metastable M/Z 144 tail for the 9-Naphthyl Laurate. The spectra shows increase in the prompt to metastable ion ratio with an increase in temperature and the magnitude of the increase is comparable to the molecular size increase.

Secondary Fragmentation - Multiphoton ionization spectra were obtained for each of the esters using 266 nm radiation. The absorption of two photons results in the production of a parent ion. Absorption of an additional photon results in both the formation of M/Z 144 and the metastable M/Z 116. The absorption of two additional photons by the parent ion results in the formation of M/Z 115. Figure 4 shows the expanded normalized region of the metastable tails for Caproate to Stearate. From this figure it is evident that there is no significant change in $k_{\text{on}}$ for the formation of M/Z 116 from M/Z 144 over this range of molecular sizes, and no "degrees of freedom effect" is observed. This result suggests that the parent ion internal energy may not be completely randomized before fragmentation.

Discussion - Statistical theories suggest that the parent ion decay rate should decrease quickly with increasing molecular size. This dependence is explained by simple RRK equations. Two extreme cases can be considered. In situation one, the parent internal energy (E) is held constant with increasing number of vibrational degrees of freedom (N). In this case k drops rapidly as N increases. However, no molecular size dependence would be observed if the fragmentation were driven by the thermal internal energy or if the energy is not randomized. This second situation would cause E/N to be constant and thus only a very small change in $k_{\text{on}}$ should be observed.

ION THERMOMETRIC STUDY OF N-BUTYLBENZENE IONS: HEATING BY A LOW POWERED CW-CO\textsubscript{2} LASER AND SUBSEQUENT IR RADIATIVE COOLING

Guy T. Uechi and Robert C. Dunbar
Case Western Reserve University
Cleveland, OH 44106

Ion thermometry is the attractive idea of probing the average internal energy of an ion at any given time. Competitive photodissociation of n-butylbenzene ions has proven to be a very successful thermometric tool\(^1\). The branching ratio of photofragments m/z 91 and 92 as a function of ion internal energy is well established\(^1\). The ion internal energy can be probed simply by inducing dissociation by the absorption of a visible photon, and detecting the photofragments.

N-butylbenzene ions were produced in a Fourier transform ion cyclotron resonance spectrometer by electron impact. The ions were trapped for two seconds at 1x10^{-8} torr to assure thermal equilibrium had been reached with the temperature of the cell. After removing electron impact produced fragment ions the cw-CO\textsubscript{2} laser (3.3 W) irradiated the trapped ions with 940 cm\(^{-1}\) infrared (IR) photons. The heating of the ions by the IR light was probed by ejecting fragment ions produced by the IR irradiation, inducing photodissociation by a 10 ns visible laser pulse at 440 nm from a pulsed Nd-YAG laser, followed by excitation and detection of all ions. Having heated the ions to approximately 0.8 eV internal energy, the CO\textsubscript{2} laser was turned off. The cooling of these hot ions was observed by again probing the internal energy of the ions as a function of trapping time.
Figure 1 shows two processes due to irradiation by the CO₂ laser. The left axis displays the rise in parent ion internal energy as the ions sequentially absorb IR photons. The right axis shows the extent of dissociation of the ions due to IR multiphoton absorption. The dissociation curve shows the existence of an induction period during which the ions must gain enough energy before the onset of dissociation. The heating curve shows that the induction period corresponds to the time it takes the ion to reach its steady state energy. Another observation from the heating curve is the lack of an absorption bottleneck indicating that the thermal energy of the ions is sufficiently high to place the ions in the region of high density of vibrational states known as the quasicontinuum where incoherent absorption of IR photons occurs.

Figure 2 is the internal energy relaxation curve of n-butyl-benzene ions at 1 x 10⁻⁶ torr. Since collisions may contribute to the cooling rate at this pressure the radiative rate is simply determined by extrapolating to zero pressure in the pressure dependent study. With an initial excess internal energy of 0.45 eV the infrared radiative rate is 1.7 s⁻¹.

HYDROGEN TRANSFER AND STEREOCHEMISTRY IN ELECTRON IONIZATION MASS SPECTROMETRY OF TBDMS ETHER DERIVATIVES OF 3-HYDROXY STEROIDS.

John B. Westmore*, Helena Majgier-Baranowska*, Wayne D. Buchannon* and John F. Templeton
1

*Department of Chemistry, *Faculty of Pharmacy, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2

For 3-hydroxy steroids there are four stereoisomers, which differ according to the orientation of the hydroxy groups (i.e. axial or equatorial) and fusion (i.e. cis or trans) of rings A and B. All four isomers can be separated by gas chromatography of their tert-butyldimethylsilyl (TBDMS) ether derivatives on non-polar columns (Fig. 1). In EIIMS, the elimination of $\text{HMe}_2\text{SiOH}$ from the $\text{[M - t-Bu]}^+$ ion, reaction [1] (confirmed by observation of a metastable decomposition), depends strongly upon stereochemistry, occurring much more readily when the TBDMSO group occupies an axial position (Fig. 2A, 2C).

![Image of molecular structure]

To clarify the stereochemical requirements for this fragmentation, which involves a double hydrogen rearrangement and is potentially important in a predictive sense for other steroid geometries, we have synthesized selectively-labelled steroids with deuterium at specific positions (i.e. 1, 2, 3, 4, 5, 6, 7, 9a and 11) to establish the origins of the two transferred hydrogens. The results for one of these isomers are here discussed in more detail.

For 17a-methyl-17β-hydroxy-3a-O-TBDMS-5a-androstane, the origins of the two hydrogens eliminated in the neutral species of reaction [1] are: H(5α), 100%; H(6), 24%; H(7), 37%; H(9a), 46%. Although not confirmed by experimental evidence we presume that, for reasons given below, it is the α-hydrogens that are lost from positions 6 and 7. Thus, within experimental error, there is quantitative loss of H(5α), while H(6α), H(7α) and H(9α) together account for the second hydrogen lost.

Because the stereochemical information is not lost we assume that reaction [1] occurs without ring-opening. Molecular models confirm that H(5α) is ideally placed for transfer to Si through a six-membered cyclic transition state, to produce a tertiary carbo-cation at C(5). The formation of trigonal planar C(5) at the A/B ring junction reduces the pucker of both rings A and B. The molecular models indicate the closest distances that O(3) can approach to other hydrogens in the strain-free $\text{[M - t-Bu]}^+$ ion (structure I, scheme I) as indicated in Table 1, which also indicates the smaller distances obtained for sp$^2$ hybridization at C(5) (structures II and III).

![Table 1. Estimated distances of closest approach (Å).]

Since the sum of the van der Waals radii of hydrogen (1.2 Å) and oxygen (1.4 Å) is 2.6 Å then a small "umbrella" vibration at C5 would be sufficient for O(3) to come within bonding distances of these hydrogens (and to no others), thus making hydrogen transfer possible. If we now invoke formation of an allyl cation as the driving force for reaction [1] what is necessary are appropriate 1,2-H and 1,2-methyl shifts, as shown in scheme 1.

Angle-Resolved Neutralization-Reionization Mass Spectrometry

Aberra Fura, Frantisek Turecek*, Fred W. McLafferty
Chemistry department, Cornell University, Ithaca NY 14853-1301

The neutral product yields from collisionally activated dissociation (CAD) of neutrals in neutralization-reionization mass spectrometry (NRMS) are found to depend significantly on the z-axis scattering angle of the neutralization event. As shown by Cooks and co-workers [1] for CAD of ions, high scattering angles favor high-energy neutral products, which can be more characteristic of the isomeric structure.

In the Cornell tandem double-focusing mass spectrometer (EBEB) used, 10 keV precursor ions are mass analyzed by MS-I (EB), collisionally neutralized with Hg in the first collision cell, reionized in the second collision cell with O2, and mass analyzed by the second electrostatic analyzer to give NR spectra. The angle of the precursor ion beam in the xz plane is electrostatically determined just before collisional neutralization; those neutrals that have a z-axis velocity component consistent with the acceptance angle of MS-II exit slit are detected after reionization. A 70 V deflection reduces the NR signal intensities by approximately an order of magnitude.

With increasing scattering angle the NR spectra of 2-propenal show increased relative abundances of C2H2, C2H3, CO, C2H4, and CHO, generally favoring products of higher dissociation energies (Figure 1).

![Graph showing relative abundances in the NR spectra, Hg(70%)/O2(50%), of 2-propenal as a function of deflection potential.]

Figure 1. Relative abundances in the NR spectra, Hg(70%)/O2(50%), of 2-propenal as a function of deflection potential.

The angle dependent NRMS spectra of 1-butene, E-2-butene and 2-methylpropene also show (Figure 2) increased isomeric differences in the relative abundances of C4H6, C4H5, C3H5, and C2H4 at higher scattering angles, consistent with their dissociation energies to these species. The ARNR spectra of n-hexenes also show more differences at higher scattering angles reflecting

875
the favored higher energy dissociations. It has already been shown that isomeric specificity of NR spectra can be greatly improved by using neutralization agents of low ionization potential [2] or CAD of neutrals [3]. These angle-resolved NR spectra offer a third, and inexpensive, alternative [4].

Figure 2. Relative abundances in the NR spectra, Hg(75%T)/O₂(50%T), of A: 1-butene, B: E-2-butene, and C: 2-methylpropene as a function of deflection potential.

DISSOCIATION DYNAMICS OF m-IODOTOLUENE MOLECULAR ION: PHOTODISSOCIATION AND METASTABLE ION DECOMPOSITION

Joong Chul Choe*, Hun Young So**, and Myung Soo Kim
Department of Chemistry, Seoul National University, Seoul 151-742, Korea

Dissociation of m-iodotoluene molecular ion (reaction 1) has been investigated on a nanosecond time scale by a photodissociation (PD) technique.[1]

\[ m-\text{CH}_3\text{C}_6\text{H}_4\text{I}^+ \rightarrow \text{C}_7\text{H}_7^+ + \text{I}^- \]  (1)

Metastable ion decomposition (MID) has also been studied, as a means to investigate the reaction over an expanded time scale. The rate constant for reaction 1 has been determined by the photodissociation/mass-analyzed ion kinetic energy spectrometry (MIKES) method developed recently.[2]

The collision cell assembly of the ZAB-E mass spectrometer located in the second field free region was modified to produce an electric field of -5 – 5 kV/cm. The laser (Argon ion) beam was made to cross the ion beam at a position within the field. The translational energy of a photoproduced daughter ion after exiting the field region changed depending on the site of its formation. Hence, time-resolved dissociation of photoexcited parent ions could be investigated by analyzing the translational energy of daughter ions. A time resolution of around 1 ns could be achieved.[2] Charge exchange ionization (CS2/N2) was used to generate the molecular ion of m-iodotoluene with a rather well defined internal energy.

Both of the MIKE spectra for the reaction 1 occurring through PD and MID are composite, suggesting participation of more than one reaction pathway. Analysis of a MID/MIKE peak can be improved by acquiring the spectrum with an electrically-floated cell.[3] Kinetic energy release distributions (KERDs) for the PD and MID were determined using a rigorous numerical method based on ion-optical calculation.[4] KERDs derived for the PD and MID are shown in Fig. 1. The bimodal nature of these KERDs is apparent. The low and the high kinetic energy release (KER) components in the experimental KERDs may be associated with the reaction channels producing m-tolyl and tropylium ions, respectively. The surprisal analysis has been employed to separate the two components. KERD calculated for the m-tolyl ion formation using phase space theory is taken as a prior expectation. Experimental KERDs thus separated are shown together with the reconstructed KERD which is the sum of these. Integrating KERDs for each component, the ratio of the small KER component to the large KER one can be determined. From the comparison of experimental and theoretical KERDs for the two components it was found that the m-tolyl ion formation occurred statistically and the tropylium ion formation occurred with a considerable reverse barrier.

In the case of PD, the rate constant has been found to exhibit a broad distribution due to thermal internal energy distribution of the molecular ion. Most probable rate constant for PD at 488.0 nm has been found to be $(3.5 \pm 0.6) \times 10^7$ s\(^{-1}\). Rate constants for each channel of competing reactions could be obtained from the branching ratio determined through the analysis of the KERDs, which are plotted in Fig. 2 for the PD experiments at two wavelengths. Rate-energy curves for the two channels calculated by RRKM-QET are shown in Fig. 2.

---

** Korea Standards Research Institute, Taejon 305-606, Korea.
Experimental rate constants on a microsecond time scale determined by MID are also shown in the same figure. Considerable negative values of activation of entropy in the RRKM-QET fitting were obtained for both of the competing reactions, suggesting that the rate constants are determined by the tight transition states. The m-tolyl ion formation can be understood by invoking the variational theory.

Figure 1. KERDs for reaction 1. (a) PD with 514.5 nm excitation, (b) MID. Points denote the experimental results. Curves are the separated and reconstructed KERDs from the surprisal analysis.

Figure 2. Rate constants for reaction 1. Filled and open circles are the experimental results for the formation of m-tolyl and tropylium ions, respectively. Solid curves a and b are the theoretical results obtained from RRKM-QET calculations for the formation of m-tolyl and tropylium ions, respectively.

INVESTIGATION OF Fragmentation MECHANISM OF 12-CROWN-4

Mehdi Moini

Department of Chemistry and Biochemistry
University of Texas at Austin, Austin, Texas 78712.

INTRODUCTION

In order to determine the mechanism of dissociation and structure of a fragment ion, one must know the chemical composition of that fragment. Chemical composition can be obtained using high resolution mass spectrometer. It is also important to know if the fragments are the result of a direct dissociation or if they are produced through consecutive reactions. Linked scanning, MIKES, and collision induced dissociation can provide information about consecutive reactions and therefore neutral counterparts. For those ions with similar chemical composition, one can also write several chemical structures, i.e., different isomeric forms. Photolization mass spectrometry provides information about appearance energies of the fragment ions from which the upper limit for the heats of formation can be calculated.

EXPERIMENTAL

VG/ZAB-E commercial mass spectrometer with OPUS data system has been utilized for the accurate mass measurement, linked scanning and metastable decomposition studies. Electron impact ionization with 70 eV kinetic energy have been used for these experiments. Reported chemical compositions have an accuracy of about one mDa or lower. Triple quadrupole mass spectrometer (Finnigan TSQ-70) was utilized for the CID study.

RESULTS

Chemical Composition. In the 70 eV electron impact mass spectrum of 12-crown-4 at low pressure the parent ion (m/z 176) intensity was never above the signal to noise level. Chemical compositions for several fragment ions of 12-crown-4 were identified using high resolution mass spectrometer. The results are listed in Table 1.

Figure 1
**Direct and Consecutive Reactions.** At higher sample pressures ions with m/zs 176 and 177 were present, probably due to the self chemical ionization. To determine whether the fragment ions are products of a unimolecular dissociation or consecutive reactions, metastable decomposition of the parent ion and linked scanning of the parent ion and its major daughter ions (formed at higher pressure) were carried out. Results are shown in Figure 1, and Table 2. Collision induced dissociation of the major fragment ions were studied in a Finnigan TSQ 70 mass spectrometer using argon as a collision gas. Experimental parameters were optimized for the maximum efficiency, i.e., multiple collisions at energies of ca 10 eV. Results are tabulated in Table 3.

**DISCUSSION**

Results of the HRMS, linked scan at constant B/E and the CID indicate that at high energies, dissociation starts by the ionization of an oxygen atom of the 12-crown-4 molecule, and for most fragments this step is followed by an intramolecular hydrogen shift which opens the ring. Molecular ions then fragment via dissociation of different bonds along the molecular ion chain, as shown in Figure 3. On the other hand, as is shown in Figure 2, loss of C2H4O and C4H8O2 (or two consecutive loss of C2H4O) are the dominant processes at low energies. Two important features of metastable ion decomposition are that these ions possess a fairly narrow range of internal energies and this energy is very close to the threshold energy of the first dissociation channel. The result suggests that at low energies, i.e., 0.1-0.2 eV above the threshold for the dissociation of the 12-crown-4, simple bond cleavages are dominant, as shown in Figure 3. In general these results are in agreement with our previous photoionization study, i.e., they suggest a mechanistic dissociation of 12-crown-4. Formation of fragments by direct dissociation or consecutive reactions can be explained by simple bond cleavages, in which daughter ions do not necessarily have the most stable structures.

INTRODUCTION

Electrospray (ES) mass spectra of recombinant bovine and porcine somatotropin (rBST and rPST) dimers were compared to their respective monomers with regard to ion intensity distribution, ion charge distribution and the effect of reduction of the dimer upon treatment with dithiothreitol (DTT). These comparisons were used as a means for probing the effect of molecular conformation on ion formation during electrospray ionization. ES/Mass Spectrometry (MS) was also evaluated for quantitating monomer in the presence of dimer.

EXPERIMENTAL

The rBST and rPST monomers were produced by biotechnology methods. The rBST dimer was isolated from a dimer rich waste stream obtained during isolation of rBST monomer. The rPST dimer was recovered from thermally stressed monomer solutions. The predicted MW's (in daltons) for these components are:

- Monomers: rBST 22116 (22120 reduced), rPST 22101 (22105 reduced);
- Dimers: rBST 44234, rPST 44204.

The ES/MS was performed on a SCIEX API III triple quadrupole mass spectrometer and circular dichroism on a Jasco Mark 5 spectropolarimeter.

ES/MS OF ISOLATED AND REDUCED rBST AND rPST DIMERS

The ES mass spectrum for the rBST dimer is illustrated in Figure 1. Three major ion distributions can be discerned in the spectrum, as indicated by the labels A-C, corresponding to MW's 44236±4 (rBST dimer, A), 44566±9 (rBST dimer + 330 daltons, B) and 22116±2 (rBST monomer impurity, C). Minor dimer components with MW's 43966±16 (A') and 44788±21 (B') were also observed. Note that the mass spacings between the dimer peaks are half that of the monomer peaks and that the monomer peaks completely overlap with the dimer peaks above m/z 1400 but below m/z 1400 the monomer peaks are isolated from the dimer peaks. Since the number of basic sites in a molecule determines the ion distribution in the ES mass spectrum, a linear relationship between molecular weight and the number of basic sites would predict the complete overlap of monomer peaks appearing in an ES mass spectrum with those of a dimer. The absence of complete overlap between rBST monomer peaks with those of the dimer peaks is probably due to conformational differences between the monomer and dimer such that the number of exposed protonatable basic sites are not proportional with molecular weight for the two structures. When the rBST dimer was reduced with DTT, the abundant ions observed in the ES spectrum (Figure 2) were consistent with MW's 22119±1 (rBST reduced monomer, D), 22367±2 (rBST reduced monomer + 247 daltons, E) and 21796±1 (rBST reduced monomer - 324 daltons, F). These data suggest that the rBST dimers principally were in reducible forms indicating that they were produced by disulfide exchange. A small amount of the unreacted starting dimers, G and H, were also observed. SDS-PAGE results, obtained under reducing conditions with beta-mercaptoethanol, indicated that 16% of the dimer did not undergo reduction.

Similar studies were performed with the rPST dimer. Electrospray results indicated that the dimer principally consisted of two components with MW's 44199±2 (rPST dimer) and 43889±5 (rPST dimer - 313 daltons) and a minor component with MW 43596±7. When the rPST dimer is spiked with rPST monomer, the lower mass monomer peaks can be clearly distinguished from the dimer peaks, as described above for rBST, suggesting again the effect of protein conformational differences on charge distribution of related monomers and dimers. Analysis by ES/MS of the DTT reduced rPST dimer indicated components with MW's 22106±3 (rPST reduced monomer) and 21788±2 (rPST reduced monomer - 317 daltons) were present suggesting that these dimers were also formed by disulfide exchange. A small amount of unreacted starting dimers were also observed. SDS-PAGE results, under reducing conditions with beta-mercaptoethanol, suggest that a significant portion of the dimer does not undergo reduction.

The secondary and tertiary structures of rPST monomer and dimer have been probed via circular dichroism (CD) spectroscopy. Changes in the secondary structure are determined by analysis of the intrinsic CD spectral region (180-250 nm) which for the rPST dimer and monomer were found to be identical. These results indicate that the alpha-helical content is the same for both proteins. The aromatic side-chain CD spectral region of rPST (250-325

INTRODUCTION

Electrospray (ES) mass spectra of recombinant bovine and porcine somatotropin (rBST and rPST) dimers were compared to their respective monomers with regard to ion intensity distribution, ion charge distribution and the effect of reduction of the dimer upon treatment with dithiothreitol (DTT). These comparisons were used as a means for probing the effect of molecular conformation on ion formation during electrospray ionization. ES/Mass Spectrometry (MS) was also evaluated for quantitating monomer in the presence of dimer.

EXPERIMENTAL

The rBST and rPST monomers were produced by biotechnology methods. The rBST dimer was isolated from a dimer rich waste stream obtained during isolation of rBST monomer. The rPST dimer was recovered from thermally stressed monomer solutions. The predicted MW's (in daltons) for these components are:

- Monomers: rBST 22116 (22120 reduced), rPST 22101 (22105 reduced);
- Dimers: rBST 44234, rPST 44204.

The ES/MS was performed on a SCIEX API III triple quadrupole mass spectrometer and circular dichroism on a Jasco Mark 5 spectropolarimeter.

ES/MS OF ISOLATED AND REDUCED rBST AND rPST DIMERS

The ES mass spectrum for the rBST dimer is illustrated in Figure 1. Three major ion distributions can be discerned in the spectrum, as indicated by the labels A-C, corresponding to MW's 44236±4 (rBST dimer, A), 44566±9 (rBST dimer + 330 daltons, B) and 22116±2 (rBST monomer impurity, C). Minor dimer components with MW's 43966±16 (A') and 44788±21 (B') were also observed. Note that the mass spacings between the dimer peaks are half that of the monomer peaks and that the monomer peaks completely overlap with the dimer peaks above m/z 1400 but below m/z 1400 the monomer peaks are isolated from the dimer peaks. Since the number of basic sites in a molecule determines the ion distribution in the ES mass spectrum, a linear relationship between molecular weight and the number of basic sites would predict the complete overlap of monomer peaks appearing in an ES mass spectrum with those of a dimer. The absence of complete overlap between rBST monomer peaks with those of the dimer peaks is probably due to conformational differences between the monomer and dimer such that the number of exposed protonatable basic sites are not proportional with molecular weight for the two structures. When the rBST dimer was reduced with DTT, the abundant ions observed in the ES spectrum (Figure 2) were consistent with MW's 22119±1 (rBST reduced monomer, D), 22367±2 (rBST reduced monomer + 247 daltons, E) and 21796±1 (rBST reduced monomer - 324 daltons, F). These data suggest that the rBST dimers principally were in reducible forms indicating that they were produced by disulfide exchange. A small amount of the unreacted starting dimers, G and H, were also observed. SDS-PAGE results, obtained under reducing conditions with beta-mercaptoethanol, indicated that 16% of the dimer did not undergo reduction.

Similar studies were performed with the rPST dimer. Electrospray results indicated that the dimer principally consisted of two components with MW's 44199±2 (rPST dimer) and 43889±5 (rPST dimer - 313 daltons) and a minor component with MW 43596±7. When the rPST dimer is spiked with rPST monomer, the lower mass monomer peaks can be clearly distinguished from the dimer peaks, as described above for rBST, suggesting again the effect of protein conformational differences on charge distribution of related monomers and dimers. Analysis by ES/MS of the DTT reduced rPST dimer indicated components with MW's 22106±3 (rPST reduced monomer) and 21788±2 (rPST reduced monomer - 317 daltons) were present suggesting that these dimers were also formed by disulfide exchange. A small amount of unreacted starting dimers were also observed. SDS-PAGE results, under reducing conditions with beta-mercaptoethanol, suggest that a significant portion of the dimer does not undergo reduction.

The secondary and tertiary structures of rPST monomer and dimer have been probed via circular dichroism (CD) spectroscopy. Changes in the secondary structure are determined by analysis of the intrinsic CD spectral region (180-250 nm) which for the rPST dimer and monomer were found to be identical. These results indicate that the alpha-helical content is the same for both proteins. The aromatic side-chain CD spectral region of rPST (250-325
nm) is sensitive to changes in the tertiary structure. The CD spectrum shows a loss of intensity for the dimer as compared to the monomer which is indicative of a slight change in conformation between the two proteins. Therefore, the differences observed in the ion distributions of the ES mass spectra for the rPST dimer and monomer are consistent with the conformational differences determined by CD spectroscopy.

USE OF ES/MS TO QUANTITATE rBST OR rPST MONOMER IN PRESENCE OF DIMER

Since the lower mass rBST monomer peaks do not overlap with the rBST dimer peaks in the ES spectrum, the amount of monomer in the presence of dimer was estimated by use of calibration curves and by the standard addition method for rBST monomer peaks below m/z 1400. Figure 3 illustrates the calibration curves for rBST monomer for a variety of ions. Note the non-linearity of the calibration curves at high rBST monomer concentrations. In a 1 mg/ml sample of the rBST dimer containing some rBST monomer impurity, the observed ion[m/z] (intensity[counts]/scan) values were 1229.7 (4363), 1302.1 (10088) and 1383.2 (15941). Interpolating these intensity values on the corresponding calibration curve gives an average value of 0.047 mg/ml rBST monomer or 4.7% rBST monomer (w/w). The standard addition method gives a value of 3.7% rBST monomer (w/w). SDS-PAGE results based on the percentage of total stain for the 22000 dalton peak estimated 20% of the sample to be rBST monomer while analysis by gel filtration estimated 10% of the sample to be rBST monomer. In a similar fashion, the amount of rPST monomer present in the rPST dimer sample was found to be 2% (w/w) by ES/MS vs. 4% found by SDS-PAGE. These results demonstrate that quantitation for monomer present in dimer can be readily achieved by ES/MS because the low mass monomer peaks do not overlap with the respective dimer peaks as a consequence of the conformational differences that exist between rBST and rPST monomers and dimers.

INTRODUCTION

A pharmaceutical use of monoclonal antibodies (MW ~150,000) actively being developed world-wide is for the targeting
of imaging reagents to the sites of tumors. The imaging reagents may be radioactive metal ions which bind to chelating agents
which are conjugated to the MoAb's through the ε-amino groups of the lysines. These small chelator molecules typically have
molecular weights between 300 and 1,500 daltons. The average number of moles of chelator conjugated to a monoclonal antibody
is referred to as the loading value of that conjugated chelator. Presently, a radioactivity trace assay or a titration assay is used to
quantitate the loading of the imaging reagents to monoclonal antibodies. A number of assumptions and experimental difficulties
are associated with both techniques that may result in inaccurate loading values. We have therefore evaluated matrix assisted UV-
LDMS and ESMS as methods for the determination of loading values. The LDMS loading values were computed from the
difference in the measured masses for the conjugated and untreated monoclonal antibody relative to the expected mass change upon
conjugation of one mole of chelator. Similar LDMS and ESMS experiments were performed after reducing untreated and
conjugated monoclonal antibodies with dithiothreitol to determine the mass of the light chains (MW ~24,000) and heavy chains
(MW ~50,000) of the monoclonal antibodies and the distribution of chelator between the light and heavy chains.

EXPERIMENTAL

The mass spectrometer used for analyzing the monoclonal antibodies was a reflector-type time-of-flight microprobe
instrument (LAMMA 1000) equipped with a Q-switched (7 ns) frequency-quadrupled Nd:YAG laser (Quantel YC 600S) which
operated at a wavelength of 266 nm with spot size diameters of 10-50 μm and irradiances between 10^6 and 10^7 W/cm^2. The
matrix used was sinapinic acid. The electrospray mass spectra were generated using a SCIEX API III triple quadrupole mass
spectrometer in solutions containing 10% acetic acid. All samples were desalted either by dialysis or gel filtration. The structures
of the conjugated MoAb chelators are illustrated in 1, 2 and 3.

RESULTS AND DISCUSSION

A) Matrix-Assisted UV-LDMS and ESMS Results for Pure and Reduced Monoclonal Antibodies

The measured masses computed from the LDMS and ESMS spectra for the pure and reduced monoclonal antibodies are
summarized in Table I together with the expected masses of the aglycosyl MoAb's obtained from the DNA sequences of the
respective components. The mass differences between the LDMS and DNA values for the respective components are attributed to
the average mass of carbohydrate present in the respective monoclonal antibodies. These data indicate that the carbohydrate is
principally present on the HC and absent from the LC, as expected. Note the excellent correlation for the light chains between the
predicted DNA masses and those measured by LDMS and ESMS. The HC's were very weak in the ES mass spectra. The peak
shapes for the molecular ions of both treated and untreated MoAb's were shown to be Lorentzian in the LDMS spectra.

B) Matrix-Assisted UV-LDMS and ESMS Results for Chelators Conjugated to Monoclonal Antibodies

Figure 1 illustrates a typical matrix-assisted UV-laser desorption mass spectra of monoclonal antibody chimeric B72.3
when pure (1A) and conjugated to a chelator (1B) and when reduced with DTT (Figures 2A and 2B, respectively). Table II
summarizes the measured masses for a number of chelators conjugated to chimeric B72.3 monoclonal antibody and compares the
LDMS loading values with loading values obtained by the radioactivity trace assay and titration assay. The LDMS loading values
tend to be higher than the respective loading values obtained by radioactivity trace assay and titration assay.

The conjugated chelators were treated with DTT to dissociate the chimeric B72.3 monoclonal antibody into reduced light
and heavy chains. The loading values for the individual light and heavy chains were computed (See the values in Table II). Since
chimeric B72.3 monoclonal antibody has 12 lysines on the light chain and 33 lysines on the heavy chain, the predicted
distribution for the chelator should be 27% on the light chains and 73% on the heavy chains.

Determination of loading values by ESMS was hampered by the fact that heterogeneous high mass MoAb samples
produce a continuum of peaks in the ES mass spectra and therefore the MoAb's must be reduced to LC's and HC's, smaller
measureable fragments. As indicated in Table II the individually measured conjugates for the LC's were obtained but no conjugates
for the HC's were observed (due to low sensitivity) which makes the calculations for the ES loading values for the whole MoAb's
unreliable.

Feasibility of GC High Mass Resolution Electron Capture MS for Quantitation of Toxaphene with Minimum Sample Preparation

Andrew H. Grange, LESC, Las Vegas, NV 89119
William C. Brunley, USEPA, EMSL, Las Vegas, NV 89119

Introduction. Toxaphene is a mixture of ~670 chlorinated camphene derivatives. Saleh found 76% were polychlorobornanes and 22% polychlorobornenes. The complexity of Toxaphene prevents resolution of individual constituents by high resolution gas chromatography and the elution window for these compounds overlaps that of numerous other polychlorinated compounds prevalent in the environment.

Instrumentation and Conditions. All GC/MS runs were made using an HP 5890 gas chromatograph interfaced to a VG 70-250SE mass spectrometer. The combination ion source for electron impact and chemical ionization was used. Cold, on-column injections of 1 μl or 3 μl were made onto a 1 m, 0.53 mm id, retention gap, which was affixed to a 30 m, 0.25 mm id, 0.25 μm film, DB-5 fused silica column. The temperature program was that used by Swackhamer: 80°C for 1 min; 10°C/min to 200°C; 1.5°C/min to 230°C; 10°C/min to 280°C. The transfer line was maintained at 285°C; the ion source at ~130°C. The pressure of the Cl gas, CH3Cl, was adjusted to maximize the signal in the Electron Capture (EC) mode. The filament current was 200 μA; the accelerating potential was 8 kV.

Standards. Toxaphene and technical chlordane standards were obtained from the EPA Repository at the Environmental Monitoring Systems Laboratory, Las Vegas, NV. The internal standard, 1,000 was used. The quantitation ions, (M-Cl)−, were: m/z 311, 345, 377, 413 and 447.

Quantitation Ions. Three factors were considered in choosing the quantitation ions for Toxaphene: 1) full scan electron capture mass spectra were recorded to determine which ions were most abundant, 2) the most or second most abundant ion created from each polychlorobornene congener was used, and 3) of these two ions, the one that is subject to a lower interference from column bleed or residual calibration standards at a resolution of 1,000 was used. The quantitation ions, (M-Cl)−, were: m/z 311, 345, 377, 413 and 447.

The single selected ion recording descriptor contained, for each congener, a confirmation ion (M+Cl)− with a mass +2 or -2 amu different from the quantitation ion and a (M-Cl)- ion, which was used to check for contamination. If a peak in a quantitation ion trace were due to a major contaminant that contained a Cl atom, a much larger peak would appear in the (M-Cl)- trace and a correction could be made. No such corrections were necessary in this study.

The ratio of the sum of the areas under the ion chromatograms to the peak area for the internal standard was determined. A linear dynamic range was obtained for injections containing 50 to 50,000 pg of Toxaphene.

Interferences. The 3 most troublesome interferences cited by Swackhamer were: 1) technical Chlordane, 2) PCBs when oxygen is available in the source, and 3) polychlorodibenzophenyls (PCDPEs).

Swackhamer made area corrections for interfering chlordane ions. Most of the interference occurred for the m/z 342 quantitation ion. We used the m/z 311 ion instead. Over the elution windows shown above, chlordane was not a significant interference and no corrections were made for it.

Jansson and Wideqvist observed major interferences from PCBs by (M+Cl)- ions. While Swackhamer was able to eliminate the O2 necessary to create these ions in the ion source, we were not. We eliminated this interference by using a mass resolution of 10,000.

PCDPEs yield ions with the same molecular formula as the (M+Cl)- ions formed from PCBs. High mass resolution also separates the signal due to the (M-Cl)- ions of Toxaphene, e.g. C18(179)C18(127)Cl18 (376.0573), from the signal due to the (M+Cl)- ions from PCDPEs, e.g. C18(179)C18(127)Cl2 (376.0236). For this example, a resolution of 11,890 is required.

Interfering (M+Cl)- ions can be formed from tetra through octa PCB congeners. A 1:1:1 mixture of Aroclors 1242, 1254, and 1260 was added to a solution of Toxaphene to observe PCB interference. Many PCB isomers eluted within the Toxaphene quantitation windows.

Interference from PCBs as a function of mass resolution was studied over the elution windows determined from the Toxaphene standard. The ratio of the sum of the integrated Toxaphene signals to the internal standard signal (TOX/IS) was determined for triplicate GC/MS runs made with solutions containing several levels of the Aroclor mixture, 500 pg/μl of Toxaphene, and 10 pg/μl of the internal standard. Figure 1 is a histogram of the TOX/IS ratios. At resolutions of 1,000 and 5,000, greater interference occurred as the Aroclor concentration increased, while little interference was observed at resolutions of 10,000 and 15,000.

Removal of Unidentified Interferences. A local soil spiked with Toxaphene was extracted by supercritical fluid extraction (SFE) with CO2 and reconstituted into hexane. Displayed in Figure 2 are ion chromatograms for the method blank and soil extract acquired with mass resolutions of 1,000 and 10,000. Most of the interferences were eliminated at the higher resolution; much of the remaining signal might be due to a background level of Toxaphene in the soil.

Quantification of Toxaphene in a Soil. Toxaphene was added to an amber colored, methylene chloride extract of a soil that contained creosote. Deterioration in chromatographic resolution was observed, caused by other compounds in the soil extract. Only the three most abundant quantitation ions were used. A standard addition of 51 pg/μl of Toxaphene was made to this extract, which already contained 40 pg/μl. Triplicate GC/MS runs were made with a resolution of 1,000. The 51 pg/μl of added Toxaphene was underestimated by -8.2%. If a significant portion of the summed areas were due to interferences, the error would be positive. Because this was not the case, higher mass resolution would not improve quantitation of this particular soil extract.
Conclusions. High mass resolution (±10,000) can be used to remove interference with the quantitation of toxaphene by PCBs, polychlorodiphenylethers, and other compounds. Quantitation of toxaphene by standard addition without sample clean-up appears to be feasible. Further study with additional soil samples and extraction procedures is necessary to validate this conclusion. High mass resolution will be required when high levels of polychlorinated hydrocarbons that yield oxygenated ions in the source are present.

DETERMINATION OF POLAR PESTICIDES AND THEIR BREAKDOWN PRODUCTS IN WATER SAMPLES USING THERMOSPRAY LC-MS

Damià Barceló and Gaël Durand, Environmental Chemistry Dept.
CID-CSIC, c/Jordi Girona 18-26, 08034 Barcelona, Spain.

Two liquid-liquid extraction (LLE) procedures with n-hexane-dichloromethane (1) and dichloromethane-ethyl acetate (2) and a liquid-solid extraction (LSE) procedure with C18 Empore extraction disks were used for the extraction of polar pesticides from water samples. The analytical protocol used for the extraction is cited below:

1-4L of water samples (surface water and artificial sea-water) containing polar pesticides with a resulting analyte concentration of ca. 25 ng/L were used. When the LLE procedure was used the pesticides were extracted first with 40 mL of n-hexane and after with 120 mL (60 mL x 2) of dichloromethane (for organophosphorus pesticides) and with 100 mL (33 mL x 3) of dichloromethane-ethyl acetate (50:50) + 0.2M ammonium formate (for the other compounds). In the case of using LSE the water sample was prefiltered to eliminate particulate matter and subsequently it was passed through the Empore extraction disk. 4 L of water were extracted with the vacuum adjusted to yield 2h extraction time which is a clear advantage over the cartridge that requires 4-8h (3).

RESULTS AND DISCUSSION

The recoveries and relative standard deviations (RSD) using LLE and LSE are listed in Table I. LSE gave much lower recoveries than LLE for the dealkylated atrazine metabolites which is explained by the highest polarity of these compounds and consequently least sorption capacity for the C18 disks with much lower breakthrough capacity. In addition, no differences in recoveries were noted when using either surface river water, drinking water and artificial sea-water samples.

In Fig. 1 the total ion current chromatograms obtained under TSP LC-MS with PI and NI modes of operation of the same water extract are shown. Under PI the chlorotropan pesticides and carbaryl exhibited higher sensitivity whereas for the organophosphorus pesticides the NI mode of operation was preferred. An exception was fenamiphos that exhibited better sensitivity in PI than in NI. Using PI mode the \([M + H]^+\) for chlorotropanes and the \([M + NH_4]^+\) for the other compounds ions are the base peaks in the TSP mass spectra. An exception is the organophosphorus pesticide fenamiphos that as a result of its amidate group exhibits a higher proton affinity than the ammonium ion and as a consequence \([M + H]^+\) is the base peak. The \([M + CH_3NH_2CO]^+\) ion obtained for carbaryl, has been previously reported (4) as a particular ion of N-methyl carbamates under TSP LC-MS conditions. The formation of other characteristic ions, such as \([M + CH_3CN + H]^+\) and \([M + CH_3COONH_4 + H - H_2O]^+\) follows a general formula proposed in a recent paper (4). Typical negative chemical ionization mechanisms were observed for organophosphorus pesticides (5). The specific fragments obtained were: the functional group + CH_3COOH, for tetrachlorvinphos, and \([M - R]^+\) (R being methyl or ethyl) and \([M]^+\) for parathion-ethyl and fenitrothion.

CONCLUSIONS

Although extraction efficiency of LLE can be higher than LSE with Empore disks for extracting certain polar pesticide metabolites, e.g., deethylatrazine and desisopropylatrazine, from water samples, the use of LSE is preferred since: avoids emulsifications, solvent consumption and potentially hazardous solvents are reduced. As an alternative to C18 cartridges, the Empore extraction disks have demonstrated the possibility of preconcentration up to 4L of water samples with shorter elution time. TSP LC-MS with PI and NI has been shown to be useful for the characterization of polar pesticides at levels of 12-30 ng/L in water extracts. When pesticides of different chemical groups are present, with different proton affinity values and/or with electron withdrawing groups that can stabilize the negative charge, the use of PI and/or NI is required.

Introduction

Tandem mass spectrometry (MS-MS) is a powerful tool in the rapid screening and quantitation of (groups of) target compounds in complex biological matrices. For the direct introduction of biological samples via an LC-MS interface, simple and versatile on-line sample pretreatment methods are needed. In this paper, the on-line combination of MS-MS and continuous-flow membrane dialysis is described. This combination allows the direct analysis of plasma samples containing a significant amount of macromolecular interferences. The potential of this method is demonstrated with the quantitative analysis of the aromatase inhibitor pyridoglutethimide (PG) in plasma samples of patients treated with PG. PG is under investigation as a potential analogue for aminoglutethimide, which is currently used in the treatment of postmenopausal women suffering from estrogen-dependent breast carcinoma.

Experimental

Plasma (1.26 ml) was introduced in an air-segmented donor stream (0.42 ml/min water) to the dialysis membrane (cut-off 10 kDa). The acceptor stream (0.60 ml/min water) was concentrated on a short trapping column (TC, 12 mm x 2 mm ID, packed with 40-63 μm C₁₈), which was subsequently desorbed. The eluate (1.2 ml/min 50% methanol in 50 mmol/l ammonium acetate) was transferred either directly to a Finnigan MAT TSQ-70 thermospray LC-MS-MS system or via an analytical LC column (100 mm x 4.6 mm ID, packed with 5 μm C₁₈) for thermospray LC-MS analysis. The thermospray system was operated in discharge-on mode (1 kV).

Results and discussion

Dialysis / concentration

In developing a system for continuous-flow dialysis various experimental parameters have to be optimized:

* selection of the packing material for the trapping column (based on the retention characteristics of the compound).
* concurrent or countercurrent dialysis.
* selection of the mobile phase to desorb the analyte from the trapping column and transfer it to the LC-MS interface.

The dialysis was performed in the countercurrent mode, while the trapping column was desorbed in the back-flush mode. The recovery for PG was ca. 33%.
Internal standard
For the quantitative analysis of PG in post-treatment plasma samples, glutethimide (Glu) was used as an internal standard. It was added to the samples prior to the dialysis step. Multiple reaction monitoring was used in the quantitative studies, using m/z=219 → 134 for PG and m/z=218 → 131 for Glu. No mutual interferences were observed in MS-MS.

Calibration plot for PG in plasma
Linear calibration was observed over two order-of-magnitude (3-300 ng/ml PG in plasma) using Glu as internal standard.

Pharmacokinetic curve
The levels of PG in plasma samples, taken from a patient suffering from breast cancer who was administered a single dose of 800 mg of PG orally, were monitored using continuous-flow dialysis in combination with MS-MS.

Discussion
The continuous-flow dialysis approach can be easily used for the monitoring of drug levels in biological samples without prior sample pretreatment. The method is used to remove macromolecular interferences from the sample in an online mode and provides selective sample pretreatment as well as preconcentration of the sample in the trapping column. Using the continuous-flow dialysis approach in combination with thermospray sample introduction and tandem mass spectrometry the quantitation limit for the parent drug is 5 ng/ml plasma. This is adequate for the monitoring of the typical levels found in clinical studies with PG. The analysis time is ca. 14 min per sample. After set-up the system can run automatically.

Conclusion
Continuous-flow dialysis in on-line combination with mass spectrometry is an easy, rapid and versatile method for the quantitative monitoring of drug levels in biological samples. The method is useful if the presence of macromolecular compounds in the biological sample prohibits the direct introduction of the sample to MS-MS via a thermospray interface. No further sample pretreatment is necessary. The determination limits that can be achieved, are compound-dependent (thermospray ionization); the method provides online sample preconcentration.

In favourable cases, the method can also be used for monitoring the levels of the metabolites by using coupling of dialysis and MS-MS. However, when isomeric metabolites are present in the samples, as in this case, the use of on-line LC-MS or LC-MS-MS is essential.
INTRODUCTION:
Aflatoxins are toxins that are members of a large group called mycotoxins. They are produced by the fungi Aspergillus flavus and Aspergillus parasiticus and have been found in various grains throughout the world where climatic conditions are favorable for their growth. The aflatoxins, especially aflatoxin B₁, are known carcinogens in many species of animals.

In the HPLC analysis of aflatoxins using fluorescence detection, aflatoxins B₁ and G₁ fluoresce naturally in aqueous solution while aflatoxins B₂ and G₂ do not. The reaction of aflatoxins B₁ and G₁, post-column with iodine at 70°C produces a compound of complex that fluoresces with an intensity similar to the fluorescence of aflatoxins B₂ and G₂. The objective of this study was to determine whether the reaction resulted in an iodine hydrated complex or a stable iodine derivative. It has been known for some time that fluorescence of aflatoxins B₁ and G₁ can be enhanced by reacting them with iodine, however, the reaction product has not been identified.

Kok et al. (1) determined aflatoxins (B₁, B₂, G₁, G₂) using post-column derivatization (PCD) with electrophoretically generated bromine and compared the results with that obtained with PCD using iodine. They proposed that the reaction between bromine or iodine with aflatoxin B₁ and G₁ was simply the breaking of the double bond on the furan moiety of the aflatoxin molecules and adding two bromine or iodine atoms.

Thermospray mass spectrometry (TSMS) was used in our study to determine (1) whether the reaction of iodine and aflatoxins B₁ and G₁ resulted in an iodine hydrated complex or a stable derivative, and (2) to identify the complex or derivative.

EXPERIMENTAL:
Thermospray mass spectrometry was performed using a Finnigan-MAT TSQ 70 triple quadrupole mass spectrometer equipped with a Finnigan-MAT thermospray probe and controller. Typically, the vaporizer was set to 110°C and the jet (aero) was set at 220°C. All analyses were performed in the positive ion, "filament off" and "discharge off" mode. Direct injection of samples was performed using an Altex model 100 dual head reciprocating pump and a Rheodyne 7125 injector equipped with a 100μl loop. The mobile phase was 0.1M ammonium acetate in water pumped at 1.20 ml/min. Typically, 20μl solutions of the samples were injected into the TSMS system for each analysis.

Thermospray tandem mass spectrometry (TSMS/MS) was conducted using the same conditions as for TSMS except that the collision gas was argon set to about 0.5 mtorr and the collision energy was set to -50 eV. The iodine aflatoxin products were injected individually and the daughter ion spectra were obtained by setting ms1 to pass the appropriate [M+H]⁺ ion and operating ms2 in the full scan mode.

Derivatization of aflatoxins B₁ and G₁ was performed by reaction of the selected aflatoxin with saturated aqueous iodine in methanol/water (50/50) at approximately 70°C for 3 minutes.
RESULTS and DISCUSSION:
The TS mass spectra of the iodine derivatives of aflatoxins B$_1$ and G$_1$ gave surprising results. The [M+H]$^+$ ion for the iodine derivative of aflatoxin B$_1$ was at m/z 471. The [M+H]$^+$ ion for the iodine derivative of aflatoxin G$_1$ was at m/z 487. If two iodine atoms had added across the double bond on the furan ring as suggested by Kok et al. (1), the molecular weight for the aflatoxin B$_1$ derivative would have been 566. Also, if only one iodine and one hydroxy group from the mobile phase had added across the double bond of the furan ring, the molecular weight for the aflatoxin B$_1$ derivative would have been 456.

The observed [M+H]$^+$ ion at m/z 471 for the aflatoxin B$_1$ derivative can be explained by the addition of one iodine atom and a methoxy group across the double bond of the furan ring of the aflatoxin molecule (See Figure 1). More evidence is given for the proposed iodine and methoxy group attachment to aflatoxin B$_1$ by the presence of a peak at m/z 344 which can be attributed to the [M+H - I]$^+$ ion.

TSMS analysis of the aflatoxin B$_1$ derivative formed in the presence of deuterated solvents (CD$_3$OD and D$_2$O) gave more evidence of the methoxy group attachment because the [M+H]$^+$ ion observed for the aflatoxin B$_1$ deuterated derivative was at m/z 474. This increase of 3 daltons corresponds to the attachment of a CD$_3$O group as compared to the attachment of a CH$_3$O group.

TSMS/MS analysis of the [M+H]$^+$ ion at m/z 471 for the aflatoxin B$_1$ derivative provided daughter ions corresponding to losses of 128(m/z 343), 156(m/z 315), 159(m/z 312), and 188(m/z 263), which can be attributed to the [M+H - HI - CO]$^+$ ion, the [M+H - HI - CH$_3$O]$^+$ ion, and the [M+H - HI - CH$_2$H$_2$O$_2$]$^+$ ion, respectively.

The TSMS and TSMS/MS results provide strong evidence that a stable iodo-methoxy-derivative is formed when aflatoxins B$_1$ and G$_1$ are reacted with iodine.

ENERGY CONVERSION IN COLLISION-INDUCED DISSOCIATION OF POLYATOMIC IONS AT
LOW AND INTERMEDIATE COLLISION ENERGY.
Jean H. Futrell, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

An unique tandem hybrid mass spectrometer utilizing a supersonic jet molecular beam source of neutral collision
gases is providing interesting new insights into the role of internal and collision energy on the mechanisms of activation
and dissociation of model systems. The observation of superelastic scattering of aceton ion led to the discovery of a
long-lived electronically-excited state of the aceton molecular ion whose dynamics have now been completely
characterized. This system provides an interesting example of microscopic reversibility in reaction dynamics as well as
providing the key insight that translational and internal energy are strongly coupled in low energy collisions under
appropriate circumstances. Further studies in our laboratory and elsewhere on CID of molecular systems have
demonstrated that electronic excitation plays a role in CID excitation for hydrogen, methane, acetone, nitromethane and
benzene---e.g., in most of the studies to date on CID reaction dynamics. Hence it is already clear that efficient T<\rightarrow E
conversion can be an important general mechanism in collisional activation of ions at low energy.

The benzene cation is another example—like acetone and nitromethane—for which the photoelectron spectrum
is quite "coarse grained" with gaps between overlapping electronic bands in which it is quite difficult to excite and ionize
the molecule. In all three cases our CID dynamcis study demonstrates a strong dependance of CID excitation mechanism
configuration. This contrasts sharply with propane, for which overlapped bands with no gaps characterize its photoelectron
structure as a preliminary step in NO formation. We have also demonstrated the microscopic reversibility concept in reaction kinetics/dynamics by translationally pumping ground state ions into the excited state manifold as well as translationally inducing the de-excitation of this electronic state. Further analysis of details of the observed scattering contour diagrams shows that dissociation occurs from both electronically-excited and ground state potential surfaces for acetone and the relative probability of these competing processes is a strong function of collision energy.

The propane ion has now been investigated in almost as much detail. In strong contrast to acetone, it exhibits
small and regular changes in its CID dynamics as collision energy is varied. At low and intermediate energy the most
probable scattering angle and energy deposition functions both correlate linearly with the general reduced scattering angle
parameter, \( \varepsilon \). This linear behavior is no longer observed as energy increases without limit, and a "saturation" behavior is eventually observed in scattering angle. This saturation occurs at the limit where toward scattering with impulsive excitation are the characteristic excitation mechanism. For this archetypical RRKM\textit{\rightarrow}QET molecular ion we also conclude that the Massey adiabatic criterion hypothesis adequately rationalizes the energy depositions in CID at all energies. Convolution of this function with the experimentally-determined breakdown graph predicts both the product ion distribution as a function of collision energy and the average energy deposited in the molecular ion for each individual ion product.

Further analysis of details of the observed scattering contour diagrams shows that dissociation occurs from both
electronically-excited and ground state vibrational surfaces for acetone and the relative probability of these competing processes is a strong function of collision energy.

The nitromethane cation is an intriguing example of a system whose mass spectrum involves several
rearrangements into highly stable cation intermediates separated by energy barriers with several transition states which are
loosely described as ion--dipole complexes. These adiabatic pathways are not traced in the CID of this ion; rather it
appears that a diabatic pathway is followed by highly-excited ground state nitromethane ions which surmount the lowest
energy barrier, leading to NO formation. Three dynamically distinct mechanisms are followed, only one of which is in
competition with \( \text{NO}_2 \) formation on the ground state hypersurface. At and above 18 eV dissociation to NO on an
electronically-excited hypersurface (level 6) becomes the dominant mechanism. These features are all consistent with the
photoelectron spectroscopy and experimental breakdown graphs for nitromethane and methyl nitrite cations, coupled with the assumption that crossing a barrier leads to rearrangement of highly excited nitromethane ions to the methyl nitrite structure as a preliminary step in NO formation.

The benzene cation is another example---like acetone and nitromethane—-for which the photoelectron spectrum
is quite "coarse grained" with gaps between overlapping electronic bands in which it is quite difficult to excite and ionize
the molecule. In all three cases our CID dynamics study demonstrates a strong dependance of CID excitation mechanism
on collision energy, with the possibility to "switch--on" and "switch--off" a mechanism by tuning the kinetic energy of the
colliding species. These are characteristic features of "curve--crossing" mechanisms in which the probability of a transition from
one hypersurface to another is strongly dependant on curvature of the surface and the rate of passage through that
configuration. This contrasts sharply with propane, for which overlapped bands with no gaps characterize its photoelectron
structure as a preliminary step in NO formation.
spectrum. We suggest that this is the primary reason that the CID dynamics for propane are relatively featureless and quite different from the other molecules we have studied.

Our attempt to generalize these observations leads to the suggestion that CID dynamics of polyatomic ions may be generally classified in three categories, depending on the "collision time" as a primary parameter. At the low energy limit adiabatic behavior is expected and detailed features of potential hypersurfaces will be important. Here the collision partner will play a very important role and "reactive gases" will be interesting activators. In an intermediate energy regime adiabatic surface crossings will be important and the dynamics may change rather dramatically with collision energy and scattering angle and will depend strongly on the individual properties of the ion investigated. At high energy the scattering gas is of little importance (in the center-of-mass frame, the mass effect on dynamics is critically important at high laboratory energies in terms of both energy deposition and scattering angle) in that small impact parameter impulsive collisions become the dominant CID excitation mechanism. In this limit the rotational times and vibrational times are both longer than the collision time and an averaged ensemble of particles undergo essentially "billiard-ball" collisions with strong forward scattering of the detected particles.

Support of this research by the National Science Foundation, Grant No. CHE-8312069, is gratefully acknowledged.
Fragment ions decrease steadily in abundance as larger and larger molecules are ionized because, as an ion gets larger, the energy put into it gets dispersed over more degrees of freedom and is less frequently in the reaction coordinate. According to RRKM calculations (by LLG), the average lifetime of a protonated oligomer of 191 alanine-glycine units (MW = 111.7 kD) containing 2930 kJ mol⁻¹ (approximately the thermal energy at 298 K in the neutral molecule plus that added by absorption of a 193 nm photon) would be 30 years if its lowest decomposition threshold were 105 kJ mol⁻¹. Adding more energy does not seem to be a feasible way to overcome the degrees of freedom effect. Therefore mass spectroscopists should turn to chemical reactions with ionized macromolecules to obtain characteristic fragments; i.e., gas phase analogs of the Edman degradation of peptides are needed.

Endothermic ion-molecule reactions can provide sequence information from protonated peptides [1]. This is a promising start in developing an ion-molecule chemistry for structural determination of biological macromolecules. Such reactions will take place through complexes between the ions and reagent neutrals. Thus understanding complex-mediated reactions is a prerequisite to using ion-molecule reactions to characterize macromolecules.

Extensive studies over the past decade on unimolecular complex-mediated reactions reveal much about their characteristics [2]. The following equation [3] indicates the factors that determine complex stability, and hence the importance of reactions mediated by a particular complex.

\[ \omega(\mathbf{r}) = -\mu q \cos(\theta)/r^2 - q^2/2\alpha + L^2/2ur^2 \]

\( \mu \) is the dipole moment of the neutral, \( q \) is the charge on the ion, \( \theta \) is the average angle between the dipole moment and the line of centers of the collision, \( r \) is the distance between the partners, \( \alpha \) is the polarizability of the neutral, \( L \) is the orbital angular momentum of the partners, and \( \mu \) is the reduced mass of the partners. According to this expression, the stability of the complex will increase with increases in the dipole moment and polarizability, and decrease with the effective distance between the center of charge and the neutral.

The polarizability of neutrals increases with size, suggesting that complex-mediated reactions will become more important with increasing size of the neutral, all else being equal. This is supported by the effect of increasing the size of alkyl radicals on complex-mediated alkane eliminations from ionized ethers [4].

The metastable decompositions for R'H elimination from a series of ionized ethyl 2-alkyl ethers increase in importance as R' is made larger. Photoionization ionization efficiency (PIE) curves demonstrate a parallel increase in the energy range of R'H elimination [4]. Thus complex-mediated reaction increase in importance with increasing polarizability of the neutral partner.

Increasing the size of the ion in the complex should increase the average distance between the center of charge and the neutral. Consistent with this, increasing the size of R in the ionized ethers decreases the abundance of metastable alkane eliminations [4]. PIE curves demonstrate that R'H elimination diminishes relative to loss of R as R is lengthened.
Changing the location of the complex-forming bond cleavage in isomeric ions will change r and therefore the importance of complex-mediated fragmentation. To explore this, we determined that ratio $\frac{r}{c}$ in the metastable decompositions of a series of ethyl branched $C_{n}H_{2n}$ isomers. The ratio was 0.31 when the ethyl was cleaved from the 2-position and 5.3 when the ethyl was cleaved from the middle (5) position. This difference could be due to a substantial difference between the center of mass and center of charge in the complex when ethyl is cleaved from near the end, and the approximate coincidence of these centers when bond cleavage occurs near the middle of the system. In the first case more then in the second, rotation of the partners will tend to move the ethyl away from the hydrogen it abstracts upon ethane elimination.

The dipole moment of the neutral should strongly influence complex-mediated dissociations (Eq 1). To test this, we characterized the dissociations of ionized 2-methylpropanol.

\[
\begin{align*}
\text{CH}_3\text{CHCH}_2\text{OH}^+ & \rightarrow \text{CH}_3\text{CHCH}_3^+ + \text{CH}_2\text{OH}^+ \\
\left[\text{CH}_3\text{CHCH}_2\text{OH}^+\right] & \rightarrow \text{CH}_3\text{CHCH}_2^+ + \text{CH}_3\text{OH} \\
\left[\text{CH}_2\text{HC} = \text{CH}_2^+\right] & \rightarrow \text{CH}_2\text{CHCH}_2^+ + \text{CH}_3\text{OH}^+
\end{align*}
\]

The complex-mediated products $\text{CH}_3\text{CHCH}_3^+$ and $\text{CH}_3\text{CHOH}^+$ are about 50% as abundant at 70 eV electron energy as the most abundant ion $C_{n}H_{2n}$. PIE curves reveal that these complex-mediated dissociations are strongly competitive with simple dissociations up to at least 190 kJ mol$^{-1}$ above threshold. In marked contrast, eliminations through ion-nonpolar neutral complexes are important only very close to the threshold for simple dissociation [4]. Thus a substantial dipole moment in the neutral partner appears to strongly enhance complex-mediated reactions.

Our work suggests that polar neutrals should be selected to get reactions between small molecules and large ions. Complex-mediated reactions tend to be confined to narrow energy ranges, so relative translational energies need to be selected with this in mind. Another problem may be that proton transfer reactions can sometimes occur to the exclusion of bond-forming reactions in ion-molecule reactions [5].

ENDOTHERMIC ION-MOLECULE REACTIONS:
FROM PROTON AFFINITIES TO PEPTIDE SEQUENCING

Robert J. Cotter
Middle Atlantic Mass Spectrometry Laboratory

Baltimore, MD 21205

R. Orlando and C. Fenselau
Structural Biochemistry Center, Department of Chemistry
University of Maryland Baltimore County
Baltimore, MD 21228

Charge-exchange reactions were among the earliest applications of the tandem mass spectrometer constructed by Lindholm in 1954 (1). In this instrument, low primary beam energies were produced by a focusing, deceleration lens system, the incoming beam, in order to select for those ions not carrying appreciable forward momentum. A similar configuration was constructed some years later by Weiner, et al. (2), and was used by one of us (RJC) for the study of endothermic ion molecule reactions: D₃O⁺ (D₂⁺ OD) D⁺ and D₃O⁺ (D₂⁺ D₂O) D⁺ involving proton transfers via a long-lived collision complex (3,4).

Phase space theory, introduced by J.C. Light (5) in 1965, suggested that product ion yields decreased at higher beam energies as additional dissociation channels of the collision complex are opened up. This led to our consideration of the possibility that fragment ions from peptides might be formed as alternate dissociation channels from a collision complex formed during an endothermic proton transfer reaction between the protonated peptide and a less basic target gas. In our earliest studies (6), protonated leucine enkephalin (MW 555) was reacted with ammonia. Proton transfer and formation of the collision complex were observed at beam energies above 6 eV (Figure 1a), while sequence ions were observed at slightly higher energies (Figure 1b). We observed a similar threshold for a cyclic, hydrophobic peptide, suggesting that the endothermicity could be estimated assuming transfer of a proton located on the amide bond to ammonia (7). Conversely, peptides containing basic residues (histidine, lysine or arginine) did not react with ammonia to produce either proton transfer or dissociation
prior to the onset of direct collision induced dissociation (CID), since such reactions would be more endothermic (7). The assumption that the endothermicity corresponds to transfer of a proton from the amide bond was further tested by subsequent reaction induced dissociation (RID) studies of N-acetylated glucosamine oligosaccharides (8).

In our current studies, we have carried out RID reactions between peptides containing the basic residues histidine and lysine with dimethylamine. In Figure 2a, low beam energy collisions between angiotensin (which contains the histidine residue) and ammonia results only in the slowly rising fragmentation expected from direct CID processes. In Figure 2b, the reaction between angiotensin and dimethylamine produces additional, abundant fragmentation due to reaction induced dissociation, whose onset corresponds closely to the predicted threshold for the proton transfer reaction. Similar results were obtained from the reaction between Leu-Trp-Met-Arg-Phe-Ala and trimethylamine.

Reaction induced dissociation, utilizing endothermic ion-molecule reactions, provides an alternative method for inducing fragmentation at very low beam energies. In future studies, we expect to extend this method to larger peptides and other biomolecules.

CID OF CLUSTER IONS: WHICH RESULT SHOULD ONE BELIEVE?

Alex. G. Harrison and Xiaoping Li
Department of Chemistry
University of Toronto
Toronto, Canada M5S 1A1

In 1980 Maquestiau et al.[1] reported that the adduct ion formed between the ammonium ion and ketones under ammonia CI conditions fragmented, after high energy collisional activation, by loss of neutrals of 17 (NH\textsubscript{3}) and 18 (\?) amu. They suggested that the neutral of 18 amu was water. Since the proton affinity of ammonia is greater than that of ketones a simple proton-bound cluster ion 1 would be expected to give NH\textsubscript{4}\textsuperscript{*} and they concluded that the ammonium ion had added to the carbonyl to give the carbinolamine 2.

\[ R_1\text{C}=O--H'--NH_2 \quad \text{and} \quad R_2\text{C}=O--NH_3 \]

They further concluded that the higher cluster containing two ammonia molecules was a protonated carbinolamine solvated by ammonia.

Figure 1 records high energy CID mass spectra for the (CH\textsubscript{3})\textsubscript{2}CO.NH\textsubscript{4}\textsuperscript{*}, (CD\textsubscript{3})\textsubscript{2}CO.NH\textsubscript{4}\textsuperscript{*} and (CH\textsubscript{3})\textsubscript{2}CO.ND\textsubscript{4}\textsuperscript{*} adducts. The major fragmentation of the unlabelled adduct ion is by loss of neutrals of 17 and 18 amu as reported by Maquestiau. The middle spectrum shows that all hydrogens lost with these neutrals come from the ammonium ion. The formation of m/z 58 in the bottom spectrum indicates considerable loss of ND\textsubscript{4} (or ND\textsubscript{3} + D) and shows that much of the loss of 18 amu in the unlabelled case must correspond to loss of NH\textsubscript{4} or NH\textsubscript{3} + H, rather than water as suggested earlier. MS/MS/MS experiments indicate that the m/z 58 in the unlabelled case is the acetone molecular ion.

Figure 2 compares the 8 keV and 50 eV CID mass spectra of (C\textsubscript{2}H\textsubscript{5})\textsubscript{2}CO.NH\textsubscript{4}\textsuperscript{*} adduct. In the high energy CID mass spectrum there is little formation of NH\textsubscript{4}\textsuperscript{*}, rather fragmentation occurs by loss of NH\textsubscript{3} and loss of NH\textsubscript{4} (NH\textsubscript{3} + H). By contrast, in the low energy CID mass spectrum NH\textsubscript{4}\textsuperscript{*} is the only significant product observed. Figure 3 shows the 8 keV CID mass spectra of the adducts of diethyl ketone with protonated methyl, dimethyl and trimethyl amines. Note that no loss of H\textsubscript{2}O is observed but rather loss of amine and amine plus H. In all three cases the low energy (50 eV) CID mass spectra showed only formation of the protonated amine. With increasing methyl substitution of the amine the loss of amine decreases in importance in the high energy CID spectra and formation of the protonated amine increases in importance, with the result that the low and high energy CID mass spectra are in agreement for the adduct with trimethyl amine.

The question arises as to how these differences between the high and low energy CID spectra originate and which spectrum one should believe when assessing structures. We believe that the results presented above as well as results for higher clusters can best be rationalized by assuming in all cases that a simple proton-bound cluster ion is formed. On low energy collisional activation, where vibrational excitation occurs, fragmentation proceeds as...
expected with the proton being found with the species of higher proton affinity. We propose that in the high energy CID electronic excitation of the ketone occurs and that fragmentation occurs before this electronic excitation is dissipated. It is known from solution studies that the electronically excited ketone has a greater proton affinity than the ground state ketone [2]. Thus it is able to compete more effectively with the amine for the proton, but loses out in this competition as we increase the methyl substitution of the amine and thus its proton affinity.

A full account of this work has been submitted to J. Am. Chem. Soc.

As part of our recent efforts to develop and apply quadrupole ion trap techniques to multiply charged ions derived from electrospray (1-3) we have embarked on a study of the ion/molecule reaction chemistry of multiply charged ions (4,5). To date, these studies have been restricted primarily to gas-phase Bronsted acid-base reactions and, within this class, to reactions of multiply protonated molecules with small gaseous bases. We have, however, studied a limited number of reactions involving proton transfer from gaseous acids to multiply charged anions. The goals of this effort are to understand fundamental aspects underlying the phenomenology of these reactions and to identify, maximize, and exploit the information that they can provide.

All experiments were carried out with a Finnigan-MAT ion trap mass spectrometer modified to allow ions formed by electrospray to be injected into the ion trap (1). The procedures necessary to form, inject, and analyze multiply charged ions have been described (1-3). For ion/molecule reaction studies a gas-phase base is admitted into the vacuum system to a pressure of roughly 1 x 10\(^{-7}\) torr. At this pressure, a mass spectrum can be obtained with minimal effect of the base provided the time between ion injection and mass analysis does not exceed roughly 50 ms. However, with delay times on the order of a few hundred ms reactions with rate constants on the order of 10\(^{-9}\) cm\(^3\)-molecule\(^{-1}\) cm\(^{-1}\) can proceed largely to completion. Gas-phase bases used to date include in order of increasing basicity: ammonia, dimethylamine, 1,6-hexanediamine, and N,N,N',N'-tetramethyl-1,8-naphthalenediamine.

All of the results observed thus far can be rationalized as involving the formation of a proton-bound complex. The fate of the complex determines whether or proton transfer takes place, adduct formation occurs, or no net reaction is observed. Reactivity can be understood qualitatively with reference to the energy diagrams of Figure 1 which show the combined energy of the reactants approaching from the left (entrance channel) and the products exiting to the right. The potential well in the center corresponds to the proton-bound dimer ion. Note that the reactants approach over an attractive surface (ion-induced dipole attraction) whereas the products experience a repulsive field due to charge separation. The exit channel therefore has a significant reverse critical energy, unlike proton transfer reactions of singly charged ions. Since there is a significant reverse critical energy in one of the channels, the occurrence or non-occurrence of proton transfer is not determined by thermodynamics but by the relative critical energies for the break-up of the cluster. In the top example of Figure 1 rapid proton transfer is expected because the reactants enter with energy well in excess of the critical energy for proton transfer. In the bottom example no reaction is expected because the reactants cannot, without some kinetic excitation, overcome the barrier to proton transfer. The intermediate case, where critical energies for cluster break-up are nearly equal, there are many degrees of freedom, and there is a deep well, is most conducive for clustering. The lifetime of the complex is maximized under these conditions thereby maximizing the likelihood for collisional stabilization of the cluster. An example of a clustering reaction is given in Figure 2 which shows the electrospray mass spectrum of bovine insulin in the absence of a gas-phase base (Figure 2a) and after the ions are allowed to react with 1,6-hexanediamine (Figure 2b).

In many ways these reactions are similar to reactions of small singly charged ions. However, major differences include the unusual shape of the energy hypersurface due to the coulombic field and the unusually high number of degrees of freedom of the ions. The shape of the energy hypersurface over which the reactions proceed is determined by the strength of the base, the intrinsic strengths of the protonated sites of the ion, the degree to which protons are multiply bound within the ion, and the relative locations of the charges. The latter factor, which determines the contribution of coulombic repulsion to the energy hypersurface, is expected to be particularly important as the charge state increases and this is consistent with observation.
In addition to their intrinsic appeal, these reactions have several useful applications. For example, we have demonstrated that charge can be concentrated into a few charge states via proton transfer reactions to increase signal/noise, we have demonstrated the use of proton transfer and clustering reactions for product ion charge state determination following collision-induced dissociation (5), and, in some cases, we have been able to determine the most likely sites of protonation in multiply charged peptides and proteins from the relative reactivities of the various charge states and those of product ions. It seems likely that as our quantitative understanding of these reactions grows, further practical applications may become available.

A COMPARISON OF NANOSCALE CAPILLARY LC AND CZE IN COMBINATION WITH FAB AND ESI

Kenneth B. Tomer, Leesa J. Deterding, Carol Parker, John Perkins

Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC 27709

With the increased emphasis in mass spectrometry on achieving lower detection limits and the need for analyzing increasingly smaller amounts of sample, usually as complex mixtures, suitable separation techniques must be devised for handling low levels of analytes in conjunction with mass spectrometric detection. We have been developing and applying two such methods which can be described as nanoscale separation techniques because of the low flow rates involved, i.e., nanoliters per minute. These are nanoscale capillary liquid chromatography (nCLC), with column ids of 50 to 75 μ packed with 5 or 10 μ particles, and capillary zone electrophoresis (CZE). Both separation techniques are characterized by high separation efficiencies and, in conjunction with mass spectrometry, high sensitivities. We have interfaced both of these separation techniques with continuous flow fast atom bombardment (CF-FAB) (using a coaxial interface) (1,2) on a VG ZAB 4F tandem mass spectrometer and with electrospray ionization (ESI) mass spectrometry on a VG 12-250 quadrupole mass spectrometer using a Vestec electrospray source.

A mixture of five peptides (Lys'bradykinin, Leu-enkephalin, proctolin, FLEEI, and MLF) was used to compare the various combinations of the four techniques. Fig. 1 a & b shows the separations obtained using nCLC (2 m x 75 μ id column packed to a depth of 25 cm with 10 μ particles) and CZE interfaced with coaxial CF-FAB. Fig 2 shows the same separations with ESI/MS detection. The table gives approximate detection limits for these compounds under the four conditions.

Several points can be gleaned from these data. A major point is that detection limits for the lower molecular weight peptides by CF-FAB on a magnetic sector instrument are better than for ESI analyses on a quadrupole. Given the better sensitivity of magnetic sectors over quadrupoles, this is not unexpected. Another point is that detection limits by CZE are approximately 40 times lower than are the detection limits obtained using nCLC (with the identical ionization technique). This is due to the higher separation efficiency inherent in CZE which leads to a greater flux of analyte per unit time. The downside of this increased efficiency and, thus, narrower peaks, is that, near the detection limits, the peaks are so narrow that magnet scans over a wide mass range are impractical. Thus, lys-bradykinin was out of the scan range used for the CZE experiments on the magnetic sector instrument. The third significant point is that the migration order is different for nCLC and CZE, because separation is based on different molecular characteristics in the two techniques. Thus nCLC and CZE represent two complementary separation techniques rather than competitive techniques.

We have recently shown that coaxial CF-FAB is a very useful technique for the analysis of biomolecules (1). Due to the ability of the nanoscale capillary LC system to deliver a high concentration of analyte in a short period of time, this coaxial CF-FAB design allows for increased sensitivities over other CF-FAB interfaces. Detection limits of 500 attomoles in the multichannel acquisition mode and 1.8 femtomoles in the scanning acquisition mode have been obtained for a tripeptide. These detection levels are comparable to levels of some biochemicals in the body. This sensitivity, therefore, has prompted us to investigate the coupling of microdialysis with coaxial continuous flow FAB. Caprioll et al. first coupled microdialysis with CF-FAB for the analysis of drug levels in blood (2). We have recently coupled microdialysis with coaxial continuous flow FAB and tandem mass spectrometry (3). The combination of these techniques allows for the possibility of determination in real time of many biochemicals in the body.

The present investigation involves the determination of the half-life of a tris organophosphate, tris (2-chloroethyl) phosphate (TRCP), in rats. Several of these tris organophosphates have been widely used in plastics and synthetic fibers as flame retardants and are suspected carcinogens. The perfusion liquid is pumped at a flow rate of 0.8 μL/min through the dialysis probe. The perfusion liquid is contained in a stainless steel reservoir under helium pressure. The flow rate through the dialysis probe can be varied by varying the helium pressure. A sample loop of 1.1 μL is used to collect the perfusate. Injections are then made using a Valco injection valve and by using a static-split injection as previously described. Using this injection system (Figure 1), injections can be made at 2 minute intervals. The microdialysis probe was inserted inside a cannula surgically placed in the jugular vein of a 200-g male rat. In our initial in vivo microdialysis/MS experiments, TRCP was observed, however, background interferences from the FAB matrix occurred. To remove the background interferences, we integrated tandem mass spectrometry (MS/MS) into the protocol. In the MS/MS experiments, MS-I was set to pass only the protonated molecular ion of TRCP. This ion was forced to fragment by collisional activation and the most prominent fragment ion was monitored by MS-II to determine the level of the TRCP in the blood of the rat. After injecting 33 pm of the standard TRCP, the animal was connected to the injection system and was given a one-time dose of 20 mg/kg of TRCP injected into the femoral artery. The fragment ion of m/z 223 of TRCP was monitored for 60 minutes. The resulting chromatogram trace is shown in Figure 2. Traditional pharmacokinetic studies were also performed on rats using 14C-TRCP where blood samples were drawn and analyzed by HPLC. Both the mass spectrometric analyses and the HPLC analyses demonstrate that the pharmacokinetics of the TRCP follow a two compartment model in the rats (Figure 3A and 3B, respectively). Two half-lives, therefore, exist for the TRCP in the blood of rats, an alpha half-life due to distribution and elimination in the body and a beta half-life due to elimination only in the body. The alpha half-life determined by the mass spectrometric analyses is 2.9 minutes in comparison to 2.0 minutes as determined by HPLC. The beta half-life from the mass spectrometric analyses is 23.1 minutes, while that for the HPLC analyses is 32.7 minutes. A T-test of these results reveal no statistical difference between the results from the mass spectrometry analyses and the HPLC analyses.

DNA-Adduct Analysis by CZE-FAB/MS

Curt Norwood, Susan Wolf, Eugene Jackim, and Paul Vouros

US EPA ERLN 27 Tarzwell Drive, Narragansett, RI 02882

Department of Chemistry, Northeastern University, Boston, MA 02115

A DNA adduct results when a chemical molecule covalently bonds to a purine or pyrimidine base of DNA. Such adducts can sometimes be removed by DNA repair mechanisms; however, analysis of existing DNA adducts provides information about both adduct persistence and the extent of exposure to genotoxic chemicals. DNA adducts can cause irreversible cellular changes that may lead to many different diseases. In some specific tissues and/or organisms, carcinogenesis may result. DNA adducts are important as Bioarkers; i.e. indicators of cellular damage that provide additional information about the future viability of a chosen tissue or organism. Thus DNA adducts may have an important role in Risk Assessment.

This preliminary research will show that a combination of Capillary Zone Electrophoresis (CZE) with flow Fast Atom Bombardment MS (FAB/MS) provides an important new mode of analysis of DNA adducts. The current post-labeling methodology is able to detect extremely low levels of adducts, but isn’t capable of providing the high degree of identification produced by MS.

The CZE (Model 3400, Applied Analytical Technology) was equipped with a 60cm, 75µm i.d. uncoated fused silica column (Polymicro Technologies) and a buffer of 0.1M pH9.6 Ammonium Acetate (Sodium [Bi]carbonate for UV analyses). The 10000V (10µA) operating voltage produced a 0.4µl/min electroosmotic flow directed toward the tail (cathode), and in less than 15 minutes resulted in excellent separations of unadducted deoxy-nucleosides and nucleotides. This performance was monitored by UV absorption with a variable wavelength UV detector (Linear Model 200) located 5cm from the tail of the column. Unadducted nucleosides eluted between 6.3 and 8 minutes, while the more negatively charged nucleotides eluted between 11 and 13 minutes. The UV detector was used both to develop CZE conditions and to establish the performance of the interface. In addition, since injections of as little as 5pg of adduct can be detected, the UV system can operated to screen samples for later confirmation by MS. Routinely, manual siphon injections are made with a height differential of 3cm for 10 seconds.

In Figure 2, the elution of both deoxy-nucleoside and nucleotide Guanine-Benz(a)pyrene adducts (Guanine is modified at the N2 position) is shown by UV absorption at 279nm. In each case the more massive adducts are less able to oppose the electroosmotic flow and thus elute earlier than would their unadducted counterparts. Note that in addition to the primary adducts, additional, as yet unidentified, nucleoside adducts elute in the intermediate region.
Both positive ion and negative ion full scan (100-600 daltons) spectra were obtained for as little as 7.5 ng of an acetylaminofluorene-guanine (AAF-G) adduct (guanine is modified at the C8 position). For a representative 15 ng positive ion analysis, Figure 3 shows an extracted ion current profile of mass 373, which corresponds to loss of the sugar from the molecular ion. The 35 second wide peak enabled the collection of 6 good scans (4.3 sec/scan) during the elution of the AAF-G. The corresponding averaged and background subtracted spectrum is shown in Figure 4. Note that the [M+H]$^+$ ion is relatively weak. The m/z 330 ion represents the loss of the acetyl group from the 373 ion, while m/z 224 represents the protonated acetylamino-fluorene. The analogous negative ion spectrum (not shown) gives complementary information, since the [M-H]$^-$ ion is the base peak, and a m/z 205 ion provides information about the C8 linkage position.

Single reaction monitoring was used to monitor the positive ion transition from the [M+H]$^+$ 489 ion to the 373 ion. Replicate injections gave reasonable reproducibility at 75 pg.

Real world application of these techniques necessitates the ability to remove from the sample almost all the unadducted nucleosides/nucleotides, since they would be present at levels of $10^6$ to $10^{10}$ times those of the adducts, and would prohibit the necessary volume reduction steps currently employed. Thus samples contaminated with a very small amount of adduct were first filtered with a BioRad SM2 membrane which retained only the adducts. Collection of the adducts with a 50% methanol rinse, and subsequent volume reduction, resulted in samples that could be analyzed. UV traces at 279 nm and 344 nm have shown the capability to recover and detect adducts present at less than 1 in $10^9$ normal nucleotides from 10 mg of DNA.
A LIQUID MATRIX PLAYS A SIGNIFICANT ROLE ON THE NATURE OF FAB SPECTRUM

Chhabil Dass
University of Tennessee, Department of Neurology, Memphis, Tennessee 38163

A liquid matrix plays a critical role in FAB-MS analysis. A number of matrices are in current use.\(^1\) Bombardment of a sample/matrix mixture by a high energy fast atom beam results in sputtering of the preformed ions in the form of protonated or deprotonated molecules. Production of radical cations have also been reported.\(^2\) A liquid matrix helps in maintaining a persistent emission of those solute molecular ions. Essential characteristics of a FAB matrix are high viscosity, nonvolatility, chemical inertness, and good solvency. Acid/base and oxidizing/reducing nature of the matrix, surfactancy of the solute relative to the matrix, and solute-solvent interaction all have profound effect on the nature of FAB mass spectrum.

In this study, we have investigated the influence of several liquid matrices on the nature of FAB spectrum of peptides and anthracycline antibiotics. The role of a matrix in promoting cleavage of the sulfate ester bond is also discussed. The matrices studied include glycerol, thiglycerol, dithiothreitol (DTT), 3-nitrobenzyl alcohol (NBA), and sulfolane. Experiments were conducted by using a VG 70 E-HF double-focusing mass spectrometer outfitted with an Ion Tech B11NF saddle-field FAB gun and DEC PDP 11/24-based VG 11-250 M+ data system.

It was reported earlier that the C-terminally-extended enkephalin undergo extensive fragmentation to produce mainly the Z'-type C-terminus ions when desorbed from glycerol matrix.\(^3\) On the other hand, CAD of the FAB-desorbed MH\(^+\) ions of those peptides resulted in cleavage of the peptide amide bond to yield Y'-type C-terminus sequence ions.\(^4\) The Z-type ions were of low abundance. This contrasting behavior clearly suggests the role of a liquid matrix in directing fragmentation of the peptide backbone. Indeed, a detailed investigation of the FAB mass spectrum of two octapeptides methionine enkephalin (Met-enk)-Arg-Gly-Leu and Dynorphin-1\(_4\) (Table 1) obtained using the above matrices demonstrates that a liquid matrix has a profound influence on FAB mass spectrum. Compared to other matrices, the use of glycerol resulted in extensive fragmentation of those peptides. Also, the type of sequence ions formed using glycerol differed from other matrices; the Z'-type ions being the dominant C-terminus ions in glycerol, whereas, the Y'-type ions dominated in the spectra obtained using the other above-mentioned matrices.

The sulfate ester bond in sulfated-leucine enkephalin (LES) is the most labile as attested by the preponderance of the loss of neutral SO\(_3\) (80 u) from the FAB-desorbed MH\(^+\) ion to yield m/z 556.\(^5\) The extent of this reaction varies with the matrix used. The (MH-80)/MH\(^+\) in glycerol, thiglycerol, DTT, NBA, and sulfolane is 2.2, 6.0, 6.2, 1.3 and 9.3, respectively. Likewise, it was noted that N-trifluoroacetamide-

All of the above observations suggest that the MH\(^+\) ions of peptides are formed with different internal energies in different matrices. An explanation consistent with these results is that MH\(^+\) ion is desorbed from the matrix as an ion-dipole cluster. Evaporation of the solvent results in vibrational cooling. The internal energy of the nude MH\(^+\), thus formed, depends upon the number of the matrix molecules associated with the initially-desorbed cluster and the Ion-dipole bond strength. Further support in favor of this explanation is the fact that the (MH-80)/MH\(^+\) of LES increases with the increase in the solute:solvent mole ratio (Figure 1). Furthermore, the fragment ion yield, as noted for Met-enk (Figure 2), increases with the scan number (in other words on the FAB irradiation time). With time, evaporation of the solvent on the probe increases the solute:solvent mole ratio.

The dominance of Z'-type C-terminus ions in the FAB spectra of the C-terminally-extended enkephalin when glycerol is used as the FAB matrix is intriguing. It was observed by us that the initially-formed ion-dipole complex of those peptides with glycerol undergoes further losses of H\(_2\)O, CH\(_3\)OH, and CH\(_2\)O to yield (MH+12)\(^+\) ion.\(^6\) It is our belief that that reaction promotes cleavage of the amino-alkyl bond to form the Z' ions. The experimental proof of this statement is the fact that FAB of Met-enk, which has poor facility for the (MH+12)\(^+\) ion formation, in glycerol yields both Y' and Z'-type sequence ions with equal ease, the Y' ions being more abundant (Table 3). In contrast, Met-enk-amide exhibits preponderance of Z' ions (Table 3), consistent with its higher propensity to undergo the (MH+12)\(^+\) ion formation. Furthermore, addition of 1 uL of 1% TFA to the Met-enk/glycerol and Met-enk-amide/glycerol mixtures results in lower abundance of Z' ions, whereas formation of the Y' ions is promoted (Table 3). This observation is parallel with the fact that addition of an acid drastically reduces formation of the (MH+12)\(^+\) ion in Met-enk-amide.

909
In summary, vibrational cooling of the ion-dipole clusters occurs by evaporation of the solvent molecules. Thus, the ejected ions are formed with different internal energies, which depend upon the number of associated solvent molecules and the strength of the solvent-solute bond. Thus, the use of different matrices produces sample ions of different internal energies, with the consequence that the spectrum obtained differs from matrix to matrix.

The transparency of the lens depends on the highly structured aggregation and packing of the structural lens proteins, called crystallins. It is believed that posttranslational modifications of the lens proteins interfere with normal close packing and lead to cataracts. Bovine lens proteins comprise α, βH, βL and γ-crystallins, which can be separated by gel filtration chromatography. After further separation by reversed phase HPLC, the homogeneity of the β-crystallins was determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and electrospray ionization mass spectrometry (ESIMS). Both methods showed that mixtures of proteins, and possibly different aggregates or degradation products, were still present after HPLC separation. While SDS-PAGE and ESIMS gave qualitatively similar results in terms of the number and molecular weight range of the components present in the β-crystallins, ESIMS gave more accurate molecular weights. For βB2, the major component of β crystallins which elutes from both βH and βL as the first HPLC peak, ESIMS gave a molecular weight of 23,215, which is only 6 Da greater than the value calculated from the cDNA determined sequence. Comparison of the ESIMS molecular weight for other β crystallins with the molecular weights expected for the gene products indicated that many modifications were present in the 2 year old bovine lens.

The primary sequence of βB2 was studied after digestion by trypsin by both conventional and continuous-flow FABMS. The continuous-flow system used (Fig. 1) consists of a gradient HPLC pump system, 2 sample injectors, a 1 mm ID microbore reversed phase HPLC column coupled to a CF-FAB probe via a fused silica capillary. The first injector was used to inject the whole peptide mixture formed from the enzymatic digestion of βB2. The second injector was used for direct injection of peptides previously separated by reversed phase HPLC or for the injection of a standard peptide to tune and check the calibration of the mass spectrometer. Post-column splitting from 50 μL/min to approximately 3 μL/min as the effluent enters the mass spectrometer was used.

Five nmoles of a tryptic digest of βB2 was injected and analyzed by continuous-flow (CF) FABMS. A gradient of 0-60% acetonitrile in water with 5% of glycerol, 3% of thioglycerol and 0.1% TFA over 30 minutes was used. Fig. 2 shows the selected ion chromatogram for the analysis. Several masses corresponding to peptides from βB2 are displayed. The spectrum of one scan of the analysis, scan 18, shows the presence of many peptides in a single scan (Fig. 3). The low chemical background of the CF-FABMS analysis makes detection of weak signals possible with less suppression from other species present. The peptides detected in this scan correspond to residues 108-111 (m/z 509), 68-75 (m/z 983), 90-100 (m/z 1216), 89-100 (m/z 1372) and 172-187 (m/z 1687) of βB2. Continuous-flow FABMS, supplemented by conventional FABMS, detected all but one of the peptides expected from a tryptic digest of βB2. The acetylated N-terminus was also confirmed. These results suggest that the proposed sequence for βB2 is probably correct.

Continuous-flow FABMS proved to be faster and gave better quality spectra than conventional FABMS for the analysis of lens crystallins. Excluding the HPLC separation and drying of each peptide fraction collected, conventional FABMS analysis of the βB2 digest took six hours. CF-FABMS analysis after an initial HPLC desalting step was completed in about 30 minutes. CF-FABMS gave better detection of very hydrophilic peptides which were difficult to detect by conventional FABMS. Continuous-flow FABMS will be a useful method for studying structures and identifying posttranslational modifications of lens proteins which may be involved in cataractogenesis.
Figure 1: Continuous-flow FABMS system used for analysis of a tryptic digest of PB2.

Figure 2: Selected ion chromatogram of some of the peptides expected to be found in a tryptic digest of PB2.

Figure 3: Mass spectrum of scan 18 of the continuous-flow FABMS analysis of PB2 tryptic peptides showing the presence of several peptides. The peak at m/z 509 corresponds to residues 108-111, m/z 983 is 68-75, m/z 1216 is from 90-100, m/z 1372 is 89-100, and the peak at m/z 1687 is residues 172-187. CF-FABMS allowed the detection of several peptides simultaneously so that optimum chromatographic resolution was not required.
CONTINUOUS FLOW-FAB MASS SPECTROMETRY OF HIGH MASS PEPTIDES

G. D. Roberts, W. P. Johnson, M. E. Hemling and S. A. Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

Previously we reported the successful implementation of on-line continuous flow fast atom bombardment mass spectrometry (CF-FABMS) on our VG ZAB-SE 4F double focusing tandem mass spectrometer and described a number of its features in detail (1). One disturbing conclusion of this study was that the response by CF-FABMS for relatively large (M_r > 3000) peptides was significantly lower than could be obtained by standard probe FABMS in an optimized matrix. This trend was counter to what we expected based on the relative response of smaller peptides (M_r < 2000) in CF-FABMS vs. standard probe FABMS.

In order to gain a more thorough understanding of this phenomena and to improve CF-FABMS sensitivity at higher masses, a systematic study of four large peptides (C-peptide, [Tyr]-C-peptide, glucagon and Insulin B chain, oxidized) using different matrices (glycerol and thioglycerol) and probe tip geometries (domed tip vs. a domed tip with a flattened area ca. 1 mm in diameter centered on the fluid exit) has been conducted. Under static conditions the peptides responded similarly using the flattened domed tip vs. the standard flat ribbon tip; under these same conditions the original domed tip gave much poorer sensitivity. Under flow injection conditions thioglycerol gave a better response than glycerol by factors of 7 to 9, while the flattened domed tip gave ca. a factor of four improvement relative to the domed tip. Thus, an overall improvement of 30 to 35 fold in sensitivity thioglycerol gave a better response than glycerol by factors of 7 to 9, while the flattened domed tip gave ca. a factor of four improvement relative to the domed tip. Thus, an overall improvement of 30 to 35 fold in sensitivity.

To check the reproducibility of these results a second study was conducted in a similar manner. This study included the four high mass peptides used earlier as well as two low mass peptides, Ac-RGVGGLGLGK-NH_2 (Pierce S4, M 903) and des-Arg-bradykinin (M 954). We again found that thioglycerol was superior to glycerol as the matrix for flow FABMS of the high mass peptides, this time by factors of about 2 to 8 (Fig. 2). As for the lower mass peptides, des-Arg-bradykinin responds best in glycerol and Pierce S4 in thioglycerol with the flattened domed tip. Most importantly, the response for each of the high mass peptides by standard FABMS in an optimized matrix is from 15 to 100 greater than the highest response obtained by CF-FABMS. Also as noted previously the difference in the response of the low mass peptides between CF-FABMS and standard FABMS is much less than for the high mass peptides (Fig. 3). Probe geometry may be less important than originally determined, since in this second set of experiments the response of the high mass peptides with each probe tip is very similar. (Fig. 1).

The variability in the results (particularly those involving probe geometry) indicates that other factors must be controlled when conducting CF-FABMS. An examination of the system used to conduct the later study indicated that one obvious difference was the probe position in the source. During the earlier study the probe was in a more forward position, extending several millimeters beyond the front of the source block. This position was chosen because it had resulted in the greatest sensitivity. Between the time of the first study and the second, repeat study, the source and cesium gun were disassembled, cleaned and reinstalled. At the time the second study was conducted the optimal probe position for greatest sensitivity had changed, and was now several millimeters back with the tip actually inside the source block. Although the response by CF-FABMS was reasonable with the probe in this back position, instability and arcing were frequently problems, probably due to poor thermal contact with the block as freezing of the eluent was often evident. The probe could not be operated in the full forward position due to low sensitivity. Thus, a compromise position was used which turned out to be about midway between the two extremes. In this position stability was achieved and the response could be made reasonable by repositioning the cesium ion gun. The repeat study was conducted using the probe in this position.

In conclusion, thioglycerol should be chosen over glycerol for high mass peptide analysis by CF-FABMS. It provides an improvement in response by factors of at least 2 to 8 and perhaps more when all conditions are optimized. Probe geometries (domed tip vs. flattened domed tip) may not be as critical. However, under certain conditions the flattened domed tip may offer an advantage by as much as a factor of 4. For the best response of high mass peptides standard FABMS should be chosen over CF-FABMS because even the greatest response of any of the four peptides by CF-FABMS is several orders of magnitude less than that of standard FABMS. Finally it should be emphasized that CF-FABMS is a complex technique whose success depends on a number of potentially critical, interrelated factors, not simply on one or two independent parameters such as probe tip geometry and matrix. The probe position appears to be among these factors, but it may not be intrinsically the critical factor; this remains to be explored. The x-position does affect probe heating efficiency, which in turn affects probe temperature (an important factor since it affects signal response and stability) due to its relationship with the source block.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Figures 1, 2, and 3 show various comparisons:

- **Figure 1** compares Domed Tip vs. Flattened Domed Tip and Glycerol vs. Thiglycerol.
- **Figure 2** shows CF-FAB vs. Standard FAB.

The figures illustrate the differences in mass spectrometry performance under these conditions.
SEPARATION AND IDENTIFICATION OF CAROTENOIDS USING CONTINUOUS-FLOW FAST ATOM BOMBARDMENT LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY.

Richard B. van Breemen, Harold H. Schmitz, and Steven J. Schwartz, Departments of Chemistry and Food Science, North Carolina State University, Raleigh, NC 27695-8204

Of the numerous plant carotenoids in the human diet, more than 50 possess provitamin A activity (1). In addition, certain carotenoids have received considerable attention as having a possible role in the prevention and treatment of cancer (1). Approximately 600 different carotenoids have been characterized, many similar in structure, and for each of these compounds, there may exist a number of geometric and optical isomers (2). The similarity of physical properties within this group of compounds poses an analytical challenge in resolving and isolating individual components for structure elucidation.

Currently, high performance liquid chromatography (HPLC) is regarded as the method of choice for the separation, identification, and quantitation of carotenoids found in biological tissues. Although HPLC is well suited for carotenoid analysis, complex mixtures of these compounds often found in biological tissues can be difficult to resolve and identify with confidence. A minimum of identical retention time and spectrophotometric characteristics with known standards are necessary for tentative identification of carotenoids, although these two parameters alone are not sufficient for positive identification (3). Obtaining a mass spectrum of an individual carotenoid in conjunction with accurate spectrophotometric and chromatographic data is sufficient to identify the carotenoid. However, additional analytical data are required to confirm the identities of stereoisomers.

Approximately 40 g of carrots or tomatoes were pureed, filtered, washed with methanol, and then extracted using 100 ml of hexane under nitrogen. The hexane extract was filtered again, concentrated to dryness under a stream of nitrogen, and stored at -20°C until analysis. The sample was reconstituted in the HPLC mobile to form a solution of approximately 1 µg/µl. All samples were handled under yellow lighting.

HPLC separations were carried out using an Applied Biosystems Model 140A dual syringe pump, Vydac C18 HPLC column (2.1 mm x 15 cm), and Applied Biosystems Model 757 UV/VIS absorbance detector set at 450 nm. The solvent system consisted of isocratic ethyl acetate/acetonitrile/methanol (20:50:30; v/v/v) or a 20 min gradient from 50/50/0/0.5 to 10/30/60/0.5 (v/v/v/w) water/methanol/ethyl acetate/glycerol. The flow rate was 100 µl/min. The eluate from the HPLC column was split so that approximately 7 µl/min flowed to the mass spectrometer. Mixtures containing approximately 5 µg of the most abundant carotenoid component were injected onto the HPLC column per analysis. Because of the solvent split, approximately 0.5 µg of each carotenoid entered the continuous-flow FAB interface. For continuous-flow FAB LC/MS, aqueous 1% 3-nitrobenzylalcohol was added to the mobile phase post-column at 1.4 µl/min. Alternatively, glycerol was added directly to the mobile phase.

FAB and continuous-flow FAB mass spectra were obtained using a JEOL HX110HF double focusing mass spectrometer equipped with a DA5000 data system. B/E linked scans were carried out following collisional activation and 5 to 8 scans were accumulated per analysis. The helium pressure in the collision cell in the first field-free region was adjusted so that the signal was attenuated 70%.

Initially, isocratic HPLC with absorbance detection without mass spectrometry was used to isolate α-carotene, β-carotene, and lycopene from the tomato extract. The isolated carotenoids were then analyzed using static positive ion FAB with 3-nitrobenzylalcohol as the matrix. Molecular ions, M+, were detected for each of these carotenoids at m/z 536. B/E linked scanning was then used with collisional activation to detect fragment ions of each of these isobaric carotenoids. Because these three carotenoids were structural isomers, fragment ions were detected which were unique to each compound (data not shown).

Next, the HPLC methods described above were used on-line with continuous-flow FAB mass spectrometry for analysis of a standard mixture of carotenoids containing α-carotene, β-carotene, and lutein. Using the gradient HPLC solvent system, the protonated molecule of lutein at m/z 569 was observed, but no ions of α-carotene, β-carotene were detected. Therefore, 3-nitrobenzylalcohol was investigated as an alternate FAB matrix. Addition of aqueous 3-nitrobenzylalcohol to the mobile phase facilitated the formation of abundant molecular ions, M+, for all carotenoids investigated. However, the chromatographic resolution was compromised. Therefore, aqueous 3-nitrobenzylalcohol was added post-column.
By using isocratic organic solvents with post-column addition of aqueous 3-nitrobenzylalcohol, a stable continuous-flow FAB signal was obtained, and molecular ions could be detected for all carotenoids investigated. For example, the total ion chromatogram (TIC) and several selected ion chromatograms for the LC/MS analysis of the carrot extract are shown in Figure 1. The five major carotenoids species in carrots were at least partially resolved from each other by reversed phase HPLC and could be easily identified by their molecular ions in the continuous-flow mass spectra. In Figure 2, the positive ion FAB mass spectrum of β-carotene acquired during LC/MS (retention time 10 min) is presented.

Figure 1. Positive ion continuous-flow FAB LC/MS analysis of carotenoids extracted from carrots showing the reconstructed total ion chromatogram (TIC) and selected ion chromatograms for the molecular ions of the five most abundant carotenoids.

Figure 2. Positive ion continuous-flow FAB mass spectrum of β-carotene acquired during the LC/MS analysis shown in Figure 1.

Isocratic reversed phase HPLC followed by post-column addition of FAB matrix, on-line absorbance detection, and on-line continuous-flow LC/MS analysis constitutes a rapid, sensitive, and specific technique for the identification of carotenoids extracted from foods. This method is the first continuous-flow FAB LC/MS method reported for carotenoid analysis. Studies are in progress to improve the sensitivity of the method by using microbore HPLC without solvent splitting.

UTILITY OF LC/FAB AND THERMOSPRAY MASS SPECTROMETRY FOR STRUCTURE ELUCIDATION OF METABOLITES FROM A FLORINATED CHLOROACETANILIDE HERBICIDE

Hideji Fujitawara, R. Thomas Solsten, and Robert C. Chott

Life Sciences Research Center, Monsanto Co., 700 Chesterfield Village Parkway, St. Louis, MO 63198

We have recently established an on-line microbore HPLC/FAB technique on a VG-ZAB HF mass spectrometer for identification of polar metabolites from herbicides and fungicides in Monsanto. This technique can now be used routinely for identification of polar metabolites with good chromatographic resolution and excellent FAB sensitivity with strong pseudomolecular ions. Scanning high-resolution LC/FAB mass spectrometry can also provide molecular formulae for structural elucidation of unknown metabolites. On the other hand, identification of less polar metabolites can still be carried out by the thermospray (TSP) method using a Finnigan quadrupole mass spectrometer. The thermospray LC/MS method provides useful structural information for both polar and less polar metabolites because their spectra show more fragmentation (pseudomolecular ions of polar metabolites are sometimes not seen) than FAB spectra. Both LC/FAB and LC/TSP techniques complement each other for analysis of metabolites of agrochemicals, since LC/FAB is generally suited to polar metabolites while thermospray LC/MS is good for less polar compounds.

The in vitro metabolism of herbicides by rat liver enzyme preparations can provide important information of the types of metabolites that may be produced during subsequent in vivo metabolism studies. Such information is obtained rapidly since in vitro incubations can usually be completed within a few hours. These LC/MS methods are ideally suited for in vitro studies since sample purification and concentration are not essential at all.

As an example, the in vitro metabolism study of an experimental Monsanto herbicide, 2-chloro-N-(ethoxymethyl)-N-[2-methyl-6-(trifluoromethyl)phenyl] acetamide, was carried out using S-9 rat liver enzymes in the presence of NADPH and glutathione.

Radiolabeled substrate was used in the incubations to allow the progress of metabolism to be monitored by HPLC and radioactivity detection (HPLC/RAD). To facilitate identification, the substrate also contained an appropriate amount of 13C-labeled material to provide a 12C/13C "doublet" in the mass spectra of metabolites. Glutathione conjugation was the major reaction observed during in vitro incubation of the herbicide. Oxidation of the chloroacetanilide by rat liver enzymes was also a significant metabolic reaction. Seven metabolites were identified, of which four were glutathione conjugates (Table 1).

Analysis of Bovine β-Casein Tryptic Digest by Continuous Flow Fast atom Bombardment Mass Spectrometry

D.S. Jones, G.A. Warburton, H. Wight, J. Moncur and C. Moore
Kratos Analytical, Barton Dock Road, Urmston, Manchester, M31 2LD, UK

Experimental

The study was performed using a CONCEPT I H mass spectrometer operating at 2000 resolution (10% valley). Accelerating voltage was maintained at 8 kV and the magnet was scanned from mass 3500 to 400, and in subsequent experiments, 2750 to 50, at 10 sec/decade. A standard FAB gun was used to produce an 8 kV primary xenon atom beam. The most stable conditions were observed at a source temperature of 70°C and source pressure of 2 x 10^{-4} Torr. Acquired centroided data were processed using a Kratos MACH 3 data system.

For the LC system, Solvent A was 0.06% trifluoroacetic acid (TFA) in water and Solvent B was 0.06% TFA in 80% acetonitrile 20% water. The gradient employed was 100% A, isocratic for 5 minutes, followed by a linear gradient to 100% B over the next 5 minutes. The column used was ODS1 Spherisorb (2 mm x 150 mm) with a flow rate of 0.2 ml per min. The injection volume was 20 μl which corresponds to 20 ng of the total digest. A further 0.2 ml per min. of 2% glycerol in acetonitrile was added post-column to provide a FAB matrix. A standard splitting device maintained a constant flow-rate to the mass spectrometer of about 5 μl per min., using a split ratio of 80:1. A schematic diagram of the liquid chromatograph introduction system is given in Figure 1.

Results

The identified peptide fragments have been matched to the relevant portion of the β-casein molecule (Table 1). There is a considerable amount of redundancy in these data as many of the peptides originate from overlapping sequences. However, it has still been possible to map 60% of the total protein.

(z, denotes phosphoserine residue) (highlighted sequences verified by this study)
A total of 25 peptides were observed in the investigation and good correlation was obtained between the UV and the total ion chromatogram. Table 2 lists identified components, protonated molecule ions and chemical origin (in elution-time order) of 20 of the peptides expected from this analysis. Figure 2 shows the ion chromatograms from some protonated molecular ions. These peptides can all be explained as arising from either tryptic and/or chymotryptic action, indicating that the trypsin used was not completely free of chymotryptic activity. The FAB spectra were used to interpret peptide sequences. Figure 3 shows a typical peptide spectrum, in this case of component X.

**Conclusions**

The combination of HPLC and continuous flow FAB MS is capable of providing a wealth of useful information to the peptide chemist. Complex mixtures are analysed speedily, and with moderate ease, without resorting to off-line separation of components or derivatization procedures. Results indicate that chromatographic integrity is adequately maintained during analysis.
Applications of a Fast Neutral Beam Ion Source Coupled to an FT/ICR Mass Spectrometer

Nicholas C. Hillt, Patrick A. Limbachi, and Alan O. Marshallt

Departments of Chemistry† and Biochemistry, The Ohio State University
120 West 18th Avenue, Columbus, Ohio 43210

The sensitivity, wide mass range, high resolving power, and versatility of a fast neutral beam ion source coupled to a Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometer have been demonstrated. The fast neutral beam ion source was originally developed by Delmore [1]. A beam of SFe⁻ ions is formed, focused, and accelerated with an energy of 5-10 keV down the bore of a superconducting magnet. Because the SFe⁻ ions are formed in short-lived excited quantum states, autoneutralization occurs, producing a beam of focused neutral SF₆ molecules which passes unaffected through the fringe field of the magnet. Undissociated ions and electrons may be removed from the beam by a charged deflector plate situated close to the superconducting magnet. The neutral beam impacts a sample placed on a solids insertion probe, and the desorbed ions are continuously trapped and then pulse-excited and -detected in a cubic ion trap. Preliminary results of the feasibility of this ion source for FT/ICR mass spectrometry were presented at the 1990 ASMS meeting [2]. Delmore and Appelhans have previously demonstrated the efficacy of the neutral beam as an ionization source for a quadrupole mass spectrometer [3], in which ions were detected up to the 350 u/e upper mass limit of the quadrupole.

We have now demonstrated the feasibility of the experiment (for both broad-band and high-resolution FT/ICR positive-ion mass spectra) with tetra-butylammonium bromide and (see Fig. 1) Tylenol®. The sensitivity of the new hybrid technique is vastly superior to static SIMS for electrically insulating samples, as demonstrated by a mass spectrum (not shown) of Teflon® extending up to m/z = 600 u/e [C₁₂F₂₄⁺]. The ability to analyze samples without the need for a matrix has been demonstrated with methyl stearate. The present results have been compared to those obtained by: (a) a fast neutral beam ion source coupled to a quadrupole mass spectrometer; (b) FAB on a double-focusing sector instrument; and (c) laser desorption on an FT/ICR mass spectrometer. All of the advantages of the fast neutral beam ion source previously demonstrated with quadrupole mass analysis are preserved, and the additional advantages of FT/ICR mass analysis (e.g., high mass resolving power, ion trapping) are retained. This work will be reported in fuller detail elsewhere [4].

Acknowledgements: The authors thank A. D. Appelhans, D. A. Dahl, and J. E. Delmore for the fast neutral SF₆ beam gun design, and for helpful advice and assistance. We also thank David Chang for providing FAB spectra. This work was supported by the National Science Foundation (CHE-8721498) and The Ohio State University.

The yield of desorbed ions in $^{252}$Cf-plasma desorption mass spectrometry is dependent upon the energy and incident angle of the fission fragment. A distribution of fission fragments, with respect to mass, energy and charge, is produced in the fission process. Asymmetric fission of the $^{252}$Cf nucleus results in the production of light and heavy ions; the "average" ions in these distributions correspond to species such as $^{106}$Mo$^{43}$ (104 MeV) and $^{142}$Ba$^{56}$ (79 MeV). The energy of these primary ions is reduced by 44 - 46 MeV after passing through the Ni foil covering the $^{252}$Cf source, the target backing and the sample itself. The ion yield for insulin is reduced by a factor of three as a result of this effect. The trajectory of the incident fission fragment also affects secondary ion yields; more oblique incident angles result in enhanced secondary ion yields. However, for $\theta \geq 80^\circ$, the light fission fragments cannot penetrate a typical sample film. To minimize these effects, the foil covering the $^{252}$Cf source was reduced from 1 $\mu$m Ni to 0.25 $\mu$m Ni. This factor accounts for almost half of the energy lost by the fission fragments. In addition, a new sample backing has been developed. This sample support is made by casting films of polyvinyl formal (Formvar) on glass slides. The films are floated off the slide and captured on a supporting ring. The films are coated with a thin (10 - 50 nm) layer of Au to provide a conducting surface. Foil thicknesses are accurately determined by measuring the energy loss spectrum of alpha particles penetrating the foil. These thin foils can be used in any application where Mylar films have been employed. For example, nitrocellulose can be electrospayed onto the surface for protein adsorption. In comparison to the 1.5 $\mu$m aluminized Mylar (polyethylene terephthalate) foils that are routinely used, the energy loss is reduced from $-13$ MeV to 1 MeV.

We have also investigated the formation of self-assembled mono- and multilayers on the Formvar films to produce surfaces with a variety of different functional properties. Self-assembled layers are formed as a result of strong specific interactions between the adsorbate and the surface resulting in the spontaneous adsorption of the reactive end of the adsorbate. The interactions may be based upon favorable electrostatic, hydrophobic and/or chemical reactions. For example, carboxylated surfaces may be prepared by constructing a cationic surfactant-fatty acid multilayer on the Formvar surface. To produce this surface, the Formvar is impregnated with tridodecylmethylammonium chloride (TDMAC). The resulting surface is nonelutable, much more hydrophilic than the Formvar surface and has enhanced binding capacities for anionic species. This surface therefore avidly binds fatty acids such as sodium stearate. If the fatty acid adsorbed with the carboxyl group oriented towards the quaternary ammonium surface, we would expect that the surface layer would consist of a
hydrophobic hydrocarbon layer. However, we have observed that this surface has a high affinity for cationic analytes and, is very hydrophilic. This can only be explained if, like the TDMAC, multilayers were adsorbed resulting in a surface layer enriched with carboxylic groups. A comparison of the positive ion spectra for CsI adsorbed onto TDMA-Formvar and CsI adsorbed onto stearate-TDMA-Formvar is shown below. The abundant iodide ion observed in the negative ion spectrum and the TDMA$_2$I$^+$/TDMA$^+_2$ clusters have been completely displaced by the stearate anion. Although the positive molecular ion of the stearate is obscured by the presence of TDMA fragment ions, the positive ion oligomers are apparent in the higher mass range. A prominent negative molecular ion of the stearate is present in the negative ion spectrum. This basic approach can be used to produce surfaces with a wide variety of functional groups which can be tailored to adsorb specific analytes.

This work was supported by grants from the National Institutes of Health (GM26096) and the Robert A. Welch Foundation (A-258).
Matrix-assisted UV laser desorption is recognised as being an extremely promising technique for the production of gaseous molecule-ions from thermally labile, non-volatile biomolecules of high masses. The presence of the matrix appears to change qualitatively the characteristics of the desorption process. In the absence of matrix, it was in our experience always difficult using laser desorption to produce molecule-ions from peptides with molecular masses much above 1000 Da. With a suitable matrix, it is possible to produce molecule-ions with masses above 100 000 Da. We have been interested in the role played by the matrix, and have investigated effects on the laser desorption mass spectra of varying the molar ratio of matrix to analyte. In the course of these investigations, we discovered that the concentration of the matrix/analyte solution loaded onto the probe (and dried before introduction into the mass spectrometer) had an effect on the mass spectrum, even though the ratio of matrix to analyte did not change. We have concluded that these effects are a consequence of differing crystal structures influencing the observed mass spectra.

The laser desorption mass spectra were measured using a time-of-flight system incorporated in the first field-free region of a large research mass spectrometer (MMM). The arrangement is designed to allow ions to be examined either by double-focussing mass spectrometry or by time-of-flight. This particular combination of magnetic sector and time-of-flight will be referred to as "parallel MAG-TOF". The laser employed is a dye laser pumped by an excimer laser. A wavelength of 266 nm has been used to irradiate the sample. In the case of nicotinic acid and insulin, we had found that at a molar ratio of about 600:1 the laser desorption mass spectra did not contain a strong peak attributable to nicotinic acid molecule-ions. This absence of matrix peaks was found at threshold irradiances and when using certain concentrations of the matrix/analyte mixed solution. The solutions were dried in a stream of nitrogen.

We report here that the macroscopic crystal structure of the sample (matrix/analyte) varies considerably, depending on the matrix/analyte ratio and on the drying procedure employed. Viewed under a low-power optical microscope, a nicotinic acid/insulin sample at a 600:1 ratio and dried under a stream of nitrogen (-200 cm\(^{-2}\) min\(^{-1}\)) has the appearance of a reasonably homogeneous crystalline material. Nicotinic acid/myoglobin at a ratio of 800:1 and dried with the aid of nitrogen has a similar appearance. When the molar ratio is higher (6000:1), samples of either nicotinic acid/insulin or nicotinic acid/myoglobin have a heterogeneous appearance, because the samples occur as discrete, larger crystals clearly separated from each other. The crystals are typically
about 10-50 \mu m in diameter in the case myoglobin. Lower molar ratios (60:1) give crystals of a homogeneous appearance. Pure nicotinic acid dries to give crystals with a voluminous, fluffy appearance.

It is possible to draw tentative correlations between the macroscopic crystal structure and the laser desorption mass spectra when using nicotinic acid as a matrix. The homogeneous (in appearance) samples at ratios of about 600:800 to 1 yield spectra at threshold irradiance, in which matrix peaks are very weak if not absent. There seems to be an optimum molar ratio, in terms of accentuating the protein molecule-ion at the expense of the matrix, which is about 600 for insulin and higher for myoglobin. The heterogeneous (in appearance) samples at ratios of about 6000:1 give spectra containing matrix peaks.

The same experiments with sinapinic acid as the matrix in place of nicotinic acid gave similar results as regards the microscopy. The apparently homogeneous samples did not, however, give spectra without matrix peaks. To date, we have not obtained any spectrum without peaks in the vicinity of the matrix mass when using sinapinic acid as a matrix.

In conclusion, we emphasise that we do not know whether or not the matrices and analytes are co-crystallising, i.e. whether mixed crystals are being formed under any of the conditions. Further experiments are required to confirm that co-crystallisation does occur. What is clear is that sample preparation is crucially important, and that the rate of drying of the sample is particularly critical. It also seems clear that subsequent to photon absorption there is a time interval prior to separation of isolated molecule-ions within which charge transfer processes can occur.

Matrix assisted laser desorption attracts considerable attention because of its capability to volatilize large molecules of biological interest. Mass spectrometry as well as other gas phase or vacuum spectroscopic and separation techniques can benefit from this progress.

One of the basic questions related to this new method concerns the mechanism of volatilization. More specifically we are interested in the nature and in the kinetics of the phase change induced by the laser pulse.

The one-dimensional hydrodynamic code developed for treating laser plasma ignition problems [1] has been adapted to this low irradiance case by taking more precise account of solid heating and phase transitions. In the calculations a matrix - vacuum interface was under the influence of a frequency quadrupled Nd-YAG laser with 10ns pulse length. The optical and thermal characteristics of the matrix were chosen close to those of nicotinic acid and of other good matrices. The model accounted for mass, momentum and energy transfer across the interface and for light absorption, heat conduction and phase transition inside the solid.

During the early period of the light pulse the solid is heated by about $10^6$K/s heating rate resulting in more and more vigorous evaporation through direct sublimation. By the end of the laser pulse a certain amount of matrix is evaporated (together with the embedded biomolecules) and the surface region of the solid is superheated (Fig. 1/a and 1/b; 10ns curves). Heat conduction and evaporation cools the surface quickly under the phase transition temperature after the laser pulse has ceased (50ns curve in Fig. 1/a). Fast expansion and translation of the plume towards the vacuum can be observed in Fig. 1/b and 1/c (50ns and 100ns curves). At the same time Fig. 1/a shows strong expansion cooling of the plume.

On the basis of these findings an interesting analogy is apparent between the matrix assisted method and the so called two-laser experiments. In these setups a separate laser is user for volatilization and ionization. The plume generated in the first step is quenched by a crossed expanding argon jet. In the matrix assisted laser desorption the expanding matrix plume acts as a “built in” jet intimately mixed with the guest molecules.

Several quantitative features of matrix assisted laser desorption experiments can be also rationalized by the heating of the solid phase and by plume hydrodynamics, as it is described by our model. Plume generation is bound to the condition that surface temperature exceeds the sublimation temperature of the matrix. The related threshold irradiance is below $10^7$W/cm$^2$; a value close to experimental observations. The mean velocity of the plume centre of mass gives an estimate of neutral particle energies in the order of ~60 meV, again close to measured figures. Furthermore, strong expansion cooling of the plume is observed down to around 100 K which may account for the stabilization of the large molecules and ions and for their appearance in the mass spectra.

The low thermal load on the embedded biomolecules during the volatilization process was demonstrated by our experiments using extremely thermolabile molecules as "molecular thermometers" [2]. The complete lack of thermal degradation processes was reflected by the mass spectra which also pointed to fast heating rates and to the existence of a stabilizing quenching mechanism.

The findings of this hydrodynamic study complement our earlier results which indicated an energy transfer bottleneck between the matrix and the embedded biomolecules [3]. According to this homogeneous bottleneck model the energy is deposited into the matrix molecules and the frequency mismatch between their intramolecular vibration and the vibration frequencies of the hydrogen bonds prevents the transfer of energy to the internal degrees of freedom of the embedded molecules. A combination of the two mechanisms (i.e. energy transfer bottleneck in the solid phase and expansion cooling in the gas phase) can give a full description of the volatilization mechanism.
Figure 1. The effect of a 10 ns frequency quadrupled Nd-YAG laser pulse ($10^7$ W/cm$^2$) on the matrix-vacuum interface. The spatial temperature (a/), density (b/) and velocity (c/) distributions are shown at different times. Surface position is marked by the vertical dashed line. In Figure 1/a the starting temperature is shown by the horizontal dashed line.

INVESTIGATION OF MATRIX-ASSISTED LASER DESORPTION FTMS FOR BIOMOLECULES

R. L. Hettich and M. V. Buchanan
Analytical Chemistry Division, Oak Ridge National Lab
Oak Ridge, TN 37831-6120

Structural characterization of biomolecules at the isomeric level is necessary for determining oligonucleotide sequences and examining DNA modification induced by carcinogenic agents. Matrix-assisted laser desorption can be used with FTMS for the detailed structural investigation of non-volatile, polar biomolecules, such as normal and modified oligonucleotides. For these experiments, laser desorption using a nicotinic acid matrix and 266 nm radiation was found to generate informative negative ions from oligonucleotides, including abundant (M-H)^- ions which could be used for molecular weight determination. The accurate mass measurement and ion manipulation capabilities of FTMS were used to obtain molecular weight, sequence information (at the isomeric level), and the identity and location of adducts for small oligonucleotides.

Experimental parameters for the matrix-assisted LD-FTMS technique were optimized with oligonucleotide dimers.[1] The negative ion spectra for these compounds revealed not only molecular weight information from the (M-H)^- ions but also detailed sequence information from the fragment ions. Two major fragmentation pathways were observed; cleavage of the glycosidic bond between the nucleic base and the sugar ring, and cleavage of the phosphate linkage to eliminate primarily the 5'-nucleoside. This latter fragmentation pathway provided not only sequence information but also identification of the 3'-nucleotide, and enabled differentiation of isomers such as d(5'-GA-3') and d(5'-AG-3').

Oligonucleotide trimers could also be characterized by the matrix-assisted LD-FTMS technique. The nicotinic acid matrix was essential for the success of these experiments. Elimination of the matrix resulted in complete loss of the (M-H)^- ions as well as most of the larger fragment ions for these oligomers. The negative ion spectrum of d(TGT) revealed an (M-H)^- ion at m/z 874 along with fragment ions at m/z 650 and 321, which result from phosphate ester cleavage and provide sequence information. For this particular compound, it is impossible to unambiguously determine whether these fragment ions result from elimination of the 5' or 3' nucleosides due to the symmetry of the compound. Isolation and collisional dissociation of the (M-H)^- ion at m/z 874 for d(TGT) revealed identical fragmentation as observed in the laser desorption experiment (i.e., m/z 650 and 321 as abundant fragment ions), implying that the cleavage of the phosphate ester linkage is the primary fragmentation pathway for collisional dissociation as well.

The negative ion spectra for tetranucleotides revealed more extensive fragmentation than that observed for the smaller oligomers. For example, Figure 1 illustrates the negative ion spectrum for the tetramer d(AGCT), with a molecular weight of 1173. This spectrum was obtained by using 2-pyrazinocarboxylic acid as the laser matrix and 266 nm radiation. Note the (M-H)^- ion at m/z 1172 and the fragment ions at m/z 939, 739, 610, and 321. The fragment ions at m/z 939, 610, and 321 are "Y" [2] fragment ions corresponding to elimination of nucleotides from the 5' end of the oligomer. This particular fragmentation provides not only sequence information but also identifies the 3' end of the oligomer. The fragment ion at m/z 739 results from a two-bond cleavage, as shown in Figure 1, and has been observed in FAB spectra of other oligonucleotides.[3] In order to verify the fragmentation pathways, an isomeric tetramer d(TGCA) was examined. The abundant Y sequence ions for this oligomer were different from the tetramer d(AGCT), as shown in Table 1. Note that "X" ions (phosphate ester cleavage from the 3' end of the oligomer) are also observed but in lower abundance than the Y ions. The presence of modifications such as alkyl adducts on these small oligomers could also be identified. For example, the fragment ions observed in the negative ion spectrum of a tetramer containing guanine alkylation provided the information necessary to determine the site of methyl attachment in the oligomer, shown in Table 1.

Extension of matrix-assisted laser desorption FTMS to larger biomolecules requires additional examination of experimental parameters which may influence the accessible mass range for FTMS. In particular, the ability to trap and subsequently detect large ions generated by matrix-assisted laser desorption is under investigation. Because ions generated by the matrix-assisted LD technique can have substantial kinetic energy distributions, it is necessary to examine methods of cooling the ions in order to improve the trapping efficiencies.

INTRODUCTION

The determination of the ingredients in a compounded polymer is often a difficult task. A complex mixture of compounds is involved, ranging from polymers to organic additives of various types. Indirect methods of separating the ingredients and identifying them have been developed. This study seeks to investigate additives by direct analysis of the substance. The organic additives are often at concentrations of 0.1-10%. The subject of this paper is laser desorption (LD) of polymer additives and laser desorption of neutrals of polymer additives with postionization (LD/postionization) by time-of-flight mass spectrometry. Although laser desorption alone has achieved some success in analysis of organic compounds, the desorption laser also acts as the ionization laser, limiting the ion yield, and thus the sensitivity. The main advantage of postionization techniques results from the separation of the desorption and ionization processes. We demonstrate the practical utility of this combination in the analysis of polymer additives.

EXPERIMENTAL

The instrument used here is a time-of-flight mass spectrometer constructed in-house. The mass spectrometer is established by a sample surface, an acceleration field, and field-free region with an ion detector at the end. The overall flight path length is 120 cm with acceleration distances of 4 mm for each of the two acceleration regions. Ions are produced at threshold irradiances to minimize fragmentation of the desorbing molecules. The ions thus formed are accelerated to 10 keV and detected using a dual-channelplate detector with a modest post-acceleration potential. Data are recorded in a LeCroy 8828 transient recorder with a maximum time resolution of 5 ns or by single-pulse counting in a LeCroy 4208 time-to-digital converter with a time resolution of 1 ns. Further processing of the data is accomplished in a PC-based software system. The typical operating vacuum is 5 x 10⁻⁹ torr. The lasers used are a 120-ps 266 nm Nd:YAG for desorption and a 10-ns 308 nm XeCl Excimer for postionization.

RESULTS

The samples used in this study were provided by James C. Tou (Dow Chemical Co.) (additives: tinuvin-234 and decabromo DPO) and Robert Lattimer (B. F. Goodrich) (additive: polychloroprene rubber vulcanizates A, B, C). The pure samples of the additives were dissolved in methylene chloride and placed on the stainless steel sample probe tip. The direct analysis of the rubber vulcanizates was accomplished by cutting small pieces of the rubber with a razor blade and retaining the piece on the sample probe tip by a copper disc with a quarter inch hole in it. The copper disc also serves to define an acceleration field for the sample which is non-conducting.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The LD/TOF mass spectra of several pure additive compounds were recorded. The mass spectrum of the negative ion of tinuvin-234 (a UV stabilizer) is shown in Fig. 1. An intense negative molecular ion signal is present with very little fragmentation. The positive ion mass spectrum also shows an intense molecular ion with weak fragment ions corresponding to loss of the hydroxyl group and phenyl groups. The flame retardant decabromodiphenyloxide shows an intense ion series. A positive and negative molecular ion is present. Masses above the molecular ion region are indicative of higher molecular weight brominated species.

The top panel in Fig. 2 is the direct analysis LD/TOF mass spectrum of the rubber vulcanizate B. Ions corresponding to the antiozonant component N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (HPPD) at m/z 268 are barely present among a large background of ions from other rubber additives and compounds. The much cleaner mass spectrum shown in the lower panel of Fig. 2 results from the reduction of the desorption laser power and addition of the postionization laser. The desorption laser power was reduced so that no prompt ions are observed. The laser irradiance was not recorded. The resulting spectrum show a single peak in the mass spectrum at m/z 268 (M++) characteristic of HPPD. At higher ionization irradiances the characteristic fragment ion (M-C4H9)+ is observed.

CONCLUSIONS

LD/TOF using threshold desorption of ions can be used as an analytical tool in the study of additives in polymers. Laser postionization of desorbed neutral molecules allows selectivity in detection of additives by direct analysis. Since different additives have different UV absorbances, careful selection of the ionization laser wavelength is expected to enhance the selectivity and sensitivity for additives. Future studies utilizing separation of the desorption and ionization processes will be used to record velocity distributions of the desorbed neutral molecules.

Matrix-assisted UV Laser Desorption of Proteins Using a 600 Picosecond Nitrogen Laser

Marc R. Chevrier and Robert J. Cotter

Department of Pharmacology and Molecular Sciences
The Johns Hopkins University School of Medicine
Baltimore, Maryland 21205

A compact laser desorption time-of-flight instrument utilizing an inexpensive, short-pulsed, and low-powered nitrogen laser has been constructed for analysis of proteins and their glycoconjugates. In addition to the simplicity of laser operation, the instrument features a multiple sample inlet system and minimal maintenance requirements thus enhancing its utility. A variety of protein and glycoprotein samples have been analyzed to demonstrate sensitivity, high mass range, resolution and mixture analysis.

The $N_2$ laser produces a 1.2 millijoule pulse in 600 picoseconds. Power utilization varies between 25 and 40% of the total pulse energy as determined by a Molelectron joulemeter. Pulse power reproducibility is better than +/- 4%. The TOF analyzer incorporates an orthogonal multi-sample inlet system, up to 30KV extraction, Einsel focussing, one meter flight tube and an electron multiplier detector. Extraction lenses have been optimized using SIMION computer simulations. Data collection is performed using a LeCroy 9400A or 9450 digital oscilloscope linked to a 386 PC. Pulse triggering is accomplished using a fast (<1 ns) photodiode. [Figure 1]
Femtomolar sensitivity, single shot, has been demonstrated. [Figure 2] Signal integration/averaging significantly enhances signal/noise ratios. [Figure 3] Mass range is in excess of 100 kDa. [Figure 4] Mass accuracy is greater than 0.1%. Picomolar protein mixtures can be analyzed. [Figure 5] Samples can be desorbed directly from nitrocellulose. [Figure 6] Observed peak widths less than mass 2000 parallel isotopic distribution widths for those compounds. [Figure 7] Since the transient recorder approaches 1 channel/amu while sampling a detector whose rise time is one-half the channel width, unit resolution at masses greater than 500 will be masked. Currently, the resolution is thus limited by the by the speed of the transient recorder and the detector. Faster devices will be required to determine the actual resolution limit using high-voltage extraction with short-pulse desorption.
MATRIX-ASSISTED LASER DESORPTION AND IONIZATION OF OLIGOSACCHARIDES

Subhodaya Aduru, Ronald C. Beavis and Brian T. Chait
The Rockefeller University, 1230 York Avenue, New York, NY 10021

We report here the application of matrix-assisted laser desorption mass spectrometry to the molecular mass determination of glycoprotein-derived complex and high mannose oligosaccharides obtained from the Dionex Corporation, (Sunnyvale, CA). Because underivatized oligosaccharides did not yield useful mass spectra, all the measurements reported here were performed on peracetylated compounds.

The linear time-of-flight laser desorption mass spectrometer was built at the Rockefeller University. The desorption and ionization are effected by frequency tripled radiation (354 nm) from a pulsed (10 nsec) Nd-YAG laser. All the oligosaccharides were peracetylated using a 2:1 (v:v) mixture of trifluoroacetic anhydride and glacial acetic acid. The matrices used were sinapic acid (3,5 dimethoxy-4-hydroxy cinnamic acid), ferulic acid (3-methoxy-4-hydroxy cinnamic acid), and caffeic acid (3,4 dihydroxy cinnamic acid). Two pmol of peracetylated oligosaccharide and 0.5 pmol of calibrant (usually neurotensin and bovine insulin) in 25 nmol of matrix in 0.5 ul of 1:2 acetonitrile and 0.1% trifluoroacetic acid was loaded onto the probe tip for mass spectral sampling.

Figure 1a shows the negative ion mass spectrum obtained for a disialylated bi-antennary oligosaccharide. The spectrum exhibits an intense (M-H)⁻ ion peak produced by deprotonation of the peracetylated molecule as well as two prominent peaks that are 42 u lower and 54 u higher than the (M-H)⁻. The former arises from the underacetylated oligosaccharide while the latter arises from the oligosaccharide containing one trifluoroacetyl group instead of an acetyl group. Analogous side reaction products have previously been observed on peracetylation of carbohydrates. The negative ion mass spectrum (Figure 1b) of a trisialylated tri-antennary oligosaccharide shows an (M-H)⁻ peak from the completely acetylated oligosaccharide and intense peaks that are 42 u apart $\text{(M-n(42)-H)}^-$ arising from different degrees of underacetylation. Thus negative ion formation occurs primarily by deprotonation in the case of complex carbohydrates containing acidic sugar residues.

The negative ion mass spectrum of the simple neutral sugar, maltoheptaose consists of a peak corresponding to (M+36)⁺ and another that is 42 u lower in mass. We assign the former as an (M+Cl)⁺ and the latter to its underacetylated analogue. Figure 1c shows the negative ion mass spectrum of a neutral, high mannose oligosaccharide. The peaks observed are (M+36)⁺, i.e. (M+Cl)⁺, and its analogues corresponding to underacetylated carbohydrate molecules $(M-n(42)+36)^+$ where $n = 1,2,3$, etc.). A peak arising from chloride ion attachment to the carbohydrate molecule [in which an acetyl group is replaced by a trifluoroacetyl group $(M-CH_2CO+CF_3CO+36)^+$ or $(M+54+36)^+$] is also observed. Similarly the mass spectrum of an asialo tri-antennary complex carbohydrate (Figure 1d) shows the (M+Cl)⁺ ion and it's underacetylated analogues. Thus, negative ion formation appeared to occur primarily by chloride ion attachment in the case of neutral carbohydrates. Truncated forms of the carbohydrate with loss of 1,2 or 3 terminal sugar residues were observed to a limited extent for all the carbohydrates studied. These are likely to arise from truncated impurity oligosaccharides in the samples studied.

Negative ion spectra of large complex carbohydrates are in general more intense, better resolved and easier to interpret than the corresponding positive ion spectra. The mass spectral sensitivity of these carbohydrates is extremely high (2 pmol) in the negative ion mode. This high sensitivity of matrix assisted LDMS provides a means for molecular mass measurement and structural studies of large biological carbohydrates that are available in extremely small amounts.
Figure 1
MATRIX-ASSISTED LASER DESORPTION OF HIGH MOLECULAR WEIGHT IONS USING TIME-OF-FLIGHT MASS SPECTROMETERS WITH AND WITHOUT REFLECTOR

F.J. Mayer, A. Holle, R. Schöfer, and R. Frey, Bruker-Franzen Analytik GmbH, Fahrenheitstr. 4, 2800 Bremen 33, Germany

Matrix-Assisted Laser Desorption (MALD) of ions is a desorption/ionization method of rising interest, which allows to determine the molecular weight of biological compounds with very high mass (up to 150,000 u and more).

As it is quite new, many important questions are still open. Our special interest are effects which limit the resolution and the accuracy of mass determination in a time-of-flight mass spectrometer. In the literature, Beavis and Chait [1] obtained better resolution with a linear TOF as Hillenkamp and Karas [2] with a reflector TOF. The basic difference between the two experiments was that Beavis and Chait used very high ion energies (20 keV and more), whereas Hillenkamp and Karas used only 3 keV. Therefore we studied all combinations of low/high ion energy, linear/reflective TOF, postacceleration/no post acceleration for detection.

The best results were obtained with high ion energies and without postacceleration in the linear and reflector TOF. The highest sensitivity was obtained in the linear TOF and the highest resolution in the reflector TOF. Fig. 1 and Fig. 2 show the results for cytochrome C in a linear and reflecting TOF. In both cases, a sharp peak is observed which comes out of a broader one. This sharp peak is much easier to obtain, when high ion energies are used. In several cases, the sharp peak could only be obtained when high ion energies were applied. If this peak is absent, the resolution is obviously lower. Still the question arises why "only" a resolution of 1,200 for mass 12,000 can be obtained with a mass analyzer which is able to perform a resolution of 5,000 for mass 2,000 with another ion source [3]. The answer is that the isotopic distribution of the high mass molecules hinder the measurement of the resolution as long as the isotopic pattern is not resolved. For example, the FWHH of the isotopic pattern of mass 12,000 is about 8 masses. Therefore the maximum resolution theoretically obtainable with unresolved isotopic pattern is 1,500.

APPLICATIONS OF MATRIX-ASSISTED LASER DESORPTION
MASS SPECTROMETRY TO BIOLOGICAL PROBLEMS

K. Blemann, C. E. Costello, I. A. Papayannopoulos and P. Juhasz
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

Matrix-assisted laser desorption time-of-flight mass spectrometry, as first introduced
by Hillenkamp and Karas, and as later modified by Chait and Beavis, offers many new and
exciting possibilities for the structural determination of biologically important compounds.
We have begun to utilize this technique as part of our overall approach to the study of
proteins, glycoproteins, glycolipids, oligosaccharides, and oligonucleotides and related
compounds. Our applications, including the projects described below as specific examples,
exploit its advantages of high mass range, high sensitivity and tolerance for the presence
of impurities.

Experimental Laser desorption mass spectra were acquired with a VESTEC 2000
instrument, using a Lumonics Nd:YAG laser at 355 nm, 9 ns pulses, 5 Hz. Accelerating
voltage 20-30 kV. Details of the instrument and its operation appear in Abstract MP111.

Core amyloid protein isolated at autopsy from persons suffering from Alzheimer's disease
who succumbed to it (Collaborator: D. L. Miller, NY State Institute for Basic Research,
Staten Island).

The analysis of components of interest after minimal workup from biological materials
is exemplified by the investigation of amyloid proteins present in neuritic plaque cores
obtained from autopsy samples of the brains of patients who suffered from Alzheimer's
disease. The protein is difficult to isolate and purify, with major losses of material
occurring during the purification step. Previous work during this collaboration has shown
that the protein has a frayed N-terminus. In order to complete the characterization of
the protein, it was necessary to determine whether the C-terminus was also frayed. Both
the highly purified proteins and the crude plaque have been analyzed by maLD-TOF. The
results (Fig. 1) demonstrated that the C-terminus is not frayed, although the N-terminal is
extensively frayed. This spectrum of crude material contains multiple peaks separated by
28 u intervals for each peptide, because of partial formylation of the native material during
the extraction.

![Fig. 1. Matrix-assisted laser desorption mass spectrum of a crude (70% formic acid)
extract of amyloid plaque from the brains of deceased Alzheimer's disease patients.
Intact core amyloid peptide has 42 residues, but it is extensively and variously truncated
in the disease state. Sinapinic acid matrix.](image-url)
Analysis of the five glycosylation sites of human α-acid glycoprotein (orosomucoid glycoprotein) (Collaborators: M.J. Treuheit and H. B. Halseall, Dept. of Chemistry, Univ. of Cincinnati).

Orosomucoid (OMD) is a plasma glycoprotein (MW ca. 45 kDa) whose physiological function remains unknown, but it is classified as one of the positive acute phase reactants because its plasma level rises as much as fourfold in some disease states. It is one of the most heavily glycosylated serum proteins, and has glycan heterogeneity at each of the glycosylation sites. Variation in the extent of processing creates discrete glycoforms that may lead to functional diversity. Chromatographic methods for resolution of the various glycoforms have been developed. Determination of the molecular weights of glycopeptides (2-6 kDa) obtained by enzymatic digestion of OMD has been accomplished by FABMS and MALD-TOF/MS analysis of seventeen HPLC fractions. The latter MS approach required much less sample, was more successful in detecting the presence of minor glycopeptides, and more tolerant of impurities. A typical spectrum obtained for 35 pmole of glycopeptide is shown in Fig. 2. FABMS spectra, on the other hand, did contain some sequence information. Several glycoforms not detected by HPLC alone were identified by mass spectrometry.

Determination of the points of truncation of modified His-tRNA synthetase (Collaborators: P. R. Schimmel et al., Dept. of Biology, MIT).

Matrix-assisted LD-TOF analysis has shown that a variant of His-tRNA synthetase (M, 47.0 kDa, 424 amino acids) which was known to have a truncated N-terminus, has also lost a part of the C-terminus. The modified form appears to have adenylate synthesis but not aminoacylation activity and is apparently produced by a cleavage of the full-length His-tRNA synthetase by a cellular protease. While detection of the N-terminal modification may be fairly easily accomplished by Edman gas-phase sequencing, unambiguous detection of the C-terminal truncation is much more difficult, if not impossible. The molecular weight of the modified enzyme was shown by mALD-TOF/MS to be 39.6 kDa, indicating that the protein lacks not only the first 63 amino acids, but also the last 14 amino acids. An additional form which contains residues 1-410 (MW 45.6 kDa) was also detected.

HIGH CURRENT ION SOURCE EXTRACTOR FOR QUADRUPOLE MASS SPECTROMETERS

J. A. Olivares, E. M. Garcia, and E. P. Chamberlin
Isotope Geochemistry and Radiochemistry Groups,
Los Alamos National Laboratory, NM 87545

Introduction:
High current ion sources, such as inductively-coupled plasmas, microwave plasmas, and glow discharges used for elemental ionization are permitting new approaches to analytical mass spectrometry. As such, most instrument designs to date use only low voltage (0-200 V dc) extractors and transport lenses. The extraction of ions from high current ion sources has been extensively studied and used in isotope separator spectrometers. The design objectives for these systems are maximum ion extraction and transport efficiency, and minimization of space charge induced effects. With these goals in mind, a simple acceleration-deceleration ion-extraction system has been built using some of the principles of high current ion extraction. In this paper we present the results obtained with this lens design using a microwave ion source and a quadrupole mass spectrometer.

Basic Theory of Ion Extraction:
Ion extraction from an ion source is achieved by the application of a voltage between the ion source and the extraction electrode. The applied field strength, shape of the emitting surface, and space-charge density of the beam affect the trajectories which ions will undertake. The beam quality or phase space depends on the absolute current and the current density. The maximum space charge limited current density which can be extracted from any ion source is described by the Child-Langmuir equation and is proportional to $V^{3/2}/d^2$, where $V$ is the acceleration voltage, and $d$ is the gap width between the extractor and the ion source. Thus the larger the extraction voltage and smaller the gap width, the greater the ion density which can be effectively extracted. Unfortunately quadrupole mass spectrometers do not tolerate ions with kinetic energies much greater than 50 eV without large losses in mass resolution. Therefore, the ion beam must be decelerated just before entering the quadrupole mass spectrometer.

The Ion Source:
The ion source and mass spectrometer arrangement is shown in Figure 1. Although the ultimate use of this mass spectrometer is for a variety of other ion sources, we chose to test it with a low pressure microwave ion source utilizing a $\lambda/4$ wave Swenson type cavity in a 0.5" o.d. fired alumina tube. This type of ion source can easily produce current densities in the order of 25 mA/cm$^2$ at 5-200 mTorr gas pressures. In our Division this ion source is regularly used to provide 1-10 nA ion beams of various elemental species for isotope separation. Argon gas is used as the plasma support gas, and a calibrated xenon gas leak of $1.2\times10^{-6}$ atm cc/s was used for efficiency tests. The ion source extraction orifice has a 0.0135" diameter. With this orifice, and a 330 L/s turbo pump, the main mass spectrometer pressure was maintained at 5x10$^{-5}$ to 5x10$^{-7}$ Torr pressure, depending on the ion source pressure.

The Accel/Decel Lens and Mass Spectrometer Arrangement:
The extractor lens, placed just behind the ion source orifice, gives a maximum ion signal at ~8000 V/in extraction field. The complete lens is comprised of two more lenses just in front of the quadrupole mass spectrometer. The ions are decelerated to 50 eV as they travel through the quadrupole. This value results from a compromise between resolution and signal intensity. Although the mass spectrometer includes an analog electron multiplier, this was seldom used since the ion signals observed were high enough that recording with the built in faraday cup was sufficient for determination of system performance.
System Performance:
Figure 2 shows the first background mass spectrum, and RF only spectrum recorded with this system. The main signal is due to the argon gas at mass 40 (Ar⁺), with minor peaks at mass 41 (ArH⁺), 80 (Ar₂⁺), 28 (N₂⁺), and some smaller peaks in the mass 12-19 region due to water, N⁺, and C⁺. Although the baseline looks very clean upon expansion or recording with the analog multiplier a "picket fence" of peaks is uncovered which attests to the high efficiency of the microwave ion source in ionizing any contaminants present in the source or plasma gas. The RF only spectrum shows 4X more signal, indicating that 75% of the signal is lost in the quadrupole when operating at unit mass resolution. The maximum Ar⁺ signal we have been able to observe with this system is 250 nA at unit mass resolution.

Figure 3 shows a spectrum of the xenon signal obtained with the calibrated leak. A total xenon signal of 60 nA could be recorded on a regular basis with this system. Therefore the detection efficiency of the system is:

\[
\text{Xe leak} = 1.2 \times 10^{-6} \text{ atm cc/s} = 3.0 \times 10^{13} \text{ atoms/s} \\
60 \text{ nA Xe} = 3.6 \times 10^{11} \text{ ions/s} \\
\text{Detection Efficiency} = 1.2\%
\]

Since at least 75% of the ions are lost in the quadrupole, the minimum ionization and transport efficiency of this system is 4.8%. Thus, the accel-decel lens design for this system is very efficient in the transport of ions from the high current microwave ion source to the quadrupole mass spectrometer.
COMPARISON OF PULSED DC AND PULSED RF GLOW DISCHARGE MASS SPECTROMETRY

J. A. Klingler and W. W. Harrison
Department of Chemistry, University of Florida
Gainesville, FL 32611-2046 USA.

INTRODUCTION

Glow discharge mass spectrometry (GDMS) is regarded as a useful analytical technique for trace elemental analysis of solid materials. Most of the popularity of GDMS has been with the use of direct current (DC) discharges operating at equilibrium. There are, however, alternative glow discharge techniques that offer advantages over the traditional DC source.

Two alternative glow discharge methods are pulsed DC and radio frequency (RF) discharges. Pulsed DC discharges periodically turn-off the applied voltage at a rate of 50 - 100 Hz with 50% duty cycles. They offer higher sputter yields and ion signals than their DC counterpart and produce ion signals useful for fundamental studies and analytical applications (1). Radio frequency discharges rely on the difference in mobilities between electrons and ions in an oscillating (low MHz) electric field to create a DC bias voltage on the sample surface that controls sputtering. Nonconducting materials as well as conducting samples can be analyzed directly with RF discharges.

Reported here is a new ion source whereby an RF discharge is pulsed ON-OFF by periodically modulating the applied voltage. The pulsed RF discharge is evaluated by comparing its ion signals with those obtained with a pulsed DC discharge operating at the same voltage.

RESULTS AND DISCUSSION

Figure 1 illustrates the ion signal profiles for both pulsed DC and pulsed RF discharges. Sputtered species ($^{57}$Fe$^+$ in Figure 1a) show the characteristic afterpeak observed in an argon discharge when the applied voltage is terminated; this is the result of Penning ionization becoming dominant in the post-pulse region as electrons rapidly thermalize. Likewise, contaminant gas species (Figure 1b, $^{18}$(H$_2$O)$^+$) in both discharges exhibit prepeaks as electrons pass through their
optimal collisional cross section as the applied voltage increases. While the signal profiles for pulsed DC and pulsed RF are very similar, there are differences between the two discharges. At the beginning of the pulse period, sputtered ion signals in a pulsed DC discharge typically appear around 0.8 msec into the pulse cycle after the high voltage is applied to the sample. In a pulsed RF discharge, the same ion signals appear approximately 0.4 msec earlier in the pulse period. This is the result of differences in how the RF and DC discharges are pulsed. In a DC discharge, it is the power supply that responds to a square wave controlling the pulse cycle. RF discharges respond to the controlling wave by changing the amplitude of the RF voltage, but the discharge is actually pulsed because ion bombardment neutralizes the DC bias. Once ions are no longer present, DC bias neutralization stops, leaving a residual voltage between 150 - 200 V on the sample surface. At the beginning of the next pulse cycle, the DC pulse must start at zero voltage, whereas the RF pulse begins at a voltage just below the threshold to initiate the negative glow.

There are also differences in the ion signals when the pulse discharge stabilizes. Figure 2 is a mass spectrum of the molybdenum region of a low alloy steel (SRM 1264). In the figure, solid peaks are from the pulsed DC spectrum while the outlined peaks are a pulsed RF mass spectrum. The DC voltage and RF bias voltage were matched at -1000 V. The pulsed RF discharge consistently yields higher ion signals than the pulsed DC discharge.

When the discharge is terminated, the afterpeaks in the two pulsed discharges are also slightly different. Figure 3 is a trace of the afterpeak region for $^{57}$Fe*. The plateau values of the two discharges are matched to draw attention to differences in the shape of the afterpeak. Pulsed RF discharges consistently produce afterpeaks that are broader than pulsed DC afterpeaks. Because the afterpeak region is dominated by Penning ionization, differences in the afterpeak profiles suggest that the population of discharge gas metastable atoms are not equal in the two discharges. To examine this possibility, atomic absorption was used to monitor the population of metastable atoms in the discharge immediately in front of the exit orifice. While absolute concentrations cannot be determined, the relative metastable population between the two discharge can be ascertained. These studies indicate that the argon metastable population in the pulsed RF discharge is 8 - 12% higher than in the pulsed DC system. This would explain why the afterpeaks are broader in the RF discharge. The higher argon metastable population may also contribute to the enhanced ion signals observed in the plateau region of the pulsed RF discharge.

**INTRODUCTION**

In recent years, glow discharge mass spectrometry (GDMS) has developed into a suitable technique for the analysis of solid samples. The applicability of GDMS to solution samples is limited, however, due to the low operating pressures of the plasma. Perturbing effects will be encountered in both the plasma and the high vacuum system if a large quantity of solvent is allowed to enter the system. In an effort to explore possible methods of solution analysis, an electrothermal vaporization (ETV) source is currently under investigation in this laboratory. The ETV device chosen for these studies takes the form of a coiled filament (tungsten or rhenium). The method used in these experiments is evaporation of the solvent from a solution sample (using the filament at a low current) resulting in a solution residue on the filament surface. The residue is then electrothermally vaporized when the filament is heated to a temperature above the vaporization point of the analyte, thus producing atoms that may be analyzed in the negative glow region of the discharge. In these analyses, the heating of the filament serves as the primary atomization step, while the glow discharge provides the only apparent ionization mechanisms. This presentation focuses on the fundamental characteristics of the system to find the optimum parameters to be used for further studies.

**EXPERIMENTAL**

Figure 1 shows the ion source configuration used in these experiments. The filament coil, attached to the end of a 1/2" stainless steel direct insertion probe, serves both as the cathode of the glow discharge as well as completing a current loop by attachment to a constant current power supply. The aqueous solutions (prepared by mixing the appropriate metal nitrate with distilled water) are analyzed by placing a 5-50 µl sample onto the coil with a micropipet. The solvent is then evaporated external to the mass spectrometer ion source at a relatively low current (the current averages between 1.5 and 2 amps and is filament dependent). The probe is then inserted into the mass spectrometer for subsequent analysis. The number of turns used for the electrothermal filament is dependent on the filament material. This value is determined by the length of wire required to produce a white hot glow using about 4 amps current. The ionization and detection are provided by the GDMS system.

**RESULTS AND DISCUSSION**

Filament Current Effects: Before proceeding with solution analysis, the initial investigations on this system were to observe the effects that the filament current has on the glow discharge system. Two experiments were conducted: one on a constant voltage discharge and one with a constant current discharge. The observed trends with the constant voltage discharge were the same for all species under investigation (three gaseous species and one sputtered species). Upon initiation of the filament current (from 0-1.5 amps) the signal begins a slow decrease and then levels off for a period (1.5-2.5 amps), but from 2.5 amps to the maximum used (4 amps) there is a sharp increase in the ion...
signals. The underlying reason for this trend is discovered when monitoring the glow discharge current which follows a similar trend. These effects are most likely due to the changing electron population in the plasma. When using a constant current discharge, the gaseous species show a sharp increase with increase of the filament current that is probably due to source heating and degassing. The sputtered species, however, show a slight increase until the filament glows incandescent and then decreases. This is probably due to the shift in optimum cathode to exit orifice distance upon influx of a large amount of electrons. This is further explained in the distance studies below.

Pressure Studies: An important parameter to be considered for glow discharge operation is the effects of the source pressure. As the pressure is increased from about 0.5 Torr, the ion signal will increase to a maximum and then decrease. This is due to the changing amount of argon metastable atoms in the discharge which controls the amount of Penning ionization. Subsequent experiments were performed at the optimum pressure because of the higher ion signal and also because any change in pressure results in a minimal ion signal change. The studies revealed that the optimum pressure for both normal discharge analysis and ETV analysis occurred at 1.3 Torr argon.

Cathode-Exit Orifice Distance Studies: Another important parameter to investigate is the change in ion signal with variation of the sampling distance. Since all detected ions come from a small zone very near the exit orifice, the distance for maximum signal should be found. These studies produced an interesting difference. Figure 2A shows the distance effects for a normal sputtered species. The maximum ion signal is obtained at about 7 mm, which is typical for GDMS studies. The unexpected finding is seen in Figure 2B, which shows that when the filament is running at 4 amperes (normal operating conditions for solution analysis) the ion signals from both the cathode material and the solution residue show a maximum at about 3-4 mm. This could be a result of the differing amount of electrons that will affect the argon metastable population and the plasma conditions. Future work with atomic absorption should clarify this.

CONCLUSIONS

Electrothermal vaporization has been shown to provide quick quantitative analysis when incorporated with a GD ion source. The ETV filament provides a nearly complete atomic population from the solution residue that is subsequently ionized and detected in the GDMS system. The optimum conditions for this system are similar to those of a normal GDMS system. The pressure for maximum ion signal was found to be about 1.3 Torr argon which is in the range of normal operating parameters, but this will change slightly from system to system. The parameter diverging most from a normal GDMS system is that of the cathode-orifice distance which decreases when the filament is running at a white hot temperature. The normal distance of about 7 mm decreases to about 3 mm. This is probably due to changes in the plasma and ionization mechanisms with the increase of the electron population.
INTRODUCTION: The glow discharge plasma, formed about cathodes containing metal oxides, is more complex in its chemical composition than that with bulk metals. The complexity arises from high concentrations of gaseous impurities brought into the plasma by the compressed samples. The effect of these gaseous species on gas phase chemistry of the oxide has been studied with direct current GDMS. It is realized that the presence of these gaseous contaminants on the cathode surface may also influence the oxide’s plasma processes, especially its sputtering mechanism. However, the degree of gas contamination on the cathode surface is difficult to monitor in a dc discharge, because the cathode surface remains at a “chemical steady state” after the initial sputter-cleaning step. In order to investigate the effect of cathode surface contamination on oxide signals, pulse GDMS was used to create a series of sample surfaces with varying yet controllable amounts of gaseous impurities.

EXPERIMENTAL: A pulse generator with variable pulse period in the range of 1-3500 milliseconds was used to drive a high voltage dc power supply. The discharge was maintained in 1.0 Torr Ar, at constant 1200 Volts during the pulse “on” time. The analyte, lanthanum oxide (La₂O₃), was mixed with two metal matrices, Ta and Ag, to form disk cathodes. All data were collected through a 1 ms data gate placed in the pulse “on” time region.

RESULTS AND DISCUSSION:

Pulse Schematics: Throughout the experiments discussed in this section, the pulse “on” time was kept at a constant 5 ms while the pulse “off” time was varied between 10 and 200 ms. As shown in Figure 1, following the pulse “on-off” cycle, the cathode undergoes repetitively the processes of sputtering/sample heating (during the “on” time) and cooling/surface deposition (during the “off” time). For completing the same number of pulse cycles, if the length of the pulse “off” time is increased, then the cathode will have longer time to dissipate heat and to accumulate surface deposition, resulting in reduced cathode temperature and increased amounts of gaseous impurities on the sample surface. By the same token, reducing the length of the pulse “off” time results in less surface accumulation of gases as well more pronounced cathode heating.

Effect of Pulse Period Change on Water Signal: As the pulse period was changed, the water signal (H₂O⁺) was monitored with four types of cathodes: bulk Cu pin, pressed Cu disk, pressed Ta/La₂O₃ disk, and Ag/La₂O₃ disk (Figure 2). The water signals show two different changing trends: one increases with increasing “off” time (Cu pin and Ta disk); the other decreases with “off” time (Pressed Cu and Ag disks). In the cases of Cu and Ag disks, water molecules trapped within the compressed electrodes are released from the sample into the discharge as the electrode heating is intensified in the low period region. For the Cu pin, with no diffusion from within the electrode, the water signal follows the surface accumulation pattern with the changing period. The Ta disk, although also compress-formed, does not
appear to release a large amount of water upon heating. This may be because heating activates Ta's gettering function, which dissolves water molecules enveloped inside the electrode into the metallic inside of the Ta granules, preventing them from escaping into the gas phase.

**Figure 2**

Effect of Surface Water on La⁺/LaO⁺ Ratio: The probable water accumulation on the Ta cathode surface has a direct influence on the La⁺/LaO⁺ ratio, as illustrated in Figure 3A. As the water signal increases with lengthened "off" time, the La⁺/LaO⁺ ratio gradually decreases. This is probably because the enhanced water deposition creates an "oxidizing" layer on the cathode surface, resulting in reduced sputtering ratio of the La/LaO neutrals. In order to confirm further that in the case of Ta matrix, the La⁺/LaO⁺ ratio is affected by water molecules deposited on the cathode surface from the gas phase, but not water vaporized from within the electrode, about 2% O labeled water was bled into the discharge gas to carry out the same pulse experiments. H₂¹⁸O⁺ signal and La⁺/La¹⁸O⁺ ratio were monitored (Figure 3A), showing similar trends as those O-containing species (Figure 3A). Since O exists only in the discharge gas phase with no history in the sample, then the strong similarities in Figures 3a & 3b tend to suggest a similar behavior between O and O waters in terms of affecting the oxide, i.e., through surface deposition during the pulse "off" time.

**Figure 3**

CONCLUSIONS: Pulse discharges were used to monitor the degree of gaseous deposition on the cathode surface, and to study the effects of such deposition on the oxide's discharge processes. Results show that water layers on the cathode surface may cause reduced elemental signal of the oxide. Studies also suggest that gettering action of Ta inside the heated electrode is possible.
A VERSATILE EXTERNAL SAMPLE MOUNT GEOMETRY FOR BULK AND THIN FILM ANALYSIS BY RADIO FREQUENCY GLOW DISCHARGE MASS SPECTROMETRY

Paula R. Cable and R. Kenneth Marcus
Department of Chemistry, Clemson University
Clemson, SC 29634-1905

Glow discharge mass spectrometry (GDMS) has become a well accepted technique for the bulk solids elemental analysis of metals and semiconductors. In this laboratory we have addressed that class of materials that do not conduct electricity by developing a family of glow discharge devices which are powered at high frequencies (13.56 MHz), thus allowing the direct analysis of the full range of bulk materials. These radio frequency (rf) powered glow discharge devices have been applied for the sputter-atomization of such materials as nuclear defense waste glass and machinable glass ceramics (MACOR). Initial efforts in rf-GDMS involved a source design employing a direct insertion probe (DIP) for sample introduction. While the DIP allows convenient sample interchange through a vacuum interlock and the ability to vary the ion sampling position, the 0.5" probe diameter limits the analytical sample size to <0.25". Clearly, if the bulk analysis of glasses and ceramics is a primary benefit of the rf source, then limiting the sample size and thus imposing a machining requirement is a major drawback. To address this shortcoming and allow for convenient depth-resolved analyses, a simple external sample mount geometry has been constructed requiring only that the sample be nominally flat with a diameter of ~0.3". Other design considerations which must be addressed include the ability to, at least initially, vary the cathode-to-sampling cone distance and to permit rapid plasma equilibration for high sample throughput. The basis of this report is a description of this source design and illustration of its operating characteristics.

Experimental

Shown on the next page is a diagrammatic representation of the rf-GDMS external sample mount geometry source. The source is comprised of a three inch squared stainless steel cube which is mounted directly to the face plate of the double-quadrupole mass spectrometer (Extrel C-50) which serves as the anode of the discharge. The discharge is struck between the anode body and the cathode sample which is held against a Teflon o-ring by a brass torque bolt to form the vacuum seal. A bellows-type assembly allows for adjustment of the cathode-to-sampling cone distance by moving the sample and anode plate. The rf potential is applied directly to the back of the sample by a 1/8" copper rod attached to a type HN rf connector. A RF Plasma Products generator and impedance matching network (RF5 and AM 5) maintain the discharge at powers of 5-25 watts. Plasma ions enter the analyzer chamber through a 0.02" orifice in the sampling cone. The sampling cone can be biased with an external potential to act as a repeller for enhanced ion throughput. The rf-GDMS source is operated with argon as the discharge gas at pressures of 0.1-0.35 torr. Mass spectra are output to an X-Y plotter.
Results and Discussion

The new external sample mount geometry source has been evaluated on the basis of the plasma stabilization times, dependence of ion signal on sampling position and discharge conditions, and its ability to sputter-atomize both nonconductors and thin film systems. In order for GDMS to be acceptable for production applications, the sample analysis times must be appreciably shorter than the 30 minutes required for the current pin-type d.c. sources. Stabilization times have been found with the source under study here to be less than one minute with the plasma remaining stable to on the order of -3% RSD for periods of over one-half hour. At the outset of these studies, it was expected that the optimum sampling conditions for the external sample mount geometry would be appreciably different from those found for the DIP described at the 1990 ASMS Conference (paper #401) due to a much lower power density in the present case. Detailed studies indicate essentially no difference, with maximum analyte signal obtained for a sampling distance of 5mm and discharge conditions of 0.15 torr and 20 watts of rf power. Under these conditions, analyte ion beam currents on the order of a few hundred picoamps are obtained. Analysis of glass and thin film samples have been possible with the source though the current 1" inner diameter of the bellows assembly is still somewhat limiting in the types of samples that can be analyzed. Future developments will focus on the use of a single sampling position arrangement, as is used for emission spectroscopy in this laboratory, which will remove the diameter restriction currently experienced and also result in a much simpler construction.
Glow discharge mass spectrometry (GDMS) is proving itself to be a valuable tool for bulk elemental analysis of metals and semiconductors. In this laboratory, we have extended the applicability of the technique to nonconductors by use of radio frequency (13.56 MHz) powered devices. In the rf glow discharge plasma, the electrons in the negative glow region experience a rapidly alternating set of field potentials, different from d.c. plasmas wherein the negative glow consists of negligible, static, fields. This difference is manifested in pronounced differences in the discharge plasma potential from which the ions are extracted. In terms of performing quadrupole mass spectrometry, this presents problems in that the kinetic energies of the rf-produced ions will be higher than in the d.c. case. With the aid of quadrupole offset potentials, energy differences may not be appreciable so long as the width of the kinetic energy packet is narrow. Another reason for differences in the kinetic energies is the fact that the actual ionization mechanisms may be different. In our rf source electron impact seems to be the dominant pathway, while Penning ionization seems to dominate in d.c. plasmas. The studies described here address efforts to increase the ion transmission efficiency in quadrupole rf-GDMS and also to gain a more thorough understanding of the ionization environments in rf and d.c. plasma sources.

**Experimental**

The radio frequency glow discharge ion source and double-quadrupole mass spectrometer system are shown on the accompanying page. The external sample mount geometry source allows analysis of nominally flat, conductive or nonconductive samples of greater than \(-0.3\)" diameter. The source operates with argon as the discharge gas at pressures of 0.1-0.35 torr, and with rf powers of 5-25 watts. The double-quadrupole system was operated with the first quadrupole (Q1) in an rf-only mode without any collision gas present. Ion kinetic energy measurements were performed by use of the quadrupole retarding potential method. In particular, the d.c. offset voltage of the mass analyzing quadrupole (Q2) was varied with the corresponding effects on ion intensities noted.
Results and Discussion

Ion kinetic energy studies confirmed earlier Langmuir probe measurements performed in rf and d.c. plasmas in this laboratory. In all of the cases, the mean ion kinetic energy values were of the order of 16-18 eV, the precise range of the plasma potential measurements. Interestingly, the energy distributions for monoatomic ions were far more narrow than those for molecular ions such as dimers and argides. This may be explained by the fact that molecular species are formed by two-body associated ionization reactions rather than simple EI or Penning collisions. Alternatively, these species may be formed not in the plasma, but in the gas expansion beyond the sampling orifice. A suite of studies were performed to elucidate the role of extraction optics on the kinetic energy distributions. It was found that the optics systems had negligible effects on the energy distributions, but were important mostly on absolute sensitivity. It was interesting to note that, of all of the ion optical elements, the "skimmer cone" potential had the most dramatic effect on the relative intensities of the various ion species. Finally, studies of the role that plasma parameters play indicated substantial influence on the ion energies. These effects are most certainly related to changes in the plasma potentials.
An Appraisal of the Glow Discharge as an Elemental Ion Source for Quadrupole, Magnetic Sector, and FTICR Mass Spectrometers

C.M. Barshick and J.R. Eyler
Department of Chemistry
University of Florida
Gainesville, FL 32611-2046

Techniques of Fourier transform ion cyclotron resonance (FTICR) mass spectrometry have been applied to a wide range of chemical problems, from ion photodissociation to comparisons of gas phase and solution reactivity to analyses of polymers and biopolymers. Until the development of external ion generation/injection, ion formation had been limited to sources that could operate under the constraint imposed by the low pressure analyzer. This precluded the use of fast-atom bombardment, supersonic expansion/photoionization, as well as several more conventional elemental ion sources, such as the inductively coupled plasma (ICP) and the glow discharge (GD). Recently, however, we have interfaced an abnormal glow discharge ion source to a Nicolet FTMS 1000 Fourier transform ion cyclotron resonance (FTICR) mass spectrometer, bringing the total number of different types of GD mass analyzers to four. While it can be argued that each GDMS instrument has a place in analytical mass spectrometry, we feel that the newest approach, GD-FTICR, offers several advantages over quadrupole and magnetic sector based instruments.

EXPERIMENTAL

The positive ions generated in the negative glow region of a coaxial cathode glow discharge were mass analyzed by a home-built FTICR mass spectrometer that employed a Nicolet FTMS-1000 electronics console to control a 4.50 cm x 2.54 cm x 2.54 cm ion analyzer cell. Figure 1 illustrates modifications necessary to interface the FTICR mass spectrometer to the glow discharge source. A series of four electrostatic lenses accelerated and focused ions sampled from a 1.0 mm diameter ion exit orifice. In the initial studies only one stage of differential pumping was employed; in this manner the analyzer pressure could be maintained at 2 x 10^-6 Torr (discharge pressure = 1.0 Torr). To obtain higher resolution mass spectra, the collision frequency in the ion analyzer cell was further reduced by placing a second 1.0 mm diameter orifice between the electrostatic lenses and the FTICR analyzer cell (Figure 1B). In this configuration the analyzer could be maintained at 9 X 10^-6 Torr, but with a concomitant loss in signal.

A typical pulse sequence involved dropping the analyzer cell trapping plates from +2V to ground for a period of 0.1 - 5.0 seconds to allow ions to be "injected" into the cell, and then raising the plates back to +2V for the detection phase. In typical experiments ions with frequencies from 10 kHz to 2.667 MHz were excited and detected with a bandwidth of 2.667 MHz. Fifty time domain signals of 16 K data points each were accumulated, and the average time domain signal was apodized by a modified Blackman-Harris window function and zero-filled once prior to Fourier transformation.

RESULTS AND DISCUSSION

Figure 2 shows the mass spectrum obtained when an NIST 1261a stainless steel pin is the sample cathode. The iron isotopes at m/z 54 and 56 are the major peaks along with interfering peaks at masses 18, 19, 28, and 29, resulting from H2O^+, H2O^+, N2^+, and N2H^+, respectively. Ar^+ and ArH^+ were ejected from the cell via a swept frequency ejection pulse and therefore don’t appear in the spectrum. Minor components of the sample at the 0.5 - 2% level are easily detected, and the isotopic ratios agree with known values to about ± 5%. Preliminary results indicate detection limits on the order of 25 ppm. Although the sensitivity is rather low when compared with other GDMS instruments, for which the detection limits are on the order of 1 ppb, improvements in our relatively simple ion injection scheme (for instance the addition of a Bessel Box energy analyzer and quadrupole ion guide) should lower the LOD by several orders of magnitude.

Moderate resolution of m/Δm = 10000 and high resolution of m/Δm = 40000 obtained in experiments to date indicate that the FTMS approach holds the potential for discrimination of isobaric...
interferences. Studies are also continuing to exploit the unique capability of ion trapping in providing other schemes for the elimination of glow discharge polyatomic interferences.

Gas Phase Photochemistry of Anionic Metal Carbonyl Complexes.
Brian T. Cooper and Steven W. Buckner, Department of Chemistry, University of Arizona, Tucson AZ, 85721

Introduction
This report involves two aspects of the gas phase photochemistry of anionic metal carbonyl complexes: (1) the photodissociation spectra and decomposition pathways of dinuclear metal carbonyl complexes \( \text{M}_2(\text{CO})_x^- \), \( \text{M} = \text{Mn, Fe, Co}, \ x = 4-9 \) and (2) the radiative relaxation of vibrationally excited \( \text{Cr(OC)}_6^- \) under collisionless conditions.

Experimental
All experiments were performed on an FT-ICR previously described in detail[1]. For the relaxation studies the metal complex precursor was introduced into the vacuum chamber via a pulsed valve. The relaxation study was commenced when the chamber pressure reached ~1.5 \times 10^{-4} \text{ torr}. All ions were generated with an ~10 usec 3 microamp beam of ~0.1 eV electrons.

The photodissociation studies of the dinuclear complexes were performed with a Coherent Ar* pumped cw dye laser. The output of the dye laser into the ICR cell can be gated on/off with a mechanical shutter which can open on the 2 msec timescale. The relaxation studies were performed with a Spectra Physics pulsed Nd:YAG operated in the long pulse mode where the temporal output consists of a train of ~200 10 nsec pulses produced in a 200 microsecond envelope.

Results
CO\(_3\)(CO\(_x\))\(_2\) and Fe\(_2\)(CO\(_x\))\(_2\), generated from dissociative electron capture by CO\(_2\)(CO\(_x\))\(_2\) and Fe\(_2\)(CO\(_x\))\(_2\), dissociate by simple loss of CO ligands in the 565 - 635 nm range. All the photoproducts also dissociate by CO loss except for the \( \text{M}_2(\text{CO})_4^- \) which dissociate exclusively by loss of M. The exclusive loss of a metal atom in the last step does not appear to be due to an energetic factor, because the lowest energy dissociation pathway for Fe\(_2\)(CO\(_x\))\(_2\) is formation of Fe(CO\(_3\))\(_2\) and Fe(CO). The unusual dissociation behavior may be due to photoexcitation to a repulsive state which eliminates a metal atom, or an activation barrier introduced by a change in spin between the photoexcited anion and the products.

The radiative relaxation of vibrationally excited \( \text{Cr(OC)}_6^- \) under collision free conditions was investigated using the two-pulse photodissociation method developed by Dunbar and coworkers[2]. The basic process is shown in scheme I. After initial photoexcitation with a 1064 nm photon \( \text{Cr(OC)}_6^- \) undergoes rapid interconversion to a vibrationally excited ground state. The relaxation of the vibrationally excited state was interrogated by irradiating the excited \( \text{Cr(OC)}_6^- \) with a second 1064 nm photon. By varying the time between the laser pulses and monitoring the amount of dissociation (loss of CO which requires two 1064 nm photons) it is possible to monitor the relaxation. The results are shown in Figure I.

Interestingly, the intermediate vibrationally excited \( \text{Cr(OC)}_6^- \) has considerably enhanced reactivity toward O\(_2\). The reactions and temperature dependence of the reaction has previously been studied[3]. This is the fourth reported observation of a photoinduced chemical reaction of a gas phase ion.

Charlottesville, VA 22908

Introduction

Isotope dilution mass spectrometry can be used as a definitive analytical method for trace element determination providing reference values for concentrations in both normal and pathological conditions. We have used a general-purpose mass spectrometry system, preparing volatile-thermally stable metal chelates, for the determination of isotope ratios and metal concentrations. Historically, the lack of suitable chelating agents was the key limitation preventing the application of GC-MS to trace element analysis. The problems of poor accuracy and precision of the isotope ratio measurements resulted, in part, from cross-contamination or "memory effect" during sequential analyses of samples of widely varying isotopic compositions. We have evaluated 8 elements and 7 chelating agents.

Experimental

All the analyses were accomplished on a Finnigan MAT 8230 GC-MS system equipped with a 10m x 0.32 mm, non-polar fused silica capillary column, DB-1. Chelates were injected at an oven temperature of 100°C followed by a 25°C/min ramp to 300°C. The ion source was heated to a temperature of 200°C and the GC-MS interface was at 280°C. GC-MS data were acquired at 2 Hz yielding approximately 20 data points across the 10-s wide GC peak. A mass resolution of 1000 was used throughout.

Normal trace metals procedures to avoid contaminations were followed. The enriched isotope solutions used as internal standard for isotope dilution were calibrated by reverse-isotope dilution GC-MS using certified atomic absorption standards.

The 70 eV El mass spectra were recorded for all the chelates and the isotopic cluster of peaks with maximum intensity was used throughout the experiments. The isotope ratios were measured in the selected ion monitoring mode using voltage peak switching and the quantitation was achieved using the chromatographic peak areas.

Urine samples were digested with a wet oxidation procedure using concentrated HNO₃ and H₂O₂ for Ni, Cr, Co, Cu, Pb and Cd. For the determination of Pt and Se, wet digestion procedure with HNO₃ + H₃PO₄ (5:1, v/v) and H₂O₂ was employed. Blood and serum samples were first deproteinized using concentrated HNO₃ and the precipitated proteins were pelleted by centrifugation and the supernate digested as the urine samples. Lead (Pb) was determined in the whole blood; and Cu was determined in serum.

Precision and accuracy of the isotope ratio measurements was evaluated at 10 ng level by performing replicate analyses of samples on different days. Memory effect was investigated using synthetic mixtures of the natural primary standard solution and the enriched isotope solution in differing proportions but containing almost equal amounts of element. Isotope dilution GC-MS methodology was validated by determining trace elements in the National Institute of Standards and Technology (NIST) reference materials, SRM-2670 for urine and SRM-909 for serum.

Results and Discussion

Lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), was successfully used for Ni, Cr, Co, Pt, Pb and Cd in the μg/L range. N,N'-ethylene bis(trifluoroacetyl)acetoneimine, H₂(enTFAJ, was used for Cu in serum and urine; while 4-trifluoromethyl-o-phenylenediamine was found to be the best chelating agent for Se. These chelating agents were synthesized in our laboratory.
No memory was observed for Ni, Cr, Co and Pt; however, a slight memory effect was observed with Pb and Cd which could be minimized by appropriate addition of the internal standard.

For the monoisotopic element Co, a novel approach using enriched isotope of Ni as an internal standard was used for its determination by GC-MS.

The values of trace elements determination by isotope dilution GC-MS were compared to the NIST certified/recommended values in the reference materials (Table 1). Good agreement between the expected and experimentally determined values proved the validity of isotope dilution GC-MS for trace elements determination at μg/L levels.

Conclusion

The results of the work todate indicate that isotope dilution GC-MS using chelating agents has great potential as an analytical method. However, it should be noted that each metal, chelate and GC-MS system should be carefully evaluated to establish the analytical limits.

FDMS and FABMS have significantly influenced the analysis of organo-metallic compounds. Usually by one or both desorption/ionization techniques molecular ions of the analytes were formed. But often mass spectra were complicated by the presence of several ions that arise by alkali metal impurities and/or by reactions with the liquid matrix. Nevertheless, the combination of the above mentioned desorption/ionization methods with tandem mass spectrometry have provided useful molecular weight and structural information (1). However, studies on fission fragment induced desorption, another "soft ionization" technique, of inorganic and organometallic compounds have been relatively scarce (2-5). Even less is known about the behaviour of metallocenes under Cf-252 fission fragment bombardment and subsequent mass spectrometric analysis (6,7). The present work focused on three objectives. The main one was to demonstrate the potential of PDMS in characterizing various ferrocenyl-phenyl-plumbanes (FPP). PD mass spectra of all FPPs showed intense M⁺ ions and only low intensity adduct ions (see Fig. 1). The second objective was to compare the molecular ion regions obtained by a linear (15 cm) and a reflecting (drift region equivalent to ca. 100 cm) TOF instrument (see Fig. 2). The resolution of the reflectron mass spectrometer turned out to be sufficient to resolve the isotopic pattern of the molecular ions (R = 1500 at FWHM). The theoretical calculated isotopic intensity distribution showed an excellent correlation with the measured distribution (correlation coefficient r = 0.9971). The last objective was to try to find significant fragment ions especially with the reflecting instrument which allow to obtain structural information. All FPPs underwent extensive fragmentation. Since these compounds contain numerous atoms with multiple isotopes, the isotopic pattern of fragment ions can be interpreted to provide compositional information. The results have given interesting new information for the synthetic chemist especially with the electrostatic mirror containing instrument as well as new insights into the desorption/ionization processes of solid thin films of metallocenes by PD.

GAS-PHASE THERMOCHEMISTRY OF METALLOCENES AND METALLOCENIUM IONS
Matthew F. Ryan, David E. Richardson, and John R. Eyler
Department of Chemistry, University of Florida, Gainesville, FL, 32611

The study of chemical reactions in the gas-phase leads to fundamental properties of a molecule that may otherwise be masked by solvent interactions. The investigation of gas-phase ion-molecule reactions involving organometallic compounds can be used to determine thermochemical information, including gas-phase basicities and acidities, electron affinities and ionization potentials. Direct comparison of gas-phase data to solution chemistry reveals the effect solvation has upon a reaction.

Fourier transform ion cyclotron resonance, FTICR, mass spectrometry has been used to investigate gas-phase ion-molecule reactions of a series of metallocene compounds, Cp²M, where Cp denotes η⁵-cyclopentadienyl. From the measured equilibrium constant for a charge-transfer reaction (equation 1), the free energy of the

\[ \text{Cp}_2M + R^+ = R + \text{Cp}_2M^+ \quad (1) \]

reaction can be determined. If the free energy of ionization, \( \Delta G^\circ \) of R, a reference compound is known, \( \Delta G^\circ[\text{Cp}_2M] \) can be calculated.

Using organic reference compounds previously studied by equilibrium techniques, the free energy of ionization of Cp₂V, Cp₂Mn Cp₂Fe, Cp₂Ni, Cp₂Ru, Cp₂Os, and a series of ferrocene derivatives has been determined. An equilibrium ladder (Fig. 1) shown below displays all charge-transfer reactions studied in this work. Newly determined \( \Delta G^\circ \) values for the metallocenes are shown adjacent to their molecular formula. \( \Delta G^\circ \) values for charge-transfer reactions lie adjacent to arrows with values in parenthesis indicating charge-transfer reactions involving reference compounds taken from the literature.

Temperature dependence studies have been performed in order to determine enthalpies and entropies for selected charge-transfer reaction. Because temperature dependent studies have not been investigated previously using FTICR mass spectrometry, a model reaction was studied in order to assess the reliability of measured equilibrium constants as a function of temperature. The CO/Kr reaction couple (eq 2) was chosen because the \( \Delta \Delta G^\circ \) is accessible on the FTICR-MS scale and

\[ \text{CO} + \text{Kr}^+ = \text{Kr} + \text{CO}^+ \quad (2) \]

sufficient spectroscopic data exist to facilitate statistical thermodynamic calculations of enthalpies and entropies for all neutral and ionic species involved. The experimentally derived entropy and enthalpy changes for the reaction are 3.3 ± 1.4 e.u and 0.3 ± 0.8 kcal/mol respectively as compared to the theoretical values of \( \Delta S^\circ \) = 1.42 ± 0.06 e.u and \( \Delta H^\circ \) = -0.2 ± 0.01 kcal/mol. The experimental values are consistent with statistical thermodynamic values and no anomalies were found for the equilibrium constants.

The results of selected temperature dependent charge-transfer reactions are shown in Fig. 2. The entropy of reaction for the ferrocene/N,N'-diethyltoluidine reaction couple is nearly 7 e.u. higher than previously reported by Mautner. For the Cp₂Ni/Cp₂Mn couple, the nearly 6 e.u. for \( \Delta S^\circ \) is not unexpected when the large geometric changes subsequent to ionization of Cp₂Mn are considered. From these studies, values of \( \Delta G^\circ[\text{Cp}_2M] \) were shown not to differ significantly from \( \Delta H^\circ[\text{Cp}_2M] \) values at experimental
temperatures employed. Thus the data obtained in this work can be used to obtain other useful thermochemical information.

Thermochemical cycles, (Fig. 3) were used to make estimates of average heterolytic, $\Delta H^{\circ}_{\text{het}}$, and homolytic, $\Delta H^{\circ}_{\text{hom}}$, bond dissociation enthalpies for metallocenes and metallocenium ions. Comparison of $E_{\text{a}}$ values with $\Delta G^{\circ}$ data gives differential solvation energies, $\Delta \Delta G^{\circ}$, the lower portion of the cycle (Fig. 3).

A series of ferrocene derivatives were studied in order to assess the effect substituent groups have upon $\Delta G^{\circ}$ of organometallics. The ferrocene derivatives also serve to link the upper and lower portions of the equilibrium ladder. A plot comparing $\Delta G^{\circ}$ for the ferrocene derivatives versus benzene analogues (Fig. 4) yields a straight line with slope of $\approx \frac{1}{3}$. Thus, the substituents have a greater effect on the ionization potential of benzene than for ferrocene. The proximity of the polarizing groups with respect to the reaction center generates an enhanced substituent effect for benzene than for ferrocene.

DECOMPOSITION OF NITROSATED 4-CHLOROINDOLES.

Nigel K Brown, Thanh T Nguyen, Koli Taghizadeh, Yousif Sahali, Steven R Tannenbaum and John S Wishnok.

Division of Toxicology and Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

In Colombia, where fava beans (Vicia faba) are an important component of the diet and where nitrate intake is high, the population is at especially high risk for developing gastric cancer. Earlier reports from this laboratory detail the isolation of 4-chloro-6-methoxy-indole from fava beans (Yang et al., 1984), which upon nitrosation (under simulated gastric conditions) forms 4-chloro-6-methoxy-2-hydroxy-N-nitrosoindolin-3-one oxime, a direct acting exceedingly potent mutagen (Buchi et al., 1986). Analogous results are obtained with 4-chloroindole (I) (see Scheme 1), which upon nitrosation yields 4-chloro-2-hydroxy-N-nitrosoindolin-3-one oxime (II), which has been developed as a model for the methoxy analogue.

![Scheme 1: Decomposition Pathway for Nitrosated 4-Chloroindole](image)

At physiological (or elevated) pH, 4-chloro-2-hydroxy-N-nitrosoindolin-3-one oxime (II) was found to be unstable and gave a number of compounds (as judged by HPLC), only one of which was shown to be mutagenic to *Salmonella typhimurium* strain TM677.

$^1$H-NMR spectra of freshly purified samples of the mutagenic decomposition product (III) clearly showed the presence of 5 protons, three aromatic (two doublets and a triplet, none exchangeable) and a >CH(OH) function (two doublets, one signal lost after exchange, the other simplifying to a singlet). Notably, there was no N-H resonance (as in compound IV) indicating a N-substituted compound (with no protons on the substituent). Furthermore, in the UV spectrum there was an absorption at 386nm, consistent with an N-nitrosoamide. The NO group was thermally labile when volatised for GC-MS analysis, but the resultant mass spectrum (see spectrum A, below) was identical to that of the synthetic de-nitrosated material, 4-chlorodioxindole (IV) synthesised (with minor modifications) according to the methods of Marvel and Heirs (1941), Sadler (1956) and Marchalk (1912). Equally, compound III exhibited an identical GC-FT-IR spectrum to IV.

In samples of 4-chloro-N-nitroso-dioxindole (III) that had been allowed to stand for several hours, it was possible to see the appearance of compound V in the NMR spectrum, identified as 4-chloroisatin by comparison with NMR measurements on the synthetic material (synthesised in the preparation of IV, above). Further proof of identity was achieved by matching GC-MS and GC-FT-
IR spectra and the UV spectrum after reverse-phase HPLC purification (see spectra B and C, below). This material was also present in the crude decomposition mixture from compound II.

Nitrosation of 4-chloroindole with \(^{15}\)N-labelled nitrite with (and without) subsequent decomposition in \(^{18}\)O-labelled water clearly demonstrated that compound V retained no nitrogen from nitrite, but incorporated one oxygen from the labelled water (consistent with oxygen attack at C-3 of compound II).

It was demonstrated that compound III induces a mutant fraction of \(-1\times10^{-4}/\mu M\) in Salmonella typhimurium strain TM677 (with compound II inducing a mutant fraction of \(-1.3\times10^{-2}/\mu M\)) as determined by the method of Skopek et al. (1978). When tested, the synthetic compounds IV and V exhibited no mutagenic activity.

After human consumption of fava beans, when nitrosated indoles are absorbed into the stomach wall, it is clear that the corresponding increase in pH may cause decomposition to the nitrosated dioxindole, and ultimately to the inactive isatin. Such factors as the rates of decomposition, and the mechanisms of mutagenesis are obviously important in determining the relative carcinogenic potential of these species.

E.I. Mass Spectra of Decomposition Products.

REFERENCES
Toxicity of benzene requires the metabolism of the parent compound to one or more metabolites (Tunek et al., 1982). Benzene is mainly metabolized in the liver by the p-450 system to the reactive intermediate benzene oxide. This epoxide is very unstable and converts to several metabolites: phenol, catechol, and toxic metabolites such as hydroquinone, benzoquinone, and muconaldehyde. Bone marrow depression in humans (Aksoy, 1985) is presumably caused by the covalent binding of reactive metabolites to macromolecules in bone marrow after the benzene exposure. This study shows new ways to derivatize the urinary metabolites of mice exposed to benzene. Benzene is a petroleum by-product, and a component of unleaded gasoline. It is volatile and fat-soluble, and absorbed by inhalation, ingestion, and dermal contact. Because of its extensive use, a large number of people were exposed regularly to benzene. Benzene is mainly metabolized by the cytochrome p-450 monooxygenase system which is mostly found in the liver, and also in the bone marrow. This toxicity in humans is characterized by panleukopenia (depression of the levels of all circulating blood cell types) or one of its cytopenic variants (depression of the levels of one or more, but not all, of the circulation blood cell types). Lymphocytopenia is one of the most sensitive and easily measured indicators of benzene toxicity in the peripheral blood. Benzene metabolites, such as free phenol, hydroquinone, and catechol were detected not only in the blood but also in the bone marrow (Rickert et al., 1979).

Male B6C3F1 (n=5) were dosed a single time by gavage with 1.4 grams/Kg body weight benzene in corn oil and urine was collected at 24-hour intervals for one week. Aliquots of urine were acidified to a pH of 4.4 and hydrolyzed by &-glucuronidase/sulfatase at 37°C for 16 hours. The metabolites were extracted with 3 % MeOH/ethyl acetate using Clin Elut disposable columns. Simultaneous derivatization of hydroxyl and carboxylic acid groups were carried out by Tri-BSA agent. Mass spectra and GC retention times of TMS-derivatives were compared with purchased compounds. All spectra were obtained on a HP 5985 quadrupole mass spectrometer equipped with capillary columns (DB-1 30 meter). Helium was used as carrier gas (25 cm/sec), and both injection port and ion source were 200°C. The column temperature was programmed from an initial oven temperature of 100°C held for 1 min, with the program rate of 5°C/min, to the final temperature of 180°C held for 1 min. Concentration of each component was calculated by comparison with standards.

TMS-derivatives of phenol, catechol, hydroquinone, and muconic acid were easily prepared by one step reaction and standards were within a linear range. One of the toxic metabolites, hydroquinone was present in the highest concentration and catechol in the lowest. No metabolites were detected after 7 days. This simple method can be used to analyze the urinary metabolites of mice exposed to the benzene and its results can be correlated with the bone marrow depression.

INTRODUCTION

The structural characterization of carcinogen-modified nucleosides derived from biological (particularly human) sources has been limited because in many cases only small (subnanogram) quantities were isolated prior to mass spectral analysis. To date, metastable ion mass spectra of protonated molecule ions derived from FAB-generated, silylated amino PAH-nucleoside adducts have been acquired using as little as 4-5 ng (applied to the probe) in a targeted compound analysis mode (1). We have demonstrated here for the first time the identification of unknown PAH nucleoside adducts for subnanogram levels of sample.

EXPERIMENTAL

All FAB MS/MS spectra were acquired using a Finnigan MAT TSQ 70 triple quadrupole mass spectrometer equipped with an Ion Tech fast atom gun. Xenon was employed in the primary atom beam at energies of 8-10 KeV and Ar as the collision gas for CID. Dithioglycerol was used as a matrix. CAD spectra of the protonated molecule ions were acquired using 50 eV (constant neutral loss, CNL) and 100 eV (single and dual reaction monitoring) collision energies. For silylated adducts, derivatization was accomplished using N-methyl-N-trimethylsilyltrifluoroacetamide (MSTFA) at 55° C for 1 hour.

CONSTANT NEUTRAL LOSS MS/MS

We employ CNL scans (2) to identify unknown (previously silylated) amino PAH-nucleoside adducts by scanning Q1 and Q3 simultaneously, with a mass offset corresponding to that of the neutral fragment lost in the CAD process (3). This neutral corresponds to a disilylated deoxyribose (260 amu). Since only those ions that fragment to lose 260 amu are detected, most of the chemical noise accompanying regular FAB analysis is eliminated. The CNL spectra of three model amino PAH-nucleoside adducts were obtained by adding all scans acquired (typically 25) from a single probe loading. Figure 1 shows the CNL spectrum obtained using 500 pg of N-(deoxyguanosin-8-yl)-2-acetylaminofluorene (dG-C8-AAF). The ions at m/z 633 and 705 correspond to the protonated modified nucleoside plus 2 and 3 TMS groups, respectively. Similar results were obtained using 2 ng of N-(deoxyguanosin-8-yl)-4-aminobiphenyl (dG-C8-ABP) and 3-(deoxyguanosin-N2-yl)-2-acetylaminofluorene (dG-N2-AAF). In each case a TMS containing protonated molecule was readily observed. However, with dG-C8-ABP, ions corresponding to protonated molecules for the bis- and tris-TMS derivatives not containing a carcinogen moiety (ABP) were also observed at m/z 412 and 484.

Single reaction monitoring (SRM) was employed to determine the detection limits for the analysis of dG-C8-ABP and dG-N2-AAF using this compound-specific methodology. This was achieved by setting Q1 to the mass corresponding to the protonated molecule for the TMS-derivatized nucleoside and Q3 to the mass of the BH2* fragment resulting from loss of the bis-silylated deoxyribose moiety. In these experiments as little as 50-100 pg of modified nucleoside could be detected.

The most significant obstacle to improving the sensitivity for the analysis of all of the compounds we have studied appears to be the silylation step. The efficiency of silylation increases with reaction time, as does the extent of cleavage of the amino-PAH moiety from the nucleoside base. Further studies will be directed towards determining the best conditions for silylation without cleavage of the carcinogen from the nucleoside base.
ISOTOPE DILUTION MS/MS

Isotope dilution studies were performed to establish the linear range and limit of detection (LOD) using a model base-amino PAH adduct. The TSQ was switched between characteristic fragmentation reactions of the deuterated standard, guanine-C8-(d4-ABP) (m/z 328 to 203) and the targeted compound guanine-C8-ABP (m/z 319 to 195). These fragmentation reactions are attributed to the same cleavage in both compounds based on FAB MS and FAB MS/MS spectra from each compound. (A single H-D exchange accompanies this cleavage.) For each analysis the probe was loaded with 125 ng of guanine-C8-(d4-ABP) and variable quantities (300 pg to 6 ng) of guanine-C8-ABP. In figure 2, the fragment ion intensity ratio (expressed in percent) for m/z 195 and m/z 203 is plotted against the amount of guanine-C8-ABP. Four replicate loadings were run for each quantity of guanine-C8-ABP and 25 scans were added to obtain each point in the plot.

The least squares line in figure 2 has a slope of 9.35x10^4 and an intercept of 0.680%, suggesting the LOD is approximately 600 pg with a background of 300 pg. This background is attributed to a low level of guanine-C8-ABP in the guanine-C8-(d4-ABP) that contributes significantly when the deuterated standard is present in excess.

CONCLUSION

We have demonstrated that the analysis of carcinogen-modified nucleosides may be carried out at subnanogram levels. These data suggest that the presence of a suspected amino PAH adduct may be confirmed using SRM with as little as 50 pg of adduct. Quantification using isotope dilution has been accomplished with a LOD of about 600 pg. Lower LODs may be achieved using smaller quantities of (or more completely labeled) internal standards.

INTRODUCTION

Accumulated oxidative damage to neuronal DNA bases has been implicated in disorders of aging such as Parkinson's and Alzheimer's diseases (1). In order to test this hypothesis, we have been developing GC/MS methods for measuring thymine glycol (2). Initially, we tried to find a suitable derivative for GC/NCl of thymine glycol, but we were stymied by its base lability, thermal instability, and failure to form a compound with sensitive electron capture properties. Instead, we have focused upon its specific conversion to 2-methylglyceric methyl ester (3) following base hydrolysis, sodium borohydride (deuteride) reduction, and acidic methanolysis. This reaction affords the significant advantage that 2-methylglyceric methyl ester can be separated from intact DNA, rather than requiring the separation of thymine glycol from the other DNA bases. Sodium borodeuteride adds specificity, because monodeuteriated 2-methylglyceric methyl ester results from its use.

We had used the bis-trifluoroacetyl-2-methylglyceric methyl ester for EI-GC/MS, but we were unable to obtain sufficient sensitivity to measure basal levels of thymine glycol in native DNAs, although we could readily measure thymine glycol in intentionally damaged DNA. In order to improve detection limits, we sought a derivative which would add mass, retard volatility, direct fragmentation to structurally characteristic ions, and have stable chemical and physical properties. Several derivatization reactions were tested, and the di-t-butyldimethyl silyl derivative was found to be most satisfactory. Note that this reaction only proceeds with acid catalysis, precluding the use of commercial t-butyldimethylsilylimidazole or MTBSTFA without silylchlorides.

EXPERIMENTAL METHODS

A solution of the internal standard (d4-thymine glycol, 16 ng/10 µL) is added to each tube. Then DNA (1-2 mg in 100-200 µL TE buffer) or thymine glycol quantitative standards (0.1-to-25 ng) are added, and 100 µL of NaBD4 (10mM) in 0.2 M NaOH (prewashed with CH2Cl2) is added next, and the mixture is heated for 1 hour at 37°C. All solutions are prepared fresh daily. The reaction is quenched with 100 µL of 6M HCl and dried in a vacuum desiccator. Methanolic/HCl (200 µL, 3% by weight) is added, vortexed, and heated 30 minutes at 70°C. The samples are dried in a vacuum desiccator, and 100 µL of t-butyldimethylsilyl imidazole reagent (prepared from 150 mg t-butyldimethylsilyl chloride, 170 mg imidazole in 1 mL acetonitrile, washed five times with equal volumes of heptane) is added and heated at 70°C for 30 minutes. The products are partitioned between 100 µL heptane/decane (90/10) and 100 µL water, and the organic phase is removed after freezing the tube with dry ice. The organic extracts in autosampler vial inserts are concentrated in vacuo to approximately 20-25 µL.

Analyses were performed using a Hewlett Packard 5890 GC and 5970 Mass Selective Detector with a 30 meter, 0.25 mm i.d., 0.15 µ DB225 column programmed from 90°C (1 minute) to 180°C at 10°/minute, followed by a 40°C/minute ramp to 240°C to remove contaminants. The di-tBDMS-2-methylglyceric methyl ester elutes at ~8 minutes.
Results
The linearity of standard curves was excellent over the range 0.5-25 ng/tube, with 0.5 ng being the lower limit of detection. The chromatographic behavior of the di-tBDMS-2-methylglyceric methyl ester is excellent, but DB-225 was preferred to non-polar phases in order to provide separation from several interfering background ions. There remains a measurable interfering background ion at m/z 306 which causes a non-zero y-intercept on standard curves and limits use of this assay to lower levels. Measuring the thymine glycol in native salmon sperm or herring sperm DNA provided a measure of the applicability of these methods to known materials. The measured thymine glycol in 1 mg quantities of salmon sperm DNA (1.61 ng ± 0.41 SD) and herring sperm DNA (1.16 ng ± 0.41 SD) were consistent with and proportional to the amounts measured in 2 mg quantities (salmon sperm DNA, 4.33 ±0.76 SD; herring sperm DNA 2.35 ± 0.43 SD).

Pitfalls
In all assay development, there are unexpected results which are encountered along the way. In the DNA thymine glycol assay, we noted an apparent improvement in the yield of product from native DNAs, up to 20-40 ng/mg DNA. Because we had optimized the reaction conditions for detection of the d_{4}-thymine glycol internal standard, we were pleased. However, when we tested this observation with thymine, we determined that thymine could be oxidized to thymine glycol during the assay unless conditions were employed to prevent such an artifactual oxidation. For example, when the thymine glycol in 100 μg quantities of commercial and recrystallized thymine was quantified, if less than 1 mM NaOH base strength was used, or if the thymine was taken to dryness from a dilute base solution, then significant quantities of thymine glycol were measured. With the conditions reported above, 4.7 ng of thymine glycol were measured in 100 μg of commercial thymine, and 2.7 ng in 100 μg of the recrystallized material.

Conclusions
A significant sensitivity enhancement has been attained with respect to the methods reported previously due to several factors. First, the use of a di-tBDMS derivative has permitted sample concentration in the final step, providing a 10-15-fold improvement. Second, adoption of a DB225 chromatographic column largely eliminated non-specific background, affording lower detection limits. Thirdly, determination of optimal hydrolysis, reduction, and methylation conditions largely eliminated artifactual oxidation of thymine in native DNAs so that consistent and mass proportional yields of thymine glycol could be quantified. These levels (~1 ng/mg DNA or 1 ppm) are quite low, such that a further sensitivity enhancement of 10-to-100 fold is desirable for application of this measurement to human brain tissue.

DNA adducts are formed by the covalent attachment of carcinogenic species to the base, sugar, or phosphate portion of the DNA molecule and are widely believed to play a role in the process of carcinogenesis. The techniques normally employed to characterize these species at physiologically significant levels including 32P-postlabeling, immunoassay, and fluorescence line-narrowing spectroscopy are generally not able to provide pertinent structural information for unknowns. We have explored the utility of dynamic FAB mass spectrometry in various modes for the characterization of these species with the ultimate goal of analyzing these compounds in biological matrices. Studies in high and low energy CID, negative dynamic FAB, and the utility of an interface between capillary electrophoresis and dynamic FAB are discussed below. The four adducts used for this work all involve carcinogen attachment to the base portion of deoxyguanosine and include N-(anthracen-9-ylmethyl)-deoxyguanosine, N-(deoxyguanosin-8-yl)-2-aminofluorene, N-acetyl-N-(deoxyguanosin-8-yl)-2-aminofluorene, and N-(deoxyguanosin-8-yl)-4-aminoazobiphenyl.

Instrumentation. Data were collected on two different MS systems. The first consisted of a VG70-250SE double focussing mass spectrometer employing a xenon FAB gun operated at 8 kV and 1.8 mA. This system was used for the negative ion work, the CE-CFFABMS interfacing, and the high energy collision studies. The second configuration consisted of a VG Quattro triple quadrupole system outfitted with a cesium ion FIB gun operated at 10 kV and 2.7 A. This instrument was used for acquiring the low energy CID data.

Negative Ion Spectra. Negative ion spectra were acquired using a dynamic FAB matrix solution of 5% glycerol, 5% ACN and 15% MeOH in water. Samples were dissolved in methanol and introduced via flow injection using a Rheodyne injector with a 0.5 uL loop. At a source temperature of 50 C, a flow rate of 5 uL/min through the 50 um ID fused silica capillary was employed.

Positive FAB analysis has been shown to have great utility for the characterization of PAH-DNA adducts (1). It has been found that the negative FAB spectra of these species also show provide many diagnostically useful ions and compare well with the positive ion spectra in terms of information content. In addition to giving ions which arise from the parent molecule ([M-H]-), loss of deoxyribose ([B-H]-), and cleavage through the sugar (Sj), the negative ion spectra contain at least two unique features which make this mode a useful complement to the positive mode. First, in all cases, molecular ions are enhanced relative to other ions in the spectra. This effect is most pronounced for the acetylaminofluorene adduct where the molecular ion that accounts for < 10% of the base peak in the positive ion spectrum becomes the base peak in the negative mode. A second noteworthy feature is the presence, in the C8 adduct spectra, of ions which provide useful linkage position information as they arise from cleavage through the guanine with charge retention on the PAH portion of the molecule (see Figure 1).

Negative FAB analysis was found to be somewhat less sensitive than positive for the conditions employed. It is anticipated that under more basic dynamic FAB conditions (e.g. the use of matrices such as diethanolamine or triethanolamine) greater sensitivity may be observed.

Capillary Electrophoresis Dynamic FAB MS. In an effort to develop an on-line separation/structural characterization technique for the analysis of DNA adducts, we have assembled a capillary electrophoresis-dynamic FAB MS system (Figure 2) which employs a liquid junction interface similar to those previously shown to have utility for CE-CFFABMS work (2,3). Our goal is to use this technique in conjunction with CE with UV detection to confirm the presence of target adducts and to characterize unknown adducts in reaction mixtures and biological samples. To date, the adduct N-acetyl-N-(deoxyguanosin-8-yl)-2-aminoazobiphenyl has been employed as a standard to evaluate the performance of the interface for this application. Good quality full scan spectra were acquired in the positive and negative modes for 7.5-15 ng adduct and single transition monitoring of the loss of deoxyribose from the molecular species allowed facile detection of as little as 75 pg of material (Figure 3). Capillary electrophoresis was conducted using a buffer which consisted of a 0.01M NH4OAc solution adjusted to pH 9.5 with NH4OH and a CE column that was a 50-70 cm 75 um ID fused silica capillary with polyimide coating. Injections were made by siphoning of 7.5-15 nL of the sample dissolved in methanol at the anode. CE analyses were conducted at 10-15 kV (7-11uA). The dynamic FAB matrix consisted of 1% glycerol, 5% ACN, and 19%MeOH in H2O which flowed at a vacuum induced rate of about 1 uL/min. A 65 cm 5C um ID fused silica capillary with a polyimide coating was employed as the dynamic FAB capillary.

High and Low Energy CID Spectra. High energy FAB CID spectra were taken using a VG70-250SE double focussing magnetic instrument at 8 kV using linked scanning techniques. Samples were dissolved in methanol and introduced to the source by flow injection dynamic FAB employing a matrix solution consisting of 5% glycerol, 5% ACN, and 19% MeOH in water. Collision conditions were established by the attenuation of the precursor ion to 30% with the helium collision gas.
Low energy CID spectra were acquired on a VG Quattro triple quadrupole mass spectrometer at 100 eV. Precursor ions were attenuated to 30% by the appropriate pressure of argon collision gas. The dynamic FAB matrix solution consisted of 1% glycerol, 19% MeOH, and 5% ACN in water. The precursor ions chosen for these studies represent the loss of deoxyribose from the [M + H]+ ion in full scan spectra. CID spectra of these ions have generally been found to be rich in structural information.

Since certain of the experimental parameters could not be held constant due to variations in instrument design for the low and high energy systems (different dynamic FAB probes, different FA(I)B guns, etc.), a comparison of high and low energy CID sensitivity is not straightforward. However, it was found that the triple quadrupole spectra were (as expected) cleaner and easier to interpret than the linked scan data. This is due both to the faster scan times (an advantage when spectra are being taken across an eluting peak) and the resolution of precursor selection in the low energy system. Conversely, while the low energy spectrum of the methylanthracene adduct is relatively featureless, the high energy spectrum shows an increase in the number of structurally significant peaks (Figure 4).

IDENTIFICATION OF POLYCYCLIC HYDROCARBON DIOL EPOXIDE-HEMOGLOBIN ADDUCTS FROM HUMAN SUBJECTS BY GAS CHROMATOGRAPHY AND MASS SPECTROMETRY

Koli Taghizadeh, Billy W. Day, Paul L. Skipper, John S. Wishnok and Steven R. Tannenbaum

Department of Chemistry, Division of Toxicology, Massachusetts Institute of Technology, Cambridge, MA 02139 USA

This research seeks to establish a method for identification and quantitation of polycyclic tetrols which are released upon hydrolysis from polycyclic diol epoxide-hemoglobin and/or DNA adducts. Since adduct levels in hemoglobin are very low (femole to pmole per gram of globin) a very sensitive method of detection is required. At present the best approach is derivatization and use of GC-MS.

Chess et al. [1] have reported the mass spectra of permethyl, peracetyl and per(trifluoroacetyl) derivatives of benzo[a]pyrene tetrol under three different ionization modes (EI, PCI and NICI). A substantial number of fragment ions are produced under the three ionization modes, which makes these derivatives unsuitable for quantitation. We have studied the mass spectra of TMS derivatives of several different polycyclic tetrols. TMS ethers have been the best derivatives for quantitation of polycyclic tetrols under NICI (methane) conditions.

As shown in Figure 1, TMS derivatives of tetrols (e.g. 6-methylchrysene tetrol) tend to fragment extensively under EI and PCI conditions, whereas under conditions for NICI (e.g. chrysene tetrol and 6-methylchrylene tetrol), they give a single dissociative electron capture fragment, (Figure 2) which corresponds to M-(TMS-O-TMS)-. One major drawback to the TMS derivatives of tetrols is that they are unstable. As shown in Figure 3, for 1,2,3,4-tetrahydroxy-1,2,3,4-tetrahydrochrysene, the signal is reduced seven-fold when the derivatized sample is stored overnight at -20 °C; no signal can be detected from an identical sample after storage for 4 hours at room temperature. This behavior is even more pronounced in biological samples (detectable lifetime of less than 20 minutes), which makes it virtually impossible to obtain duplicate chromatograms of a biological-derived sample.

We have begun using a new method in which derivatization takes place in the injection port of the gas chromatograph. Reproducibility using this derivatization method is excellent as shown in Figure 4. As long as the underivatized sample is stable in a solvent compatible with the derivatization reagent, such as acetonitrile, this method is satisfactory. Figure 5 shows two gas chromatograms where the two different derivatization methods discussed above were used on the reaction products of (±)-trans-7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene and ethanol. The two methods of derivatization are comparable with respect to relative peak intensities. Total signal is much higher using the new method (the sample mixed and derivatized with N-methylsilylimidazole/pyridine in the GC injection port) than that seen after using the old method (sample mixed with N-methylsilylimidazole/pyridine in vial).

All of the analysis were done with a HP 5989 MS and a 5890 GC inlet system. Good separation was obtained for the TMS derivatives of polycyclic tetrols (benzo[c]phenanthrene tetrol, benz[a]anthracene II tetrol chrysene-tetrol, 5-methyl- and 6-methylchrysene tetrols) using a 30 m DB-17 fused-silica (J&W Scientific GC column).

In conclusion, the new method of derivatization is the best solution to the quantitation for selected ion monitoring of the dissociative electron capture fragments from perTMS derivatives of benzo[a]pyrene tetrahydrotetrols under the negative ion chemical ionization mode, as well as the identification of the other tetrols which are released upon hydrolysis of hemoglobin and DNA adducts.

COMPARISON OF THE TWO METHODS ON THE REACTION PRODUCTS OF 6-MTH DII. SODIUM OF RENIFOLAPHINE AND ETHANOL.
INTRODUCTION: Over eighty different natural nucleosides are presently known in nucleic acids, the greatest number being in tRNA. Because new nucleosides from these sources are usually isolated in small amounts, MS/MS plays a potentially important role in the identification of submicrogram amounts without isolation. Hence, experiments have been undertaken to assess the utility of trimethylsilylation coupled with tandem mass spectrometry for the structure analysis of nucleosides in mixtures. The extra step of derivatization adds increased effort and the uncertainty of uniform reaction yield; however, in many situations, the advantages outweigh the disadvantages, as follows: (1) CID generally produces more extensive and informative fragmentation of the silylated nucleoside compared with the underivatized compound, and a wealth of structure assignment data from EI-MS studies can be readily used.

(2) Silylation results in greater dispersion of molecular weight values for most nucleosides, and shifts them to a higher and more interference-free region of the spectrum for MS-1 mass selection. (3) In the case of the FAB-TMS approach, a significant increase in sensitivity is obtained due to surface activity conferred by the silyl group in the FAB ionization step.

EXPERIMENTAL: 20 μg of dried sample was added to a 20 ul mixture of N,N-bis(trimethylsilyl)acetamide (BSA), trimethylsilylchlorosilane (TMCS) and pyridine (100:1:10) and heated for one hour at 105° C. Transfer RNA* (25 μg) was hydrolyzed to nucleosides by a standard procedure using nuclease P, and bacterial alkaline phosphatase. The dried digest was silylated as described above. All mass spectra were acquired on a VG 70SEQ Instrument. FAB spectra were derived from 1 μg sample added to 1 ul of 3-NBA.

RESULTS AND DISCUSSION: Fig. 1 illustrates the CID spectrum of guanosine-TMS5 M+*. In general, the EI-MS of trimethylsilyl nucleoside derivatives exhibit three series of ions:

(1) molecular ion series: M-15, M-90, M-105, M-180; (2) base series ions: B+1, B+2, B+30, B+58, B+74, B+116, B+132, B+204, B-14; and (3) sugar series ions: S-H, S-90, S-105, S-116, S-180, m/z 217, 169, 103. The same pattern is exhibited by the CID of M+* but with a considerable difference in the abundances of ions. The silyl ions m/z 73 (base peak), 147, and 217, which are structurally uninformative, are usually more abundant in the primary spectrum and are reduced in intensity manifold in the CID spectrum. The structurally more diagnostic base series ions are significantly increased in abundance. The CID spectrum of even electron ion (M-CH3)+ produced less fragmentation when compared to M+* with the predominant ions being those missing a silyl methyl e.g., m/z 352, 260. MS/MS studies with 15CD3 in the base and 2H3 in the sugar of uridine-TMS4 shows that B+58 is predominantly formed from (M-CH3)+ in the unlabeled derivative instead of the alternative precursor B+74.

Fig. 2 shows the CID spectrum of guanosine-TMS5 MH+ ion. This spectrum exhibited two intense ions: BH+ and m/z 259; BH+ is formed by base protonation followed by glycosidic bond cleavage. The m/z 259 ion is also present in all U, C and A TMS derivatives and is therefore a sugar fragment ion (S+TMSOH). Its intensity is reduced significantly in 2'-O-methyluridine-TMS3 and an abundant new peak appears at m/z 201 (S*-CH2OH). However, this effect is reversed in 3'-O-methyl nucleosides, suggesting that the 2'-O substituent is lost preferentially in the formation of m/z 259, providing a means to distinguish 2'- and 3'-substitution in nucleosides. A simple mechanism can be envisaged for its formation by the loss of BH and TMSOH from MH+ (Scheme 1).

IDENTIFICATION OF MODIFIED NUCLEOSIDES IN tRNA: An application of FAB-MS/MS, with silylation as described above, applied to one μg of crude enzymatic digest of E. coli tRNA, is shown in Fig. 3. The assignments shown indicate side chain-related ions which are highly improved over those produced for underivatized nucleosides by EI, FAB or thermospray ionization. The quantity of nucleoside Q detected in this experiment is estimated as 10 ng, an amount 5 to 10 times lower than without silylation. Further studies of applications involving RNA hydrolysates are in progress.

Determination of Unique Oligonucleotide Composition from Molecular Mass.

S. C. Pomerantz, J. A. Kowalak and J. A. McCloskey, Departments of Medicinal Chemistry and Biochemistry, University of Utah, Salt Lake City, UT 84112.

Recent advances in ionization techniques and technologies available to the biomedical mass spectrometrist have brightened the prospect for mass measurement of structurally significant nucleic acid oligomers. Electrospray and matrix-assisted laser desorption methods have successfully demonstrated the production of large gas-phase ions for mass analysis. Several researchers have recently reported [1,2] the mass measurement of intact tRNA molecules (Mr ~25,000). In contrast to peptides and proteins, the preponderance of nucleic acids are composed of only four structural elements. The current work focusses on the possibility of treating a mass measurement of a nucleic acid oligomer for determination of base composition in a manner analogous to the elemental composition determination of small organic molecules by measurement of exact mass. Unforseen results were obtained in which it was found that ±1 Da accuracy in molecular mass measurement allows substantial reduction in compositional (A, U(T), C, G) possibilities, often to a unique value.

The magnitude of the problem was investigated by formulating software to exhaustively calculate the molecular weight and composition of all possible DNA and RNA oligomers up to 100 bases long. It is readily apparent from Figure 1 that a mass measurement accurate to only 1 Da is insufficient to uniquely define the composition of an oligonucleotide with an Mr greater than ~2500, when there are no constraints on the composition (DNA curve). This limit arises from mass redundancies resulting from specific linear combinations of certain nucleotides. For example, the oligomers C2G3, Mr = 1584.031, and A5, Mr = 1584.083, Δm = 0.052 u, are the first such redundancies. The ability to distinguish these two compositions based on mass measurement is just barely within the current state of the art, using magnetic sector instruments [3]. Typical resolution requirements for the unambiguous base composition determination are 10 ppm at mass 5,000, and 0.4 ppm at mass 10,000. These requirements are far in excess of the capabilities demonstrated to date for quadrupole mass analyzers with electrospray ion sources.

When additional information about the oligomer is available (e.g. the number of residues), then the uniqueness of a mass measurement may be extended to larger molecules. This is due to the elimination of certain mass redundancies from the overlap of pyrimidine rich oligomers of length n+1 with purine rich oligomers of length n. Note that although the number of potential candidate compositions is reduced by the structural constraint (number of residues), the mass accuracy required to differentiate them remains the same. However, at lower masses, more significant reductions are possible where length overlap occurs, often reducing the candidate compositions to one.

When the composition of an oligonucleotide is constrained in any dimension, then the measured mass uniquely defines the composition in increasingly larger oligomers. For example, enzymatic digestion of RNA with RNase T1 yields ribonucleotides with a single G, at the 3' terminus. This compositional constraint of one and only one G eliminates any mass redundancy up to 4640 u, and succeeds in reducing the number of
possible compositions by a factor of 10 (Figure 1, RNA curve). This principle is presently being used as part of a strategy to identify and locate modified nucleotides in large ribosomal RNAs [4].

![Diagram](image)

Figure 1  The average number of compositions per 1.0 u mass interval. The DNA curve is unconstrained data, while the RNA curve is compositionally limited such that each oligomer has only one G residue. Data points were computed by counting the number of possible oligomers within a 100 u interval, centered about selected masses.

Introduction

The EI mass spectra of adenosine-TMS₄ (Ado-TMS₄) and uridine-TMS₄ (Urd-TMS₄) have been studied¹,² and showed a large number of structurally significant fragment ions, including a weak [M]+ ion. The FAB mass spectrum of Ado-TMS₄ contained³ numerous structurally related fragment ions and a strong [MH]+ ion. The FAB spectrum of free adenosine (Ado), on the other hand, contained few fragment ions but a strong [MH]+ ion. Consequently, formation of TMS derivatives of nucleosides increases the amount of structural information from the FAB mass spectrum. Difficulty in identifying structurally important ions occurs, however, because of interference from matrix ions and the presence of ions from both the TMS₄ and TMS₃ (hydrolysis product) forms of the nucleoside.

Mass spectrometry-mass spectrometry (MS/MS) is not subject to the above mentioned problems of interference or ambiguous ion assignment, and has been used to generate daughter ion spectra of Ado-TMS₃ (negative ion) and Urd-TMS₃ (positive ion). A comparison is made between the low-energy CID mass spectra obtained using an EBqQ hybrid instrument versus high-energy CID spectra from a BEBE four-sector mass spectrometer.

![Ado-TMS₃ and Urd-TMS₃](image)

Experimental

The low-energy CID studies were performed on a VG 7070 EBqQ mass spectrometer with FAB ionization. m-Nitrobenzyl alcohol (NBA) was chosen as the matrix for both Ado-TMS and Urd-TMS. Unit resolution was selected for both parent and daughter ions. Daughter ions were formed in the first quadrupole at a collision energy of 70 volts with argon as the collision gas. Daughter ions were detected after the second quadrupole.

The high-energy CID studies used an AMD custom built four-sector instrument with LSIMS ionization. The matrices selected were NBA for Urd-TMS and tetraethylene glycol for Ado-TMS. Resolution of parent ions was 1000 (10% valley definition) and 200-300 for daughter ions. Production of daughter ions between MS-1 and MS-2 was enhanced by collision with Ar at 5925 volts in a collision cell. The high energy collision process required that MS-2 be scanned in a B/E=constant linked scan mode.

979
Results

A. CID Daughter ions of Urd-TMS3 [MH]+ observed:
[C3H3O2TMS]+, [S-2TMSOH]+, [CH2OTMS]+
[S-2TMSOH]+

B. CID Daughter ions of Ado-TMS3 [M-H]- observed:

Discussion

Comparison of low- and high-energy CID results are limited to the total numbers of ions observed in each mode of analysis and the types of ions present in the mass spectra, i.e. ions belonging the molecular ion related (M) base related (B) and sugar related (S) series. Comparison of relative intensities of the ions is not meaningful because of software differences between the EBqQ and BEBE instruments.

The low-energy CID positive daughter ion spectrum of Urd-TMS3 contains ions derived from the M-series, B-series and the S-series. The high-energy CID daughter spectrum contains essentially the same number and types of ions observed in the low-energy spectrum, with both mass spectra being dominated by S-series ions—as reported for the EI mass spectra of pyrimidine-TMS nucleosides.

The low- and high-energy CID negative daughter ion spectra of Ado-TMS3 show the same degree of fragmentation reported for the negative EI mass spectrum of Ado-TMS3. In addition, S-series ions are not observed in either low- or high-energy daughter ion spectra, consistent with the negative EI normal spectra.

Conclusions

The positive daughter ion spectrum of Urd-TMS3 contains numerous structurally significant fragment ions similar to the normal EI and FAB spectra of Urd-TMS3, but without the ambiguity and interferences observed in FAB.

The low- and high-energy CID negative daughter ion spectra of Ado-TMS3 contain the same fragment ions. Consistent with conventional spectra, the negative ion CID results reveal much less fragmentation than the corresponding positive ion studies.

The low- and high-energy CID positive daughter ion spectra show no significant difference in the fragmentation of Urd-TMS3.

As a compound class, oligonucleotides have proved to be particularly difficult to ionize intact. For this reason, the analysis of this important compound class by mass spectrometry has not kept pace with that of other important biopolymers, such as peptides and proteins. However, oligonucleotides have recently been shown to be amenable to ionization by both matrix assisted laser desorption (1) and by electrospray (2). These developments provide new opportunities for the analysis of oligonucleotides by the host of mass spectrometric techniques developed in recent years for large polyatomic ions. In particular, we have been applying the quadrupole ion trap with its many capabilities for ion analysis, to large multiply charged ions formed by electrospray.

In this paper we describe the results of a study of multiply charged anions formed from several small (n=4-8) oligonucleotides carried out using a quadrupole ion trap. The focus of this work was the behavior of the anions under ion trap collisional activation conditions to explore the potential applicability of MS/MS and MS^n to multiply charged oligonucleotide anions.

All experiments were performed with a Finnigan-MAT ion trap mass spectrometer modified to allow ions formed external to the ion trap to be injected. Details of the instrument as it is used to perform experiments with electrospray have been reported (3-5). Analyte solution concentrations in 9:1 HPLC methanol/water fell within the range of 40-100 fmol/µL except for that of the hexamer 5'-d(ATGUAT)-3' which was 2 pmol/µL. All solutions were admitted by direct infusion at a flow rate of 1 µL/min with the syringe needle held at a potential of 3000--5000 V.

Anions derived from 5'-d(AAAA)-3', 5'-d(ATGUAT)-3', 5'-d(CGGATCCG)-3', 5'-d(GTGGCCAC)-3', and 5'-d(GGACGTCC)-3' were subjected to collisional activation under various conditions. Figure 1 provides illustrative data showing the MS/MS spectrum and MS^3 spectrum of the (M-5Na^+) ion from 5'-d(ATGUAT)-3'. The nomenclature used to label the ions in the spectra is illustrated in Scheme 1. The results from this study can be summarized as follows:

- Multiply charged parent anions give high MS/MS efficiencies (>50%).
- Both complementary ions from a cleavage involving charge separation are observed under gentle collisional activation conditions.
- Under relatively violent collisional activation conditions, sequential fragmentation occurs which complicates product ion charge state determination.
- There is a very strong tendency to form the adenine anion and its complementary ion as the lowest energy dissociation channel in oligonucleotides containing adenosine. There is a weaker tendency to form the guanine anion. No anions of the pyrimidines were observed.
- After loss of the adenine anion, there is a very strong tendency for cleavage of the 3' C-O bond of the sugar from which the adenine was lost.

These observations lead to the conclusion that the application of MS/MS techniques to multiply charged anions derived from small oligonucleotides should be particularly useful. The high MS/MS efficiencies observed and the tendency to yield complementary ion pairs is particularly conducive for MS^n experiments and the interesting fragmentation behavior suggests that much useful structural information can be obtained.

The ANALYSIS OF OLIGONUCLEOTIDES AND THEIR PHOSPHORAMIDATE ANALOGUES
BY LSIMS MASS SPECTROMETRY.
H. Muenster, E. Schroeder. Finnigan MAT, Barkhausenstr-2, D2800, Bremen 14, Germany.

Oligonucleotides, and chemically modified oligonucleotides are of therapeutic interest. As early as 1978 the concept of "Anti-Sense" oligonucleotides was put forward to allow intervention in cell processes in order to inhibit gene expression in cells carrying abnormal genetic material. Typically synthetic oligonucleotides and their modified analogues are characterised by polyacrylamide gel electrophoresis, ion exchange HPLC, reversed phase HPLC, CZE and base composition analysis. The first gives an idea of molecular weight and to some extent purity, the following three indicate purity, and the latter is an averaging technique.

It was proposed that mass spectrometry could provide backup to statements on purity and molecular weight, moreover it could uniquely define sequence.

Oligonucleotides by their very nature have not readily lent themselves to mass spectrometric analyses. They are very polar, thermally labile materials, exhibiting poor surface activities (and therefore poor FAB qualities).

We have drawn from spectra of the following materials:
1) 5'TTT-TTT-TTT-TTT-TTT 3'
   where * denotes a modified phosphoramidate linker lie.

2) 5' TTT - TTT - TTT - TTT - TTT 3'

3) Synthetic 15-mer Oligonucleotide containing the bases C, G and T.

The -ve LSIMS spectrum of the modified oligonucleotide (1 above) is shown in Fig. 1. It shows good molecular weight information and provides bidirectional sequence along the whole molecule. The 3' phosphate sequence ions are more intense than those of the 5'. The unmodified oligonucleotide (2) gave a very poor LSIMS spectrum exhibiting a molecular ion in +ve mode only, and no sequence ions though this may well be due to an unfavourable (NH$_4^+$) counter ion. These observations accord with the findings of Grotjahn et al. The 15-mer material (3) was analysed as an Et$_3$NH$^+$ salt, and this material gave molecular weight and bidirectional sequence data (Fig. 2).

FULL SCAN SPECTRUM 5'TTT-TTT-TTT-TTT-TTT 3' (LSIMS, -ve)

Inherent in producing antisense oligonucleotides, are chemical modifications aimed at modifying the phosphodiester bridges to confer stability to extra and intracellular enzymes. Unfortunately modification of each internucleotide phosphate can introduce a new chiral centre, and the diastereomer mix produced can give rise to a complex chromatographic pattern (Fig. 3).
Information can be gleaned from the mass spectrum as to the presence of truncated species, this data may not be readily obtained from the chromatogram if diastereomeric components overlay truncated impurities. Generally molecular ions of truncated oligonucleotides fall at different masses from the phosphate sequence ions.

Conclusions.
As an ionisation mode LSIMS provides sufficient sensitivity to provide good molecular weight data on modified and unmodified synthetic oligonucleotides. LSIMS however has an important advantage over ionisation techniques such as Electrospray Ionisation in that it also produces sequence information, though is probably less sensitive for unmodified oligonucleotides. Judgements can be made from the spectrum regarding the presence of truncated oligonucleotides. In the case of unmodified oligonucleotides the quality of the spectrum seems heavily dependant on the nature of the counter cation. Modified oligonucleotides carry an overall reduced net charge, and are readily desalted - as such they are less prone to these effects.

Instrumentation and Methods.
All materials were dissolved in MeOH/H$_2$O and inoculated into a Thioglycerol matrix. Secondary ion spectra were derived from bombarding this matrix/analyte mix with 30 KeV Cs$^+$ primary ions. The spectra were recorded on a Finnigan MAT 900 forward geometry double focussing mass spectrometer fitted with a multi channel array detector.

CHARACTERIZATION OF MANDUCA SEXTA JUVENILE HORMONE ESTERASE PEPTIDES USING CONTINUOUS-FLOW FAST ATOM BOMBARDMENT MASS SPECTROMETRY.

David R. Goodlett, Frank B. Armstrong, R. Michael Roe, and Richard B. van Breemen, Departments of Biochemistry, Entomology, and Chemistry, North Carolina State University, Raleigh, North Carolina 27695-7622

Juvenile hormone (JH) esterase, an enzyme important in insect development and a potential target for selective chemical control of insect pests, was purified to homogeneity from hemolymph of fifth larval stage day three Manduca sexta using a trifluoromethylketone affinity column (1). Purified JH esterase was shown to be a glycoprotein based on its reaction with the lectins concanavalin A and peanut agglutinin, but not wheat germ agglutinin (2). Derivatization of the enzyme with digoxigenin, immobilization on nitrocellulose by dot blot transfer, and then visualization by reaction with an alkaline phosphatase-linked antibody to digoxigenin produced a positive response indicative of the presence of vicinal diols found in glycoproteins (3). Attempts to release the carbohydrate moiety by either chemical or enzymatic methods failed. Trypsinization was possible only in the presence of 6 M urea for extended periods of time up to 72 hours using immobilized trypsin (4). A peptide map was prepared using LC-MS which will be used in future studies to sequence the active site and further characterize the carbohydrate moiety.

Purified JH esterase was electroblotted from a SDS-polyacrylamide gel onto nitrocellulose for the purpose of lectin binding studies. Circular dichroism was carried out on a JASCO J-600 spectropolarimeter at room temperature and the resultant spectrum was adjusted for background. Reduced and carboxymethylated JH esterase was dissolved in 50mM Tris-HCl, pH 8.0, 1 mM EDTA, 6 M urea, and incubated for 48-72 hours at 37 °C with immobilized trypsin.

A 10 min. 100% aqueous wash on a Vydac C18 analytical column removed the urea present in the tryptic digest and was followed by a 30 min. linear gradient from 100% water to 100% acetonitrile with 0.1% trifluoroacetic acid in both solvents. The flow rate was 1mL/min. and peptides were detected at A214nm. All tryptic peptides were collected in one fraction, concentrated to dryness and dissolved in 90% H2O, 10% acetonitrile, 0.1% trifluoroacetic acid, and 0.5 % glycerol (v/v/v/w). LC-MS separations were carried out using an Applied Biosystems Model 140A dual syringe pump and Vydac C18 HPLC column (2.1mm x 15cm). The solvent system consisted of a gradient from 90:10:0.1:0.5 to 10:90:0.1:0.5 (v/v/v/w) of water/acetonitrile/trifluoroacetic acid/glycerol over 30 minutes at a flow rate of 70 µL/min. The flow was split so that approximately 7 µL/min flowed to the mass spectrometer. Mass spectra were obtained using a JEOL HX110HF double focusing mass spectrometer equipped with a DA5000 data system and trit-FAB version of a continuous-flow FAB (CF-FAB) LC-MS interface.
The lectins concanavalin A and peanut agglutinin, but not wheat germ agglutinin reacted with JH esterase indicating the presence of D-glucose, D-mannose, and galactose (1-3) N-acetyl-D-galactosamine and the absence of tri-N-acetyl-D-glucosamine. The circular dichroism spectrum of JH esterase showed the following secondary structural features: 46.0% α-helix, 6.5% anti-parallel β-sheet, 3.0% parallel β-sheet, 19.5% β-turn, and 25.0% unidentifiable. Tryptic digestion of JH esterase required 6.0 M urea and 48-72 hours at 37 °C. Reversed phase HPLC analysis with uv absorption detection showed a series of poorly separated hydrophobic peptides. Positive ion CF-FAB LC-MS analysis of the tryptic digest of JH esterase revealed the presence of more peptides than were expected based on uv absorption detection alone. Figure 1 shows examples of the protonated peptide molecules detected in the tryptic digest of JH esterase during CF-FAB LC-MS analysis. Figure 2 shows an example of the positive ion CF-FAB mass spectrum of the ion at m/z 705 in the LC-MS analysis shown in Figure 1.

COMPARISON OF B/E LINKED SCANS, MIKES, AND Q-DAUGHTER SCANS FOR OBTAINING STRUCTURAL INFORMATION FROM COMPLEX OLIGOSACCHARIDES.

D.J. Harvey, Glycobiology Unit, Department of Biochemistry, University of Oxford, South Parks Road, Oxford, OX1 3QU;

and

N. Ordsmith and C. Porter, VG Analytical Ltd., Floats Road, Wythenshawe, Manchester, M23 9LE, UK.

Complex oligosaccharides obtained from glycoproteins can be examined by mass spectrometry using ionization methods such as FAB, LSIMS and FD. However, not all of these techniques produce sufficient fragmentation for structural elucidation and, furthermore, problems in interpretation can be encountered when mixtures are present. This paper describes the use of linked-scan and MS/MS techniques on a hybrid instrument for obtaining the required structural information.

The compounds examined were commercial bi-, tri- and tetraantennary N-linked oligosaccharides containing 9, 11, and 13 monosaccharide residues respectively. They were permethylated (1) and LSIMS (Cs) spectra were obtained from 0.1 μg (about 50 pmole) samples dissolved in a 1:1 glycerol:thioglycerol matrix using both VG ZAB-VSEQ and AutoSpec-EQ instruments. B/E linked-scan data and MIKES spectra were obtained under normal conditions; Q-daughter spectra were obtained using xenon as the collision gas.

All three oligosaccharides (MW = 2047.05, 2496.2, and 2945.5, 12C-isotope) gave fragment ions by direct LSIMS and by the three CID techniques. Fig. 1 shows the LSIMS spectrum of the biantennary oligosaccharide and illustrates the production of major fragment ions produced by cleavages adjacent to most of the monosaccharide units with the major ion representing loss of GlcNAc from the reducing terminus as shown in Fig. 2 for the same biantennary oligosaccharide as that shown in Fig. 1. The spectrum is cleaner than the LSIMS spectrum as the ions due to the by-products of methylation are missing. Less fragmentation was present in the spectra of the larger sugars but major ions were still the result of cleavages adjacent to the GlcNAc units.

Fig. 1. LSIMS spectrum of the permethyl derivative of a biantennary oligosaccharide.
Fig. 2. B/E Linked-scan spectrum of the molecular ion of the biantennary oligosaccharide from Fig. 1.

Q-Daughter spectra were very similar to the linked-scan spectra although the ion abundance was slightly lower. Even so, spectra were obtained from all three sugars; that from the tetra-antennary sugar is shown in Fig. 3.

Fig. 3 Q-Daughter spectrum of the molecular ion of a tetraantennary oligosaccharide (per-Me derivative).

The MIKES spectra tended to be less informative, although fragmentation was, again, similar. B/E linked-scan data were also obtained from several daughter ions and yielded sequence information.

STRUCTURAL CHARACTERIZATION OF THE HOST SPECIFIC SIGNAL OLIGOSACCHARIDES OF \textit{R. leguminosarum} BY SFC AND FAB-MS

INTRODUCTION

Higher Organisms are unable to convert atmospheric $N_2$ into biochemically useful organic nitrogen. For this, we depend on certain species of algae and bacteria. Bacteria of the genus \textit{Rhizobium} are able to infect the root hairs of specific leguminous plants, leading to the formation of nodules in which nitrogen fixation occurs.

Selected genera are able to infect only a small number of plant species, and this host specificity appears to be dictated by a set of bacterial genes, called nodulation (\textit{nod}) genes, because their influence on this step in the infection process.

These genes are activated by a stimulatory signal from plants. The \textit{nod} genes code for a series of proteins that give rise to an oligosaccharide structure which is secreted by the bacteria, causing the process of infection to begin in specific host plants. It is this specific bacteria-to-plant signal which ultimately determines host specificity.

Differences in the occurrence and expression of the \textit{nod} genes regulate the structure of the host specific signaling molecule. The host-specificity signal of \textit{R. leguminosarum}, as well as several mutant strains containing altered \textit{nod} genes, has been isolated and it is the goal of this study to examine the function of certain \textit{nod} proteins and the structure of the oligosaccharides produced by this system.

RESULTS

The oligosaccharide products of wild type and mutant \textit{R. leguminosarum} strains have been isolated and characterized by mass spectrometry, in order to determine their structures and the role of the \textit{nod} genes in the signal's biosynthesis. In order to approach this problem, glycans isolated by HPLC were analysed by FAB-MS to determine molecular weight and sequence, SFC and SFC-MS were utilized to profile the oligosaccharides, and Glycosidic linkage was determined by methylation analysis.

The fully active molecule isolated from wild type \textit{R. leguminosarum} (Figure 1) consists of five (1-4)-linked glucosamines, all N-acetylated except the terminal residue. This residue is substituted with an N-linked fatty acid, and an O-linked acetyl group. The linkage position of the acetate has not been conclusively determined. FAB-MS was used to determine to which residue of the oligosaccharide chain these substituents are bound. Figure 2 is the positive ion FAB spectrum of a precursor molecule containing one less GlcNAc than the fully active material. Analogous spectra are observed for the entire series of compounds.

The \textit{nod} genes present in \textit{R. leguminosarum} include \textit{NodABC}, \textit{FE}, and \textit{L}. By determination of molecular weights for oligosaccharide signals from mutants in which the \textit{nodL} and/or \textit{nodFE} genes are deleted, some insight into the function of these genes can be obtained. It is evident that the \textit{nodL} gene product is responsible for O-acetylation of the molecule, because deletion of this gene results in a decrease in molecular weight of 42 amu. Similarly, deletion of the \textit{nodFE} sequence results in a change of 64 amu in molecular weight. This difference can be traced to the fatty acyl residue on the terminal glucosamine.

Figure 3 is the SFC-FID profile of a mixture of glycans from the wild type \textit{R. leguminosarum} after permethylation. The profile showing 4 major peaks is consistent with results from HPLC, and SFC-CIMS provides abundant molecular ions of the expected products. Because of the difficulties inherent in purifying individual components from these systems, as well as the variety of subtle structural motifs, this is a potentially valuable tool for the rapid characterization of this class of glycans.

SFC of Permethylated Oligosaccharides from Wild Type *R. leguminosarum*
OXYGENATION OF POLYUNSATURATES IN RAT BRAIN

H.Y. Kim, S. Sawazaki and N. Salem, Jr.
Section of Analytical Chemistry, LCS, DICBR, NIAAA
Building 10, Room 3C-102, 9000 Rockville Pike, Bethesda, MD 20892

Hydroxylation of polyunsaturates has been reported in various regions of rat brain and many of these hydroxy products are known to possess important biological activities. Lipoxygenation, cyclooxygenation, cytochrome P-450 dependent epoxidation or peroxidation could possibly be responsible for their formation. However, brain hydroxylation seems to occur mainly by peroxidative processes, as evidenced by the racemic stereochemical purity of the products as well as the inhibitor profile. This finding contradicts previous reports concerning leukotriene production, which suggested that 5-lipoxygenase activity exists in the rat brain. In order to determine whether leukotrienes could instead be formed by peroxidation, leukotriene B_{4} production was examined by thermospray LC/MS after pentafluorobenzyl derivatization. We also examined production of hydroxy compounds in various brain regions including cerebrum, cerebellum, hypothalamus, thalamus, pituitary and pineal body.

Male Sprague-Dawley rats were anesthetized with chloral hydrate (300 mg/kg, i.p.) and the brains were perfused with oxygen saturated saline containing heparin. After decapitation, the pituitary, pineal body and brain were quickly removed and the forebrain was further dissected into various regions. Each part or region of the brain was either homogenized or sliced and incubated with 35 μM radiolabeled or non-labeled arachidonic acid (20:4w6) or docosahexaenoic acid (22:6w3) in the presence or absence of 2 mM CaCl_{2} and 2 μM of the calcium ionophore A23187. In order to prepare reference hepoxilin-like compounds, porcine leukocyte 12-lipoxygenase was incubated with 20:4w6 or 22:6w3. Reaction was terminated by acidification to pH 3 and metabolites were extracted with dichloromethane, dried and redissolved in methanol in order to inject into HPLC/UV/radioactivity detector or HPLC/UV/thermospray MS.

For leukotriene measurement, metabolites were extracted with ethyl acetate or by solid phase extraction using a C-18 cartridge according to Powell (1) in the presence of 4 ng of 13C_{2}-LTB_{4}, then derivatized to pentafluorobenzyl esters. However, when M-PFB ions were measured by Nl/thermospray MS, no LTB_{4} production was observed above the 500 pg level, while non-perfused pituitary produced ng levels of LTB_{4}. This indicated that the observed 5-lipoxygenase activity was a result of blood cell contamination.

Among the regions examined, only the pineal body produced significant levels of lipoxygenase products. Both arachidonic acid (20:4w6) and docosahexaenoic acid (22:6w3) were metabolized to the corresponding 12- and 15-lipoxygenase products when incubated with pineal body homogenate. As shown in Figure 1, both 17- and 14-hydroxy 22:6w3 (HDHE) were produced by the pineal body. Their thermospray spectra contained M-NH\textsubscript{4}+, M+NH\textsubscript{4}+-H\textsubscript{2}O and MH+-H\textsubscript{2}O at 362, 344 and 327, indicating they were monohydroxy compounds. Their retention times coincided with those of the previously characterized 17- and 14-HDHE which were prepared by the reaction of 22:6w3 with soybean and platelet lipoxygenases, respectively. In addition to these monohydroxy products, variable amounts of a 22:6w3 metabolite was observed at a retention time between 26 and 27 min. This compound eluted at the same retention time as the epoxy,hydroxy-22:6w3 (hepoxilin-like compound) produced by the porcine leukocyte 12-lipoxygenase (Figure 2). Thermospray LC/MS spectra indicated that this compound was 13,14-epoxy,hydroxy-22:5w3, as the cleavage of the epoxidated C-C bond, which is typical for epoxidated compounds, produced fragment ions at m/z 214 and 197 as shown in Figure 3. Biological effects of these compounds are not clear at the present time, although it has been reported that melatonin release was inhibited by lipoxygenase inhibitor. Since 22:6w3 is the major polyunsaturated fatty acid in the pineal body, its lipoxygenase products may be important mediators of the synthesis or release of melatonin.
Figure 1. Oxygenation of 22:6w3 by rat brain pineal body homogenate. Metabolites were separated on an Axxiom-ODS column (4.6 mm x 25 cm, 5 μ) using a gradient of a 0.1M ammonium acetate/methanol mixture changing from 40/60 to 15/85 in 50 min, then to 0/100 in 10 min, with a flow rate of 0.8 mL/min.

Figure 2. Production of oxygenated metabolites of 22:6w3 by porcine leukocyte 12-lipoxygenase.

13,14-epoxy-hydroxy-22:6w3 (m.w.=360)

Characterization of N-Linked Oligosaccharides by Electrospray and Tandem Mass Spectrometry

Kevin L. Duffin and Jack D. Henion, Drug Testing and Toxicology, Cornell University, 925 Warren Drive, Ithaca, NY 14850
Joseph K. Welply, Monsanto Corporate Research, Monsanto Company, 800 N. Lindbergh Boulevard, St. Louis, MO 63167.

INTRODUCTION

Many proteins of therapeutic value are glycoproteins, including antibodies, hormones, growth factors, clotting factors, immunomodulators, carrier proteins and a host of cell-attached receptors. Exploration of the role of complex sugar molecules in cell function could lead to a new class of carbohydrate-based therapeutics with a large potential market. Mass spectrometry, because of its sensitivity and selectivity, already has proven valuable as an analytical tool for characterizing oligosaccharides and glycoproteins [1-3]. Electrospray mass spectrometry promises to enhance the analytical capabilities of mass spectrometry toward the characterization of oligosaccharides and glycoproteins, by virtue of its great sensitivity and its ability to accurately measure the masses of large glycoproteins and resolve mass heterogeneities caused by differences in oligosaccharide structure. This paper presents electrospray mass spectrometric characterization of complex underivatized oligosaccharides and of ovalbumin, a glycoprotein with one occupied glycosylation site. Methodology developed for the mass analysis of oligosaccharide standards is applied to the mass analysis of a mixture of oligosaccharides that have been enzymatically digested from ovalbumin.

EXPERIMENTAL

Oligosaccharide standards were purchased from Dionex Corp. (Sunnyvale, CA). Ovalbumin was purchased from Sigma Chemical Co. (St. Louis, MO).

Enzymatic Digestion

10 mg of ovalbumin was dissolved in 200 mL of 200 mM sodium phosphate buffer containing 1% 2-mercaptoethanol. The sample was heated to boiling for 5 minutes and diluted to 1 mL with sodium phosphate buffer containing 0.6% NP-40. 20 milliunits of N-glycanase (Genzyme) was added to this mixture, and the enzymatic reaction was allowed to proceed for 12 hrs at 37 °C. An additional 20 milliunits of N-glycanase then was added and the mixture was incubated for another 24 hrs. The sample mixture then was diluted to 70% ethanol and incubated for 2 hrs at 4 °C. Precipitated protein was removed by centrifugation. Nonionic detergent was removed by application on two C-18 Sep-pak cartridges in succession, and salts and ionic detergent were removed by application on Dowex Ag-50W X-12 and QAE-sephadex in succession. The sample was evaporated under vacuum and 20% sent for electrospray mass analysis.

Mass Spectrometry

mass spectrometer: Sciex TAGA 6000E triple quadrupole with a mass range of 1400 amu.
sample concentration: 30 pmol/mL
sample solvent: water/methanol (4:1, v:v) containing either 10 mM ammonium acetate or 10 mM sodium acetate
infusion rate: 2 mL/min
scan range: 300-1400 amu for electrospray mass spectra
10-1400 amu for MS/MS spectra
scan rate: 100 amu/sec
spectral averaging: 5 scans- electrospray mass spectra
20 scans-MS/MS spectra
MS/MS collision gas: argon
MS/MS collision energy: 30-100 eV

RESULTS AND DISCUSSION

Electrospray mass spectrometry provided molecular weight assignments of oligosaccharides without prior derivatization. Oligosaccharides that were characterized in this study had a higher affinity for sodium or ammonium than for protons, so sample solutions were modified with sodium acetate or ammonium acetate to enhance the ionization efficiency of the oligosaccharides. Protonated oligosaccharides were difficult to generate when the sample solution was acidified and were only generated in high abundance when ammoniated oligosaccharides were subjected to
collision-induced dissociation to expel neutral ammonia. Singly-, doubly-, and triply-charged oligosaccharides were observed in the electrospray mass spectra resulting from the addition of one, two, or three cationic species to the oligosaccharides. Oligosaccharides that contain sialic acid did not exhibit a large ion current in the positive ion mode but did yield large ion signals in the negative ion mode. The maximum number of negative charges that were incorporated on these oligosaccharides (deprotonation) corresponded to the number of sialic acids contained on the oligosaccharide.

Collision-induced dissociation of oligosaccharides allowed differentiation of high mannose, complex, and hybrid oligosaccharides. Fragmentation generally occurred through dissociation of glycosidic bonds, and cleavage of the glycosidic bond adjacent to an N-acetylglucosamine was especially favored [4]. MS/MS analysis allowed identification of most of the structural sequence of the oligosaccharides, including the presence of core fucose units, but branch points were sometimes difficult to distinguish. Monomeric sugar units of the same mass and linkage positions could not be determined using this methodology.

Oligosaccharides present on the glycoprotein ovalbumin were enzymatically cleaved by N-glycanase and separated from the protein portion of the compound. Characterization of these oligosaccharides by electrospray and tandem mass spectrometry resulted in identification of two high mannose oligosaccharides (G2M6 and G2M5) as the most abundant sugars present on this glycoprotein. The relative abundances of digested ovalbumin oligosaccharides present in the electrospray mass spectrum were consistent with those obtained by ion chromatography/pulsed amperometric detection. However comparison of the carbohydrate content of ovalbumin as determined by both the electrospray mass spectrum of intact ovalbumin and the oligosaccharides digested (N-glycanase) from ovalbumin showed inconsistencies in the relative abundances. This was attributed to an incomplete digestion by N-glycanase, which favored enzymatic cleavage of lower molecular weight, high-mannose oligosaccharides.

Use of Ammonium Acetate As A Matrix Additive: Enhancement of Oligosaccharide FAB Mass Spectra

E. Kolodziej, C. Lisek, J. Doom and P. Toren

Monsanto Corporate Research, Monsanto Co., 800 N. Lindbergh Blvd., St. Louis, MO 63167

Fast atom bombardment mass spectrometry is a well-established method for the analysis of oligosaccharides and glycoconjugates. Recent work in our laboratory has focused on the use of matrix additives for the enhancement of native and derivatized oligosaccharide mass spectra. The results of investigating the utility of ammonium acetate as a matrix additive for the FABMS analysis of native and permethylated oligosaccharides are presented below.

The oligosaccharides studied were maltoheptaose (Sigma), isomaltoheptaose (BioCarb), OligoStandard GP-16 (Dionex), and OligoStandard GP-15 (Dionex). Permethylated derivatives were synthesized by reaction of the native sugars with methyl iodide/sodium hydroxide in dimethyl sulfoxide. Matrices used were: (1) GT-HCl: 1 ml each of glycerol (G) and thloglycerol (T) plus 5 drops of concentrated HCl, (2) GT-NH₄OAc: 1 mL each of G and T plus 10 drops of 1 M NH₄OAc, and (3) T-NH₄OAc: 2 mL T plus 10 drops of 1 M NH₄OAc. FABMS analyses were performed on a ZAB-SE double-focusing magnetic sector mass spectrometer (accelerating voltage 10 kV) equipped with a cesium ion gun (35 kV). Data was accumulated (5 scans) in the multi-channel analyzer (MCA) mode scanning over a 300-2000 amu mass range at 25 seconds per decade.

Maltoheptaose and isomaltoheptaose, 5 ug each, were analyzed by FABMS in the above three matrices. Protonated molecular ions MH⁺ were observed in all spectra. In the ammonium acetate matrices, MNH₄⁺ ions were also observed. The MNH₄⁺ species predominated over MH⁺ in T-NH₄OAc. No increase in ion intensity for the molecular ion species was observed in GT-NH₄OAc versus GT-HCl. However, in the T-NH₄OAc matrix, a 5-fold increase over GT-HCl in molecular ion intensity was observed. Although significant enhancement of molecular ion species for the native sugars was not observed in the ammonium acetate matrices, the overall signal/noise was improved due to a reduction in matrix background ions. A more dramatic effect was observed upon analysis of permethylated derivatives of maltoheptaose and isomaltoheptaose, 1 ug each, in the same three matrices. Increases of 15-fold and 50-fold were observed in GT-NH₄OAc and T-NH₄OAc, respectively, versus GT-HCl. The predominant ion in both GT-NH₄OAc and T-NH₄OAc was MNH₄⁺. Permethylated maltoheptaose was further analyzed at the 100 and 10 ng levels to determine the limit of detection. The 10 ng sample was easily detected with a signal/noise of 5:1 for MNH₄⁺. Shown in Fig. 1 are the spectra obtained for permethylated maltoheptaose at the 1 ug and 10 ng levels in T-NH₄OAc. Permethylated derivatives of two complex oligosaccharides, GP-16 (Fig. 2) and GP-15 (Fig. 3) were also analyzed by FABMS in the T-NH₄OAc matrix. Intense MNH₄⁺ ions and structurally significant fragment ions were observed. Finally, even though ammonium acetate has been demonstrated to be a useful matrix additive, one drawback that has been observed is the persistence of the additive in the ion source which necessitates more frequent source cleaning.

In summary, the addition of ammonium acetate to the FAB liquid matrix slightly enhanced the mass spectra of native oligosaccharides and significantly enhanced the mass spectra of permethylated oligosaccharides.

DIFFERENTIATION OF TYPE 1 AND 2 CHAIN GLYCOSPHINGOLIPIDS
BY CID POSITIVE ION FAB-MS WITH B/E LINKED SCANNING
*MEK Salyan, MR Stroud, SB Levery, and S Hakomori
The Biomembrane Institute, 201 Elliott Ave. W, Seattle, WA. 98119

CID/*FABMS spectra were obtained at constant B/E ratio from the pseudomolecular ions of
underivatized glycosphingolipids. The spectrum of a difucoglycolipid with type 1 chain core
structure, Leb ([M+H]+ at 1535.9 u.) is reproduced in Fig. 1A, while that of an isomeric type 2
chain structure, Lei ([M+H]+ at 1631.9 u.), is reproduced for comparison in Fig. 1B. As expected,
the spectra displayed a number of similar features. Ceramide ions, Z0, of Leb and Lei were found
at m/z 536 and 632, respectively. Ceramide containing ions, Y1, and Z1, and non-reducing end B1
ions were observed as shown in Schemes 1A,B. In both spectra the m/z 658 ion was observed in
high abundance, the result of preferential cleavage of the GlcNAc glycosidic bond (1) to form the
oxonium ion, (Fucor3-Gal[4-Fucor4]-3GlcNAc)*. Such preferential cleavage at HexNAc linkages
have been reported for both derivatized and native glycoconjugates in a variety of ionization modes
(1-4).

The primary ion m/z 658 further fragments via β-cleavages (3) to form a number of second
generation fragments, found at m/z 512, 366, 350, and 204. A number of pathways are possible,
as shown in Scheme 2. The spectra of Leb and Lei differ in the relative abundance of these product
ions. This clearly must depend on differences in rates of cleavage, which should in turn reflect
differences in the stereochemistry of the primary ions. For example, the m/z 350 ion is present
only in the spectrum of Leb and not observed in that of Lei. This could result from the influence
of the adjacent 2-NAc group. CID *FAB studies on synthetic model oligosaccharides, reported by
Laine et. al. (2), suggest that the instability of the 3-position of GlcNAc is due to steric crowding,
which restricts the distribution of energy among normal mode vibrations in the transition state for
glycosidic cleavage. In the vicinally branched Lewis structures, this restriction may be enhanced by
the presence of the residue linked in the adjacent 4-position, while in the case of the Leb isomer,
this effect may be further enhanced by the steric interaction between the NAc group and the
Fucβ1→2 residue on the type 1 linked Gal. The same phenomena may be responsible for the
appearance of fragments at m/z 1227 and 1209 in the spectrum of Leb, when no analogous
fragments were observed for Lei.

These differences were examined in more detail by further experiments employing CID daughter
ions from the primary ion m/z 658 (not shown), and precursor ion scans of the monosaccharide ion at m/z 204 (see Figure 2). In the daughter ion spectrum of m/z 658 from Lei,
production of some m/z 350 fragment could be observed. Nevertheless, the ratio of m/z 350/366
is clearly greater in the case of Leb. These results were further confirmed by precursor ion scans
for the m/z 204 fragment, which were obtained at much lower resolution, but which had the
advantage of eliminating contributions from the matrix ions. In the spectrum obtained from Lei
(Fig. 2B), the considerable abundance of the m/z 366 ion, compared to both m/z 350 and 512,
implies that m/z 204 is produced from the m/z 658 fragment chiefly by a sequence of three β-
eliminations: facile losses of the two Fuc residues from their respective sites, followed by loss of the
4-linked Gal residue. On the other hand, with Leb (Fig. 2A), a significant contribution is probably
made from loss of the 3-linked Fuc-Gal disaccharide as a unit to form the m/z 350 ion, followed
by loss of the 4-linked Fuc residue. Overall, the m/z 658 fragment appears to be somewhat more
stable in Lei, as evidenced by its greater abundance in the B/E spectrum.

Finally, it is worth noting a number of other common ions amongst the spectra shown in Figs.
1. The ion at m/z 264 may be produced by ring cleavage of the m/z 366 fragment (at bonds 2
and 5). The ions found at m/z 186, 168, and 138 have been proposed (2) to arise from further
successive decompositions of the m/z 204 fragment, representing (204-H2O), (186-H2O), and (168-
HCHO), respectively.

a. The nomenclature of Domon and Costello (5) has been adopted.

THE STRUCTURAL IDENTIFICATION OF EVERNINOMICIN-6

P. Bartner, B. Pramanik, P. Das, A. Tsarbopoulos, A. Ganguly, A. Saksena, V. Girijavallabhan, O. Sarre

Schering-Plough Corp. Bloomfield, New Jersey 07003

Everninomics (D, B, C, 13-384-1 and 13-384-V), a novel class of oligosaccharides antibiotics, are produced by Microgonospora Carbonaceae. They are highly active against gram-positive bacteria and Neisseria, including strains resistant to beta-lactams, macrolides, lincomycins, tetracycline and rifampicin. Everninomics have many unusual structural features: an ortho ester functionality, an aliphatic methylene dioxy group, a completely substituted phenolic ester functionality and a nitro sugar. The structure elucidations of these Everninomics were carried out in our laboratories using chemical degradation, NMR and MS methods. Our subsequent studies using FAB and LSIMS indicated that these techniques are extremely useful for the structure analysis of this class of oligosaccharides.

This presentation describes the mass spectral analysis of a new Everninomicin component, EV-6, that further demonstrates that LSIMS (FAB) provides a simple, sensitive and structurally informative method for the analysis of this essentially non-volatile class of oligosaccharides. Both negative and positive ion LSIMS were highly successful in the identification of this new component. Negative ion LSIMS produced a strong (M-H)^- molecular ion and a single fragmentation series indicating the sugar sequence from the phenolic side of the molecule. Positive ion LSIMS did not produce a strong molecular ion, but the addition of NaCl to the EV-6 solution resulted in an intense (M-Na)^+ molecular ion. One also observed a more complex and far richer fragmentation pattern with NaCl enhanced positive ion LSIMS compared to negative ion LSIMS. Three distinct sugar sequence series were observed; one involving the phenolic side of the molecule and two involving the methylene dioxy side of the molecule. Thus, these complimentary LSIMS techniques provided both molecular ion information and fragmentation information that provided the sugar sequence.

QUANTIFICATION OF LEUKOTRIENE C4 AND N-ACETYL LEUKOTRIENE E4 IN RAT BILE USING CARBON-13 ISOTOPE DILUTION AND GAS CHROMATOGRAPHY-MASS SPECTROMETRY

Mark J. Raftery, Hartmut Jaeschke and Simon J. Gaskell

Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030

Cysteine-containing leukotrienes (LTs) are formed from arachidonic acid via the 5-lipoxygenase pathway and conjugation with glutathione, yielding LTC4. Sequential removal of the gamma-glutamyl and glycyl moieties yields LTD4 and LTE4, the latter of which may be further metabolized to N-acetyl LTE4. Leukotrienes are commonly quantified in biological extracts using a combination of HPLC and immunoassay. A strategy for GC-MS determination of cysteine-containing LTs has been reported by Murphy and coworkers (1,2). Hydrogenation and thioether cleavage yields 5-hydroxyeicosanoic acid as a common product of all the cysteine-containing LTs. Conversion to the pentafluorobenzyl (PFB) ester, trimethylsilyl (TMS) ether gives a derivative with excellent gas chromatographic properties that is detected with high sensitivity during negative ion electron capture MS. Application of the hydrogenation/derivatization/GC-MS approach has hitherto been limited by the lack of suitable internal standards; deuterium-labelled analogues are not suitable because of loss of the isotopic label during hydrogenation. We recently reported (3) the preparation of [13C4]-analogues of cysteine-containing leukotrienes and their use as internal standards is described here.

Abundant protonated molecular ions are generated during FAB MS of leukotrienes; recent work (4) has established that significant structural information is obtained by collisional activation of [M+H]^+ and [M-H]^− ions during tandem MS analyses. We have suggested (4) that FAB/tandem MS provides the basis for quantitative determination of cysteine-containing LTs and a preliminary report of this approach has been presented (5).

We report here the determination of cysteine-containing LTs in rat bile in an assessment of the role of these mediators in endotoxin shock. Aliquots (25 ul) of bile were supplemented with 400 pg of [13C4]LTC4 and 850 pg of N-acetyl [13C4]LTE4 and were separated by reverse-phase HPLC to give fractions corresponding to LTC4 and N-acetyl LTE4. These fractions were hydrogenated using a rhodium black catalyst. The products were converted to the PFB ester and further purified by straight-phase HPLC prior to preparation of the TMS ether derivative. During GC-MS analysis, ions of m/z 399 (corresponding to [M-PFB]^−) for the 5-hydroxyeicosanoic acid derivative) and m/z 403...
Biliary LT concentrations were determined in four animals prior to, and following, i.v. endotoxin administration. Marked increases in the concentrations of LTC₄ and N-acetyl LTE₄ were observed after endotoxin administration, with maximum values of approximately 250 pg/ul and 1500 pg/ul, respectively (Figures 1 and 2). Concentrations of LTC₄ were restored to pre-dosing levels 60 min after endotoxin but concentrations of N-acetyl LTE₄ remained elevated.

The production of cysteine-containing leukotrienes following endotoxin administration to the rat has been studied previously by Keppler and colleagues who postulated a role for these mediators in eliciting the cardiovascular effects characteristic of endotoxin shock (6). On the basis of HPLC isolations and RIA, these workers determined N-acetyl LTE₄ to be the principal cysteine-containing leukotriene present in rat bile. Estimated concentrations, however, were approximately 50 times lower than those determined in the present study. The discrepancy may be attributable to the different strain of rat used and/or to the lack of internal standardization in the immunoassay study.

INTRODUCTION

Linoleic acid (18:2\text{co}6) is biosynthesized to arachidonic acid (20:4\text{co}6) via a series of enzymatic steps which carry out chain elongation and desaturation. Intermediates formed in the pathway to 20:4\text{co}6 are 18:3\text{co}6, 20:2\text{co}6, and 20:3\text{co}6. In addition, 20:4\text{co}6 is further transformed to minor amounts of 22:4\text{co}6 and 22:5\text{co}6. Desaturation occurs at specific sites along the carbon chain through the action of \Delta6 and \Delta5 desaturases which are membrane bound in the lumen of the endoplasmic reticulum.

A negative ion GC/MS method using pentafluorobenzyl derivatives (PFB) of the deuterated fatty acids was developed to investigate the in vitro biosynthesis of 20:4\text{co}6 from liver homogenates. This was compared to a method using methyl ester derivatives of the fatty acids in positive chemical ionization with the goal of decreasing detection limits and thereby lowering the amount of deuterated fatty acid needed in these analyses.

Incubation time, substrate concentration and cofactors were varied to examine their effects on product formation. All intermediates to d4-20:4\text{co}6 production were detected and quantified using 23:0 as an internal standard. The d4-20:4\text{co}6 was not fully resolved from the d0-20:4\text{co}6. Isotopic ratios were used to determine the quantity of d4-20:4\text{co}6 formed during the incubation.

METHODOLOGY:

LIVER PREPARATION-INCUBATION

Homogenates of whole rat liver were prepared according to the method of Cook (1). Adult male rats (Sprague-Dawley) were fed a standard laboratory chow diet and decapitated. Livers were removed and the tissue was homogenized in glass tubes with 0.1 M-phosphohate buffer at pH 7.4 containing 2 mM reduced glutathione and 25 mM sucrose (4 ml medium per g tissue). Protein content of fractions were determined by the method of Lowry, et. al.(2) Incubation mixtures contained 0.1 M-phosphate buffer at pH 7.4, 0.2 mM-Co-A, 2 mM-MgCl2, 2 mM-ATP, 0.5 mM-NADH, 0.5 mM-NADPH, 0.5 mM malonyl-CoA, 0.025 mM fatty acid and 0.050 mM BSA. Protein 4-7 mg was added to the incubation mixture in a final volume of 2 ml. Samples were incubated at 37° C for 15 min in a shaking water bath.

EXTRACTION-DERIVATIZATION

Reactions were stopped by the addition of 4 ml of 10% methanolic KOH. The fatty acid methyl ester, 23:0, (5 ug) was added as an internal standard. Mixtures were heated at 65° C for 30 min and acidified with 7N-HCl. Samples were extracted with 50% diethyl ether in petroleum ether 3X, dried over anhydrous ammonium sulfate, divided into two fractions and evaporated under N2. One fraction was derivatized to the fatty acid methyl esters with BF3 in methanol (14% w/v). Samples were brought up in 1 ml heptane. The other fraction was derivatized to the PFB esters with 70 ul of a solution of pentafluorobenzyl bromide, disopropylamine in acetonitrile (1:10:1000) and heated at 60 deg. for 15 min. The solvent was evaporated and the residue dissolve in 1 ml heptane for GC/MS analysis.

GC/MS CONDITIONS

Fatty acid methyl esters (ME) and PFB esters were run on a 25 \text{um} coated, 30 m x 0.25 mm i.d., DB-FFAP capillary column using splitless injection. The oven temperature was programmed from 80°-185°@20°/min, 185°-240°@10°/min and held for 30 min. The injector temperature was 250° and transfer line 280°. Source temperature was 150°. The source pressure of methane (99.99%) was 4 x 10^-4 torr. Tally acids were analyzed in the selected ion mode using the M+1 ion for the ME derivatives and the M-PFB ion for the PFB derivatives. Source tuning and system optimization was carried out for each ionization mode and the same electron multiplier voltages were used for both positive and negative.
CONCLUSION

A negative ion GC-MS method was used to follow the course of conversion of d4-18:2ω6 acid to d4-20:4ω6 in in vitro preparations of rat liver homogenates. Intermediates in the biosynthesis of d4-20:4ω6 were characterized. Incubation conditions such as protein concentration, cofactors, and time were varied to evaluate optimum product formation. Fatty acids were derivatized to their PFB esters and the M-PFB ion was observed in the negative ion mode. The deuterated fatty acids eluted just prior to the unlabeled counterparts. The d4-20:4ω6 fatty acid co-eluted with the unlabeled material.

Deuterated fatty acids were quantified using a standard curve, generated from the ion ratios of the M-PFB fragments of the internal standard, 23:0, and the analyte against a known concentration of the internal standard.

This method was compared to the detection of the M+1 ions of methyl esters of deuterated compounds in the positive ion mode. Negative ion detection was generally three orders of magnitude more sensitive than positive ion detection. Ten femtograms of the pure d4-18:2ω6 PFB ester was detected with a signal to noise ratio of 3 in the negative ion analysis. Fatty acids labeled with four or more deuterium atoms were preferred because of the diminished ion interference resulting from the M+4 isotope of the unlabeled compound. This method makes possible cost effective metabolism studies because smaller quantities of the deuterated fatty acid are needed.

Nutritional Effects on In vitro Prostaglandin Production In Rat Brain Slices
Robert J. Pawlosky*, Aron Yoffe, Hee -Yong Kim, Shigeki Sawazaki and Norman Salem Jr.
Laboratory of Clinical Studies, DICBR, NIAAA, Bethesda, MD. 20892

ABSTRACT
In order to assess the role that alcohol exposure together with dietary lipid manipulations have on the capacity of the brain to produce prostaglandins (PGs), in vitro, rats were placed on diets where the lipid content was precisely controlled. Animals were maintained on 10% fat diets supplemented with 9% of either borage (23% 18:3ω6), olive (72% 18:1ω9), or menhaden fish (14.7% 20:5ω3 and 8% 22:6ω3) oils. After 2 weeks of dietary treatment ethanol was administered to the animals for a period of seven days by inhalation. Control and treated animals were then decapitated, whole brains were sectioned into slices and incubated at 37° with the calcium ionophore A23187 and CaCl2. The supernatants were collected, prostaglandins extracted, and PGD2, PGE2-α, 6-keto-PGF1-α and TXB2 were derivatized to their pentafluorobenzyl-trimethylsilyl-methoxime derivatives and analyzed by negative ion chemical ionization by gas chromatography/mass spectrometry.

INTRODUCTION:
Dietary unsaturated fats provide a major component of the fatty acids which are incorporated into membrane phospholipids. Animals elaborate dietary linoleic (18:2ω6) and linolenic (18:3ω3) acids to the chain elongated highly unsaturated fatty acids (HUFAs). The fatty acid, 18:2ω6 is converted to 20:4ω6 (arachidonic acid) and 18:3ω3 to 22:6ω3 (docosahexaenoic acid) via a series of shared desaturating and elongating enzymes which reside in the lumen of the smooth ER of hepatocytes. The ratio of dietary 18:2ω6 to 18:3ω3 is important in determining the final composition of membrane phospholipids which are the substrates for the oxygenated derivatives of fatty acids, the prostaglandins, leukotrienes, and lipoxins. Phospholipase A2 (PLA2) releases HUFAs to the cytosol where they are converted to prostaglandins, thromboxanes and prostacyclin via the cyclooxygenase pathway. 20:4ω6 is the substrate for the two series prostaglandins. Prostaglandins carry out a number of regulatory roles in homeostasis. PGD2 regulates body temperature and sleep. PGE2-α is a smooth muscle contractor. PGI2 increases vasodilation and inhibits platelet aggregation. Thromboxane A2 (TXA2) increases platelet aggregation and vasoconstriction. Ethanol has been shown to ameliorate PLA2 activity and thereby effect substrate levels for prostaglandin production.

EXPERIMENTAL
Rats were fed three diets consisting of the nutrients specified in the AIN-76A diet but varied in lipid composition for 21 days. The lipid content was varied by adding 9% of either borage oil (23% 18:3ω6) olive (78% 18:1ω9) or fish (14.7% 20:5ω3 8.7% 22:6ω3) plus 1% corn oil (78% 18:2ω6). Alcohol was administered by inhalation beginning the third week. Animals were decapitated after the seventh day, and the entire brain removed. One half of the cerebral hemisphere was sliced into approximately 100 mg slices and assayed for cyclooxygenase activity.

Tissue slices were rinsed twice with 1 ml cold PBS (pH 7.4). Samples were placed in 1.5 ml of PBS with 5% glucose. Indomethacin controls were pre-incubated with the 10 μM of the reagent. At zero time, 20 μl of 2 mM CaCl2 and 10 μM of the calcium ionophore, A23187 were added to the slices. 400 μl of the supernatant was removed for zero time point comparisons. Samples were incubated for 30 min at 37° in a shaking water bath. The reactions were stopped by the addition of 60 μl of formic acid.

The pH was adjusted to approximately 6.5 by adding 100 μl of pyridine. 800 μl of a 2% solution of methoxime HCl was added to each sample. Samples were mixed on a vortex and allowed to stand overnight at room temperature. The methoxime derivatives were extracted on SEP-PAK C18 cartridges with 2 ml methanol after conditioning the columns. The solvent was evaporated under nitrogen and samples were reacted for 30 min at 60° with pentafluorobenzyl bromide and dimethoxypropylamine in acetonitrile (1:10:1000) to their PFB esters. Reagents were evaporated under nitrogen and trimethylsilyl ethers were formed by adding 50 μl of BSTFA and 50 μl of acetonitrile at 60° for 15 min. The reagents were evaporated and the samples brought up in 40 μl of dodecane.

Samples were analyzed in the negative ion mode on a Kratos MS80 mass spectrometer with a 15 m X 0.25 mm DB5 capillary column using on-column injection. The oven temperature was programed...
from 215 to 310 at 30° per min. Methane, 0.5 torr was the chemical ionization gas and the M-PFB ions of the prostaglandin derivatives were detected. The prostaglandins were quantified using tetradeuterated internal standards added to the samples prior to derivatization. Thromboxane (TXB2) was quantified using the ion from d4-6-keto-F1-α with a response factor of 0.71. Final calculations were based on 100 mg of tissue, wet weight. Prostaglandins from Indomethecin and zero time controls were subtracted from quantities formed after 30 min incubation.

RESULTS

PGD2. Tissue from control animals on fish oil diets had significantly lower levels of PGD2 than tissue from olive oil fed animals. No significant differences were found between ethanol treated and control animals.

PGF2α. Tissue from animals receiving olive oil in their diet produced significantly higher levels of PGF2α than tissue from either two control groups. Significantly lower levels of PGF2α formation were found in ethanol and control animal comparisons from the olive and fish oil groups.

6-Keto-PGF1α. Tissue from animals receiving fish oil produced significantly lower amounts of 6-keto-PGF1α than tissue from animals on the olive diet. The ethanol exposure had opposite effects in the borage and olive oil diets that were statistically different from their controls.

TXB2. Tissue from animals on the fish oil diet produced significantly lower levels of Thromboxane TXA2 (it's metabolite TXB2 is actually measured) than tissue from the olive oil group.
IN VITRO Desaturation of Deuterated Linoleic Acid (d₄-18:2ω6) to d₄-18:3ω6 In Adult Rat Livers from Alcohol Exposed Animals.

Robert J. Pawlosky*, John Karanian and Norman Salem Jr. Section of Analytical Chemistry, Laboratory of Clinical Studies, DICBR, NIAAA, Bethesda, MD. 20892

INTRODUCTION
Desaturation of the essential fatty acid, linoleic acid (18:2ω6) to 18:3ω6 occurs through the action of membrane bound Δ6 desaturase within the endoplasmic reticulum. Dietary lipids are known to influence the fatty acid composition of membranes in various tissues. Chronic alcohol exposure has a profound affect on fatty acid metabolism within the liver. In this study, rats were maintained on normal diets supplemented with either fish oil or corn oil as a lipid source and then exposed to alcohol vapors for seven days. The animals were killed and liver homogenates assayed for Δ6 desaturase activity using deuterated linoleic acid (d₄-18:2ω6). Fatty acids were derivatized to their pentafluorobenzyl esters and analyzed by NCI GC/MS. In addition, 18:2ω6 and 20:4ω6 were measured in the tissue and the amount of 18:2ω6 was correlated with enzyme activity.

EXPERIMENTAL
Adult male Sprague-Dawley rats (control groups n=3, ethanol exposed groups n=4) were maintained on a rat chow diet for two weeks that was supplemented with either corn or fish oil as a primary source of lipid. Ethanol treated animals were then placed in alcohol inhalation chambers for 7 days and continued on their same diets. On the seventh day animals were killed and the livers removed, homogenized in PBS buffer (pH 7.4) with 2mM glutathione. Liver homogenates were incubated with 25 μM d₄-18:2ω6 complexed to BSA 50 μM and containing 0.2 mM CoASH, 2 mM MgCl₂, 2 mM ATP, and 0.5 mM NADH at 37°. for 15 min. Reactions were stopped with addition of 4 ml 10% KOH in methanol and heated to 85° for 1 hour. Samples were acidified with 14 N HCL and extracted with ether:hexane 1:1 three times and derivatized to their PFB esters with pentafluorobenzylbromide, diisopropylamine in acetonitrile for 15 min at 60°. The reagent was evaporated under nitrogen and samples brought up with 1 ml heptane and injected onto a 30 m X 0.25 um FFAP column and analyzed in the selected ion mode by negative ion GC/MS.

FINDINGS
Liver concentrations of 18:2ω6
Significantly higher amounts of 18:2ω6 were found in livers from rats on the corn oil diet than in livers of those animals on the fish oil diet (p< .02). The ethanol groups also had higher levels of 18:2ω6 than the controls and this was significant at p< .05 in animals on the corn oil diet

Liver concentrations of 20:4ω6
Fish oil fed animals from control groups had lower levels of liver 20:4ω6 than livers from corn oil fed animals. However, no significant differences in levels of 20:4ω6 were found in ethanol treated animals on either diet.

Ratio of 20:4ω6 to 18:2ω6 In livers
The ratio of 20:4ω6 to 18:2ω6 appeared about equal in control animals on either diet. Ethanol treated corn oil fed animals had a lower ratio of 20:4ω6 to 18:2ω6 than did control animals. This difference was due to the higher levels of 18:2ω6. The ethanol treated fish oil group had a lower 20:4ω6 to 18:2ω6 ratio but this was not significantly different from the control group.

Δ6 desaturation in corn and fish oil fed animals.
Desaturation of d₄-18:2ω6 to d₄-18:3ω6 was highest in livers from those animals on the fish oil diet. Ethanol treated animals on either diet had lower levels of enzyme activity than their controls. Fish oil fed animals with and without ethanol had higher levels of enzyme activity than corn oil fed animals.
DISCUSSION:
Dietary lipids effect fatty acid liver composition and metabolism. Animals fed a corn oil based diet (52% 18:2ω6) had an overall higher level of 18:2ω6 in liver tissue than those on the fish oil diet (1.5% 18:2ω6). The same animals also had higher levels of 20:4ω6 in the liver than fish oil control group. Desaturation of d4-18:2ω6 was lowest in the corn oil group and highest in the fish oil group. This data suggests that the desaturase may be regulated by end-product inhibition. An alternative explanation fitting this data would be substrate inhibition. Similar amounts of 18:2ω6 were found in fish oil ethanol and corn oil control groups. These two groups also had similar desaturase activity.

Ethanol increased the liver concentration of 18:2ω6. Although the mechanism for this is not known, it may be due to cofactor competition by alcohol dehydrogenases (ADH) and the desaturase. The oxidation of ethanol to acetaldehyde by the microsomal ethanol oxidizing system (MEOS) ADH requires NADPH which is also needed in the fatty acid chain elongation step. Ethanol’s oxidation may possibly explain increased levels of 18:2ω6 in liver. It is reasonable to assume from this data that alcohol plays some role in essential fatty acid metabolism whereby it leads to elevated levels of the fatty acid precursor. In addition, these elevated levels were negatively correlated with desaturase activity. Diets high in 18:2ω6 had higher levels of this fatty acid in liver tissue with comparatively lower desaturase activity. Conversely diets low in this substrate such as fish oil had higher enzyme activity.

Characterization of 14,15-Epoxyeicosatrienoid Acid Metabolites from Human Platelets by GC/MS.

*Ji Y. Zhang, Chandra Prakash, Kouwa Yamashita and Ian A. Blair.
Department of Pharmacology, Vanderbilt University, Nashville, TN 37232.

The epoxyeicosatrienoic acids (EETs) are cytochrome P-450 mediated oxidation products of arachidonic acid (AA) (1). Exogenous EETs have been reported to influence the function of endocrine, vascular and renal tissues, suggesting a possible mediator role for these compounds. It has also been proposed the human platelet can synthesize the EETs (2). We have shown that EET formation by human platelets is simply due to autooxidation of AA. Although the EETs are not produced from the platelet there is still potential for interaction with the platelet enzyme systems with EETs released from vascular tissue.

Human platelets were obtained from Vanderbilt Clinical Blood Bank. The platelets were centrifuged at 500 x g for 15 min. The pellets were collected and suspended in buffer (145 mM NaCl, 5 mM KCl, 5.5 mM Dextrose, 1 mM MgCl2, 0.2 mg/ml BSA, 100 mM HEPES, pH 7.4) and adjusted to a suspension of 1 x 10^9 platelets/ml. Aliquots of platelet suspensions (5 ml) were incubated with 14,15-EET (5 mCi/mmol, 3 uM) at 37 °C for different time (5 min to 1 hr). The incubations were stopped by addition of 5 ml of iced-cold methanol. The whole lipids were extracted into chloroform/methanol (2/1, V/V). The extracts were separated by TLC or reversed phase HPLC. The phospholipids fractions were isolated and then separated by normal phase HPLC. The metabolites were isolated and converted to the corresponding methyl ester (ME) and pentafluorobenzyl ester (PFB). The derivatives were further purified by HPLC and converted to their trimethylsilyl (TMS) derivatives for GC/MS analysis.

EI and GC/PCI-MS were performed on a Finnigan-MAT INCON 50 quadrupole mass spectrometer interfaced with Hewlett Packard 5890 gas chromatograph. GC/NICI-MS was carried out on a Nermag R-1010C quadrupole instrument equipped with a Varian Vista 6000 gas chromatograph. Chromatography was carried out a SPB-1 (15 m x 0.32 mm ID., Supelco) fused silica capillary column. The temperature of injector, transfer line and ion source was kept at 260 °C. Helium and methane were used as a carrier and regent gas, respectively. The GC oven temperature was held at 190 °C for 0.5 min, then programmed to 320 °C at 20 °C/min, then held for 5 min at this temperature.

When 14,15-EET was incubated with human platelets, it was metabolized to four compounds. The EI mass spectrum of metabolite 1 as its methyl ester (ME), trimethylsilyl (TMS) derivative showed a base peak at m/z 295, suggesting a hydroxy group at C-12 (Figure 1). The NICI mass spectrum of its pentafluorobenzyl (PFB), TMS derivative was dominated by the ion of m/z 407 corresponding to (M-PFB). These data suggested that metabolite 1 was 12-OH-14,15-EET. The EI mass spectrum of the ME-TMS derivative of metabolite 2 exhibited significant fragment ions at m/z 173, 275, 323 indicating two hydroxy groups at C-14 and C-15. The NICI mass spectrum of its PFB, TMS derivative gave a base peak at 481 (M-PFB). This suggested that metabolite 2 was 14,15-dihydroxyeicosatrienoic acid (DHET). Similarly, the EI mass spectrum of metabolite 3 as its ME-TMS derivative showed characteristic ions at m/z 295, 173, 275, indicating the presence of three hydroxy groups at C-12, C-14, and C-15. Its PCI spectrum exhibited a protonated molecular ion at m/z 585 and subsequent elimination of three TMSOH from the protonated molecular ion. This resulted in the formation of ions at m/z 495 (MH-TMSOH), 405 (MH-2TMSOH) and 315 (MH-3TMSOH). In addition, an intense ion at m/z 669 (M-PFB) appeared in the NICI mass spectrum of its PFB-TMS derivative. Thus, metabolite 3 was characterized as 12,14,15-trihydroxyeicosatrienoic acid (THET). Metabolite 4 was identified as phosphatidylcholine containing 14,15-EET at C-2 by comparing its retention time on HPLC with that of authentic compound. 12,14,15-THET was formed from 12-OH-14,15-EET via epoxide hydrolase. 14,15-DHET was not a substrate for 12-lipoxygenase.

In summary, human platelets metabolized 14,15-EET into the corresponding 14,15-DHET, 12-OH-14,15-EET and 12,14,15-THET by epoxide hydrolase and 12-lipoxygenase. Also, 14,15-EET was mainly incorporated into phosphatidylcholine at C-2 position of glycerol (Figure 2).

INTRODUCTION: Eicosanoids are important endogenous mediators in the pathology of respiratory diseases, making measurement of their relative concentrations following various treatments important in further elucidating their role. While GC/MS has become the definitive methodology for detection of the isolated eicosanoids, their sampling remains a challenge. Measurement of the eicosanoids from plasma has been questioned by many workers because of sampling artifacts, while measurement of metabolites in the urine can be difficult to relate back to respiratory production. A novel methodology for sampling the large airways utilizing microdialysis may provide an in-vivo means of observing post-treatment changes in eicosanoid production.

METHODS: Microdialysis probes were of radial design, constructed of nested fused silica tubing and 4 mm of exposed dialysis membrane having a molecular weight cutoff of 40,000 dalton. The probe was perfused at 3.8 µL/min with PBS solution. The in vitro recoveries were determined immediately prior to use using standard solutions. Male Hartley guinea pigs (400-500 g) were presensitized two weeks prior to experiments with an i.p. injection of ovalbumin and Al(OH)3. At the start of an experiment, guinea pigs were anesthetized by an i.p. injection of urethane, supplementary glucose supplied was i.v., and a tracheotomy was performed. Microdialysis probes were inserted approximately 2 cm into the tracheal opening past a guide cannula. Samples were collected into 4 mL polypropylene tubes for six one hour intervals. The treatment groups received either saline or ovalbumin i.v. during the second hour of microdialysis sampling. Prostaglandins E2, D2, F2α and 6-keto-F1α and thromboxane B2 were determined by GC/MS. Tetradeuterated standards were added to aqueous solutions, which were treated (1% MOX-HCl, pH 5-7) overnight to produce the N-methoxime, extracted with C18 SPE, derivatized to the PFB ester (0.1% PFBBr, 60°C for 15 min), TMS ether (BSTFA,60°C for 15 min), and dissolved in 50 µL dodecane. Derivatives were injected on-column into a 1 m retention gap and separated in less than 3 min on a 15 m, 0.25 mm i.d. DB-5 column housed in an HP5890 gas chromatograph. The HP5988A mass spectrometer was operated in resonance electron-capture ionization mode, with SIM switching between the predominant [M-PFB]- ion for each eicosanoid.

RESULTS: Microdialysis probe recoveries varied between 5 and 10%. Intraday variations for a given probe were less than 1% and interday variations, including before and after an animal experiment, were less than 2%. The eicosanoids quantified in the present study were separated in under 3 minutes (Figure 1 displays an exemplary separation). PGE2, PGD2, PGF2α were quantified in most microdialysis samples. TXB2 showed inconsistent assay recovery leading to large day-to-day variations, while 6-keto-PGF1α was below current quantification limits in most samples. In control guinea pig experiments, in which animals were unsensitized and unchallenged, consistent eicosanoid levels below 200 pg/sample were observed. For sensitized guinea pigs, treated with saline only, PGE2, PGD2, PGF2α levels tended to increase in the final three hours of sampling. Ovalbumin treatment did not produce a large increase or decrease in any of the measured eicosanoids, however, levels of PGE2, PGD2, PGF2α and TXB2 tended to increase in first hour following ovalbumin challenge. Table 1 summarizes levels for each group with all time points averaged, while Figure 2 shows the time resolved means for PGD2.

DISCUSSION: Eicosanoids have been successfully measured in the trachea of anesthetized guinea pigs. In particular, mean levels for PGE2, PGD2, PGF2α and TXB2 were in the range 20-60 pg / one hour microdialysis sample. Levels for 6-keto-PGF1α were typically below the standard curve's lowest point (10pg/sample). No statistically significant increases or decreases were observed upon challenge with ovalbumin, however, every animal responded with some increase in PGE2, PGD2, PGF2α and TXB2 in the first hour following challenge. Clearly, a more robust change will be necessary to observe a statistical increase. In conclusion, in-vivo microdialysis has been demonstrated to be a potentially useful means of sampling the trachea as a measure of respiratory production of eicosanoids. Future experiments will address the possibility of concurrent measurement of respiratory function, as well as the effect of more specific challenge protocols (e.g. LTD4 challenge).

SIMULTANEOUS GC-MS QUANTITATION OF PLATELET ACTIVATING FACTOR (PAF) AND 1-0-HEXADECYL-2-LYSO-SN-GLYCERO-3-PHOSPHOLIPIDS IN BRONCHOALVEOLAR LAVAGE (BAL) FLUID FROM HUMAN LUNG.

The Johns Hopkins Asthma and Allergy Center, Baltimore, MD 21224.

PAF is a phospholipid mediator released by inflammatory cells in vitro in response to antigenic and nonantigenic stimuli. Demonstrated biological activities of PAF suggest that PAF released by inflammatory cells in human airways in vivo may modulate, in part, certain characteristic events in asthma such as cellular infiltration, microvascular leakage and bronchial hyperreactivity. Assessment of in vivo biosynthesis of PAF in the airways of a human model of asthma is therefore, critical for determination of the role of PAF in asthma. If significant metabolism of PAF does not occur in airway fluid, a reliable index of in vivo PAF production in peripheral airways of asthmatic subjects may be obtained via measurement of levels of the phospholipid mediator in BAL fluid obtained via a standardized wedged bronchoscope technique. Studies of the metabolism of PAF to its 2-lyso-metabolite (lyso-PAF) in BAL fluid in vitro indicate that the rate of PAF deacylation in BAL fluid varies significantly depending upon whether an antigenic response has been initiated. The life-half of PAF is > 90 minutes in BAL fluid from unchallenged subjects and < 12 minutes in BAL fluid from antigen-challenged subjects. These findings indicate that assessment of PAF levels in BAL fluid may not always provide a reliable index of in vivo PAF biosynthesis in airways of human asthmatic subjects, particularly in BAL fluid from subjects after antigen challenge.

Since measurement of PAF levels in BAL may not provide a reliable index of in vivo production of the phospholipid mediator in human airways, simultaneous measurement of PAF and lyso-PAF in BAL may provide an index of in vivo production of PAF in human airways. Aliquots (2 ml) of BAL fluid were first treated immediately with 8.8% formic acid (20 μl/ml BAL fluid) for inactivation of acid-labile acetylhydrolase. Two to 10 ng of 2H3-PAF and 2H4-lyso-PAF with 2H-label in the 1-0-hexadecyl moiety were added to 2 ml aliquots of acidified BAL fluid as internal standards. The samples were submitted sequentially to protein denaturaton (40% methanol; v/v), solid phase extraction (C18), elution with methanol, drying under N2, phosphate ester hydrolysis with 49% HF, hexane extraction of HF hydrolysis products, drying under N2, and pentafluorobenzoyl esterification of the hexane-extracted residue. Following hexane extraction of pentafluorobenzoyl esterification products, 0.5-1.5 μl aliquots of the residue containing the analytes and 2H-analogs of PAF and lyso-PAF internal standards dissolved in 30 μl dodecane were subjected to GC-MS analysis. Molecular anions at m/z 552, 555, 704 and 708 were simultaneously monitored for detection of injected analytes and internal standards as shown in Figure 1. Signal at m/z 552 and 555, respectively, are characteristic for the pentafluorobenzoyl ester of the HF hydrolysis product of PAF and 2H4-PAF (Panel A). Ions at m/z 704 and 708, respectively, represent signal from molecular anions of bis(pentafluoro-benzoyl) esters of HF-treated 1-o-hexadecyl-2-lysoglycerophospholipids (lyso-C16-alkyl-PL) and 2H4-lyso-PAF (Panel B). Simultaneous GC-MS analysis of PAF and lyso-C16-alkyl-PL extracted from BAL fluid is completed within < 30 minutes and are of adequate purity for detection of low picogram levels of analytes. Standard curves relating ratios of PAF/2H3-PAF and lyso-PAF/2H4-lyso PAF added to BAL fluid are linear from low picogram to nanogram ranges with < 20% inter- and intra-assay variations.

Levels of PAF and 1-o-hexadecyl-2-lysoglycerophospholipids extracted from BAL fluid from an asthmatic subject are shown in Figure 2. PAF levels in BAL fluid obtained at the different time intervals (30 minutes and 24 hours after antigen) do not vary significantly indicating either that significant in vivo PAF biosynthesis does not occur in the airways or that PAF deacylation occurs with such rapidity that the phospholipid mediator may not be consistently present in BAL fluid.

Elevations in lyso-C16-alkyl-PL in BAL fluid reflect accumulation of this family of phospholipids in human airways in vivo. Potential sources of the lyso-C16-alkyl-PL in BAL fluid obtained subsequent to antigen challenge include deacylation of PAF, phospholipase A2 catalyzed hydrolysis of fatty acids from 1-o-alkyl-2-acyl-sn-glycero-3-phospholipids. Further studies are required for determination of source of lyso-C16-alkyl-PL in BAL fluid observed subsequent to antigen challenge and the portion of these compounds derived from PAF deacylation.
Figure 1: Detection of PAF and 1-O-hexadecyl-2-lyso-sn-glycero-3-phospholipids extracted from BAL fluid. Ordinate = signal intensity. Abscissa = time in minutes: seconds.

Figure 2: Endogenous levels of PAF and 1-O-hexadecyl-2-lyso-sn-glycerophospholipids in human BAL fluid 30 minutes and 24 hours after instillation of normal saline and antigen. PAF levels = pg/ml. 1-O-hexadecyl-2-lyso-sn-3-glycerophospholipids = ng/ml.
MAKING THE TRANSITION FROM HPLC TO GAS PHASE ANALYSIS IN STRUCTURAL STUDIES OF ARACHIDONIC ACID METABOLITES

Joseph A. Zirrolli and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street, Denver, CO 80206

Mass spectrometry has played a singular role in the structure elucidation of the ever-increasing members of the arachidonic acid cascade family including leukotrienes, prostaglandins and cytochrome P450 metabolites. Electron ionization GC/MS analysis of derivatized eicosanoids provides critical structural information on carbon skeleton modifications, while molecular weight information is obtained by positive ion CI or negative ion electron capture GC/MS analysis of pentafluorobenzyl ester derivatives. These strategies combine the high specificity of mass spectral analysis with the high selectivity of capillary column gas chromatography.

Problem: Biological extracts require exhaustive purification

Arachidonate metabolites thermally unstable

Solution: HPLC purification- metabolites found by radioactivity detection

Molecular Weight Information

High Sensitivity LC-MS

METABOLISM OF 12(R)-HETE. 12(R)-hydroxy-5,8,10,14-eicosatetraenoic acid [12(R)-HETE] is one of the major cytochrome P450-dependent arachidonate metabolites in the bovine, rabbit and human corneal epithelial microsomes. 12(R)-HETE is biologically active. In addition to chemotactic and chemokinetic properties, this eicosanoid inhibits Na-K ATPase activity in corneal tissues.

We also reported that 12(R)-hydroxy-5,8,10,14-eicosatetraenoic acid is formed from arachidonic acid in corneal epithelial microsomes and has unique biological activities also, including vasodilatation and neovascularization. However the synthetic pathway of this compound was not fully elucidated. It was postulated that this dihydro compound is formed from arachidonic acid via either an 11,12-epoxide intermediate by epoxide rearrangement and keto reduction or via 12(R)-HETE by an oxidation and two consecutive keto-reduction steps. We, therefore, studied the metabolic degradation of 12(R)-HETE in corneal epithelium, the tissue of origin, and identified the major metabolites in intact and broken cell preparations.

Possible Pathways in the Formation of 12(R)-HETE

Arachidonic Acid

\( \text{COOH} \)

OH 12(R)-HETE 11,12-EET

\( \text{COOH} \)

\( \text{O} \) 12-oxo-ETE 12-oxo-ETrE

\( \text{OH} \) 12(R)-HETE

These studies were done in collaboration with Dr. Michal Lanilo Schwartzman at the New York Medical College in Valhalla, NY. Tissue preparation, 12(R)-HETE incubations and initial purification (extraction and first HPLC separation) were all performed in Dr. Schwartzman’s laboratory. Samples were then sent to National Jewish Center for analysis.

HPLC-Mass Spectrometry. HPLC-MS was performed on a Vestec model 201 quadrupole mass spectrometer with thermospray Interface (Vestec Corporation, Houston, TX). Samples were analyzed by negative ion electron capture mass spectrometry following conversion of carboxyl moieties to the pentafluorobenzyl esters. Samples were taken to dryness then reacted with 10 ul of pentafluorobenzyl bromide and 10 ul of n,n-disopropylethylamine in 100 ul acetonitrile for 30 minutes at room temperature. Excess reagent was removed under reduced pressure and the PFB-esters were separated by reverse-phase HPLC on a Phenomenex 5 u C18 ODS column (250 X 4.6 mm, Jones Chromatography, Columbus, OH) using a linear gradient from 60% acetonitrile:water to 100% acetonitrile in 15 min and then isocratic for 30 min in 100% acetonitrile. Fractions were collected and appearance of
radioactivity determined by scintillation counting techniques. Radioactive fractions from the HPLC were introduced into the mass spectrometer through the thermospray interface with the control tip temperature at 200 °C and the thermospray source at 300 °C.

**IDENTIFICATION OF PEAK V.** Following derivatization as the pentafluorobenzyl ester, HPLC chromatography separated many components; however the radioactivity was detected in two fractions, fraction 28 (45%) and fraction 29 (29%). At this retention time there were no compounds eluting which had UV absorption at 236 nm, a chromophore diagnostic for conjugated dienes. LC-MS analysis of the component eluting at this retention time (28-29 min) revealed production of abundant ions at m/z 319 and 321. Considering that m/z 319 was identical to that of the starting carboxylate anion from 12(R)-HETE and yet this component lacked substantial UV absorbance at 236 nm, this metabolite was likely isomeric, for example a 12-oxo-metabolite. With the possible existence of a keto moiety in this metabolite, the methoxylamine derivative was made prior to trimethylsilylation in order to improve gas chromatographic behavior for GC-MS analysis. By negative ion GC-MS this metabolite formed two derivatives (ECL=21.08 and 21.18) with very similar spectra containing abundant ions at 348 (M-181) and m/z 206 (loss of 111 and CH3O from m/z 348). This later ion would be expected for the methoxime derivative following cleavage of the carbon bond adjacent to the imino moiety. The two separable components would correspond to the syn and anti-isomers typically observed with methoxime derivatives. Furthermore Peak V was also found to co-elute with synthetic 12-oxo-5,8,14-eicosatrienoic acid on HPLC. All information obtained for this metabolite is consistent with the identification of Peak V as 12-oxo-5,8,14-eicosatrienoic acid.

**Acknowledgements.** Supported in part by NIH grants EY 06513, HL34303, GM4 1206 and GM 3178.

**HPLC Separation of peak-V**

**PEAK V**

This later ion would be expected for the methoxime derivative following cleavage of the carbon bond adjacent to the imino moiety. CHARACTERISATION OF SYNTHETIC PEPTIDES
BY LASER DESORPTION MASS SPECTROMETRY

K. K. Mock, M. Davey, M. P. Stevenson, J. S. Cottrell,
Finnigan MAT Ltd., Hemel Hempstead HP2 4TG, UK.

The value of molecular weight measurement for characterising synthetic peptides has been amply demonstrated by the work of Chait's group at Rockefeller using $^{252}$Cf PDMS [1]. Out of a sample of 800 synthetic peptides from 15 different laboratories, almost half were found to be either inhomogeneous or incorrect! As Chait has observed, it is not surprising that many errors of synthesis go unnoticed when the technique most commonly used for assessing purity and identity, RP-HPLC, is the same technique as is used for purification.

Matrix Assisted Laser Desorption Mass Spectrometry (LD) provides an alternative to PDMS with certain advantages. LDMS is generally a more rapid and more sensitive technique, particularly for large peptides. The optimum sample loading for proteins and peptides is around 1 pmol, irrespective of mass, and a realistic time for sample preparation and analysis is 5 minutes. Mass measurement inaccuracy better than 0.1% is readily achieved for peptides and small proteins.

Matrix Assisted Laser Desorption Mass Spectrometry is also exceptionally useful in characterising modified and N-terminally blocked peptides which are not amenable to Edman sequencing.

The mass spectrometer consisted of a laser desorption ion source coupled to a Time-of-Flight mass analyser. All of the spectra reported here were obtained in positive ion mode. Negative (deprotonated) ions are produced by the ionisation process but, for these samples, the positive ion spectra were generally more intense.

Operating conditions and procedures were modelled on the work of Karas et al [2]. The sample concentration was adjusted to between $10^{-6}$ and $10^{-8}$ mol. Approximately 0.1 µl of sample solution was mixed with 0.5 µl of sinapinic acid matrix solution in the centre of a stainless steel target and the droplet allowed to dry at room temperature before introduction into the instrument. The matrix was dissolved in 70% acetonitrile, 30% water, 0.1% trifluoroacetic acid to give an approximate concentration of $5\times10^{-2}$ molar.

Example 1: The predicted sequence is RSFVCEVCTAROFARQENLKRHYRSHTNEK

The calculated average molecular weight for the protonated ion is 3568.0u. This species is present in the spectrum as a minor peak, but the major peak is at 3440u. The mass difference of -128u suggests a deletion product resulting from loss of either glutamine, lysine, or glutamic acid (-129u). This was later confirmed to be loss of glutamine by Edman sequencing.

Example 2: The predicted sequence is VERMVSPIESAEDC

The calculated average molecular weight for the protonated ion is 1565.8u. The major peak corresponds to the desired product, but there are also numerous other peaks present. The doublet at +90u and +105u may represent incomplete removal of a benzyl protecting group and a condensation product with thioanisole scavenger. It is interesting to observe the triplet in the vicinity of 1750u which represents the three permutations of peptide exhibiting both of these modifications: +90+90, +90+105, +105+105. There are also weak peaks at (MH+251) and (MH-78) which we are not able to assign.
Mass Spectrometric Signature of S-Prenylated Cysteine Peptides

Albert A. Tuinman,* Deborah A. Thomas,* Kelsey D. Cook,* Chu-Biao Xue,† Fred Naider,‡ and Jeffrey M. Becker*  

*Department of Chemistry, University of Tennessee, Knoxville, TN 37996;  
†Department of Chemistry, College of Staten Island, Staten Island, NY 10301;  
‡Department of Microbiology, University of Tennessee, Knoxville, TN 37996.

Protein prenylation is a recently discovered post-translational modification that has important ramifications for protein structure and function. For example, farnesylation of the RAS oncogene product is required for its membrane association and subsequent oncogenesis of the cell overexpressing the RAS protein. A large percentage of pancreatic and colon tumors express the RAS protein.  

Hitherto, identification and differentiation of S-prenyl cysteine derivatives has been a laborious process involving degradation of the thioether with Raney nickel, purification of the reaction mixtures, and identification of the hydrocarbon fraction by gas chromatography/mass spectrometry (GC-MS); a process requiring 150-200 µg of material.

SIGNATURE FRAGMENTS Examination of the FAB mass spectra (requiring only 2-5 µg of material) of thirteen synthetic analogs of the α-factor pheromone (H-Tyr-Ile-Ile-Lys-Gly-Val-Phe-Trp-Asp-Pro-Ala-Cys(S-farnesyl)-OCH₃) of Saccharomyces cerevisiae, revealed a consistent fragmentation which serves as a mass spectrometric signature of cystein prenylation. Fig. 1 displays two such spectra (FAB matrix = thioglycerol + 1% trifluoroacetic acid) whereby clusters A represent the protonated molecules, and clusters B and C the signature fragments. The mass difference A-B = n x 68 Dalton (n = number of isoprene units in the prenyl substituent) characterizes fragment B. The difference B-C = 34 Dalton characterizes fragment C. Only the observation of both fragments signals the presence of an S-prenylated cystein. The proposed mechanism for generating these fragments is presented in Fig. 2.
STRUCTURAL VARIATIONS

Variations in the nature of substituent Y (Fig. 2) did not effect the signature fragments substantially. Thus, Y = OCH₃, OC₂H₅, or NH₂ generated approximately the same abundances of fragments B, and C for identical peptide residues and prenyl chain lengths. By contrast, the intensities of the fragment clusters B and C (relative to A) were found to increase dramatically for smaller peptide residues, and to decrease somewhat for smaller prenyl chain lengths.

COLLISION INDUCED DISSOCIATION

Low energy CID (15 eV collisions with Ar at ca. 10⁻⁴ Torr) of the protonated molecules of prenylated cysteins having short peptide chains generated the signature fragments almost exclusively, whereas collision energies in excess of 50 eV produced numerous smaller fragments as well (Fig. 3).

LIQUID SECONDARY ION MASS SPECTROMETRIC ANALYSIS OF
ABNORMAL PROTEINS: Hb Coventry

G. John Shaw, John M. Allen and Stephen. O. Brennan.

1. Department of Scientific and Industrial Research, Palmerston North, New Zealand.
2. Department of Clinical Biochemistry, Christchurch, New Zealand.

Haemoglobin Coventry (Hb Coventry) is one of a group of abnormal or unstable human haemoglobins associated with mild haemolytic anaemia. Hb Coventry (B 141 leu deleted, B\textsuperscript{ Coventry}) has been reported on three previous occasions. In each case it was presented as a minor component which co-precipitated with another unstable haemoglobin during stability tests. Hb Coventry was first reported in association with Hb Sydney (B 67 Val\rightarrow Ala, B\textsuperscript{ Sydney})\textsuperscript{(1)}; later in association with α-Thal-1 (2 genes deleted)\textsuperscript{(2)} and more recently (3), with Hb Atlanta (B 75 Leu\rightarrow Pro, B\textsuperscript{ Atlanta}). Indeed in this latter case the propositus was found to have three different haemoglobin B chains, namely - B\textsuperscript{ Atlanta} (23%), B\textsuperscript{ Atlanta-Coventry} (11%) and B\textsuperscript{A} (normal, 66%). A re-investigation of the Hb Coventry by cDNA sequence analysis and by LSIMS analysis of the B\textsuperscript{ Coventry}-14 peptide arising from the tryptic digest of the aminoethylated B\textsuperscript{ Atlanta-Coventry} chain suggests that the modification arises from a post-translational change rather than from deletion of the leucine residue, B 141.

Experimental

Chain separations were performed in CM-Cellulose at pH 6.8 in 8M urea. Tryptic digestion, 2D- and reverse phase mapping were carried out using established procedures (3). Automated amino acid analysis was carried out with both ninhydrin detection and precolumn derivatisation with PITC. cDNA sequencing was performed using reverse transcriptase, polymerase chain reaction and direct sequence analysis. Automated amino acid analysis was carried out with both ninhydrin detection and precolumn derivatisation with PITC. cDNA sequencing was performed using reverse transcriptase, polymerase chain reaction and direct sequence analysis. Pure B\textsuperscript{A} and B\textsuperscript{ Coventry} peptides were hydrolysed with Chymotrypsin and then incubated with Carboxypeptidase A. Samples were analysed by LSIMS after 0,30,60,120 minutes incubation. 25keV LSIMS peptide mass spectra were obtained from a VG70-250S instrument fitted with a VG LSIMS ion source and associated caesium ion gun. Accurate mass measurement (RP 3000) of the protonated molecular ion was carried out using a software based multichannel analysis technique with CsI as external standard.

Results and Conclusion

Maps of the tryptic peptides were prepared from digests of isopropanol precipitated globin, total globin and isolated total B-globin. 2D peptide maps of total B- chains showed all the expected normal peptides. There were, however, three additional histidine-staining peptides present B\textsuperscript{A}9, B\textsuperscript{A}8-9 and B\textsuperscript{A}14. This analysis was repeated using the corresponding peptides from the same digests following HPLC separation (Figure 1). Repeated peptide amino acid analysis of B\textsuperscript{ Coventry} showed a composition identical to B\textsuperscript{A} except for the absence of the only leucine residue. There was no evidence of a substituted amino acid or proline or tryptophan. From this data it was concluded that the B-14 peptide from Hb Coventry was B 141 Leu deleted in agreement with previous studies.

Recent cDNA sequence analysis has shown that the mRNA and gene giving rise to the B-globin protein in Hb Coventry does code for the B 141 Leu residue and that this region of the gene is identical to that coding for normal B globin.

LSIMS of the B\textsuperscript{A}14 (1150 daltons) and B\textsuperscript{ Coventry}14 (1166 daltons, Figure 2) tryptic peptide either measured directly from 2D electrophoretograms by mounting the paper spot onto the LSIMS target or by analysing the corresponding HPLC fraction gave identical results. Accurate mass measurement of B\textsuperscript{ Coventry}14 and B\textsuperscript{A}14 using CsI and gramicidin S as external standards gave masses of 1165.5848 daltons and 1149.6501 daltons, respectively.

To investigate the primary sequence further, the B\textsuperscript{ Coventry} dodecapeptide was digested with Chymotrypsin to give an isolatable nonapeptide (829 daltons) in which the carboxy terminus was shown to be the post-translationally modified residue (designated Leu-X). Subsequent hydrolysis with Carboxypeptidase A for different times up to 2 hours gave an LSIMS map (Figure 3) showing the sequential loss of Leu-X (700
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

daltons), Ala (629 daltons) and Asn (515 daltons).

$\beta^{397\text{ery}}_{14}$ peptide: $^{133}\text{Val-Val-Ala-Gly-Val-Ala^*-Asn^*-Ala^*-Leu^*-Ala-His-Lys}^{144}$

(a = Carboxypeptidase A hydrolysis sites; c = Chymotryptic hydrolysis site)

These results indicate that Hb Coventry is not due to a deletion of a Leu residue at $\beta$ 141. Instead the residue at $\beta$ 141 was found to be 16 daltons higher than Leu. This suggests Hb Coventry arises from a post-translational change at $\beta$ 141. Work is continuing to characterise Leu-X.

Fatty acyl coenzyme A (acyl-CoA) thioesters are essential intermediates in all aspects of fatty acid metabolism: synthesis, degradation, and lipid esterification. Long chain acyl-CoA compounds have also been implicated in a number of pathological conditions where increased concentrations may lead to cellular injury.

Recently it was shown that arachidonoyl-CoA inhibits platelet activating factor (PAF, 1-O-hexadecyl-2-acetyl-sn-glycero-3-phosphocholine) synthesis in bovine neutrophil cell homogenates but free arachidonic acid had no effect on PAF synthesis (2). Also, trilacosin (an inhibitor of acyl-CoA synthetase) is reported to potentiate PAF production in rat polymorphonuclear leukocytes (3). Studies from our laboratory have shown a modulating effect on the synthesis of PAF in stimulated neutrophils due to exogenously added fatty acids. The fatty acid specificity of PAF synthesis inhibition suggested a role for long chain fatty acyl-CoA acyltransferase in competition with acetyl-CoA acetyltransferase in the utilization of 1-hexadecyl-CoA (1). Recently it was shown that arachidonyl-CoA inhibits 

Sonic-3-phosphocholine) synthesis in bovine neutrophil homogenates but free arachidonic acid had no effect on PAF synthesis. Also, trilacosin (an inhibitor of acyl-CoA synthetase) is reported to potentiate PAF production in rat polymorphonuclear leukocytes.

Methods

Standard long-chain acyl-CoA compounds were obtained from Sigma (St. Louis, MO). All standards were dissolved in methylene chloride:methanol (2:1) to give a final concentration of 1 ug/ul. Aliquots (1 ul) were applied dissolved in methylene chloride:methanol (2:1) to give a fatty acyl-CoA acyltransferase in competition with acetyl-CoA acetyltransferase in the utilization of 1-O-hexadecyl-sn-glycero-3-phosphocholine, the immediate precursor to PAF. For this reason, we investigated the negative ion FAB/MS behavior of long chain fatty acyl-CoAs and developed tandem FAB/MS/MS and CID protocols for the analysis of both specific acyl-CoAs and complex mixtures.

Coenzyme A Diagnostic Ions

A m/z 766 [CoA-H]+
B m/z 428 [3',5'-ADP-H]+
C m/z 408 [Acyl-CoA]+
D m/z 357 [phosphopantetheine-H]+
E m/z 339 [Acyl-2H2O]+

For identification of the specific acyl thioester, the second series of ions which retain the acyl group are more important.

Fatty Acyl Diagnostic Ions

I m/z 875 [acyl diphasophopantetheine-H]+
II m/z 857 [ion [H2O]+
III m/z 595 [acyl phosphopantetheine-H]+
IV m/z 577 [ion [H2O]+
V m/z 571 [C15H27CO]+, acyl thiolate anion

Negative ion FAB/MS produced more abundant ions which retained the acyl group than the reported positive ion spectra (4,5). This prompted further study of their CAD behavior to evaluate specific decompositions for the analysis of complex mixtures.

Tandem FAB/MS/MS and CID of Acyl-CoAs

The most abundant product ions from the collision induced decomposition of [M-H]+ ions were B and C, ions which contained only the diposphoadenosine structure. As these ions were not very abundant in FAB/MS and do not retain any acyl information they were not considered suitable for the analysis of complex mixtures or specific acyl-CoAs.

The product ion spectra of III and IV (m/z 595 and 577 for palmitoyl-CoA) contained very abundant ions at m/z 357 and 339 (ions D and E), respectively, corresponding to the loss of alkylketene. Although these ions also do not retain any acyl information, appropriate precursor and neutral loss protocols were developed to take advantage of this very favorable decomposition.

A mixture of seven long-chain fatty acyl-CoAs were analyzed by both single and tandem FAB. The single FAB/MS spectrum (Fig. 2) displayed quite a mixture of ions. However as the ion at m/z 339 (ion E) is common to all acyl-CoAs, the tandem FAB/MS/MS analysis of the precursors of m/z 339 yields a clear series of ions which are diagnostic of the molecular acyl species present (Fig. 3).

Likewise, the same decomposition can be used to analyze for a specific acyl-CoA. As this fragmentation involves loss of the alkylketene from the acyl group, a tandem mass spectrometric analysis for the neutral loss of a specific alkylketene will produce a spectrum diagnostic for that acyl-CoA.

Analysis of Acylcarnitines as their N-Demethylated Ester Derivatives by Gas Chromatography-Mass Spectrometry

Zhi-Henq Huang, Douglas A. Gage, Loran L. Bieber and Charles C. Sweeley*, Department of Biochemistry, Michigan State University, East Lansing, MI 48824-1319

Carnitine is essential for the transport and metabolism of long-chain fatty acids. It is also involved in the detoxification of specific short- and medium-chain acyl groups that are poorly metabolized. In certain disease states, quantitative and qualitative analysis of urinary acylcarnitines enable the recognition of metabolic defects that may not be easily detected by organic acid analysis [1]. The analysis of acylcarnitines has been difficult because of the presence of a quaternary ammonium group and the resulting involatility. Presently available procedures, mostly based on HPLC, FAB-MS and TSP-HPLC-MS, generally have limitations in specificity and sensitivity, or require specialized equipment [2]. Recently, a procedure was reported to overcome these limitations [3] which involved the conversion of acylcarnitines into corresponding volatile acyloxybutyrolactones followed by GC-MS analysis.

We report here a new, simple procedure in which the acylcarnitines are analyzed as the N-demethylcarnitine esters (R’= Et, Pr) by a two-step derivatization followed by GC or GC-CI(methane)-MS.

![Chemical Structure](attachment:image.png)

**DERIVATIZATION**

**Step 1.** Direct esterification by extractive O-alkylation with Et or Pr chloroformate in aq. EtOH (or PrOH) in the presence of pyridine.

**Step 2.** Ion-pair extraction using KI-chloroform to remove the acylcarnitine ester iodides into organic phase.

An aliquot of the above derivative is directly injected onto the GC-column to effect N-demethylation. Consequently, the mass spectra of the thermolytic products are registered as corresponding acyl N-demethylcarnitine Et (or Pr) esters (ADMCEE or ADMCPE). For urine samples, the derivatization is preceded by purification through a column of AG 1X8 anion exchanger followed by enrichment using a C-18 cartridge.

**INSTRUMENT** Spectra were acquired on a JEOL AX 505H double focusing mass spectrometer coupled with a HP 5890J gas chromatograph. GC-MS conditions: DB-1 column (30 m x 0.25 mm x 0.25*m film coating) programmed at 5 or 10 C/min between 100-300 C, or 150-300 C. He gas flow 1 ml/min. Reagent gas methane. Scan rate 50-500 Daltons in 1 s/scan.

**RESULTS** The dequaternized derivatives exhibited well-separated peaks in the chromatogram. Distinctive mass spectra were recorded that permitted the chain features of individual molecular species, including those of isomeric compounds to be distinguished. Figures presented below are gas chromatogram and selected CI mass spectra of derivatized acylcarnitines which were obtained from the urine of a patient suffering from medium-chain acyl-CoA dehydrogenase (MCAD) deficiency.

**CONCLUSION** The present method, owing to the extreme simplicity and unambiguous characterization it can achieve, may constitute a potentially useful tool in the study of fat metabolism. The advantages include:

1. Simple operation, applicable to carnitine esters derived from mono- and dibasic acids.
2. Good GC separation and distinctive mass spectra allow qualitative and quantitative analysis of mixtures.
3. Nanogram detection, suitable for analysis at physiological levels.
4. High overall efficiency of sample processing: The analysis of a urine sample can be completed within 1 h - 15 min for urine pretreatment, 15 min for derivatization, and 15-30 min for GC-MS analysis.

DETECTION OF 2-HYDROXY-3-METHYLVALERIC ACID ENANTIOMERS
BY CAPILLARY GC/MS

Mark L.J. Reimer and Orval A. Mamer
Biomedical Mass Spectrometry Unit, McGill University
Montreal, Quebec, Canada H3A 1A3

Introduction. Elevated levels of 2-hydroxy-3-methylvaleric acid (HMVA) in body fluids are symptomatic of maple syrup urine disease (MSUD), a disorder resulting from any of several inherited defects in the multi-enzyme complex, branched chain alpha-keto acid dehydrogenase. Earlier GC/MS studies of branched-chain keto and hydroxy acids were limited by poor chromatographic resolution through the use of packed columns. We now present the analysis of HMVA as its silylated derivative on a DB-1 capillary column coupled directly to a quadrupole mass spectrometer; the improved chromatography allows the resolution of two diastereomeric pairs of HMVA (R,R; S,S and R,S; S,R) in urine. Reaction with a chiral reagent resolves the four enantiomers of racemic HMVA on a non-chiral DB-1 column.

Sample Preparation. Racemic HMVA and D$_2$-HMVA were prepared by the reduction of KMVA with NaBH$_4$ or NaBD$_4$, respectively, in a basic (pH 12) aqueous solution. Extraction of organic acids from both MSUD urine and standards was as follows: a 2 ml aliquot was made basic (NaOH; pH 12), saturated with NaCl and extracted twice with diethyl ether (ether layers discarded); the sample was acidified (HCl; pH 2), extracted three times with ether and dried over Na$_2$SO$_4$. The chiral derivatization was carried out by reacting HMVA with an excess of (S)-(++)-2-methylbutyric anhydride (MBA) in pyridine at 60°C for 3 h and extracting as described above. TBDMS derivatives of HMVA and D$_2$-HMVA and the TMS derivative of HMVA-MBA were prepared by standard methods.

Instrumental. GC/MS analyses were performed using an HP 5890A gas chromatograph directly coupled to an HP 5988A quadrupole mass spectrometer. Samples were introduced by splitless injection onto a fused silica DB-1 capillary column heated from 100 to 200°C at 5°C/min. El mass spectra were acquired under standard conditions while NH$_3$/CI spectra were obtained at a source pressure of 0.45 Torr and an ionizing energy of 150 eV.

Results and Discussion. Fig. 1 depicts the El mass chromatograms (m/z 303) for the TBDMS derivatives of (a) the MSUD urine extract and (b) authentic HMVA. The corresponding El mass spectra for the four GC eluates are shown in Fig. 2. The excellent correlation in retention times and mass spectra confirm that the MSUD urine extract contains the two diastereomeric forms of racemic HMVA. Some of the major ions in the El mass spectrum of HMVA-(TBDMS)$_2$ ([M]+, m/z 360) are: [M-56]+ (m/z 304, loss of C$_4$H$_9$ from acid backbone), [M-57]+ (m/z 303, loss of t-butyl from TBDMS group), [M-85]+ (m/z 275, loss of CO from m/z 303) and [M-159]* (m/z 201, loss of CO$_2$TBDMS). These fragmentations were substantiated by the analysis of D$_2$-HMVA-(TBDMS)$_2$ ([M]+, m/z 362), which gave prominent ions at m/z 305 ([M-57]+), m/z 277 ([M-85]+) and m/z 203 ([M-159]*). Molecular weight confirmation was obtained by the NH$_3$/CI analysis of the urine extract, giving prominent [M + NH$_4$]+ (m/z 378) and [M + H]+ (m/z 361) ions. The El mass chromatogram (m/z 171) for the TMS derivative of the HMVA-MBA complex ([M]+, m/z 288) is depicted in Fig. 3 and shows partial resolution of the four HMVA enantiomers. The corresponding mass spectra reveal the following major ions: [M-14]+ (m/z 274, loss of CH$_2$), [M-15]+ (m/z 273, loss of methyl from TMS group), [M-57]+ (m/z 231, loss of C$_4$H$_9$ from acid backbone), [M-89]+ (m/z 199, loss of -OTMS) and [M-117]+ (m/z 171, loss of CO$_2$TMS). This study demonstrates the potential for performing conformational analyses on optically active metabolic products using simple and proven sample preparation methods and readily available GC/MS instrumentation.

URINARY ORGANIC ACID PROFILE STUDIES IN A PATIENT WITH CYTOCHROME C OXIDASE DEFICIENCY

MATSUMOTO, I., KUHARA, T., MATSUMOTO, M., YOKOTA, K.*;
Division of Human Genetics, Medical Research Institute, Kanazawa Medical University, Uchinada, Ishikawa, Ishikawa 920-02, Japan and

Introduction

As causes of chronic lactic acidosis, abnormalities of the pyruvate dehydrogenase complex, abnormalities of gluconeogenesis, the respiratory chain disorders and other disorders including organic acidurias are known.

A number of patients with disorders in the respiratory chain affecting mitochondrial respiration and manifested clinically as a mitochondrial myopathy have been reported.

We have studied the urinary organic acid profiles in a female infant with cytochrome C oxidase (CCO) deficiency by capillary gas chromatography-mass spectrometry. The urinary organic acid profiles of a patient with glucose-6-phosphatase deficiency and one with fructose-1,6-diphosphatase deficiency during hypoglycemic attacks were also examined. These organic acid profiles were clearly different from those of patients with the respiratory chain disorders.

The urinary acid profiles of a patient with pyruvate carboxylase deficiency, during a ketotic attack and during remission, were also investigated.

Methods

To urine equivalent to 0.5 mg creatinine, 20 μg each of 3-hydroxymyristic acid and heptadecanoic acid was added, after acidification to pH 1.0 with 6N HCl. The urinary acids were extracted with ethylether three times and converted to their trimethylsilyl derivatives.

A JEOL JMS DX-300 gas chromatography-mass spectrometer supported by a JMA 3500 data acquisition system was used for GC/MS analysis. A MPS-50 fused-silica-capillary column (25m x 0.32 mm i.d., 1.0 μm film thickness, Quadrex Corporation, Connecticut, USA) was used for the chromatographic separation.

Results and Discussion

The urinary organic acid profiles in a case with cytochrome C oxidase (CCO) deficiency (case 1) were always characteristic of those found in the disorders in the electron transport system: markedly increased excretion of lactate and 2-hydroxybutyrate, with an increased serum lactate/pyruvate ratio and frequently with an increased 3-hydroxybutyrate/acetoacetate ratio.

Citrate, malate, fumarate and 2-oxoglutarate were all increased. 2-Hydroxyglutarate/2-oxoglutarate ratio was also increased. In addition p-hydroxyphenylacetate, the reduced form of a tyrosine catabolic intermediate (p-hydroxyphenylpyruvate), was also significantly increased. Fumarate/succinate ratio was also elevated.

The disorders of gluconeogenesis (pyruvate carboxylase deficiency, glucose-6-phosphatase deficiency, fructose-1, 6-diphosphatase deficiency, during clinical attacks) showed quite different metabolic profiles from those of CCO deficiency. During a ketogenic attack in pyruvate carboxylase deficiency, lactate and ketone bodies were dramatically increased but citrate, malate, 2-oxoglutarate, 2-hydroxyglutarate, succinate and fumarate were markedly decreased. The amino acids, asparagine and glutamine which are metabolically very close to the TCA cycle, were also greatly decreased. The 3-hydroxybutyrate/acetoacetate ratio was dramatically increased. After citrate
supplementation for the purpose of providing TCA-cycle-substrates, these TCA-cycle-related amino acids and TCA-cycle intermediates were increased to the control level.

During the hypoglycemic attack in glucose-6-phosphatase deficiency and fructose-1,6-diphosphatase deficiency, lactate, ketone bodies and TCA-cycle intermediates were significantly increased. The increase in 2-oxoglutarate was most impressive. Fumarate was also greatly increased; however, the 2-oxoglutarate/fumarate ratio was also increased in these two disorders of gluconeogenesis. Dicarboxylic acids (adipate and suberate) were not increased in any of the three disorders of gluconeogenesis.

Conclusion

The present investigation showed that the urinary organic acid profiling is useful for the differential diagnosis of chronic lactic acidosis which is critically important for the correct treatment of patients with lactic acidosis.

Organic acid patterns in urine of patients with congenital lactic acidosis

RAPID DIAGNOSIS OF DISORDERS IN AMINO ACID METABOLISM; QUANTITATIVE ANALYSIS OF SPECIFIC AMINO ACIDS IN SMALL BLOOD SAMPLES BY FAB MS/MS.

Donald H. Chace, Diane S. Gale, Naoto Torada, and David S. Millington, Department of Pediatrics, Division of Genetics and Metabolism, Duke University Medical Center, Durham, N.C. 27710

Tandem mass spectrometry (MS/MS) coupled with fast atom bombardment ionization (FAB) is well suited for the rapid analysis of complex biological samples. Numerous compounds of various structural classes can be analyzed with excellent selectivity and specificity without the need for time-consuming chromatographic separations. This laboratory routinely uses FAB MS/MS techniques for the detection of abnormal urine and plasma metabolic profiles in patients with inborn errors of metabolism. We report here a new application of this technique to screen for disorders of amino acid metabolism such as phenylketonuria (PKU) and maple syrup urine disease (MSUD). Quantitative analysis using isotope dilution has been developed for several amino acids in plasma and small blood spots on filter paper.

Preparation of plasma and blood spot samples was as follows. Two hundred μL of plasma was deproteinized with ethanol. A 6 mm diameter circle containing approximately 12 μL of blood was punched from a PKU card (Guthrie card) and mixed with 1 mL of methanol. Internal standard was added to each sample and the contents were vortexed (PKU card allowed to stand for 30 minutes), dried, and butylated with 3 M HCl-butanol at 65°C for 20 minutes in a capped vial. After this, the mixture was dried and reconstituted in 50 μL of methanolicoliglycerol. Five μL of final sample solution were placed on the FAB probe tip for analysis. Two triple quadrupoles were used, a VG QUATTRO with Lab-base data system and a VG TRIO-3 with DEC 11-250 data system. The TRIO-3 used a sledge-field FAB gun to generate 8 Kev xenon atoms and the QUATTRO used a cesium ion gun operated at 10 Kev. Argon was used as the collision gas and the collision energy optimized. All MS/MS spectra (daughter and neutral loss scans) were recorded in 'multi-channel analysis' mode (60 consecutive scans, 1 sec/scans) at unit mass resolution and accumulated in a single raw spectrum.

The butyl ester derivative of amino acids provided satisfactory results (high sensitivity, few Interfering peaks) for their detection in blood or plasma as compared with MS/MS for non-derivatized amino acids or their methyl esters. The CID spectra of the MH+ ion of many amino acids are characterized primarily by a common neutral loss of the butyl ester group (102 daltons). For LYS, ARG, GLN, and ASN, the loss of ammonia (m/z 17) is more prominent. For these amino acids loss of 102 (butyl ester) occurs in addition to loss of ammonia. Therefore, these are detected in a neutral loss of 102 scan as an [MH+ - 17] ions. The scan function employed to generate the amino acid profiles was the constant neutral loss of 102 daltons. This profiling technique was applied to analysis of 200 μL aliquot of pooled plasma from normal patients Figure 1a. The lack of chemical Interference is notable and suggests feasibility for quantitation of several amino acids by isotope dilution mass spectrometry. Samples were also analyzed from blood spots placed on filter paper. Amino acid profile obtained from a 6mm spot of blood cut from a normal patient is presented in Figure 1b. A strikingly similar pattern with less chemical interference is observed relative to the plasma profile (Figure 1a).

Simple isotope dilution assays for leucine, phenylalanine, and tyrosine were developed in using D3,Leu, D3-Phe, and D3-Tyr as internal standards. A calibration curve was derived from analysis of standard solutions containing varying amounts of labeled amino acid in the presence of internal standards. The results showed excellent linearity for each amino acid with correlation coefficients of 0.99 or greater. The detection limits for LEU, PHE, TYR were less than 25, 5, and 45 nmol/mL, respectively. LEU, PHE, and TYR were quantified in 200 μL plasma samples or 6 mm spot from a PKU card from normal patients. The ratios of peak areas were obtained after using a neutral loss scan over a limited mass range. The results from the analysis of 10 normals by FAB MS/MS were compared with those obtained from a Beckman model 7300 amino acid analyzer and the data were in close agreement with each other (10%).

The quantitative determination of phenylalanine is important in the detection of phenylketonuria (PKU) a metabolic disorder characterized by a deficiency or absence of phenylalanine hydroxylase, an enzyme which converts phenylala-nine to tyrosine. The result of this disorder is elevated phenylalanine and depressed tyrosine concentrations in plasma and urine. The State of North Carolina currently screens all infants for PKU. Their method only quantifies the concentration of phenylalanine by a fluorometric assay. However, elevated phenylalanine may also present in certain liver metabolism disorders in addition to other amino acids. A more specific test for PKU would be a method which quantifies the phenylalanine to tyrosine ratio. FAB MS/MS has this capability. Several PKU cards were sent to us from the State of North Carolina screening program and categorized as normals, known PKU, and false positive (by their method). The samples were quantified by FAB MS/MS and the mole ratios of PHE/TYR were determined. It was found that the PHE/TYR ratio for normals was quite distinct for known PKU patients as compared to normals or false positives.

An amino acid profile of a known PKU patient obtained from 6mm blood spot from a PKU card is presented in Figure 1c. The quantitation of leucine/isoleucine (LEU/ILE) resulted in the detection of Maple Syrup Urine Disease (MSUD) which is characterized by highly elevated leucine concentration in plasma. An amino acid profile of one patient with MSUD is presented in Figure 1d. The concentration of LEU/ILE is over 2000 nmol/mL (normals < 250 nmol/mL).

The results presented here suggest the general applicability of FAB MS/MS for diagnosis of metabolic disease. This technique is rapid and is amenable to large scale automated analysis and screening. If combined with acylcarnitine profiles now currently performed in this laboratory, the number of metabolic disorders which could be detected in one test is greater than 15. MS/MS is so versatile that new classes of compounds may be potentially screened. The authors would like to acknowledge the following: Grants from NICHD Division of the NIH (HD-24908) and the State of North Carolina, Division of Maternal and Child Health. We also thank Fisons-VG Biotech for the temporary loan of a TRIO-3 tandem quadrupole mass spectrometer.
Figure 1A: Neutral loss scan of 102 mass units by FAB MS/MS from 200 µL of pooled plasma of normal patient. An internal standard, D₃-LEU (80 nmol) was added to 200µL of plasma. B: Neutral loss scan of 102 mass units by FAB MS/MS from a 6 mm blood spot punched from a PKU card from a normal patient. The internal standards, D₃-LEU 1 nmol, D₅-PHE 1 nmol, and D₃-TYR 1 nmol, was added to the spot which is equivalent to 6 µL of plasma. C: Neutral loss scan of 102 mass units by FAB MS/MS from a 6 mm blood spot punched from a PKU card from a patient with phenylketonuria (PKU). The internal standards, D₃-LEU (1 nmol), D₅-PHE (1nmol), and D₃-TYR (1 nmol) was added to the spot which is equivalent to 6 µL of plasma. D: Neutral loss scan of 102 mass units by FAB MS/MS from 200 µL of pooled plasma of an MSUD patient. An internal standard, D₃-LEU (80 nmol) was added to 200µL of plasma.

Lysoplasmenylethanolamine (1-0-alkenyl-sn-glycero-3-phosphoethanolamine, also denoted as lyso-VEPE for lyso vinyl ether phosphoethanolamine) and its diacetyl analogs (diacetyl-VEPE) are being utilized in our laboratories for studies related to Platelet-Activating Factor (PAF). When fast atom bombardment mass spectrometry was used during our development of new methods for high purity preparation of these phosphoglycerides (Hanahan, D.J., Nouchi, T., Weintraub, S.T. and Olson, M.S. J. Lipid Res. 31, 2113-2117, 1990), we observed several interesting features about the spectra. Not only did acetylation strongly influence the nature of the spectrum, but a chemical reaction between the thioglycerol matrix and the analyte was also found to occur.

FAB mass spectra of lyso-VEPE, using a matrix of either glycerol or thioglycerol, are shown below.

![FAB mass spectra of lyso-VEPE](image)

In both cases, distinct \([M + H]^+\) ions can be seen for each molecular species. Note that the fragmentation patterns in both spectra are quite similar, except that the ions at m/z 331, m/z 357 and m/z 359 are only present when thioglycerol is the matrix. From the mass separation and overall appearance of this ion cluster we suspected that the alkenyl side chains of the VEPE homologs were included in these fragments. We hypothesized that in the slightly acidic environment of thioglycerol, fatty aldehyde could be liberated which could then react with the matrix to form the compound shown on the next page. Alternatively, direct attack of thioglycerol on the vinyl ether might occur. In order to confirm the composition of the reaction product, accurate mass analysis was undertaken. The results for the ion at m/z 357 are: measured mass, 357.2836; formula, \(C_{21}H_{41}O_2S\); difference from calculated value, 0.9 mmu (2.5 ppm).
Further insight into the nature of these ions was gained by exposing lyso-VEPE to strong acid and then analyzing the liberated fatty aldehyde by FAB/MS. No ions above background were observed when a glycerol matrix was utilized, but in thioglycerol, the majority of the ion current was found in the m/z 357 base peak. While the composition of the fatty aldehyde released from the lyso-VEPE has not been ascertained through dimethylacetal formation followed by GC/MS analysis, the ion at m/z 357 is consistent with the protonated reaction product of thioglycerol with 18:1 aldehyde.

During these studies we have also been investigating the effects of acetylation on the ability of lyso-VEPE to inhibit PAF-induced platelet aggregation and secretion. From FAB/MS of the diacetyl derivatives we observed that there were much greater differences in the fragmentation patterns as compared to that of lyso-VEPE than just the addition of 42 or 84 mass units to appropriate ions. In the spectrum of our first batch of diacetyl-VEPE, [M + H]+ ions for each molecular species were clearly detectable in addition to lower intensity [M + K]+ ions. However, in subsequent preparations, [M + H]+ ions were essentially not detected, and [M + K]+ increased in relative intensity. In addition, the ion at m/z 222, representing potassium cationized acetylphosphoethanolamine, was the base peak. It was interesting to note that the ions at m/z 331, m/z 357 and m/z 359 were detected in the diacetyl analogs, albeit at lower intensity in the more highly potassium cationized samples.

We presume that the K+ became associated with the lyso-VEPE as a consequence of the alkaline methanolysis with KOH (even though ions representing either [M + K]+ or thioglycerol-potassium adducts were not seen in the FAB mass spectrum of lyso-VEPE). Not only have we been unable to determine why our initial sample differed somewhat from later preparations, but we have also not been able to dislodge the potassium without destroying the vinyl ether moiety.

From an examination of lyso-phosphatidylyethanolamine (lyso-PE) and its diacetyl derivative, we found that the enhanced attachment of potassium was not limited to vinyl ethers alone. Similarities with the between the FAB spectra of diacetyl-PE and diacetyl-VEPE were clearly seen, in particular, an increase in intensity for the ion at m/z 222, and a decrease for the ion at m/z 117.

We conclude that vinyl ether phosphoethanolamines can react with thioglycerol to form a covalent compound between the matrix and the alkenyl side chain. A comparable reaction does not occur when acyl or ether side chains are present. In addition, acetylation of the ethanolamine moiety significantly affects ion binding to the phosphate, resulting in strong complexation with adventitious potassium ions which remain associated after alkaline methanolysis.

CAD FRAGMENTATION OF TAUROCONJUGATED BILE ACIDS AT LOW ENERGY

*E. DE HOFFMANN, F. VAN HOOF AND R. LIBERT
University of Louvain, Place Pasteur 1, 1348 Louvain-la-Neuve, Belgium

FAB MS/MS negative ion spectra at low collision energy of bile salts mixtures from biological samples are useful in the diagnosis of several metabolic disorders\(^1\). A better understanding of the fragmentation pathways will allow to get more structural information from these spectra. We have thus studied the fragmentation of tauroconjugated bile acids anions with a Finnigan MAT TSQ70 triple quadrupole instrument. Xenon was used as a collision gas at .8 mTorr uncorrected gauge pressure reading.

Tomer et al.\(^2\) have described remote charge site fragmentations occurring at high energy CAD such as depicted by A to F in figure 1. We have observed that the FAB spectra of pure bile salts display the same remote charge site fragments (figure 2).

CAD spectra at 15 eV collision offset voltage also display remote charge fragments of the rings, but only when unsaturations and heteroatoms are present. Thus, taurotriketocholanic acid (figures 3 and 4) and tauroconjugated \(\Delta 4\) unsaturated bile salts display strong remote charge site fragments.

Saturated bile salts with hydroxyl groups display fragments corresponding to parts of the side chain and others corresponding to neutrals lost from the side chain, indicated by arrows in figure 1. These appear to be remote charge site fragments too, but with the charge now located on an hydroxyl group rather than on the taurine moiety. Changing the number or the position of the hydroxyl groups changes the relative intensities of these fragments. Moreover, additional hydroxyl groups induces losses of water molecules from these fragments, as illustrated in the figures 5 and 6.

In conclusion, fragments from the side chain are always present, and this allows for example selective detection of tauroconjugates by scanning the parents of 124 amu. Remote charge site fragments of the rings are observed at low collision energy when unsaturations, either as ring double bonds or keto groups, are present. Otherwise, the main observed fragments result from neutrals lost from the side chain. They differ in relative intensities for positional isomers, but are identical for geometric ones. For example, taurine conjugates of chenodeoxycholic (3,7\(\alpha\) diOH) and ursodeoxycholic (3,7\(\beta\) diOH) display the same spectrum, while deoxycholic (3,12\(\alpha\) diOH) display a very different one.

DEVELOPMENT OF DYNAMIC FAB-MS TECHNIQUES FOR DETECTION OF DISORDERS OF STEROL AND BILE ACID METABOLISM

James E. Evans, Barbara A. Evans, Amit Ghosh and Marvin R. Natowicz
The Shriver Center, Mass Spectrometry Facility and Division of Medical Genetics, 200 Trapelo Rd., Waltham, MA 02154-6332.

INTRODUCTION
The usefulness of negative ion FAB-MS as an efficient screening tool for metabolic disorders affecting the conversion of cholesterol to bile acids is well established (1,2). Because this technique relies upon the appearance of only a few pathognomonic, pseudomolecular ions from the analysis of a urine extract for detection of a disorder, it is susceptible to interference from other extract components. Confirmation is usually accomplished by use of GC, GC-MS or thermospray LC-MS. This is a report of the use of CF-dynamic FAB-MS for either a rapid screening of patient urines by direct injection or for confirmation of findings by uHPLC-MS. Confirmation when a ketone or lactone containing compound is suspected is achieved by addition of NaBD₄ to the urine before extraction. This reduction is useful for elimination or confirmation of several isobaric, interfering or pathognomonic ions.

EXPERIMENTAL
Urine samples are extracted by a modification of the procedure of Lawson et al(1). A Brownlee Labs., Micro Gradient solvent delivery system is used for both direct injection CF-FAB/MS and uHPLC-FAB/MS with a VG 70-250 SE mass spectrometer. Chromatography is performed on a 1mm X 10cm uHPLC column packed with 3μm C-18 particles (Keystone Scientific). A gradient from 55% to 75% methanol in aqueous 0.1 M ammonium acetate in 40 min at 60 ul/min is used for these separations. The column effluent is split 1:20 with 3 ul/min going to the FAB probe. No sample splitting is used for direct injection analysis. Bile acid standards were obtained from Sigma Chemical Co.

RESULTS
Fig.1 demonstrates the use of direct injection CF-FAB/MS for screening of patient samples. One ul of urine extract (equivalent to 2ul of urine) was injected from 50% aqueous methanol containing 2% glycerol at a 6ul/min flow rate. Spectra from two of these injections are shown. This technique allows samples to be injected at 3 min intervals. Fig.2 is a standard curve for taurocholic (TCA) and glycocholic (GCA) acids from 0.5 to 15 ng injected with tauroursodeoxycholic acid (5ng) as an internal standard. A 5% coefficient of variation for 7 repeat injections of the sample containing 5ng was obtained.

Fig.3 shows the separation of a mixture of 13 standard bile salts obtained by uHPLC-CF/FAB. Also, shown are [M-H]⁻ plots for each component. Linear standard curves are obtained from 5 to 250ng injected using ursodeoxycholic acid as an internal standard.

Fig.4 shows the results of uHPLC-CF/FAB analysis of a urine extract from a patient with neonatal adrenoleukodystrophy under the conditions described above. Extracted ion plots for several pathognomonic bile salts are shown. The identification of the presumed isomers resulting in the multiple peaks seen in individual ion plots is currently being investigated.

Synthesis of $[\text{6,6,19-}^3\text{H}]\text{vitamin D}_3$ and quantitation of plasma vitamin D$_3$
by capillary gas chromatography-mass spectrometry.

Introduction: Vitamin D and its metabolites play an important role in calcium homeostasis and are widely studied using assay techniques based on competitive binding or high performance liquid chromatography (HPLC). Reference methods based on stable isotope dilution with GC-MS analysis have been developed for quantifying several vitamin D metabolites in blood plasma, however no such method exists for vitamin D$_3$ itself. Most literature methods for labelling vitamin D and its metabolites rely on treatment of steroidal precursors with deuterated reagents such as CD$_3$/Mg. A simpler approach, in which vitamin D itself or any metabolite can theoretically be used as the starting material, was outlined by Yamada et al. (Tetrahedron Lett. 22:3085, 1981). We used a modified version of this method to synthesize $[\text{6,6,19-}^3\text{H}]\text{vitamin D}_3$. The product was characterized by several chromatographic and spectrometric techniques and was subsequently employed as the internal standard in the development of a GC-MS assay for vitamin D$_3$ in human plasma.

Methods:

Synthesis of $[\text{6,6,19-}^3\text{H}]\text{vitamin D}_3$: Vitamin D$_3$ (100mg) was refluxed with an excess of liquid SO$_2$ for 1h using a dry-ice condenser. Excess reagent was removed by aspiration and the SO$_2$ adduct (a mixture of C$_2$ epimers) was purified by chromatography on silica gel (28-200 mesh, 5g) using ethyl acetate as eluent. Hydrogen-deuterium exchange was performed at the activated C$_2$ and C$_3$ positions using 200µl deuterium oxide (minimum isotopic purity 99.996 atom % D, Aldrich Chemical Company, Milwaukee) in dimethylformamide (800µl) containing potassium t-butoxide (50mg). After stirring at room temperature for 1h the reaction was quenched by adding ice water and extracted with ethyl acetate. The extract was washed with brine, dried over Na$_2$SO$_4$ and evaporated to dryness. The deuterated adduct was purified on silica gel using ethyl acetate/methanol (99/1 v/v) as eluent. The adduct was then heated for 1h at 80°C under argon in a solution of sodium bicarbonate (5mg) in dimethylformamide (500µl) to drive off SO$_2$. After cooling, the mixture was diluted with ethyl acetate, washed, dried and evaporated. The resulting 5E-vitamin D$_3$ was purified on a small (2g) silica gel column eluted with ethyl acetate/hexane (1/1 v/v). The 5E-isomer was dissolved in ethanol/water (95/5 v/v) containing 2mg Eosin Y. This mixture was saturated with argon during a 2h irradiation with a 20W halogen lamp. The solvent was then evaporated and the product was again purified on silica gel. The final product was further purified by HPLC using a Hypersil 5µ C18 column (25 x 0.46 cm) eluted with methanol at a flow rate of 1ml/min with UV absorbance detection (264nm). The collected fraction corresponded to a partially resolved doublet on the chromatogram indicating the presence of a mixture of 5Z- and 5E-vitamin D$_3$ in a ratio of 6:4. The overall yield was relatively low (1.5mg).

Extraction of Vitamin D$_3$ from Blood Plasma:

1. Add $[\text{2H}]\text{Vitamin D}_3$ (40ng in 100µl methanol) to 1ml plasma
2. Add 2ml water and 1.5ml 2-propanol
3. Sonicate and equilibrate at room temperature
4. Prime a 8ml C18 Bond-Elut cartridge
5. Load sample under vacuum
6. Wash with 10ml water and 10ml methanol/water (85/15 v/v)
7. Elute with 4ml methanol and add 1ml water to the eluate
8. Wash the Bond-Elut cartridge
9. Load extract
10. Wash with 2ml methanol/water (85/15 v/v)
11. Elute with 6ml hexane/chloroform (95/5 v/v)

Extracts were further purified (to remove cholesterol) by two HPLC systems:

1) 25 x 0.46 cm Hypersil ODS column, eluted at 1ml/min with methanol/water (99/1 v/v) with UV absorbance detection (284nm)
2) 25 x 0.46 cm Whatman Partisil column, eluted at 1ml/min with hexane/2-propanol (98/2 v/v) with UV absorbance detection (284nm)

1039
GC-MS analysis:

- Derivatization: Plasma extracts and standards were converted to trimethylsilyl ether derivatives by heating with 50 μl 1% TMCS in BSTFA at 65°C for 15 min.
- Instrument: Finnigan 4535 quadrupole GC/MS system with Incos data system.
- Chromatography: A fused silica capillary column (30m × 0.25mm i.d., DB1 coated, J&W, Folsom, CA) was programmed from 250-320°C at 15°C/min and held at 320°C for 5 min.
- Mass spectrometry: The mass spectrometer was operated in electron ionization mode. Full scan spectra were recorded over the mass range m/z 50-800 every 2 s during the run. For quantitation the molecular ions of the trimethylsilyl ethers of vitamin D₃ and deuterated vitamin D₃ (m/z 456 and 459) were selectively monitored with a cycle time of 0.25 s.

Summary and Discussion:

A sample of [6,6,19-'H₃]Vitamin D₃ was prepared by deuterium exchange into the s-cis diene sulphur dioxide adduct of vitamin D₃. The product was of high isotopic purity ([^{1}H₃]:[^{2}H₃] = 0.031) and was stable to extraction. The concentration of vitamin D₃ in pooled plasma collected from 8 healthy adults in late summer was measured as 5.4 ng/ml, a value within the normal range determined by Seemark et al. (5.1 ± 4.8 ng/ml, J. Steroid Biochem. 13: 1057, 1980) using a GC-MS method with vitamin D₃ as internal standard. Our method represents the first stable isotope dilution assay for vitamin D₃ in human plasma. It should be possible to apply a similar hydrogen-deuterium exchange procedure to prepare high isotopic purity trideuterated analogues of the more biologically active 25-hydroxy and 1,25-dihydroxy metabolites of vitamin D₃ for use in stable isotope dilution GC-MS assays for these compounds.
APPLICATION OF FAST ATOM BOMBARDMENT MASS SPECTROMETRY TO BIOCHEMICAL STUDIES OF SECOND MESSENGERS: II, INOSITOL PHOSPHATES

Terence J Walton, Frank M Harris, Soraya Y Hughes, James Langridge, Russell P Newton, A Gareth Brenton and David E Games

INTRODUCTION

In a wide variety of cell types inositol-1,4,5-trisphosphate (Ins(1,4,5)P₃), generated by receptor-activated hydrolysis of membrane bound phosphatidylinositol-4,5-bisphosphate, causes rapid release of calcium from internal stores in a signal transduction mechanism regulating diverse cellular activities (1). Subsequent agonist-sensitive Ins(1,4,5)P₃ metabolism involves both further phosphorylation and an inositol salvage pathway catalysed by phosphatase systems, the specificities of which result in the formation of isomeric inositol mono-, bis- and trisphosphates. (1,2) Eukaryotic cells thus contain a large total number of inositol phosphates, exemplified by tumour cells which were recently shown to contain thirteen inositol polyphosphates (3). Identification of inositol phosphates in cell extracts, in particular isomer composition, is central to many metabolic and clinical studies and is currently routinely based on anion exchange HPLC; only rarely is more direct proof of structure obtained via the established four-step sequence of periodate oxidation, borohydride reduction, dephosphorylation and chromatographic/enzymic analysis of the resulting polyols (4,5). Fast atom bombardment (FAB) allows mass spectrometric analysis of inositol polyphosphates without derivatization (6), and, in tandem with collision-induced dissociation mass-analysed ion kinetic energy spectrometry (C1D/MIKES), enables positional isomers of other classes of highly polar, involatile compounds eg the 2',3' and 3',5' isomers of adenosine cyclic monophosphate to be unambiguously distinguished (7). As part of our assessment of the value of mass spectrometric techniques for the analysis of inositol phosphates, we have carried out FAB-CID/MIKES on representative inositol mono-, bis- and trisphosphates.

EXPERIMENTAL

Cyclohexylammonium salts of inositol-1-phosphate and inositol-2-phosphate were obtained from Sigma Chemical Company Limited and the ammonium salts of the 1,4-, 2,4- and 4,5- isomers of inositol bisphosphate and the 1,4,5- and 2,4,5- isomers of inositol trisphosphates were supplied by Boehringer Corporation Limited. Positive ion FAB mass spectra were determined on VG MS 70/70 and ZAB-2F instruments using xenon (8 keV) atoms in the primary beam. FAB-CID/MIKES spectra were obtained on the latter instrument using N₂ as collision gas in the second field-free region, and scanning the electric sector under data system control.

RESULTS AND DISCUSSION

Evaluation of alternative matrix systems, including glycerol, thiglycerol, triethanolamine and polyethylene glycol, together with their aqueous admixtures, established that thiglycerol-based systems gave optimal signal-to-noise ratios in the positive ion FAB mass spectra of the inositol phosphates, typically some three times that obtained with glycerol matrices. Comparison of the sensitivity in the positive ion mode with that in the negative ion mode showed sample derived high mass peaks had absolute intensities 2-3 times those of the corresponding ions observed in the negative ion mode. A small but significant (1-2% relative abundance) peak, corresponding to the protonated molecular ion of the free acid form [MH⁺], was observed in the FAB mass spectrum at m/z 261 (inositol bisphosphate) and m/z 341 (inositol trisphosphates), and these ions were selected with the magnetic sector for CID/MIKES.

For inositol monophosphates characteristic CID-MIKE spectra were obtained from 2 nmol of sample. They were dominated by an intense peak at m/z 99 [H₂PO₄]⁺, which was accompanied by strong peaks at m/z 243 ([MH-H₂O]⁺) and m/z 163 ([MH-H₂PO₄]⁺), together with a series of peaks separated by 18 mass units representing further loss of water at m/z 145 ([MH-H₂PO₄-H₂O]⁺), m/z 127 ([MH-H₂PO₄-2H₂O]⁺) and m/z 109 ([MH-H₂PO₄-3H₂O]⁺). The CID-MIKE spectra of inositol-1-P and inositol-2-phosphate were similar and could not be distinguished either by the presence of isomer specific peaks or comparison of the relative intensity of peaks common to both spectra.

The CID-MIKE spectra obtained from m/z 341 in the FAB mass spectra of the three inositol bisphosphate isomers (25 nmol) each contained peaks at m/z 323 ([MH-H₂O]⁺), m/z 243 ([MH-H₂PO₄]⁺) and m/z 109 ([MH-2H₂PO₄-2H₂O]⁺). However, in the spectrum of inositol-4,5-bisphosphate (Fig. 1(A)) there were prominent ions at m/z 179 and 197 which were absent from the spectra of inositol-1,4-bisphosphate (Fig. 1(B)) and inositol-2,4-bisphosphate (data not shown), which are
Fig. 1. CID/MIKE spectra of m/z 341 generated by FAB-MS of Inositol-4,5-bisphosphate (A) and Inositol-1,4-bisphosphate (B). The m/z values of significant peaks are indicated.

provisionally assigned to rearrangement ions originating from the vicinal phosphate groups (m/z 179 [H₂P₂O₇]⁺, m/z 197 [H₃P₄O₉]⁺). The presence of these peaks only in the spectrum of inositol-4,5-bisphosphate indicates that they may represent a valuable diagnostic indicator for identification of vicinally substituted Inositol polyphosphates.

With inositol-1,4,5-trisphosphate and inositol-2,4,5-trisphosphate determination of characteristic CID-MIKE spectra required a minimum of 38 nmol of sample. The spectra, generated from m/z 421 in the FAB mass spectrum, were dominated by the ion at m/z 403 ([MH-H₂O]⁺), all other ions in the spectrum having relative abundances below 7%. For both isomers, these included m/z 323 ([MH-H₃PO₄]⁺), m/z 305 ([MH-H₂PO₄-H₂O]⁺), m/z 109 ([MH-3H₂PO₄-H₂O]⁺) and m/z 99 ([H₂PO₄]⁺), and in addition, the spectra of both isomers contained a peak at m/z 179, supporting the view that a peak at this mass is characteristic of the CID-MIKE spectra of vicinally substituted inositol polyphosphates.

NITROGEN-CONTAINING SCHIFF BASE DERIVATIVES FOR THE STRUCTURAL DETERMINATION OF LONG-CHAIN ALDEHYDES BY GC/MS.

D.J. Harvey

Department of Pharmacology, University of Oxford, South Parks Road, Oxford, OX1 3QT, UK.

The mass spectra of long-chain aliphatic aldehydes and their simple derivatives such as the alkyl oximes do not, in general, contain abundant ions conveying structural information on the alkyl chain. This paper describes the use of Schiff base derivatives containing pyridine or pyrimidine groups for inducing the formation of abundant diagnostic ions containing this structural information.

The aldehyde (0.01 to 0.1 µg) was dissolved in acetonitrile and heated for 15 min with 10 times its weight of 3-(aminomethyl)pyridine, 3-aminopyridine or 2-aminopyrimidine. Aliquots of the reaction mixtures were injected directly onto the GLC column. GC/MS data were recorded with a VG 70/70F mass spectrometer interfaced to a Varian 2440 gas chromatograph which was fitted with a 15 m X 0.2 mm OV-1 fused silica capillary column. The column was operated in the temperature range 200 - 300°C and spectra were recorded at both 25 and 70 eV.

All three types of derivative were produced in quantitative yield and gave a single GLC peak with little tailing. The spectra contained abundant molecular ions and a series of fragment ions produced by cleavage of each carbon-carbon bond of the aliphatic chain. These were formed by a radical-induced cleavage induced by hydrogen abstraction by the heterocyclic nitrogen-containing group (Scheme 1) in the manner previously reported for picolinyl esters of fatty acids and nicotinates of alcohols (1). Although of somewhat lower relative abundance than the comparable ions in the spectra of the pyridine-derived derivatives of fatty acids and alcohols, these ions carried the required structural information.

Scheme 1

The 3-aminopyridine and 3-(aminomethyl)pyridine derivatives of straight-chain, saturated aldehydes produced the diagnostic ions in comparable relative abundance at 14 mass unit intervals as illustrated in Fig. 1 for the 3-aminopyridine derivative.

Fig. 1. Mass spectrum of the 3-aminopyridine derivative of octadecanal.

Aldehydes containing methyl branching produced the characteristic pattern of ions shown in Fig. 2 where the position of the methyl group was indicated by the absence of one of the diagnostic ions (m/z 343 in Fig. 2).
Unsaturation was indicated by both a reduction in spacing of the ions adjacent to the position of unsaturation [40 rather than 42 mass units between the ions at m/z 245 (d) and 285 (f), Fig. 3] and by the appearance of ions of increased relative abundance produced as the result of the abstraction of the allylic hydrogen atoms (ions g and h, Fig. 3). The two abundant ions at m/z 120 and 133 in the spectra shown above can be rationalised by the mechanisms shown in Schemes 2 and 3 respectively.

In general, the 3-aminopyridine derivatives gave slightly simpler spectra than the 3-(aminomethyl)pyridine Schiff bases and both pyridine-containing derivatives gave more abundant diagnostic ions than the Schiff bases prepared from 2-aminopyrimidine.

1,1,1,7,7,7-HEXAFLUOROHEPTAN-4-ONE: A NEW DERIVATIZATION REAGENT FOR THE GC/MS OF DIOLS

S.P. Markey, J.T. Simpson, R. Sherman, and H. Zitter*
Section on Analytical Biochemistry, National Institute of Mental Health
and *Laboratory of Chemical Physics, NIDDK, NIH, Bethesda, MD 20892

Introduction
The use of cyclic derivatives of diols or amino alcohols has been investigated to enhance the selectivity of the derivatization processes, improve chromatographic properties, or direct mass spectrometric fragmentation. We previously employed hexafluoroacetone to form cyclic ketals of diols, but found that harsh reaction conditions were required to effect ring closure (1). The reaction conditions were incompatible with many of the compounds which we wanted to derivatize, and consequently we have sought an alternative reagent. The strong inductive effect of fluorine in hexafluoroacetone influences the cyclization reaction pathway, so that in contrast to acetone, an oxygen atom from the diol leaves during the cyclization, as shown below.

We reasoned that displacing the electron withdrawing CF₃ function from the ketone by one or more -CH₂- groups would alter the reaction characteristics of 1,1,1,7,7,7-hexafluoroheptan-4-one (HFH), and thus restore the facile cyclization chemistry characteristic of acetone. Further, it was anticipated that HFH-ketals might have desirable electron capture properties for negative chemical ionization analyses.

Experimental
The preparation of HFH was similar to that reported by Carpenter et al. (2). Briefly, the magnesium Grignard reagent of 1-chloro-3,3,3-trifluoropropane was condensed with ethylformate, and the resulting alcohol (1,1,1,7,7,7-hexafluoroheptan-4-yl) purified as its p-nitrobenzoate salt (m.p. 73-74 °C). The hydrolyzed alcohol was then oxidized at 0°C using Jones reagent to the product HFH, which was purified by distillation (b.p. 60-61°C/28 mm) prior to use. The mass spectrum of HFH matched that published (2), dominated by the bp at m/z125.

Several published methods for cyclization of ketals were tested. Copper sulfate, trifluoroacetic acid, sulfuric acid, p-toluenesulfonic (TsO') acid, and TsO' pyridinium salt were among the catalysts tested with acetonitrile and/or toluene as solvents, and temperatures varying from 25 to 115°C. The most satisfactory conditions produced the results shown below in Figure 2. Cis-1,2-cyclohexanediol (0.0086mM, 1 mg/mL) in acetonitrile was added to HFH (0.009mM, 2 mg/mL) in acetonitrile in a 13 mm glass tube, and 0.2 mg of TsO' pyridinium salt in 0.1 mL acetonitrile added as catalyst. The tube was heated to 110°C on a hot block in a chemical hood, and fresh acetonitrile added to replace the solvent which evaporated (reaction was never allowed to go dry). The reaction was sampled after 4 hours, and again after 7 hours, adjusting the volume to 1 mL.

1045
Analytical Conditions
Spectra were obtained on either a HP-5970 mass selective detector, or a Finnigan TSQ - 70 operating in single quad mode, scanning Q3. For chloride attachment experiments, methylene chloride was introduced into the source via a leak valve connected to a Vacumetrics probe. An ion abundance of 500,000 at m/z 35 was used to set the methylene chloride valve. GC was performed using a J&W Scientific DB-225, 30 m x 0.25 mm x 0.15 μm film thickness column on the HP-5980; and an HP Ultra-1, 12 m x 0.20 mm x 0.33 μm film thickness column on the Varian 3400 GC on the TSQ-70. GC conditions were similar on both instruments: 40°C to 200°C at 10°/min., with injection port: at 220°C, transfer line at 200°C.

Results
Reaction products were consistent with the expected in that HFH ketals were formed of both propylene glycol and cis-1,2-cyclohexanediol. The total ion chromatogram and mass spectrum below are typical of these reaction products.

Conclusions
HFH ketals of simple diols can be formed using similar reaction conditions to those traditionally used for acetonide derivatives; however, somewhat more vigorous temperatures, drying or catalysis may be required. The HFH ketals exhibit good chromatographic properties and the expected electron impact fragmentation characteristics. The HFH ketals show a marked temperature dependence with regard to electron capture and chloride attachment in negative chemical ionization. Although the HFH ketals do not exhibit substantial sensitivity in negative chemical ionization, they do show potential as derivatives for positive chemical ionization or electron impact studies of diols.

TRACE QUANTITATION OF SCHIFF BASE-BOUND 4-HYDROXY-2-NONENAL AS ITS OXIME, BIS-T-BUTYLDIMETHYLSILYL DERIVATIVE USING 3-HYDROXYNONANAL AS AN INTERNAL STANDARD

Michael Kinter, Shannon Sullivan, Robert Roberts and Douglas Spitz
Departments of Pathology and Pediatrics, University of Virginia Health Sciences Center
Charlottesville, VA 22908

4-hydroxy-2-nonenal (4HNE) is emerging as a biologically relevant by-product of lipid peroxidation. 4HNE has been shown to inhibit glucose-6-phosphatase, to be toxic to cultured cells and to be able to modify low density lipoprotein (LDL) in a manner which promotes atherosclerosis. The method described here uses a novel analogue of 4HNE, 3-hydroxynonanal (HNA), as an internal standard. In addition, the derivatization scheme results in a derivative in which fragmentation is limited and a large portion of the total ion current is concentrated in a characteristic M-57+ ion.

The metabolism of 4HNE is largely unknown. One reaction of 4HNE is binding to protein through Schiff base-linkages. This reaction would not be expected to be enzyme catalyzed but the large number of free amine residues available on proteins in biological material could make this an important pathway. Quantitation of 4HNE in either its free form or bound to protein through Schiff base-linkages is achieved by forming an oxime derivative of the aldehyde in a nucleophilic substitution reaction. The bis-t- butyldimethylsilyl derivative is then formed prior to analysis by selected ion monitoring (SIM) gas chromatography/mass spectrometry.

Experimental. All solvents and reagents are purchased from commercial sources. 4HNE is synthesized according to the method of Esterbauer. HNA is synthesized by the reaction of mercuric acetate with 2-nonenal.

Sample preparation. Several types of samples have been analyzed including cultured cells, tissues, whole blood and plasma. For the analysis of cultured cells, the media is poured off, the cells harvested, lysed in 2 mL of deionized water and derivatized as described below. 1-50 mg tissue samples are homogenized directly in the oximation reagent described below. 1.0 mL aliquots of whole blood or plasma are analyzed directly under the reaction conditions described below. In each case, an appropriate amount of HNA in water is added as an internal standard immediately before beginning the oximation reaction.

The oximation is carried out in 4 mL of 0.3 M hydroxylamine hydrochloride in a 0.1 M acetate buffer, pH 5 with 50 µM butylated hydroxytoluene an 1 mM DETAPAC. The samples are thoroughly mixed and reacted for 1 hour at 70°C. The lipid aldehyde-oximes are recovered by octadecylsilyl solid phase extraction and eluted in methanol. The methanol is evaporated and the residue reconstituted in 50 uL of MTBSTFA and 200 uL dimethylformamide and reacted at 70°C for 1 hour. The derivatives are extracted into petroleum ether, evaporated to dryness and reconstituted in 50 uL of isooctane for analysis.

Gas chromatography/mass spectrometry. A double focusing, reverse-geometry mass spectrometer (Model 8230, Finnigan-MAT) is used. The instrument is equipped with a Varian 3700 gas chromatograph with a 15 m x 0.32 mm capillary column with a 0.25 µm film thickness bonded phase polydimethylsiloxane stationary phase (SE-30 Econoscap, Alltech Associates). Injections are made on-column and the gas chromatograph programmed from 100°C to 290°C at 15°C/minute. The mass spectrometer is operated with 70 eV electron ionization in the selected ion monitoring mode at a mass resolution of 2500 monitoring m/z 342.2 (4HNE, M-57+), m/z 344.2 (HNA, M-57+) and using 342.9793 of the reference compound perfluorokerosene as a lock mass. Quantitation is achieved by integrating the appropriate chromatographic peak areas for 4HNE and HNA. The area ratio of 4HNE/HNA is converted to pmoles of 4HNE using a calibration curve determined from standard amounts of 4HNE and measured in the same experiment.

Results and Discussion. The electron ionization mass spectra of the oxime, t-butyldimethylsilyl derivatives of 4HNE and HNA are shown in Figure 1. As can be seen, an ion of high relative intensity is observed for each compound which corresponds to the loss of C₄H₉ from the respective molecular ions.
Calibration curves have been found to be linear from 0 pmoles to > 700 pmoles. In these experiments a limit-of-detection of approximately 1 pmoles (156 pg) has been found. This limit-of-detection is sufficient for the analysis of the sample types encountered in our investigations.

Typical chromatograms are shown in Figure 2 for the analysis of cultured cells and human plasma. These samples contain 29 and 18 pmoles of 4HNE, respectively. An excellent signal-to-noise ratio is observed and few additional peaks are observed in this time window. The doublets formed in the oximation reaction are typical for this nucleophilic substitution reaction.

An important concern in these experiments is the possibility of auto-oxidation of the sampler and the artifactual formation of 4HNE. We found that the oximation, without the addition of antioxidants (BHT and DETAPAC), does result in the formation of significant amounts of 4HNE. In our hands this amounted to 200 to 400 pmoles of 4HNE formed in cell samples which contained approximately 60 pmoles. The concentrations of BHT and DETAPAC used here were effective in eliminating the formation of 4HNE in even high concentration linoleic acid solutions and does not interfere with the assay.

Precision was evaluated in a number of different ways. Replicate analysis of standards indicate relative standard deviations of 7.4% and 4.1% at 100 pmoles and 500 pmoles levels, respectively. The analysis of a series of paired blood samples indicates an average relative standard deviation of 10.3% in samples ranging from 10 to 30 pmoles/ml. Finally, the analysis of triplicate sets of cultured cell exposed to 95% and 20% oxygen show average relative standard deviations ranging from 7% to 47% with an average of 26% (n=18). Overall, precision consistent with this type of assay was observed.

Accuracy was evaluated by standard addition analysis of human plasma samples. This analysis indicated no significant bias in the assay. The accuracy of the method is aided by the chromophore due to the α,β-unsaturated carbonyl. This chromophore allows the preparation of dilute solutions of accurately known concentration. Finally, the use of the methoxime analogue of 4HNE for the preparation of standards allows the Schiff base-to-oxime reaction to be more closely modeled and further enhances the accuracy of the method.
Mass Spectrometry of Some Novel Amino β-Lactam Carboxylic Acids (ABCs).
New Matrices and Exact Mass Analyses.

and
K. Jayasimhulu
Department of Environmental Health, College of Medicine,
University of Cincinnati, Cincinnati, OH 45267

FABMS analysis of some zwitter-ionic β-lactams has given poor signal-to-noise (s/n) values in treitol/erythritol, glycerol, and/or thioglycerol. Ion-pairing the analyte provided a way to improve the value of s/n from ~1 to ~20% of base peak (1). Ion-pairing as a technique for increasing ion-emission by FAB has been reviewed (2). It remains difficult to analyze the numerous β-lactams we produce by our four step, Leuchs anhydride based, synthetic strategy (3). In this report we describe three MS based strategies used to provide mass spectrometric data: 1) derivatization to afford exact mass data; 2) an acidic matrix with useful surface concentrations of the zwitter-ionic analyte; and 3) the use of an ancillary reagent to enhance analyte ion intensity.

The derivatization proved viable as illustrated by compounds I and II. These novel biologically active monobactams I and II were synthesized through the Leuchs anhydride strategy (3,4). After methylation both yielded confirmatory exact mass data:

Other zwitter-ionic monobactams gave useful information by this strategy. Benzoylation and methylation was combined to give a derivative useful for LC clean-up as well as characteristic useful fragmentation patterns. 6-Aminopenicillanic acid illustrates this:
The indicated $M^+$ (m/z 334) and cleavage products were readily confirmed by exact mass EIMS. $\beta$-Benzyolamidopenicillanic acid methyl ester was generated as a reference compound for our characterization of the ABCs. All of the cleavages typical of penicillins shown here were confirmed by EIMS exact mass. The importance of benzoylated ABC methyl esters will be their relative ease of clean-up by C18 RP HPLC. The ABCs typically are produced as a mixture of four diastereomers which must be separated for structural assignment and characterization for antibiotic activity.

FABMS of these labile zwitterionic ABCs was facilitated by the use of pyruvic acid as a matrix. As a matrix it shows only ions of low mass. The base peak was m/z 143; no identifiable monomer (m/z 176), dimer, trimer, ... peaks were seen above background. Peaks as yet not identified provide a low background up to $\sim 700$ m/z. Pyruvic acid is a good solvent for peptides and proteins as well as $\beta$-lactams. Unlike glycerol where a surface excess for APA is not found (1), a signal $\sim 12$% of the base peak is seen for MH$^+$. It is possible that the pyruvic acid preparations have a tendency to form reverse micelles. Outside of the as yet unknown micelle concentration range, the more polar compounds give a useful surface concentration if not a surface excess.

Enhancement of FAB ion yield was achieved by using an ancillary reagent. It was felt that if a component of the matrix breaks down to gaseous products by the action of the high energy atomic beam, then a substantial increase in gas phase ion yield should result. The reagent showing the desired effect was tetrazole. Tetrazole is known to decompose to gaseous products when heated:

$$\text{NCH}_2\text{N} \stackrel{\Delta}{\rightarrow} 2\text{N}_2 + [\text{CH}_2]$$

To be useful, the ancillary reagent concentration must not be high enough to allow an uncontrolled chain reaction to be triggered by the atom or ion beam. It has good solubility in pyruvic acid (15-20%) at room temperature. The quasi-molecular ion of the gastrin peptide WMDF-NH$_2$ was enhanced sixfold when tetrazole was in the matrix.

Characterization of Reactive and Dissociative Behaviors of Biolactones. Tracy Donovan and Jennifer Brodbelt, University of Texas, Austin, TX 78712-1167.

In this work, we have undertaken an examination of the ion-molecule chemistry of some analytically relevant biolactones: ascorbic acid, several gluconolactones, and a pyrrole lactone (dimethylpyrrole-$\gamma$-butyrolactone) which is a potent plant growth regulator (see Figure 1). The reactive and dissociative behaviors of these biolactones were studied using a quadrupole ion trap mass spectrometer and a triple quadrupole mass spectrometer, and compared to simple lactones.

All three biolactones studied in the quadrupole ion trap (D-gluconolactone, L-glucono-1,5-lactone, and the pyrrole lactone) were protonated by dimethyl ether ions, but none formed methyl addition products that were commonly formed in the earlier study of simple lactones. Rather, each of the biolactones formed a methylene substitution product, (M+13)$^+$. In the case of the pyrrole lactone, the intensity of the (M+13)$^+$ adduct was nearly fifty percent higher than the intensity of the protonated pyrrole lactone. Methylene substitution adducts of the two gluconolactones were roughly one quarter the abundance of their corresponding protonated molecules.

In order to determine the site of methylene substitution, dimethyl ether ion reactions with simpler compounds representative of small portions of the biolactones were compared. For example, upon dimethyl ether chemical ionization, dimethyl pyrrole forms an (M+13)$^+$ adduct, but $\gamma$-butyrolactone does not. Therefore, methylene substitution of the pyrrole lactone presumably occurs at the pyrrole ring rather than at the lactone ring.

A comparison of the CAD spectra of protonated pyrrole lactone and its (M+13)$^+$ adduct, shown in Figure 2, reveals similar structural information about the adduct. The ion at m/z 94 in the spectrum of protonated pyrrole lactone, presumably due to the cleaved pyrrole ring, shifts 13 amu to m/z 107 in the CAD spectrum of (M+13)$^+$. This gives additional support to the proposal that the site of methylene substitution is the pyrrole ring rather than the lactone ring.

A mechanism which has been elucidated for (M+13)$^+$ formation with substituted aromatic substrates may also be responsible for (M+13)$^+$ formation from the pyrrole lactone:

![Reaction Diagram]

The reaction is initiated by nucleophilic attack on the dimethyl ether cation by the double bond, and is followed by elimination of methanol. The adduct structure has a high degree of resonance stabilization, which may explain the greater abundance of this ion relative to the protonated pyrrole lactone.

Upon collisional activation of all three protonated biolactones, the predominant dissociative pathway is dehydration followed by decarbonylation (loss of 46). A possible mechanism which parallels the dissociative routes of simple protonated lactones is shown in Scheme 1. Additional dissociative pathways
include decarbonylation and decarbonylation combined with loss of multiple water molecules. Pathways such as neutral alkene or ketene loss which are important dissociative pathways in less complex protonated lactones are not observed in the fragmentations of the protonated biolactones.

The reactive behavior of protonated biolactones with neutral reactive gases was investigated in a triple quadrupole mass spectrometer. After FAB ionization and mass-selection by the first quadrupole of a triple quadrupole mass spectrometer, each protonated biolactone was allowed to undergo reactive collisions with selected molecules in the collision quadrupole. The protonated biolactones were completely unreactive with ethylene in the collision quadrupole, but they formed abundant proton bound dimers with dimethyl ether and ethylene oxide at reactive gas pressures above 2 mtorr and collision energies between >0 and 8 eV.

Mass Spectrometric Validation of Cadaverine and Putrescine in Fish.

*F. Aladar Bencsath¹, Don Mowdy² and Anthony Guarino²
¹: University of South Alabama, College of Medicine, Department of Biochemistry, Mobile, Alabama 36688, and
²: Fishery Research Branch, Food and Drug Administration, P.O.Box 158, Dauphin Island, Alabama 36528

Cadaverine and putrescine occur naturally in food of animal origin as the results of microbial spoilage. These diamines (C₄ and C₅ alfa,omega-diamines) are good indicators of the food-decomposition in fishery products for human consumption.

The presently used analytical method is J.A.O.A.C. 64, 584, 1981. This is a gas chromatographic (GC) procedure carried out with the pentafluoropropionyl derivative of the purified and dried fish-extract. 1,6-diaminohexane is used as internal standard, and nitrogen-specific or electron-capture detector is recommended to achieve adequate sensitivity together with some degree of specificity. The method, however, has never been verified by mass spectrometry.

We carried out the analysis on several fish samples using a hybrid-tandem instrument as a mass specific detector in capillary GC work and verified the results obtained by an ordinary GC with packed column and nitrogen specific detector. Improperly handled salted, smoked fish samples had putrescine levels of up to 233 µg/g (vs 2.1 for fresh controls) and up to 2346 µg/g (vs 3.2 for fresh controls) of cadaverine.

Electron ionization (EI), positive chemical ionization (PCI) and electron capture CI (EC-CI) was used in these measurements. The spectra, especially the CI spectra showed some interesting characteristics. The methane PCI spectra consisted of two peaks: a base peak representing the molecular cation (MH⁺) and a minor one formed by the loss of a pentafluoropropionamide molecule. The negative spectra consisted of several peaks, and the changes of the fragmentation patterns between the homologous diamines were surprisingly unpredictable. The total ion current was 100 times larger in the negative spectra than in the positive spectra, and the intensity ratios between the dominant negative and the positive ion-species were about 40.

In addition to the pentafluoropropionyl derivatives, dimethylaminomethylene derivatives were prepared using dimethylformamide dimethylacetal reagent. These derivatives formed even easier than the fluoroacetyl derivatives and exhibited excellent chromatographic and mass spectral characteristics both for GC/MS and GC/MS/MS analyses.

DETECTION AND IDENTIFICATION OF COMPOUNDS RELATED TO OKADAIC ACID USING LC/MS AND TANDEM MS

J.C. Marr¹, T. Hu¹, A. S.W. deFreitas², S. Pleasance², ³, M.A. Quilliam², and J.L.C. Wright²;

¹Fenwick Laboratories Limited, 5595 Fenwick St., Halifax, N.S.; ²Institute for Marine Biosciences, NRCC, 1411 Oxford St., Halifax, N.S.; ³under contract from Sirex, 55 Glen Cameron Road, Thornhill, Ontario.

Okadaic acid, a diarrhetic shellfish poisoning (DSP) toxin, has been identified in several dinoflagellate species, including Prorocentrum concavum¹. Illness attributed to DSP is due to the consumption of shellfish contaminated with these dinoflagellates.

The development of instrumental methods for DSP toxins has been a challenge due to their low concentration in complex matrices, structural complexity, and high molecular weight (Table 1). The development of any analytical method requires standards. Okadaic acid (OKA) is currently the only DSP toxin that is available commercially and it is extremely expensive. We chose to culture the dinoflagellate, P. concavum, in our laboratory as an alternate source of OKA.

The most widely-used instrumental method is reversed phase HPLC with fluorescence detection (FLD). Fluorescent derivatives of OKA are synthesized by esterification of the carboxyl group using derivatizing reagents such as 9-anthracenyl diazomethane (ADAM)². Using this method, confirmation of peak identity is not possible. An ion-spray HPLC-MS method has been developed for the confirmation of OKA, and for the detection of related compounds in marine samples³.

OKA is isolated from the cultured dinoflagellates using a sequential chromatography column method developed in our laboratory. To date, hundreds of milligrams of pure OKA have been isolated and characterized using several NMR and MS techniques.

Recently, other compounds, related to OKA, have been detected in the P. concavum culture. Isolation and subsequent analyses of these compounds indicated that they are the methyl ester and two diol ester derivatives of OKA. Other diol esters have been identified in cultures of P. lima², but not in P. concavum. These compounds are not naturally-fluorescent and would not be detected using the conventional HPLC-FLD method, since the carboxyl functionality is not available for derivatization. Ion-spray HPLC-MS was used for the initial screening of the culture samples containing these compounds (Figure 2). Positive ion LSIMS (Figure 3) and NMR were used to aid in the identification of these natural derivatives.

Ion-spray LC-MS has proven to be a powerful method for screening samples for DSP toxins and related compounds. We are currently using this technique to screen other strains of Prorocentrum and other samples, including shellfish tissue, for new DSP toxins. Utilization of ion-spray LC-MS/MS to aid in the characterization of these compounds has begun.

ANALYSIS OF MICROORGANISMS BY QUARTZ TUBE PYROLYSIS GAS CHROMATOGRAPHY MASS SPECTROMETRY

Philip B.W. Smith 1 and A. Peter Snyder 2
1 GEO-CENTERS, INC., 10903 Indian Head Highway, Ft. Washington, MD 20744
2 U.S. Army Chemical Research, Development and Engineering Center, Aberdeen Proving Ground, MD 21010-5423

The detection and identification of microorganisms is of significant interest in numerous scientific areas. Of the myriad of chemical compounds that can be found in microorganisms the determination of their lipid composition has been suggested to be closest to an ideal chemotaxonomic method, and is the basis of the fatty acid methyl ester (FAME) approach. The utility of this approach has been extended by the recent demonstration that bacterial species could be successfully differentiated by analysis of their underivatised lipid components using a Curie point pyrolysis gas chromatography ion trap mass spectrometry (Py-GC-MS) system(1). Quartz tube pyrolysis offers several advantages over Curie point pyrolysis, both in terms of sample preparation and control over pyrolysis conditions. A quartz tube Py-GC-MS system was constructed and evaluated by investigating three bacterial species: Bacillus anthracis, Bacillus subtilis, and Staphylococcus albus.

The lipid compositions of the three bacterial species could be easily distinguished by a visual inspection of the high boiling point region (300-450s) of the total ion chromatograms (Figure 1.). The signal averaged mass spectra for this region are also reproduced in Figure 1. The spectra are characterised by a series of ions differing by consecutive 14 amu increments, which is consistent with the assignment that this region comprises the lipid components of the bacteria. The three bacterial species could be readily distinguished by differences in the relative intensities of the ions at m/z 522, 550 and 578 in the averaged spectra.

There is widespread interest in the structure elucidation of isolated natural products because of the diversity of biologically active compounds that are produced by plants and micro-organisms. The structure elucidation of complex natural products at Bristol-Myers Squibb typically involves the use of gentle ionization techniques (FAB or thermospray) for the generation of molecular ion species and fragment or substructure ions in the gas phase. Through the coordinated use of tandem mass spectrometry and high resolution mass spectrometry, these substructures are rapidly characterized and identified. This strategy results in a more rapid, streamlined structure elucidation process.

We have recently employed both chemical and enzymatic microscale reactions on the FAB probe tip to further characterize and identify unknown isolated natural products. This allows for the selection of a specific chemical or biochemical reaction to produce substructures that may not be formed in the gas phase. This strategy provides an alternate method of substructure analysis that is complementary to MS/MS analysis. Furthermore, the specificity of this method allows for the direct evaluation of chemical reactivity, determination of amino acid sequence, and identification of targeted functional groups.

This methodology requires small quantities of sample with minimal sample handling. Reaction mixture can be directly analyzed by FAB/MS with no reaction work-up. The coupling of our existing structure elucidation protocols with this novel methodology provides further insights into the molecular structure of unknown natural products.

Here we demonstrate that microscale chemical and enzymatic reactions with isolated natural products can be performed on probe and directly monitored and analyzed by FAB/MS. This methodology is illustrated with amino-aveninomycin D, aveninomycin D, esperamin A, and substance P. All reactions were performed on the FAB probe tip and directly analyzed by FAB/MS on a Kratos MS50 mass spectrometer. Aveninomycin D (2 µg), aveninomycin D (2 µg), and esperamin A (0.2 µg) were dissolved in 2 µl of m-nitrobenzyl alcohol, and treated with 0.1 µl of acetic acid for three hours (aveninomycins) or 0.2 µl of thioglycerol for 20 minutes (esperamin A). The substance P digest with carboxypeptidase Y was carried out with 2 µl of 50 mM ammonium acetate (pH 6), 1 µg of substance P, and 0.01 units of carboxypeptidase Y. The reaction was stopped by the addition of 1 µl of m-nitrobenzyl alcohol.

The full scan negative ion FAB mass spectrum of aminoverninomycin D (MW 1505) contains ions that correspond to the losses of successive sugar substructures (m/z 1158, 968, 808, 664, and 534). To determine the location of the ortho-esters, aminoverninomycin D and an everninomycin D standard (MW 1535) were exposed to hydrolysis conditions on probe and analyzed by FAB/MS. The resulting mass spectra exhibit two additional protonated molecular ions 18 and 36 amu higher, corresponding to the addition of a water molecule to each ortho-ester (Figure 1). By comparing which fragment ions were shifted by 18 and 36 amu, the location of the ortho esters of aminoverninomycin D were determined to be sugars three and seven.

Treatment of esperamin A (MW 1324) with thioglycerol reduces the trisulfide and triggers the cyclization of the diones moiety.2 The mass spectrum of this microscale reaction mixture (MW 1248) contains new and more abundant fragment (substructure) ions than that of the parent compound. Furthermore, by noting those ions that are shifted by 76 amu, the altered substructure is readily indicated. Analysis of this product by our coordinated approach with MS/MS and HRMS would result in complementary substructure information and aid the structure elucidation process if this were an unknown.

To demonstrate that the selectivity and mild reaction conditions associated with enzymatic reactions can be utilized with this methodology, the carboxypeptidase Y digest of substance P was performed on probe. Carboxypeptidase Y successively cleaves the C-terminal amino acid of a peptide/protein, so the sequence from the C-terminus can be determined by monitoring the reaction.4,5 From the FAB mass spectra of this reaction performed on probe, the sequence of five successive amino acid residues from the C-terminus is readily indicated (Figure 2).

Coordinated Use of Tandem Mass Spectrometry and High Resolution Mass Spectrometry for the Rapid Structure Elucidation of Isolated Natural Products

Mike S. Lee, Steven E. Klohr and Ira E. Rosenberg
Bristol-Myers Squibb Company, 5 Research Parkway, Wallingford, CT 06492

Many of the current therapies for the treatment of cancer and infectious diseases are developed from isolated natural products. These compounds are components of complex mixtures isolated from micro-organism fermentation broths or extracts of plant material. These sources often yield novel classes of compounds that possess a unique mechanism of action or spectrum of activity. Since natural products are a source of truly novel lead compounds, Bristol-Myers Squibb has an active world-wide research effort dedicated to the rapid discovery and identification of novel natural products.

A structure elucidation strategy involving the coordinated use of tandem mass spectrometry (MS/MS) and high resolution mass spectrometry (HRMS) is employed to provide rapid and accurate insights into the various substructures of an unknown molecule. The premise of the method is based on the fact that fragment or substructure ions observed in daughter MS/MS spectra are typically observed in full scan mass spectra. Our approach involves the daughter MS/MS mode to divide a complex molecule into smaller and perhaps simpler substructure molecules. The parent MS/MS mode is utilized to determine "mass spectral connectivity" and link the related substructures. The utilization of the parent MS/MS mode to provide substructural connectivity is analogous to a retro-synthesis in the gas phase. Once related substructures have been identified, accurate mass measurements and molecular formulas are obtained via high resolution mass spectrometry.

Figure 1 shows the major substructures of Amino-Evennimicin D formed via full scan DCI/MS experiments. Further detailed substructural information was obtained via the daughter MS/MS spectrum of m/z 666 (Figure 2). Parent MS/MS analysis of the major daughter ions observed in the spectrum established substructural connectivity and the resulting accurate mass measurements were performed. For example, the parent MS/MS spectrum of the m/z 233 substructure contained the m/z 345, 353 and 491 ions establishing connectivity. Accurate mass measurements of these ions resulted in possible molecular formulas of these substructure ions as well as molecular formulas for the resulting neutral loss substructures. However, the parent MS/MS spectrum of the m/z 158 substructure (amino sugar) does not contain the m/z 233 ion indicating that no mass spectral connectivity exists between these two substructures. Thus, the two substructures result from separate and unique fragmentation schemes. No neutral loss information (mass and molecular formula) can be derived from the m/z 158 and 233 substructures of Amino-Evennimicin D.

Figure 1. The Major Substructures of Amino-Evennimicin D Observed Via Methane DCI/MS.

Figure 2. The Daughter MS/MS Spectrum of the m/z 666 Substructure of Amino-Evennimicin D.
A similar methodology was utilized to elucidate substructures of Taxol and Luzopeptin (Figure 3). Figure 4 shows the parent MS/MS spectrum of Taxol selecting the m/z 105 substructure (benzoyl). Structural information corresponding to the taxol side-chain (m/z 286) is present along with an ion corresponding to baccatin substructure (m/z 509). The presence of the m/z 509 ion is due to a separate benzoyl substructure on the baccatin moiety. Figure 5 shows the daughter MS/MS spectrum of the m/z 592 substructure of Luzopeptin. Fragment ions corresponding to the quinoxaline and each amino acid substructures are present. The accurate mass measurements provided molecular formulas of these corresponding substructures.

DETERMINATION OF OLIGOGALACTURONIDES HAVING PHYTOALEXIN ELICITING ACTIVITY IN PLANT CELL CULTURES BY FAB AND IS MASS SPECTROMETRY.

Andrea RAFFAELLI, Sergio PUCCI, Flavia MARINELLI, Plero SALVADORI

Pathogenic fungi and bacteria

Plants respond to phytopathogenic attacks with a complex of pre-formed and inducible defence reactions (Figure 1). Signals able to trigger defence reactions in plant cells are called elicitors. Elicitors can be of abiotic origin, such as agents of physical and chemical stress, or biotic molecules both exogenous or endogenous. The identification of the "chemical signals" responsible of the elicitation process can be extremely useful in the field of biotechnology, in order to force plant cells to produce specific chemicals of potential interest as drugs.

Partial digestion (Figure 2) of polygalacturonic acid in the presence of endopolygalacturonase, isolated from a commercial preparation of Aspergillus niger pectinase, produces mixtures of α-D-1,4-galacturonide oligomers which elicit the phytoalexin metabolism in some plant cell cultures. These oligomer mixtures, obtained at different digestion times (30 min., 2, 4 and 20 hours), were analyzed by FAB mass spectrometry to establish their composition and the nature of the oligomers present.

This method of analysis could be of large interest for the identification and structural determination of oligosaccharides coming from enzymatic degradation of plant cell walls, which is one of the most important points in the investigation on the phytoalexin elicitation.

Figure 1 Schematic representation of the defence reactions of a plant cell against phytopathogenic attacks.

acetic acid and desalted by a cation exchange resin to convert carboxyl groups to their protonated form. These samples were dissolved in a glycerol/thioglycerol matrix and analyzed by a VG 70/70E mass spectrometer in FAB negative ion mode using a xenon gun. The results obtained allow to establish the oligomeric composition of the longest hydrolysis times mixtures, ranging from 2 to 8 depending on the hydrolysis time. The spectrum of the 2 hours mixture, the one containing the highest oligomer detected, is reported in Figure 3. The 30 min mixture behaves differently with respect to the others. The background is very high and it is not possible to estimate the presence of oligomers with a degree of polymerization higher than 6.

This method of analysis could be of large interest for the identification and structural determination of oligosaccharides coming from enzymatic degradation of plant cell walls, which is one of the most important points in the investigation on the phytoalexin elicitation.
The same mixtures were examined also in LC-MS with ionspray (IS) ionization on a NERMAG R3010 triple quadrupole instrument with a custom built ion source. The results obtained are in a very good agreement with those obtained by FAB.

Membrane introduction mass spectrometry has received considerable attention in our laboratory. The work has resulted in the development of a hollow fiber membrane direct insertion probe [1] that is unique in that it locates the membrane in the ion source of the mass spectrometer. This location of the membrane reduces problems due to analyte dilution, memory effects and poor response times observed in interfaces where the membrane is located remote from the ion source. The flow-through design of the direct insertion membrane probe facilitates analyte transfer to the mass spectrometer and allows the use of flow injection analysis sampling methods, thereby greatly facilitating the task of automated, continuous monitoring. Recently a second generation membrane probe has been developed that employs a sheet membrane and temperature control [2]. The direct insertion sheet membrane probe (Figure 1) has been well characterized [2] and then utilized for bioreactor monitoring [3].

A schematic diagram of the flow injection analysis (FIA) instrumentation is given in Figure 2. The membrane probe utilized was a sheet direct insertion membrane probe (Figure 1) when a triple quadrupole instrument [3] was used and a simple capillary membrane probe when an ion trap detector was used [4]. Both membrane probes were held at a constant temperature of 70°C for these experiments. The membrane is a dimethyl vinyl silicone polymer with a thickness of 0.01 in. Plugs (250 µl) of fermentation broth or standard solution are injected into the continuous stream of dilute acid by a Waters Filter Acquisition Module (FAM). All valves are controlled via a flow injection analysis control unit built on-site. A sampling rate of 15 times/hour is possible with this system. Recently a gas mixer, which allows automatic changes in the oxygen concentration in the feed stream, was added to the measurement system. The mass spectrometer, the flow injection analysis unit and the gas mixer can all be controlled by a personal computer, a combination which allows feedback control of bioprocesses.

The fermentations of particular interest are the fermentation of the microorganisms Bacillus polymyxa and Klebsiella oxytoca. Bacillus polymyxa produces high optical purity (R,R)-(−)-2,3-butanediol. Interest in Klebsiella oxytoca is based on the ability to produce 2,3-butanediol almost exclusively in the meso form. These organisms produce carbon dioxide, acetic acid, acetoin, 2,3-butanediol and ethanol as the major products in relative proportions which depend on the availability of oxygen.

On-line quantification of the major solution phase products was done using external standards with the automated FIA method of sampling. These methods provide a sampling rate sufficient to give smooth curves displaying the concentration of the products during a complete fermentation. The concentration profiles of the products, acetoin, ethanol and acetic acid, were derived from the protonated molecules, (M + H)+, appearing at m/z 89, 47 and 61 respectively. For butanediol, the (M + H - H2O)+ ion m/z 73 was monitored since it was far more abundant than the protonated molecule. Measurement of acetic acid required on-line acidification of the sample, since acetic acid is in its dissociated form in the fermentation pH range of 5.7 to 7 and therefore does not pass the membrane. An example of on-line quantitation of the major products is shown in Figure 3. The concentrations measured by on-line membrane introduction mass spectrometry were confirmed by off-line gas chromatography.

In the course of the on-line monitoring experiments, fermentation off-gases and dissolved gases could also be measured [3]. Based on the measured off-gas data and measured concentrations of the major solution phase products, a reaction network was developed which allowed estimation of glucose and biomass concentrations [5]. Excellent estimates of biomass and of glucose concentrations were produced, as compared to experimental measurements, during the course of fermentation [5].

The tandem mass spectrometry capability of a triple quadrupole mass spectrometer is useful in allowing confirmation of product identity and identification of metabolites and intermediates by comparison with MS/MS spectra of authentic compounds [3]. This capability also forms the basis for analysis of optical isomers; for example the R,R and meso forms of 2,3-butanediol were distinguished by recording MS/MS product spectra of phenylboric ester derivatives of these compounds. A large difference in the ratio of the fragments at m/z 133 and 73 for the two derivatives makes isomer distinction possible.
The fully automatic flow injection analysis-membrane introduction mass spectrometry system is capable of on-line feedback control of bioreactors. From fermentations without feedback control it is known that the production rate of acetic acid is related to the availability of oxygen in the fermentation broth. A decrease in acetic acid production rate reflects a decrease in the oxygen availability (large oxygen consumption) and an increased rate of formation of acetol, 2,3-butanediol and ethanol. The amount of 2,3-butanediol might therefore be increased if the oxygen feed were adjusted during the fermentation, while controlling the feed of oxygen on the basis of the rate of acetic acid formation. Figure 4 shows the product distribution for an experiment controlled by this way. After approximately 2 hours, the production rate of acetic acid passed a preset upper limit and the oxygen partial pressure was slowly reduced until a lower limit in the production rate was reached (hour 5). In order to maintain a fast production rate of butanediol the oxygen feed was increased again. From Figure 4 it can be seen that the production rate of butanediol increases again until the oxygen availability becomes too high (hour 6).

References
There are several commercial operations using CYANEX® 272 extractant to selectively recover cobalt from aqueous cobalt/nickel streams. CYANEX 272, a dialkylphosphinic acid, is used in conjunction with a diluent - usually a mixture of C10-C16 hydrocarbons. When the two phases are contacted under slightly acidic condition, the cobalt is quantitatively and selectively extracted into the organic phase (1). However, in the absence of an antioxidant cobalt will catalyze the air oxidation of the diluent to fatty acids. (2) The long chain fatty acids are detrimental in that they build up in the solvent and will extract both cobalt and nickel in a non-selective manner. Rigid control of the fatty acids is critical of the successful operation of the plant.

This paper discusses a rapid GC/MS method to quantify the fatty acids as their methyl esters using a HP 5870 MSD. Normal GC techniques to determine the fatty acids as their methyl esters are not applicable since they coelute with the multitude of varsol components which are 1-2 orders of magnitude higher in concentration.

The esters were detected by operating the HP 5870 in the selective ion mode (SIM) using only the 74.00 amu ion. This ion is characteristically abundant in the spectra of all linear fatty acid methyl esters. It’s not found in the spectra of hydrocarbons or other oxidation products such as alcohols and aldehydes which coelute with the esters.

Fatty acid esters can be detected by extracting the 74.00 amu ion chromatogram obtained from the SCAN mode of operation. However, detection limits are at least an order of magnitude higher and quantitation is poor with only 2-4 data points per peak.

Docosanoic acid was used as an internal standard since only C5 to C18 acids were observed in the matrix. 0.1 - 4.0 g/l C5 to C24 acid standards were prepared using 250 g/l CYANEX 272 extractant in a C10-C16 hydrocarbon diluent as the solvent. The standards were derivatized by heating 400 μl of each standard mixture with 400 μl of 1.57 g/l docosanoic acid and 400 μl of METHYL-8 (4) at 60° C for 45 minutes. The inlet for the MSD was a HP 5890 GC fitted with a 30 m X 0.25 mm DBS column - film thickness 0.25 microns. 0.1 μl were injected at a head pressure of 11 psig and with the vent flow set at 100 cc/min. The injection port was at 300° C while the oven was heated from 50 to 300° C at 10°/min.

The 5970 MSD was operated under SIM conditions using only the 74.00 amu ion at low mass resolution i.e. 0.7 - 0.9 amu. The instrument was manually tuned using ions 219, 131 and 69 from the perfluorotributylamine calibration gas for masses 1, 2 and 3. This optimized the MSD for maximum 74.00 ion sensitivity. The electron multiplier tune value was 1800 V. It was increased to 2000 V for increased sensitivity. Using a dwell time of 50 ms, 10-15 data points were obtained on the smaller peaks.

All calibration curves were linear over the expected operating range of 0-5 g/l. Figure 1 is a typical example. The lower detection limit (S/N = 4) was 0.005-0.01 g/l for most acids. The relative response factors (docosanoic acid = 1) varied from 0.8 to 1.85 with undecanoic acid having the maximum sensitivity (Figure 2). The variation in response factors is a result of two opposing factors: 1) the fraction of 74.00 amu ion content of the total ion current and 2) the disproportionate splitting of the sample. The lower fatty acids have a higher proportion of 74.00 amu ion but at higher injection port temperatures, a greater fraction passes through the vent. High injection port temperatures (300° C vs 250-280) produce a more consistent splitting of the higher boiling esters. This reduces the random errors at the expense of a slight loss in detection limit for the lower acids.

For six samples at 1 g/l concentration, the average % standard deviation for the seventeen calibrated acids was 1.97.

Figure 3 is a typical chromatogram of an oxidized solvent. C1 to C4 acids are not observed since they partition into the aqueous phase. The minor peaks between the linear esters are branched isomers. They were not individually identified or calibrated.

MULTIELEMENT THERMAL IONIZATION ON DISCRETE PARTICLES FOR GEOLOGICAL DATING

Michael J. Kristo, The Mcllolan Central Laboratory, Mcllolan AFB, CA, 95652-6437

We have developed a technique for dating microscopic particles, using the electron microprobe (EMP) for elemental analysis and sequential thermal ionization mass spectrometry (TIMS) on a three sector (BBC) mass spectrometer for isotopic analysis. This EMP/TIMS technique has several advantages over standard methods. The standard analysis for geological dating uses isotopic dilution mass spectrometry (IDMS) for each element of interest, e.g., U, Th, and Pb. These analyses are typically performed on bulk samples, although some work has been done on dating distinct particles using microdissolution techniques (1-2). Isotopic analyses are performed almost exclusively on single sector mass spectrometers, although one group has used a double sector (BB) mass spectrometer to date ocean basalts (3).

This standard technique has several advantages. First, isotopic dilution is one of the most accurate and precise methods of quantitation. Second, one can correct for isotopic fractionation during the analysis by double spiking the sample (4-5). Third, only a single analytical technique is used. However, the current technique has certain disadvantages as well. First, it is tremendously labor intensive, requiring chemical dissolution, spiking, elemental separation and purification, followed by separate thermal ionization analyses for each element of interest. Second, the chemical preparation leads to significant procedural "blanks." Even using the microdissolution technique, blanks are in the picogram to tens of picograms range. These blanks eventually limit the smallest sample which can be analyzed accurately. Third, the single stage mass spectrometer provides poor sensitivity to lower abundance isotopes, e.g., Th$^{230}$. A 2-stage mass spectrometer improves on this situation somewhat, providing abundance sensitivities around $10^{6}$ as opposed to around $10^{4}$ for single sector instruments.

The EMP/TIMS technique improves on the conventional technique in several areas. First, analyses are much faster. Thus, EMP/TIMS can be used a valuable survey technique. In fact, the EMP can be used as a very fast prefilter to select only the most interesting particles for further analysis. Second, direct analysis of microscopic particles virtually eliminates chemical blanks. Combined with the high ionization efficiency of TIMS and the high transmission efficiency of the three stage design, this technique achieves high overall sensitivity. Third, use of a three-sector mass spectrometer improves abundance sensitivity to greater than $10^{6}$. Drawbacks to this method are possible inaccuracies in electron microprobe data due to "small particle effects," lack of correction for isotopic fractionation (since spiking is not possible), and the necessity of a refractory matrix when analyzing Pb using single filament TIMS.

We recently analyzed a thorite sample of unknown origin using EMP/TIMS. The sample provide four decay schemes useful for dating each particle:

- $^{238}U\rightarrow^{206}Pb$ (1)
- $^{235}U\rightarrow^{207}Pb$ (2)
- $^{232}Th\rightarrow^{208}Pb$ (3)
- $^{230}U\rightarrow^{226}Th\rightarrow^{208}Pb$ (4)

Of course, decay schemes 1 through 3 occur through unstable intermediate products whose half-lives are short compared to the radioactive parent. So, after about 100 years, one can simplify the calculations for scheme 3 and neglect the intermediate decays. After 100,000 years, one can make the same approximation for scheme 2 and, after 1 million years, for scheme 1. Decay scheme 4 is only useful for dating samples less than about 400,000 years old. After 400,000 years, the level of Th$^{230}$ increases to such an extent that its decay rate equals its rate of formation from the decay of U$^{235}$. Secular equilibrium is established and the level of Th$^{230}$ remains constant. The equations for decays 1 and 2 can also be combined to date samples based only on the Pb$^{207}$/Pb$^{208}$ ratio (since the natural U$^{235}$/U$^{238}$ ratio is constant throughout the earth's crust). Therefore, it is possible to date particles using only mass spectrometric data. In fact, this can be the most accurate method of dating the particle in the event of recent loss of lead (6). We obtained the following results on particles from 40 to 150 μm in size:

1069
Percent relative deviations calculated from EMP and TIMS data using propagation of error analysis are given within the parentheses. Dashes (-) indicate particles which had insufficient ion currents to measure one or more of the elements. The variations in the calculated ages are systematic and are caused by either lead diffusion or episodic loss of lead (7-12). Plotting \( \text{Pb}^{207}/\text{U}^{235} \) vs. \( \text{Pb}^{206}/\text{U}^{238} \) for each datum yields a straight line which intersects the concordia curve (7-8) at 2.04 (+/-0.01) billion years.

Although not useful for dating this sample (being much older than 400,000 years), the \( \text{Th}^{230} \) levels from 1.5 to 2 ppm were measured. Despite the extremely low levels, the measured \( \text{Th}^{230} \) levels compared favorably with the expected equilibrium concentrations. Samples which did have large errors suffered from interferences from polyatomic ions as measured at background masses. Geochemical or geophysical fractionation can also lead to differences in the measured and theoretical \( \text{Th}^{230} \) concentrations.

In conclusion, EMP/TIMS allows fast geochronological surveys on microscopic particles, allowing quick characterization of granular samples. EMP/TIMS virtually eliminates interferences from chemical blanks, allowing us to look at smaller particles than IDMS. The increased abundance sensitivity of the three sector mass spectrometers allows measurement of large isotopic ratio characteristic of U/Th systems.

THE USE OF TIMS/IDMS TO CHARACTERIZE THE EXTRACTION OF 44CALCIUM-ENRICHED BIOLOGICAL FLUIDS USING ION EXCHANGE MEMBRANE FILTERS

Nancy E. Vieira1, David L. Hachey2, and Alfred L. Yergey1

1National Institute of Child Health and Human Development, NIH, Bethesda, MD. 20892; 2USDA/ARS Children's Nutrition Research Center, Houston, TX 77030

We have been involved in the study of calcium absorption and kinetics in a variety of populations including premature infants, pregnant and lactating women, and patients with disorders of calcium metabolism. Oxalate precipitation has been the method used for the extraction of the calcium from serum and urine (1). However, this precipitation procedure requires 2 days to complete and may coprecipitate other cations that could interfere with the thermal ionization process of the extracted calcium. This interference may cause irreproducible sample volatilization which results in the occasional interruption of automated data acquisition that we observe principally with urine samples. Our objective in this study was to evaluate the use of ion exchange membrane filters for the extraction of a more uniform chemical form of calcium from the biological samples so as to minimize the irreproducibilities of volatilization. Parallel ion exchange and precipitation experiments were designed to test for the occurrence of isotopic fractionation.

The ion exchange membrane filters evaluated were Bio-Rex® 25 mm Sample Preparation Discs (Bio-Rad Laboratories, Richmond, CA) with: a) AG® 50W-X8 Cation Exchange Resin and b) Chelex® Chelating Ion Exchange Resin. The matrices investigated were: water, serum, and urine. Reagents used in the sample preparation were: deionized water, J.T. Baker Ultrex II® grade acids and base, and HPLC grade methanol . Isotope ratios were determined using the Finnigan MAT THQ Thermoquad Mass Spectrometer with electron multiplier detection in the dual filament mode.

Membrane filters were loaded with 1, 1, and 3 ml of water, serum and urine, respectively. Calcium was eluted from cation and Chelex® filters with 6 M and 1 M HCL, respectively. Three ml of eluant extracted most of the Ca from both types of filters. The results for total % recovery of the calcium loaded onto the membrane filters and directly precipitated are shown in Table 1. They demonstrate that cation filter Ca extraction is more efficient for water and urine samples. Comparable results for either method was observed for serum samples.

Duplicate standard curves of the sample matrices of a water standard (0.1 mg/ml Ca), serum (0.091 mg/ml Ca) and urine (0.045 mg/ml Ca) were prepared by the addition of highly enriched (98.95%) 44Ca tracer to result in 44Ca excesses approximating 10, 20, and 30%. Following a 24 hour equilibration, the calcium was extracted from one-third volume of each sample by precipitation, cation and Chelex® ion exchange. The serum (but not the water or urine) filters were washed with 10 ml of deionized water prior to elution of the calcium. Calcium was extracted with 2 ml of eluant. The elutions were then heated and dried in an Ar stream and dissolved twice in HNO3 and dried. All precipitates (oxalate, cation, Chelex®) were dissolved in 3% HNO3 for TIMS.

Table 2 shows the regression line comparisons of direct precipitation versus cation and Chelex® ion exchange A%excesses. Each line represents the regression of the duplicate curves for the respective extraction procedure. The results show that isotopic fractionation does not occur as a result of ion exchange extraction of calcium in these experiments.

The results of the assessment of automated sample analysis are shown in Table 3. Interruption of automated data acquisition of oxalate precipitated calcium is a problem principally seen with urine samples. An improvement in automated filament analysis was observed for water and urine calcium samples extracted with ion exchange filters.

1071
We conclude: 1) ion exchange membrane filters can be used for calcium extraction of biological fluids for TIMS, 2) sample preparation time is 1 day, 3) urinary calcium should be extracted using cation exchange filters, 4) Chelex® filters are to be used for calcium extraction from water or acid digests, 5) serum calcium can be extracted by using any of the 3 methods.

ISOTOPE RATIO MEASUREMENTS BY "WHOLE MOLECULE" MS: COMPARISON OF A QUADRUPOLE AND A MAGNETIC INSTRUMENT.
Pratt,D., Hanzlik,R., Williams,T.D.,Department of Medicinal Chemistry University of Kansas, Lawrence, Kansas 66045

Introduction

Kinetic isotope effects (KIEs) in the enzymatic conversion of substrate to products are frequently used as probes of reaction mechanisms. The usual methodology used to determine a KIE is to detect the small change in isotopic content caused by enzymatic discrimination in the isotopic variants of the substrate at natural abundance levels, requiring the use of an isotope ratio mass spectrometer.

This study presents an alternative methodology using "whole" molecule mass spectrometry to determine KIEs in the enzymatic hydration of epoxides to diols. KIEs are measured by following the change in isotopic content of partially labeled (deuterium or $^{13}$C) substrates. Label to unlabel ratios are kept close to 1:1 and the change in isotopic content from substrate to product is measured by observing the isotope cluster associated with the molecular ion and/or a major fragment.

Experimental

Quadrupole -Nermag R10-10 with SPECTRAL data system and a Girdel GC modified with a J&W scientific split/splitless capillary injector.
Magnetic -VG ZAB-HS with 11/250 data system and a Hewlett Packard 5790 GC
Chromatography - 15 or 30m of bonded phase capillary column
Sample size: 50-100 ng per injection
All experiments on the ZAB were by Voltage scan SIR

Emissions (µA) 200 100
Electron energy (eV) 70 70

* variables on cycle time adjusted to give 15-20 cycles during a GC peak
ion measurement time(ms) 18, 38, 74 80-100
ion switch time .036 5
cycle switch time 168 na
Bromonaphthalene is used as a test case of a 1:1 isotopic mixture to determine the precision and accuracy attainable using capillary GC SIM MS techniques on a quadrupole and a magnetic deflection instrument. The theoretical ratio for the $^{81}$Br/$^{89}$Br molecular ions is 97.9% (208/206). Eight trials of five GC SIM injections each were done over 8 months. On the magnetic instrument the average 208/206 ratio was 97.2% ± 1% relative standard deviation for the trials and the range of deviations for each set of five injections was 0.1-0.4%. On the quadrupole the average of the trials was 95.4±1.2% and the range of deviations for individual trials was 0.3-1.0 %.

Other Compounds Tested: The magnetic deflection and quadrupole instruments were compared using the samples of $^{13}$C or deuterium labeled mixtures at label to unlabel ratios of 1:1. The test mixtures included: D0/D5 methylbenzoate, $^{13}$C/Nature abundance or D0/D2 p-phenystyrene acetone and $^{13}$C or deuterium labeled p-nitrostyrene epoxide. In all cases the magnetic instrument provided precision 2-5 times better than the quadrupole. The range of precision on the magnetic instrument for the $^{13}$C labeled samples was 0.2-0.7%, on the quadrupole the range for the same samples was 0.5-1.5%. The measurements using deuterium labeled samples were consistently 1.5-3 times less precise than from $^{13}$C labeled compounds. For the deuterium labeled compounds, measurements from the magnetic instrument remained 2-3 times more precise than from the quadrupole.

The KIE in the enzymatic hydration of p-nitrostyrene epoxide (PNSO) to diol was determined as outlined in figure 1. Also, a mixture of 1:1 natural abundance and $^{13}$C PNSO was spiked with natural abundance PNSO to provide samples with the range of isotopic content

1073
expected from KIEs in this reaction. The precision of the 5 injections of each standard was in the range of 0.1-0.3%. The results show that 2-3% change in isotope content can be detected reliably.

**Experimental Plan:**

Starting PNSO → Time = 0 aliquot → PNS-Acetamide

Incubate with MEH

10% Conversion → quench 90% of the reaction volume, isolate the dial, convert to PNS-Acetamide

100% Conversion → isolate dial, convert to PNS-Acetamide

Analyze samples A, B and C to determine 13C-enrichment

The KIEs determined here agree within experimental error to the values determined for the same system using an isotope ratio instrument.

**Conclusions:**

With proper controls and experimental design, this method is adequate for measuring many small KIEs (e.g. secondary 2H or primary 13C, 18O, or 15N) which are of interest to mechanistic enzymologist.

**Acknowledgments:** The authors wish to acknowledge the technical assistance of Mr. Bob Drake and the valuable comments and advice of Dr. Charles M. Judson on quantitation by MS. Funding has been provided by NIH GM-21784 and GM-31910.
data, denoted by $o$, was fitted to the theoretical curves. In the case of simple background (Fig. 3a), the only background effects and combined reduction/background effects for pressinolc acid. The experimental contributor to the elevated ($A+2J/A$) values measured. Figure 3 presents the calculated curves considering the dependence of the extent of reduction with concentration would imply that reduction cannot be the sole cause the greatest increase in the measured ratios. It was assumed for these calculations that the analyte signal is little attention, however, is the interference of "peak-at-every-mass" signal due to beam-induced chemical damage. The aim of this work was to develop a method for quantifying that the beam-induced background contribution to the isotopic peaks so that it could be removed from experimental values, thereby providing a true representation of the extent of analyte reduction alone. Mass spectrometric measurements were made using a VG Autospec-Q spectrometer. The VG FAB/LSIMS source was equipped with a caesium ion gun. In a typical experiment, sample solutions were prepared in glycerol and 2 µL portions were then placed on the probe tip using a syringe. Isotopic peak ratio measurements were made using narrow voltage scanning and multi-channel acquisition over a period of 5 minutes in order to maximize reproducibility.

Bombarding beam density values were measured using a Faraday cup detector placed at the target.

Several parameters have been studied independently in attempts at gaining insight into the reduction processes believed to be responsible for the observed phenomenon. Surprisingly, the chemical background interference, which results from interactions of analyte and matrix molecules with the fragments or electrons produced during the bombardment event, was not given much consideration until recently. The parameters which could reflect changes in the signal/background ratio (sample concentration, beam energy and primary beam flux) were examined. A series of experiments were conducted at constant beam density (0.03 µA/mm$^2$) where concentration and beam energy were varied independently. Figure 1 illustrates the variation in $(A+2)/A$ values relative to the concentration of met-enkephalin (Fig. 1a) and pressinolc acid (Fig. 1b) at different primary beam energies. It can be seen from this figure that the bombardment energy has little, if any, effect on the ratios measured. This data is contrary to results reported by Kazakoff et al. which suggest that the concentration effect is eliminated by decreasing bombardment energy. It should also be noted in Figure 1 that the measured isotopic ratios are consistently higher at the lower concentrations, regardless of the bombardment energy. This trend could be attributed either to a poor S/N ratio or to an enhanced amount of reduction occurring in the more dilute solutions. It would be expected, however, that reduction of the analyte be favoured in the more concentrated solutions where the population of analyte subjected to the beam would be higher. The effect observed, therefore, appears to reflect the decrease in analyte signal with respect to chemical background, not a greater extent of reduction occurring at the lower concentrations.

The effect of primary ion flux on the $(A+2)/A$ values was also studied. Figure 2, which presents the variation of isotopic peak ratio values for a pressinolc acid sample (0.005M) measured at various beam densities and beam energy of 24 KeV, shows that a small increase in beam density has a substantial influence on the measured ratios. These results indicate that the beam density rather than energy is promoting reduction or increasing radiation damage. In order to determine the relative contributions of reduction processes and background interference to the peak enhancement effect, the system was simulated mathematically. The relative increases in reduction and background contributions to the $A+n$ peaks would occur experimentally by increasing beam densities. Three possible causes for the inflated isotopic peak ratios were considered: simple background increase, reduction processes in the analyte alone, and a combination of reduction/background interference. It was assumed for these calculations that the analyte signal is linearly related to the sample concentration in the range studied. The background interference, reduction, and combined background/reduction effects were then applied individually at each relative concentration. It is reasonable to expect under these conditions that: a) without any background interference or reduction effects, the isotopic ratios would not change with concentration, b) an increase in background signal will cause higher isotopic ratios as the beam density is increased, c) an increase in the extent of reduction for the analyte would appear at higher concentrations, and d) combined reduction and background effects would cause the greatest increase in the measured ratios.

The dependence of the extent of reduction with concentration would imply that reduction cannot be the sole contributor to the elevated $(A+2)/A$ values measured. Figure 3 presents the calculated curves considering only background effects and combined reduction/background effects for pressinolc acid. The experimental data, denoted by $o$, was fitted to the theoretical curves. In the case of simple background (Fig. 3a), the
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Experimental points could not be fitted properly while for combined reduction/background effects (Fig. 3b), a very good fit was achieved with the theoretical curve representing 2% background and 2% reduction (denoted by A in Fig. 3b). It is obvious from this example, that both reduction and background interference are playing a role in the distortion of measured (A+2)/A values. Once the background contribution is evaluated, its removal should provide (A+2)/A values containing only the natural isotopic contributions and the signal due to reduction of the analyte alone. The experimental data for pressinoic acid was background corrected by 2% as determined in Fig. 3b. The raw and corrected data are shown in Figure 4. The corrected data can be used to quantify the extent of reduction which can be expressed as the variation of corrected values from theoretical values. The isotopic ratio values at very low concentrations remain above the plateau region of the curves despite background removal. This effect is due to an increase in the error of measurement where the analyte signal is very low. For this sample, the extent of reduction was found to be in the order of 2%. The background removal method described, therefore, should allow an accurate representation of the quantity of reduction occurring in different combinations of analyte and matrix.

Effect of Sample Preparation Temperature on D/H Isotope Ratios in Water Samples

L. J. Joseph, G.G. Dolnikowski
USDA-HNRCA at Tufts University, Boston, MA 02111

Introduction
Quantitative reduction of D$_2$O/H$_2$O mixtures to H$_2$ and HD by zinc at high temperature is a popular sample preparation technique prior to mass spectrometric measurement of the D/H isotope ratio in geological and biological samples. A number of different temperatures and types of zinc are currently being employed by mass spectrometry labs around the world. Therefore, we have prepared samples using four different lots of zinc over a range of temperatures from 440°C to 500°C to determine the optimum conditions for the zinc reduction method. All of the samples we prepared were run versus an NBS standard, Standard Mean Ocean Water (SMOW). We used 4 samples, a deuterium-depleted NBS standard, Greenland Ice Sheet Precipitation (GISP), a baseline urine sample which has approximately the sample D/H ratio as SMOW, a deuterium-enriched standard prepared locally, and a deuterium-enriched urine sample collected from an adult who had been given doubly-labelled water to drink.

Experimental
A pyrex tube with a teflon stopcock (Ace Glass, Inc.) is filled with 120 mg of zinc (or 300 mg when using urine) in the tube is evacuated. The tube is flushed with dry nitrogen while five microliters of water or urine is added to the tube. The sample is frozen with liquid nitrogen and the tube is re-evacuated. The stopcock is closed to preserve the vacuum above the zinc and the frozen sample. The tube is placed in a heating block and heated to the desired temperature (440-500°C). To ensure that all samples in a set were heated equally (to within 1°C), the temperature of each hole in the heating block was measured with a mercury thermometer and a digital thermocouple which had been calibrated to freezing and boiling water. The samples are left in the heating block until a grayish ring appears in the tubes just above the level of the heating block (0.5-1.0 hours).

Results
The deuterium enrichment of the samples is reported in delta units and calculated according to the formula:

$$\delta = 1000 \times \left( \frac{D_{\text{sample}}}{D_{\text{SMOW}}} - 1 \right)$$

The standard deviation of replicate analyses of a single sample on a VG SIRA-10 gas isotope ratio mass spectrometer employed for this study was in all cases less than 0.2 delta units, with D-enriched samples standard deviations in the 0.15 delta range and D-depleted samples standard deviations in the 0.07 delta range. These figures represent the internal precision of the instrument and are independent of the sample preparation method.

Figure 1 shows the behavior of GISP when it is subjected to sample preparation using different types of zinc over a range of temperatures. Figure 1A shows the temperature versus delta value curves of two lots of Analar BDH Zinc, and Figure 1B shows the temperature versus delta value curves of two lots of zinc manufactured in John Hayes' lab at the Indiana University. Figure 1 indicates that not only are the temperature versus delta value curves different for different types of zinc, but that there are significant differences between batches of the same kind of zinc.

Figure 2 shows the behavior of a deuterium-enriched standard using different types of zinc over a range of temperatures. Figure 2A shows the temperature versus delta value curve of Analar BDH zinc and Figure 2B shows the curve of John Hayes' zinc. Figure 2 indicates that the D-enriched samples have higher standard deviations than the D-depleted samples in Figure 1. Figure 2 also shows that whereas the standard deviation of the Analar BDH zinc increases with increasing temperature, the standard deviation of the John Hayes' zinc decreases with increasing temperature. We observed similar trends with baseline urine samples and D-enriched urine samples. Figures 1 and 2 also show that the accuracy of the analysis to the certified value of the standard is also strongly dependent on the temperature of sample preparation and the type of zinc chosen.

Conclusion
The delta values and the standard deviations of both enriched and depleted deuterium samples varied with the type of zinc, the lot number of zinc, and the sample preparation temperature. Therefore, it seems advisable to determine the optimum temperature for each new batch of zinc with a standard that has a D-enrichment similar to that of one's samples. The standard deviations we obtained for D-enriched samples were 5-35 times greater than the internal precision of the isotope ratio instrument. It would seem that there is considerable room for improvement in the precision of the zinc reduction technique for D-enriched water samples.
ISOTOPIC ANALYSIS BY TOF SIMS

Isotopic analyses require high precision and extreme dynamic ranges. Ion statistics alone dictates that $10^6$ ions must be detected for a possibility of 0.1% RSD on measurement of a single ion signal. Part per thousand or lower ratios therefore dictate that minor isotope signals be observed at levels that produce major isotope ion counts higher than $10^8$.

Traditionally these measurements have been made using Thermal Ionization, Glow Discharge or other types of mass spectrometry that utilize bulk vaporization of the metal sample during ionization. These instruments produce large ion currents which are measured with Faraday cup detection systems.

The vaporization of metal atoms from the bulk sample produces solid and vapor phase isotopic compositions that change with time as the sample fractionates. High precision and accuracy are achieved only by carefully reproducing sample loadings, temperatures and analysis times so that a Fractionation Bias correction can be applied to the data.

Another problem associated with traditional isotopic analysis of metals is carry-over. Evaporated material from one sample can condense nearby and be heated or sputtered back into the vapor phase to interfere with results from later samples. The traditional answer to the cross contamination problem is to make much of the ion source removable as part of the sample introduction assembly. These precision components must then be cleaned external to the ion source before use in running other samples.

There is now a need to run environmental samples where the loading is not known in advance, making fractionation corrections less accurate. There is also a growing interest in accurate isotopic analysis of light metals where carry-over, fractionation and any other isotope effects are the most troublesome.

**PROPOSAL**

The new low primary-ion-dose Time-of-Flight Secondary-Ion Mass-Spectrometry Instrumentation should be ideal for isotopic analysis. TOF SIMS need not involve bulk heating of the sample. Use of beam raster, short pulses and low currents can allow stable work at incident ion levels near and below the static SIMS limit ($<1\%$ or $<10^5$ surface site collisions per cm$^2$ at a rate just fast enough to expel adsorbed gasses).

SIMS ion collection optics allow nearly a square millimeter of sample surface to be in focus for mass analysis. Concentration of all the incident current into $<10^7$ second pulses, as required for TOF mass analysis, allows time for heat to dissipate between shots. The lack of bulk heating or sample vaporization along with direct ionization from the solid sample surface alleviate the two most bothersome problems traditionally associated with isotopic analysis. Fractionation is prevented since there is effectively no removal of material from the sample. And, since so little material is removed, effectively none is sublimed onto vacuum chamber components or other samples, eliminating carry-over.

Time of Flight mass analysis also has advantages necessary for measuring high precision isotope ratios. The ions in the ion packet extracted from each shot are mass analyzed according to differences in drift time and can all be quantified at the ion detector for each shot. This parallel detection scheme makes isotopic analysis independent of signal stability with all of the advantages of multiple Faraday detectors.

TOF is a more versatile detection scheme for isotopic analysis. TOF instrumentation collects thousands of channels over a wide mass range allowing simultaneous measurement of several isotope ratios and/or de-convolution of complex interferences. Traditional multiple Faraday magnetic instruments, on the other-hand, typically measure from two to ten channels over a range of only a few mass units.

Modern reflectron equipped TOF SIMS instruments easily achieve the 300 to 600 mass
resolution of traditional instruments and could even be set to much higher resolutions (>10,000) if required to solve problems with isobaric interference.

The modern TOF SIMS instrument can achieve the quantitative dynamic range required for isotopic analysis. The ion counting electronics on the instrument used here saturate at 8 counts per channel per shot. The primary ion gun and mass analyzer can be cycled at one million shots per minute giving about a $10^5$:1 dynamic range for a single channel per minute of integration time. The experiment can be set up so that each mass signal of interest is spread over 10 or more channels to give $10^6$:1 dynamic range per mass of interest per minute. Therefore, integration times well under an hour should be sufficient for the $10^7$ dynamic range needed to solve the hardest isotope quantitation problems.

EXPERIMENTAL

We used a KRATOS / Cambridge Mass Spectrometry Limited PRISM TOF SIMS instrument which was temporarily located at the KRATOS Analytical Applications Lab in Ramsey, New Jersey. This instrument was used with an ion extraction energy of 3KV and a drift energy of 4.5KV. The effective ion flight length is 3 meters including a two-stage one-meter Mamykin-type reflectron for energy refocusing. The ion detector is a two stage channel plate. LeCroy high speed multichannel analyzer electronics are used to count and time the ion events at the detector. The user interface for experiment control and data presentation is an HP 9000 series computer utilizing 32 bit Workstation Basic.

SET-UP: The primary ion beam was 25KV Ga⁺ produced from a liquid metal ion gun. The effective spot size during these experiments was about 1 micron and could be rastered to cover up to a one square millimeter area within the focus of the ion optics. The gun was operated at 600 pico-amps with a gate-on pulse width set up to 100 nano-sec.

The experiment was run at a 10KHz repetition rate so that the ion current was 0.6 pico-amps at the sample surface. Alternately the primary ion current can be expressed as $6 \times 10^{-17}$ coulombs or about 375 ions per shot. This primary ion current level was selected because it was sufficient to give between 1 and 10 detected ions per shot.

Sample Presentation: Our samples were all deposited as spots dried from solution onto a 3.5cm Dia. aluminum foil disk. The samples were non-charging, allowing use of a static extraction field with no need to utilize the instrument’s versatile charge neutralization capabilities.

Two lithium solutions were used for these tests. One solution was highly basic and contained lithium that was highly enriched in $^6\text{Li}$ (about 93 atom %). The other solution had a more neutral PH and contained Li enriched to about 95 atom % $^6\text{Li}$. One of the $^6\text{Li}$ spots was placed near the $^7\text{Li}$ spots to check for cross contamination as is shown on the photograph.

CONCLUSIONS & OBSERVATIONS:

The precision obtained for the one million shot lithium isotope analysis was near the theoretical predictions based on the number of ions detected. This indicates that essentially any required precision and dynamic range might be obtained, granted sufficient time for integration of the signal.

The data taken at higher current densities seems to indicate that some form of fractionation with preferential enhancement of the $^7\text{Li}$ signal is possible with a Ga⁺ beam. We expect to minimize these effects with an O⁺ beam.

Analysis of the foil background shows that the near neutral solution spread over the entire foil apparently by capillary action along surface cracks. The strongly basic solution however reacted strongly with the Al foil apparently stabilizing the water via the hydration of aluminum oxides.

The deviation of the isotopic analysis of Li on uncontaminated foil from the accepted natural abundance (97.3% $^7\text{Li}$ measured as opposed to 92.58% reported) indicates that more work needs to be done to seek out sources of bias.

The variation of the isotopic analysis with changing raster area and primary ion current may indicate the expected requirement for low energy to prevent fractionation. However, the next experiment must be to use an oxygen beam from a Penning Ion Gun to get the same ion yield at much lower currents and with much lower total energy transfer to the surface.

DIRECT MASS DETERMINATIONS OF NEUTRON DEFICIENT NUCLEI CLOSE TO $^{100}$Sn

K.S. Sharma, G.R. Dyck, and R.C. Barber, University of Manitoba, Winnipeg, Manitoba, Canada, R3T 2N2, and E. Hagberg, V.T. Koslowsky, J.C. Hardy, H. Schmeing, W. Perry and M. Watson, AECL Research, Chalk River Laboratories, Chalk River, Ontario, Canada, K0J 1J0.

1. INTRODUCTION

The mass of a nuclide is one of its most fundamental properties. A systematic knowledge of atomic masses provides an abundance of nuclear-structure information. Various techniques have been used to measure atomic masses. One of the most reliable and precise methods has been direct mass measurements made with high-resolution, double-focusing mass spectrometers. Unfortunately, this technique is only readily applicable to naturally occurring nuclides. For nuclei far from stability, mass information has, in the past, been obtained predominantly with decay-energy measurement techniques, which require detailed knowledge of the decay schemes of the nuclides investigated. However, recent technical advances have opened up the possibility of routine direct mass-spectrometric determination of the masses of such exotic atoms. We describe here the results obtained with one such method, based on the high-resolution Chalk River on-line isotope separator.

Considerable interest has been shown recently in the masses of nuclides in the vicinity of the proposed doubly magic $^{100}$Sn. Information on nuclear masses in this region makes it possible to test the theories of nuclear masses and to delineate nuclear structure near a double shell closure. In one case of particular interest, Wouters et al. have reported large discrepancies between their results for $^{105}$In and values arrived at from mass formulae and systematics for nuclei near $^{100}$Sn. Subsequently, the $\beta$ spectra from all three isotopes were re-measured. The results of these recent measurements combined with level-scheme information yield $Q$-values for $^{105}$In and $^{106}$In and, in a less direct manner, one for $^{106}$In as well.

We have directly measured the atomic-mass ratios for $^{103,104,105}$In, $^{106,107,108}$Sn and $^{102,103}$Cd using mass-spectrometric techniques, with the Chalk River on-line isotope separator. Our results are in good agreement with both the results of systematics and mass formulae, and are consistent with the recent results of Bom et al. A preliminary report on our work has been presented earlier. The values presented here are consistent with but supersede those given in that report.

2. EXPERIMENTAL PROCEDURE

A detailed description of our mass-measurement apparatus has already been published. The radioactivities of interest were produced by the bombardment of a target, placed near the entrance window of a FEBIAD ion source, with a heavy-ion beam from the TASCC accelerator. The reaction products recoil out of the target, through a few heat shields and are implanted into a low-density graphite catcher inside the ion source. They subsequently diffuse out of the catcher and are ionized in the plasma region of the source. An ion beam is extracted and formed by the extraction potential (nominally 40 kV) applied to the source. The ion beam is then analyzed by the separator magnet and brought to a focus at an image slit. With an ion-source exit orifice of 0.5 mm and an image-slit width of 0.25 mm, a resolving power ($M/\delta m$, where $\delta m$ is the FWHM of the mass peak corresponding to the mass $M$) of 7,000 was achieved for the measurements described here. Ions that pass through this slit are guided through an electrostatic beam-transport line into a low-background area where they are implanted into an aluminized mylar tape of a tape-transport station. At the end of a preset interval, the activity collected on the tape is moved in front of a HPGe detector where the gamma-ray spectrum of the sample is recorded.

To measure the mass ratio between two species, the ion beams corresponding to the selected masses are swept across the image slit by changes of the extraction potential in a series of pre-programmed steps. At each of these steps a gamma-ray spectrum is taken for the ions transmitted to the tape station and the corresponding extraction voltages are recorded. In this manner, each of up to three mass peaks may be scanned over. The duration of each step is dictated by the half lives of the activities involved.

The raw data consist of numerous gamma-ray spectra and their corresponding values of the extraction potential. We generate a mass spectrum by plotting the area of selected gamma-ray peaks against the applied voltages. Because of the gamma-ray tagging, it is possible to generate mass spectra that are free of contamination from unwanted isobars or isomers even when the resolving power of the separator is insufficient to resolve the untagged mass-spectral peaks.

The centroid voltages of the generated mass-spectral peaks are used to calculate the mass ratio between two species through Bleakney's theorem, which states that two ions of masses $M_i$ and $M_j$ will follow identical trajectories through the separator if all magnetic fields are kept constant and all electric potentials applied to the instrument are changed so that:

$$M_i V_i = M_j V_j \quad (1)$$
Therefore, from a knowledge of the centroidal voltages, $V_1$ and $V_2$, and one of the masses, it is possible to calculate the unknown mass.

Until recently, the mass scans were conducted in a sequential manner; i.e., the data points were accumulated in order of increasing (or decreasing) voltage. Thus, first one mass and then another would be scanned across the slit and detected. A slow drift in any one of several crucial components of our system would therefore have had a sizable impact because of the relatively long time spent completing the scan over one mass before data collection began on the next. In order to average out the effect of such drifts, this sequential method has been replaced by interleaved scans. Now data collection alternates between points corresponding to each of the two (or three) different masses being scanned. In addition to interleaving the scans over the various peaks, the sequence also alternates between either side of each individual peak. All peaks are therefore observed quasi-simultaneously, greatly reducing the likelihood of systematic errors arising from slow drifts.

3. CONCLUSION

The mass ratios determined by us have been combined with the auxiliary data to yield values for the previously unknown atomic masses of $^{107}$Sn and $^{102}$Cd as well as the less well known atomic masses of $^{104}$In. The results are given in Table 1. These values are in excellent agreement with values that are based only on systematics. The results for $^{107}$Sn and $^{102}$Cd are preliminary. Our result for $^{104}$In may also be combined with the known mass of $^{106}$Cd to yield a Q value for $^{104}$In of 7938 (140) keV. This value disagrees substantially with an earlier result by Wouters et al. of 7260 (250) keV but is seen to be in good agreement with systematics (as demonstrated by the agreement of the deduced mass) and the value of 7800 (250) keV recently determined, via an indirect route, by Bom et al.

An examination of $S_{2n}$ values provide a means of studying nuclear binding energies for nuclei in this region. The results of Wouters et al. show unexpected features at N = 58. When these results were published they represented the nuclides with known mass closest to the doubly magic nuclide, $^{100}$Sn, and their odd behavior stimulated further research into the atomic masses in this region. With the inclusion of the new values from this work and the work of Bom et al., no evidence of any unusual behavior in the systematics of atomic masses for these nuclides is observed.

The results described here represent the first such to be accomplished after the move of our separator to its new location in the TASCC facility. Recent improvements of the separator stability and changes in our mass-measurement procedures have led to an increased precision in our directly determined masses. We have directly determined the mass of $^{104}$In to an accuracy of 1.2 ppm and find that our value agrees with and substantially improves upon the recent result from Bom et al.

MASS SPECTRAL CHARACTERIZATION OF FOULANT DEPOSITS FORMED DURING COMMERCIAL PHTHALIC ANHYDRIDE PRODUCTION

*Chrls Sutton, Ruska Laboratories, Inc., Houston, Texas 77023 and Sandra H. Seale, Aristech Chemical Corporation, Pasadena, Texas 77501

Solid, foulant deposits taken from different points in a commercial phthalic anhydride plant were analyzed by Thermal Extraction-GC-MS and by Thermal Degradation-GC-MS. Samples were thermally extracted by heating at temperatures up to 330°C in an all fused quartz ThermEx instrument manufactured by Ruska Laboratories. Thermal degradation of samples was accomplished by heating up to 750°C in the same instrument. Compounds evolved from the deposits during heating passed through a heated transfer line (300°C) where they were cryofocused on the head of a 30m x 0.32mm DB-5 capillary GC column at -45°C in the oven of a Hewlett-Packard 5890 Series II GC. The detection of compounds eluting from the gas chromatograph was accomplished with either a Hewlett Packard 5970B or a 5971A MSD scanning over a 34 to 650 amu mass range once per second during GC column temperature programming.

Three types of foulant deposits have been identified. Type I is composed of a complex mixture (Figure 1, for example) of condensed aromatic ketones (e.g. 9-fluorenone, 9,10-anthracenedione), aromatic acid anhydrides (e.g. trimellitic acid anhydride), and isobenzofuran-based compounds. Mass spectra of these compounds typically contain fragment ions representing multiple losses of carbon monoxide and/or carbon dioxide (Figures 2,3). Loss of anhydride groups are easily recognized by a difference of 72 amu between major fragment ions. Type II deposit consists of various salts including sodium benzoate, sodium phthalate, and disodium phthalate. Thermal decomposition of such salts leads to the formation of a characteristic suite of compounds such as the parent acid of the sodium salt and a series of polynuclear aromatic hydrocarbons such as biphenyl, terphenyl, quaterphenyl, and various aromatic substituted fluorenes. The exact nature of Type III deposits is not known but they may consist of a mixture of phthalic anhydride and iron phthalates. Thermal decomposition of such deposits produces aromatic ketones, phenyl substituted aromatic hydrocarbons, and isobenzofuran compounds.

CHARACTERIZATION OF IEC AND SEC CHROMATOGRAPHIC FRACTIONS FROM ASPHALTS USING THERMAL CHROMATOGRAPHY COMBINED WITH MASS SPECTROMETRY

Bryan L. Bentz
David Sarnoff Research Center, CN 5300, Princeton, NJ 08543-5300

Using thermal chromatography coupled with flame ionization detection (TC/FID) and with gas chromatography and mass spectrometry (TC/MS), we have studied the chemical composition of a number of fractions of paving asphalts obtained by ion exchange chromatography (IEC) and by size exclusion chromatography (SEC). The objective of this work is to develop thermal chromatographic methods for determining gross differences in chemical composition and structure of asphalt cements. Chemical components include aromatic and aliphatic entities and polar functional groups. "Structure" in this context refers to the nature of the intermolecular assemblies which form in the neat asphalt.

Core asphalts from the Materials Reference Library of the Strategic Highway Research Program (SHRP) were obtained and fractionated by IEC and SEC at the Western Research Institute. Samples were subjected to computer-controlled heating in the Ruska ThermaChrom instrument. Species evolved during the heating process were delivered in a stream of helium to the FID or to the GC/MS (Hewlett-Packard 5985B) for analysis.

The thermal profiles obtained from TC/FID characterization of asphalt fractions show differences in the amounts of material being evolved and the temperatures at which the evolution occurs. Fig. 1 shows thermal profiles of IEC neutral fractions from three diverse asphalts. AAM-1 underwent a solvent de-asphalting process at the refinery: TC/FID and TC/MS data of the neutral fraction indicate this process removes semivolatile, low molecular weight asphaltenes. For a given asphalt, differences are observed in the composition of the IEC neutral, strong acid, and strong base fractions, shown in Fig. 2.

TC/MS data have been obtained from IEC and SEC fractions using a one slice method. Gross differences in composition among the fractions are readily apparent. For example, Fig. 3 shows TC/MS data from the strong acid fraction of asphalts AAA-1 and AAG-1. The strong acid fraction of AAA-1 is

Figure 1. TC/FID analyses of IEC neutral fractions from three asphalts.
observed to have a greater thiophenic content than the strong acid fraction of AAG-1. Interestingly, this finding is consistent with the levels of sulfur in the two fractions, determined by elemental analysis.
CHARACTERIZATION OF LOW-VOLATILITY HYDROCARBONS IN SOILS BY PROBE MICRODISTILLATION/MASS SPECTROMETRY

Ronald D. Grigsby

IIT Research Institute
National Institute for Petroleum and Energy Research
P.O. Box 2128, Bartlesville, OK 74005

INTRODUCTION

Petroleum, in the form of crude oil and refined products, is responsible for the most common organic contaminants found in soil. By far, the largest number of known pollution sites have been traced to leaking underground tanks used for storing gasoline and diesel fuel (1).

Over a period of time, petroleum contaminants in soil undergo significant changes in composition. These are a result of "weathering" caused by evaporation, dissolution, and biodegradation. Although accepted methods of analysis may be adequate for identifying compounds from recent contamination, as the pollutants age in the soil they become less recognizable. Therefore, to comply with anticipated future environmental regulations, new methods of analysis are required that are capable of identifying the larger molecules of lower volatility left behind as the lighter contaminants are either leached away, dissipated by evaporation, or converted to more stable products by chemical reaction.

Probe microdistillation/mass spectrometry is well suited for producing analytical data on low-volatility mixtures, such as those resulting from the weathering of petroleum-contaminated soil (2,3). The method could be applied just as well to the characterization of petroleum contaminants in marine and fresh-water sediments or of tar balls found along beaches as a consequence of oil spills at sea.

The capability of PMU/MS to distinguish contaminated from non-contaminated soil is illustrated with results obtained from the analyses of two soil samples. The first was taken from a site known to be contaminated with crude oil and the second (control) from a non-contaminated residential site. Mass spectra of the two samples were dramatically different, showing that more than enough information was provided to identify hydrocarbons in the contaminated soil and to distinguish these compounds from naturally occurring organic compounds, such as humic acids, in the non-contaminated soil.

EXPERIMENTAL

All data were acquired with a Kratos MS-50 high resolution mass spectrometer. The soil from the petroleum-contaminated site was introduced into the mass spectrometer via a cooled/heated quartz probe over a temperature range from -60 °C to +201 °C with programming by ion-current feedback. No preliminary sample preparation was performed. A sample weighing approximately 70 mg was loaded. Ions were generated by 70 eV electron impact and separated at a dynamic resolving power of 10,000.

The soil from the residential location contained a large amount of water, consequently, it had to be dried before introduction into the mass spectrometer. The water was removed by storing the sample overnight in a desiccator containing calcium sulfate. In addition, the sample was pulverized to maximize surface area. No other preparation was undertaken prior to analysis. The same method of introduction and instrumental conditions were used as for the petroleum-contaminated soil, except that temperature was programmed linearly to distill the sample over a range from -80 °C to +600 °C.

RESULTS AND DISCUSSION

Very strong peaks were evident for aliphatic hydrocarbons (m/z 71, 85, 99, ...) and alicyclic hydrocarbons (m/z 83, 97, 111, ...) in the mass spectrum of the contaminated soil recorded at a probe temperature of 198 °C. In addition, significant peaks for alkylbenzenes were present in the spectrum at m/z 77, 91, 105, ..., as well as peaks for other aromatics. Taken together, these peaks were more than adequate to identify petroleum in the soil sample. In contrast, the spectrum of the non-contaminated soil (control) recorded at a probe temperature of 185 °C was entirely different. Although a few peaks in the spectrum originated from hydrocarbons (e.g., m/z 91), other peaks corresponded to compounds containing oxygen. The latter types were represented, for example, by peaks at m/z 82 (C₂H₄O₂), m/z 96 (C₃H₆O₂), and m/z 98 (C₄H₄O₂). Elemental compositions were confirmed by high resolution mass measurements. Oxygen-containing compounds probably arose from humic material in the soil (4).
Peaks observed at m/z 207 and m/z 281 in the control had elemental compositions of C_{6}H_{15}O_{3}Si_{3} and C_{7}H_{21}O_{9}Si_{4}, respectively. They identified silicones in the sample. The only plausible explanation for silicones in the soil is that they originated from high-vacuum silicone grease used on the glass seal of the desiccator in which the control sample was dried. That is, silicones were adsorbed onto the soil by gaseous transfer from the grease. Although the limit of detectability for silicones was not established, this observation provides evidence of the very high sensitivity of PMD/MS.

A recent modification to the software used to process PMD/MS data permits calculation of apparent Arrhenius activation energies and frequency factors for desorption processes (3). First order kinetics is assumed (5). The calculated values are useful in defining the binding energy which must be overcome when compounds are desorbed from the surface into a vacuum.

A plot of ion intensity vs. temperature for m/z 91, C_{7}H_{7}, from spectra recorded for the non-contaminated soil was made. At least two minima were seen, corresponding to independent desorption processes. The first of these occurred between 450 K and 500 K and the second between 700 K and 900 K. Although the lower-temperature portion of the curve was not defined well enough to allow calculation of the kinetic quantities, its position on the temperature scale indicated that a process was occurring in which one or more aromatic compounds were being desorbed from the soil by rupture of relatively weak bonds.

Between 700 K and 900 K, the curve was smooth enough to allow calculation of an apparent activation energy and frequency factor from the equations for desorption. Values of 33.0 ± 7.2 Kcal/mol and 1.20 x 10^{6} s^{-1} were obtained. The magnitudes of these values are not explained by simple desorption as described by first-order kinetics. More likely, they describe a complex model in which one or more aromatic compounds were being desorbed by a process involving rupture of covalent bonds and diffusion through an organic matrix adsorbed onto the surface of the soil.

CONCLUSIONS

Probe microdistillation/mass spectrometry provides a very sensitive method for detecting low-volatility organic compounds in soil. When used with a high resolution mass spectrometer, the method readily distinguishes between hydrocarbons in the soil and naturally occurring organic compounds, such as humic acids. No sample preparation is required other than desiccation and pulverization.

Ion intensity vs. temperature data acquired in PMD/MS experiments can be analyzed to provide apparent Arrhenius activation energies and frequency factors for the desorption of compounds into a vacuum. These quantities are useful for defining a model by which compounds are bound to the surface of the soil and the pathway through which they are released.

Introduction: Organic compounds known as biological markers have played an increasingly important role in petroleum chemistry during the last 10 to 15 years. Biological markers are organic compounds detected in the geosphere whose basic skeleton suggests a link with a known natural product. Biomarkers are used to help characterize the source, thermal history, depositional environment, migration history, and extent of biodegradation of petroleum.

The majority of gas chromatography/mass spectrometry methods of biomarker analysis ignore absolute concentrations and rely on ratios to assess various maturation parameters. A technique has been developed to quantify selected petroleum biological markers. The method entails fractionating oils into aliphatic and aromatic components using an HPLC technique. Biomarkers from both fractions are quantified based on surrogates, internal standards, and external calibration standards by GC/MS in selected ion monitoring.

By quantifying biomarkers, crude oils may be correlated by visual methods and ratios based on peak heights or areas, and also on absolute concentrations of biomarkers. Advantages of quantitating biomarkers include: 1) direct intercomparisions between instruments; 2) maturity ratios using different ions will not be affected by mass discriminations; and 3) absolute amounts of biomarkers for downhole trends and basin evaluations.

Methods: A known amount of oil, approximately 50 mg and 500 ml of the surrogate standard were carefully added to the top of a ten centimeter by two centimeter column packed with alumina (80/200 mesh). Oil was eluted from the alumina column with 15 ml of dichloromethane and collected in 20 ml vials. The elutriate was then gently evaporated to 0.5 ml with purified nitrogen. The prepared samples were fractionated using an HPLC. This method separates the prepared samples into aliphatic and aromatic components using two Whatman Partisil 5µm PAC analytical columns and a solvent gradient from 100% hexane to 100% dichloromethane. The fractions were evaporated to 0.1 ml with purified nitrogen. Aliphatic fractions were subjected to adduction with 5Å molecular sieve beads to remove the n-alkanes prior to injection.

Prior to analysis of the aliphatic and aromatic fractions, the GC/MS was calibrated with the appropriate multi-component calibration standard to obtain response factors. The aromatic fraction was separated on a 30m x 0.32 mm i.d. DB-17 capillary column, and the aliphatic fraction was separated on a 30m x 0.32 mm i.d. DB-5 capillary column.

Results: One hundred and eleven oils and condensates from two oil fields offshore of Louisiana (South Marsh Island - 128 and Eugene Island - 330) and one onshore oil field in south Texas (Sarita Oil and Gas Unit) were analyzed for their biomarker composition. Total biological markers refer to the sum of steranes, triterpanes, and aromatized steranes with 20 to 35 carbons. The biomarker compounds in the Sarita oils contained 70.1% triterpanes and 19.4% steranes. 0.4% mono-aromatic steranes, and 4.6% tri-aromatic steranes. Total biomarker concentrations ranged from 49 to 2800 ppm with an average of 1138 ppm. The biomarker compounds in the Eugene Island-330 oils were comprised of 26.1% triterpanes, 59.8% steranes, 4.2% mono-aromatic steranes, and 7.3% tri-aromatic steranes. Total biomarker concentrations ranged from non-detectable to 2100 ppm with an average of 1475 ppm. South Marsh Island-128 oils exhibit the lowest concentrations of biomarkers of the three fields studied, ranging from 130 to 426 ppm with an average of 244 ppm. Total biomarker concentrations were 11.7% triterpanes, 79.5% steranes, 0% mono-aromatic steranes, and 4.0% tri-aromatic steranes.

Conclusions: The quantitative abundance of biomarkers can be used to distinguish these three fields. Quantitative differences in concentrations of biological markers in similar oils can be
due to variations in organic matter inputs to source rocks, processes that remove or alter selective fractions of petroleum, and thermal cracking of compounds during maturation. Quantitative determinations are potentially useful as conservative markers to detail losses during alteration, identifiers of precursor/product relationships in chemical reactions, and precise and accurate measurements for three-dimensional, mass concentration basin models. The relationships between biomarker concentration and bulk organic carbon must be defined in order to provide quantitative estimates of organic matter inputs to describe depositional and/or oceanographic settings.

A DYNAMIC BATCH INLET FOR GROUP TYPE ANALYSIS BY MASS SPECTROMETRY
By E. J. Gallegos and E. C. Pazzi

ABSTRACT
A new miniature dynamic batch inlet has been designed for group-type analysis of petroleum hydrocarbons. This system is designed to replace all other large, all-glass, glass-valved, free-standing batch inlets used previously. The new system uses an expansion bulb with an inside volume of only 2 cc. This bulb is placed in the oven of a gas chromatograph set at 300°C with one end connected to the injection port of the GC and with the other coupled directly to the source of the mass spectrometer. Hydrogen is used as the carrier gas at a flow of about 1 cc/min. Injection volume of the sample is between 0.02 and 0.03 µL using a 1-µL syringe. Acquisition time is just over a minute, with a total turnaround time including calculations of about 5 to 10 minutes.

EXPERIMENTAL
This work was done using a Hewlett-Packard 5790A gas chromatograph coupled to our VG 7070E or 70SE double focusing mass spectrometer. A small volume expansion bulb is coupled to the injection port of the GC via a 0.3-meter long, 0.25-mm ID uncoated fused silica column, whereas the other end was threaded to the ion source of the mass spectrometer via a meter long 0.1-mm ID fused silica capillary column. A schematic diagram of this system is shown in Figure 1. Hydrogen, set at a head pressure of 5 psi, is used as the carrier gas. The oven, injection port, and transfer line were all set at 300°C. The injection port is set to the splitless mode. Typical scan cycle time, 5 sec.

RESULTS AND DISCUSSION
Figure 2 shows the elution trace and mass spectra generated by using injection volumes of the 22 x 22 standard of 0.05, 0.1, 0.2, 0.4, and 0.8 µL. Using the 2 cc bulb, the sample remains in the source of the MS for about 1 min. for a 0.05-µL injection. There is a slight boiling point bias in these elution curves, but by summing across the top of the elution curve, the bias is completely eliminated.

Figure 3 shows the field ionization mass spectrum, obtained using the dynamic batch, of an atmospheric equivalent 450°C to 550°C vacuum distillation cut of Altamont crude identified as ALT 180 R. This compares to the same sample run using a direct insertion probe. The probe field ionization mass spectrum is shown in Figure 4.

CONCLUSIONS
This small dynamic batch inlet offers several clear advantages over the previous type batch inlets. The advantages are the following:
1. Turnaround time is orders of magnitude shorter.
2. Sample size is up to 1/100th of that used previously.
3. Because of the above and continuous carrier gas sweep, the MS source, transfer line, and bulb stay clean longer.
4. Low cost, easy maintenance.
CRUDE OIL CHARACTERIZATION BY DIRECT SAMPLING ION TRAP MASS SPECTROMETRY*

M. V. Buchanan, R. L. Hettich, C. Y. Ma, and M. R. Guerin
Oak Ridge National Laboratory, Analytical Chemistry Division,
P. O. Box 2008, Oak Ridge, TN 37831-6120

The purpose of this work was to evaluate the potential of direct sampling ion trap mass spectrometry (ITMS) techniques for the rapid differentiation of crude oils. Twelve crude oils (Table 1) from five Middle Eastern countries were examined in this study by gas chromatography (GC) with flame ionization detection, combined gas chromatography/mass spectrometry (GC/MS) and direct sampling ITMS. All crudes were obtained from the National Institute for Petroleum and Energy Research, Bartlesville, OK. The gas chromatographic profiles (requiring 50 minutes analysis time) of the twelve crudes exhibited predominant aliphatic hydrocarbons (paraffins), as well as many minor components, and were qualitatively quite similar, differing primarily in the abundance of the paraffins. Although small differences in the minor components were observed in some cases, the ability to differentiate the oils based only on this information was very difficult.

To selectively examine the non-paraffinic components of these crudes, methanol chemical ionization (CI) mass spectrometry was evaluated. Methanol CI permitted selective protonation of the alkyl aromatic hydrocarbons, alkenes, and heteroatom-containing compounds present in the crudes, while eliminating ionization of the more abundant paraffins. The resulting mass spectra for crudes under these conditions consisted primarily of C7- to C9-substituted benzenes and C9- to C14-substituted naphthalenes. Selected ion chromatograms revealed differences in the relative and absolute abundances of these components in the various oil samples, but the ion signal levels were quite low in most cases and difficult to reproducibly quantitate. In addition, this chromatographic-based technique required approximately 30 minutes analysis time.

Previous research in our laboratory has demonstrated the capability of detecting and quantitatively measuring volatile components in a solution by purging the analytes directly into an ITMS without chromatographic separation. To adapt this approach to the differentiation of crude oils, aliquots of the oils were diluted into a methylene chloride/methanol mixture. The resulting solution was spiked into distilled water. The volatile components from the oil samples were then purged from the solution with helium directly into the transfer line of the ITMS, with no chromatographic separation. The effluent entering the ITMS was ionized using water chemical ionization, using the water purged from the sample as the CI reagent. As observed previously with methanol CI, this allowed selective ionization of alkyl aromatics and heteroatom-containing compounds, but not the more predominant paraffins. The volatile components could then be characterized in approximately 3 minutes, compared to 30 or more minutes for the chromatographic based techniques.

From the resulting mass spectra, relative ion abundances for the alkyl aromatic hydrocarbons (ions with m/z 93, 107, 121, 135, and 149) from the 12 crude oils were normalized to the signal from ions with m/z 107, which was usually the most abundant ion. Replicate analyses demonstrated good precision in the relative ion abundances, as shown in Table 1. From these data, it may be seen that differentiation of many of the crude oils is possible using these ion ratios. In two cases, 90SPR53 and 75047, the relative ion ratios were observed to be similar, however the absolute abundances of the alkyl aromatics varied considerably and could be used to distinguish these oils. In order to quantitatively compare absolute ion abundances more readily, an internal standard (such as deuterated xylene) could be added to the oil samples prior to analysis. It should be noted that the alkyl aromatics used in these initial investigations may not be the best components for identification purposes because weathering of the crudes can change the relative and absolute abundances of these volatile compounds. Instead of using direct purge into the ITMS, thermal desorption ITMS could be used to examine the higher molecular weight constituents of the oils (e.g., naphthalenes, phenanthrenes, and heteroatom-containing compounds), which should be less susceptible to weathering effects since they are less volatile. Previous work in our laboratory has demonstrated that thermal desorption ITMS, another direct sampling ITMS technique, also offers advantages of speed and sensitivity for the detection of targeted compounds in mixtures, such as oils.

Table 1. Ion abundance ratios from twelve Middle Eastern crudes determined by direct sampling ion trap mass spectrometry.

Low ppm Detection of Stigmastanes and Propylcholestanes in Biomarkers Analysis Using GC/MS/MS

Siu T. Teng*, Finnigan MAT, San Jose, CA; Paul Lipson and J. Michael Moldowan, Chevron Oil Field Research Company, Richmond, CA

Introduction

The use of biomarker analysis in petroleum exploration has been established during the last two decades [1]. Recent developments in tandem quadrupole mass spectrometry regarding MS/MS ion transmission, sensitivity, and reproducibility have made the application of these advanced GC/MS/MS techniques suitable for biomarker analysis in petroleum exploration [2].

Experimental

All experiments used a Finnigan MAT TSQ 700 triple stage quadrupole mass spectrometer interfaced to a Varian 3400 GC.

GC conditions

A J&W bonded phase methyl silicone (DB 1) fused-silica capillary column, 60 meters long, 0.25 mm I.D., 0.25 mm film thickness was connected directly to the ion source through a transfer line maintained at 280°C. The temperature program was 2°C/min. from 150°C to 300°C. Helium carrier gas was used at an inlet pressure of 16 psi which gave a linear velocity of 19 cm/s measured at 300°C isothermal.

Selected Reaction Monitoring (SRM) in Parent MS/MS mode was performed using Argon collision gas at 0.8 mTorr as indicated at the meter, with no correction for gas type. Electrometer gain was 10E-8 A/V and electron multiplier voltage 1600 Volts. Four homologous ions, the parents of m/z 217, and four daughters of m/z 414.4 were monitored in an automated multi-mass experiment. The SRM mode used a scan time of 100 msec and a mass window of 0.3 daltons centered on the ion mass. A collision energy of -14 eV was the best of a series from -8 to -20 eV at m/z 414.4. The sample volume was 0.1 μl of undiluted material. All experiments were automated using the ICL procedure which also controlled the GC parameters.

A petroleum saturate fraction with known concentrations of steranes and diasteranes served as a standard. This was examined at 5, 10, and 15 kV conversion dynode voltages. The other experiments were conducted using 15 kV conversion dynode voltage.

Results and Discussion

Fig. 1 shows the mass chromatograms of the 5 parent ions of m/z 217.2 for the standard run. The peaks are numbered to correspond to the steranes listed in Table 1. The separation of the mass chromatograms from the multi-mass experimental data was done using the Interactive Chemical Information System (ICIS) software. Fig. 2 shows the mass chromatograms of 5 of the homologous parent ions of m/z 217.2 in the sample run. Fig. 2 also shows m/z 414.4 as the parent of m/z 231.2, 290.5, and 304.3. Fig. 3 shows the mass chromatograms of the sample run with numbered peaks for comparison with Table 1. The quantitation estimate for the sample gave values ranging from 0.1 to 10 ppm as summarized in Table 2. The very weak mass chromatogram (peak near noise level) of the MS/MS transition of m/z 414.4 to m/z 231.2 (Fig. 2) shows methylated C-30 sterane isomers to be present at or below the detection limit of this instrument. Fig. 2 also demonstrates the typical dynamic range of 3 orders of magnitude in the SRM mode of the system, based on the scale ranges shown at the right of the chromatograms.

Fig. 2.

Fig. 3.
The discovery of low levels of organoarsenic compounds in natural gas from certain production fields has now required developing methods to scrub these compounds from the gas before it is used as industrial and domestic fuel. Engineering the most effective scrubbing method requires knowing which arsenic compounds are present. We have employed low temperature capillary gas chromatography-mass spectrometry (gc-ms) combined with various enrichment techniques to identify the molecular form(s) in which the arsenic is found.

Instrumentation: All gc-ms experiments were performed on a Hewlett-Packard 5995c quadrupole instrument, equipped with a DB-5 (J&W Scientific) bonded phase column, 30 m x 0.32 mm x 1.0 μm film. A H-P Pascal ChemStation datasystem was coupled to the gc-ms. Standard autotuning was performed using perfluorotributylamine calibrant. The standard chromatographic temperature program adopted was: initial temperature -50°C, programmed at 5°C/minute to 60°C, to give a 22 minute run. Split injections of from 0.1 to 1.0 ml (at ambient temperature and pressure) at 15:1 to 30:1 split ratios were made into a 300°C injection port with a valved gas-tight syringe. The mass spectrometer was scanned repetitively from m/z 15 to m/z 550 at appx. 0.7 scans/second. Subambient temperatures in the gc oven were achieved by using liquid nitrogen coupled to and controlled by the datasystem and gc-ms hardware.

Compounds: Hydrocarbon retention indices were established using a calibration mixture of appx. 0.1% (by volume) CH₄ through C₆H₁₄ in helium (Scott Specialty Gases) for identifying unknowns. Both methylarsine and dimethylarsine were synthesized in order to measure retention indices[1] and record authentic mass spectra. They were prepared by reduction of, respectively, methanearsenic acid and dimethylarsenic acid with NaBH₄ in acidic solution. Trimethylarsine, available from our own reference collection, was also run. Natural gas sampled from the laboratory jet (Lone Star Gas Co.) was used as an additional reference material.

Reference Spectra: Spectra of methylarsine, dimethylarsine and trimethylarsine are shown in the accompanying figures. The first two compounds are not present in the NIST/EPA/MSDC mass spectral database. Our spectrum of trimethylarsine is at variance with the one found in the NIST database. The database spectrum shows m/z 77 as base peak, m/z 75 at appx. 95%, followed by m/z 103, m/z 105 and m/z 120 (M⁺) at 80%, 66% and 64%, respectively. No information on origins or conditions for recording the reference spectrum was available to us. Our results suggest the m/z 75, 76 and 77 peaks in the NIST reference spectrum are extraneous, but that the abundance ratios of the remaining peaks to each other are correct. Chromatographic retention indices for these three compounds on the DB-5 column are: methylarsine, 404; dimethylarsine, 504; trimethylarsine, 553.

Direct Analysis of Gas: Direct injection of laboratory gas and the hydrocarbon reference mixture demonstrated that, while separation of methane and ethane was less than optimal, the rest of the normal hydrocarbons were well spaced along the retention time axis. However, injection of a natural gas sample, determined by total arsenic analysis[2] to contain 650±40 ng arsenic per liter, demonstrated the levels of arsenic compounds present to be undetectable by such a simple approach. Two procedures were tried in order to selectively enrich organoarsenic compounds over the large amounts of hydrocarbons.

Enrichment Procedures: The first procedure used cryogenic trapping to concentrate the less volatile components of natural gas. The boiling points of the three model organoarsines are 2°C, 36°C and 52°C[3]. These compounds should be cryogenically trapped using frozen mixtures of dry ice or liquid nitrogen and various solvents[4]. Measured volumes of arsenic-containing natural gas were passed through an appropriately flushed cold trap, and the cold trap was sampled for gc-ms analysis. While very clearly enriching the less volatile hydrocarbon components of the natural gas, this procedure failed to enrich for organoarsenic compounds.

The second enrichment procedure consisted of oxidizing the organoarsines from the +3 to the +5 oxidation state and trapping them by bubbling gas through a 2.5M HNO₃ solution. After bubbling the appropriate amount of gas through the acid solution, NaBH₄ was added to reduce the dissolved organoarsine oxides back to their parent organoarsines. The regenerated organoarsines were then purged from solution with helium, cryogenically trapped, and sampled for gc-ms analysis.

Results & Discussion: We do not know at this time why the cryotrapping technique did not collect organoarsenic compounds. The oxidative trapping technique succeeded in collecting a very small amount of methylarsine. The selected ion chromatograms of m/z 57 (hydrocarbon fragment) and m/z 92 (M⁺ of methylarsine) shown below indicate a very small amount of methylarsine on the trailing side of the large n-butane peak. The
presence of methylarsine was only detected by reconstructing selected ion chromatograms with the datasystem software. The correct intensity ratios of the important ions in the molecular ion region are present in this small peak, and it occurs at the correct retention index determined for methylarsine.

We have direct gc-ms evidence only for the presence of methylarsine. Indirect evidence exists, however, for the presence of other compounds from total arsenic determinations[2,5], and from identification of various mixed methyl and ethyl arsine sulfides found in solids collected from gas pipelines and fouled pipeline valves. Examination of such solids by electron ionization direct insertion probe experiments clearly showed the mass spectral details expected for such compounds, and matched our observations on materials synthesized in the laboratory[6].

While low temperature gc-ms provides the structural specificity to unambiguously identify organoarsine species in natural gas, a reliable enrichment scheme must be developed. Our attention will be focused here in future work.

NITRIC OXIDE CHEMICAL IONIZATION GC/MS IN THE STUDY OF THE SOURCE OF LIGHT CYCLOALKANES
IN PETROLEUM  T. P. Fan, F. D. Mango,  Shell Development Company Bellaire Research Center, Houston, Texas 77025

A theory developed by Thompson suggested that the polycycloalkanes are less thermally
stable than open-chain structures and thus decompose earlier during catagenesis. He
proposed that the heavier polycyclic hydrocarbons, such as steranes and triterpanes, are
the precursors to the lighter cycloalkanes through thermal decomposition. Mango
disagrees with the above theory in various aspects. He indicates that theoretically,
more energy is required to thermally crack ring structures than to crack open chain
configurations. An alternative explanation is that the lighter cycloalkanes are formed
through a steady-state catalytic process similar to that of the isoheptanes.

Thompson's theory was tested experimentally by thermally decompose a mixture of
cholestane (Figure 1) and octadecane under a simulated subsurface temperature of 330°C
for 4 weeks. The resulting solution was submitted for GC/MS identification. The
components in the C5-C8 region are expected to be a mixture of alkanes and olefins,
derived from thermal cracking of octadecane and from cholestane side-chain, and
possibly the cycloalkanes produced from cholestane. It is the goal of this experiment
to determine whether C₅ to C₈ cycloalkanes are present. However they are difficult to
distinguish from olefins by EI due to spectral similarity, also not all the olefin
isomer standards are available for identification by their retention times.

The identification was successfully accomplished using nitric oxide chemical ionization
(NOCI) GC/MS. The NOCI GC/MS technique employs Townsend discharge for producing
reagent gas ions NO⁺ in the ion source. Interaction of alkanes and cycloalkanes with
NO⁺ results in exclusively (M-H)⁻ ions. While interaction of olefins with NO⁺ produces
(M+NO)⁺ ions and characteristic even mass fragment ions (corresponding to (MNO-C₅H₁₀)⁻)
ions at m/z 86 (C₅H₉NO⁻), 100 (C₆H₈NO⁻), and other alkyl homologues. These spectral
characteristics provide a clear distinction between cycloalkanes and olefins.

Figures 2(a) and 2(b) shows the EI GC/MS chromatogram of the C5 to C8 products and the
sample spiked with seven standard compounds respectively. Figure 2(b) demonstrates that
several components closely eluted with spiked standards, including two of the major
products peaks 11 and 19, and their EI spectrum are very similar. Using NOCI, peaks 11
and 19 are unambiguously identified as 1-heptene and 1-octene respectively, as
de decomposition product from octadecane. Figures 3 and 4 show the clear distinction of
olefins and cyclic components in the ion chromatograms (M-H)⁻, (M+NO)⁺ covering the
retention regions I and II indicated in Figure 2(b). The NOCI spectra of 1-octene and
1,2-dimethyl cyclohexane are shown in Figures 5 and 6.

Based on NOCI GC/MS spectra, all the components within the C5-C8 region were
successfully identified (Figure 7). Approximately equal amounts of paraffins and
olefins were found. They contributed more than 90% of the product in this range with
equal contribution from the side chain of cholestane and octadecane. Only
insignificant amounts of cyclic compounds were present. The findings here provided
positive evidence for cracking of the cholestane side-chain before the opening of
cyclic ring structure under thermal decomposition conditions.

ANALYSIS OF FOSSIL-FUEL FRACTIONS BY ON-LINE COUPLED MICROCOLUMN HPLC CAPILLARY GC-MS

Kenneth J. Welch* and Norman E. Hoffman
Chemistry Department, Marquette University, Milwaukee, WI 53233
* Current Address: S. C. Johnson and Son, Inc., Racine, WI 53403

INTRODUCTION: Multidimensional chromatography (e.g., HPLC-GC) allows one to take advantage of the peak capacity [1] (number of completely resolved analytes) in each technique; because, the peak capacity of the combined technique is the product of the individual techniques [2]. A micro HPLC-GC-MS system was developed and applied to the analysis of solvent-refined coal (SRC-II).

EXPERIMENTAL: An ISCO syringe pump supplied mobile phase (10% heptane in pentane) at a flow rate of 10 μL/min to a Rheodyne 7520 injector (0.2 μL). A 0.32 mm ID x 300 mm fused-silica column, slurry packed with 5-μm 2,4-dinitrophenylmercaptopyrrol silica [3], was connected between the injector and a 0.065-mm ID fused-silica transfer line. The column ends were fitted with 0.32 mm OD x 2 mm Teflon® frits. The column effluent was monitored by UV detection through a window burned in the polyimide coating of the transfer line.

The transfer line was attached to a Valco ten-port valve (0.010” ID ports). A 50-μL sample loop and a7.6-μL flush loop were attached to the valve. Helium GC carrier gas entered the valve at a pressure of 15 PSI and exited via a 0.32 mm ID x 5 m retention gap connected to the GC column.

An HP-5890A GC was interfaced to a Finnigan 4000 with an SGE open-split interface. A 0.25 mm ID x 30 m J&W DB-5 column was connected between the retention gap and the open-split interface. The operation of the open-split interface was modified slightly to allow it to function as a high-volume solvent vent during concurrent cosolvent evaporation.

SRC-II was diluted to 4% with hexane, filtered with a 0.45-μm membrane filter, and repetitively injected into the HPLC system. While HPLC fractions were collected in the sample loop (as shown) the flush loop was filled with pentane. After collection the valve was switched. An interval timer switched the open-split interface to vent for a specified period of time (25-45 minutes). During this interval of concurrent-cosolvent evaporation, the GC oven was maintained at 65°C. At the end of the timed interval the open-split interface reverted to normal flow and the GC temperature program and data acquisition were actuated.

RESULTS: The fractions were characterized as: 1) alkyl benzenes, indenes and tetrains, 2) alkyl naphthalenes, 3) fluorenes, dibenzofurans and 4) phenanthrene. Generally biphenyls elute with naphthalenes; however, as observed here and in other analyses, ortho-substituted biphenyls elute earlier.

USE OF HYDROCARBON HOMOLOGUES AS INTERNAL MASS CALIBRANTS FOR ACCURATE MASS MEASUREMENTS

Kuangnan Qian and Chang S. Hsu
Exxon Research and Engineering Co.
Route 22 East, Clinton Township, Annandale, NJ 08807
Scott Campbell
VG Instruments, 809 Sylvan Ave., Modesto, CA 95350

Petroleum and synthetic fuel fractions are very complex mixtures which contain thousands of components. Accurate mass measurement of a wide range of components using high resolution mass spectrometry (HRMS) is a common practice in the petroleum industry for the determination of compound type distributions. The petroleum distillate is usually separated into fractions by chromatography either on-line or off-line, and then each fraction is subjected to mass spectrometric analysis. Since accurate mass measurement using a double focusing mass spectrometer requires the presence of both the mass calibrant and the sample, the calibrants are chosen not to contain components present in the sample. For example, in high voltage (70 V) electron-impact ionization (EI) perfluorokerosene (PFK) is chosen for HRMS accurate measurement of hydrocarbons because (1) no fluorine-containing compounds are present in petroleum and synthetic fuels, (2) PFK components cover a wide mass range, and (3) there are reasonably small mass differences between adjacent PFK peaks for calibration.

When other ionization methods are used, PFK becomes an unsuitable calibrant and other synthetic blends are usually needed. One example is the use of a blend of halogenated aromatic compounds for low voltage EI high resolution MS measurements of hydrocarbon mixtures because PFK is not ionized under low voltage EI conditions.

There are several disadvantages in using external mass calibrants (calibration standards): (1) various calibrants need to be prepared for different ionization conditions, (2) the calibrant dilutes the sample, therefore reduces the sample detectability, (3) a proper ratio of calibrant to sample needs to be maintained so that calibrant peaks can be recognized, (4) the calibration range of the standard may not cover the whole range of the sample components and (5) the spacing between calibrant components is too wide to provide accurate measurements for sample components in between.

To eliminate these difficulties, we have developed a new calibration procedure using the major homologous series present in the sample mixture as internal mass calibrants for accurate mass measurement. An external standard is used for preliminary confirmation of the most abundant series. Once the series is identified, the members of the whole series are used as calibrant peaks. The presence of the external standard is no longer needed. Since other series are present in about the same mass range as the calibrant series and the spacing between the members of the calibrant series is 14 mass units apart, more accurate measurements of other series are obtained than using external standard alone. A computer program has been developed on the VG OPUS data system for quickly editing the reference mass reference files of homologous series.

Figures 1 and 2 show that different results were obtained from calibration using external and internal standards. In the examples shown, a blend of halogenated aromatics was used as an external calibrant for low voltage EI high resolution MS measurement. Due to low volatility, no components with molecular weights greater than 500 could be introduced into the ion source via calibrant entrance of the mass spectrometer. As a result, shown in Figure 1, all of the heavy components were missing after calibration. However, the whole of both series was identified when an internal standard was used to calibrate the same two series, as shown in Figure 2.
The internal standard can also be combined with the external standard to further confirm the identification of internal standard series. If the internal standard series is correctly identified, all of the calibrant peaks will be included in the final calibration table, as shown in Figure 3. If the series has been mis-assigned, then many calibrant peaks will be missed in the calibration table, as shown in Figure 4.

In conclusion, the use of homologous series as internal calibrants facilitates mass calibration and provides more accurate mass measurements. The internal calibration procedure is found particularly useful for on-line LC/MS high resolution MS analysis of high boiling hydrocarbon mixtures.

**Figure 1**

All the heavy components are missing using an external standard.

**Figure 2**

Entire series are identified using an external standard.

**Figure 3**

Combination with external calibrant peaks confirms the identification of internal calibrant series.

Misidentification of internal calibrant series is recognized by a combination with external calibrant peaks.
Characterisation of Crude Oils by Field Ionisation Mass Spectrometry using a Retractable All Glass Heated Inlet System (AGHIS) for Sample Introduction.

M.R. Green, R.H. Bateman, H.J. Major

Fisons Plc., VG Analytical, Floats Road, Wythenshawe, Manchester, M23 9LE, England.

Introduction

Field ionisation mass spectrometry (FIMS) is an excellent method for analysing complex mixtures since FIMS yields practically fragment-free molecular ion spectra. This technique is therefore ideally suited to the characterisation of crude oils and crude oil fractions since the molecular weight distribution can be directly determined and the contribution from all the components evaluated.

This study involves the comparison of data obtained from two crude oil fractions by 70eV El (which has traditionally been used to evaluate oil fractions on the basis of selected fragment ions) low eV El and FI techniques.

All the samples were introduced through a retractable All Glass Heated Inlet System (AGHIS).

Experimental

The comparative study of the three different ionisation techniques were performed using a VG AutoSpec mass spectrometer. Sample was introduced through the ACHIS heated to between 300 and 350°C. The ACHIS is mounted in a bellows mechanism and can be moved within the source housing by means of a scissor jack. This allows the inlet to be used with either the EI or FI sources. The new open construction of the VG FI/FD source, allows the tip of the ACHIS jet to be positioned 1 to 2mm away from the FI emitter wire, increasing sensitivity. This open construction also reduces the surface area of the source, minimising memory effects and background problems.

The spectra shown FIG 1 & 2 (SAMPLE A, SAMPLE B) are of two crude oil fractions run using the retractable ACHIS, comparing 70eV EI, low eV EI and FI data in each case.

Discussion

Differences in the amount of fragmentation and the relative response of peaks at different masses are evident from the results shown. Analysis using 70eV EI ionisation produces good quality reproducible data. The high degree of fragmentation, however, limits the amount of information and its accuracy. The analysis of this data is based on the summation of characteristic fragment ions to indirectly determine the relative concentration of the component hydrocarbon types present.

With low eV EI conditions this fragmentation is significantly reduced but with an associated drop in intensity. Much more molecular ion information is present, however some shift to lower mass fragment ions is visible.

FI yields fragment free molecular ion information with a high degree of reproducibility. The oil fractions can be easily characterised from the relative intensities of the molecular ions from each z-number series.

As the new open design of the AutoSpec FI/FD source allows the ACHIS to be close coupled to the emitter wire, sensitivity is very good. This allows good quality, reproducible, high resolution data to be obtained in FI.
FT-IR studies of absorbed probe molecules are currently being used to elucidate the acid-base properties of metal oxide supports. Such studies for the reactions of alcohols chemisorbed on gamma alumina by Knozinger et al. (1,2) led them to suggest that short chain alcohols chemisorb on alumina to form two species: an alkoxide, which is formed by the dissociative chemisorption of the alcohol on an acid-base site; and a coordinated species, formed by the chemisorption of the alcohol onto coordinatively unsaturated aluminum ions (Lewis acid sites).

We report here some preliminary results of the application of a novel mass spectrometric technique to study the adsorption sites and subsequent reactions of short chain alcohols on calcined gamma alumina. This technique involves using the direct temperature-controlled probe as the reaction chamber to perform in situ mass spectrometry with isotopically labelled alcohols. We have found that this technique provides both greater sensitivity and a more precise experimental record for the various catalytic reactions than conventional techniques such as temperature programmed desorption and the use of ultra high vacuum systems.

The analyses of catalyzed reactions of both 1-propanol and of ethanol-18O will be used to illustrate the technique. Reconstructed partial ion chromatograms of the reaction of 1-propanol on alumina are shown in Figure 1. Initially, at a relatively low temperature, only desorption of physisorbed water and alcohol is observed as evidenced by the selected ion traces of m/z 17, 18 and m/z 59, 60. As the temperature increases, two products are observed: the lower temperature product on the m/z 73, 102 trace can be attributed to dipropyl ether; the higher temperature product is the propene which gives a signal at m/z 41, 42. These products are the result of dehydration reactions in which water is produced. Evidence for the coproduction of water is seen in the m/z 17, 18 ion trace, which shows inflections corresponding to the formation of the ether and the alkene.

Ether formation is a bimolecular reaction and requires that the alkoxide groups are on adjacent sites while the alkene is formed by the unimolecular elimination of water from an isolated alkoxide species. This accounts for the ether being formed initially, and only when all adjacent alkoxide species have been depleted does the alkene formation reaction begin to occur.

To learn more about the nature of the alkoxide species giving rise to these products, similar reactions were carried out using ethanol-18O (Figure 2). In addition to the elimination of the two different water species (m/z 17, 18 and m/z 19, 20) and the production of ethene (m/z 26, 28), this reaction produces two isotopically different ether products as evidenced by ion chromatograms for m/z 59, 74 and m/z 61, 76. These are molecular ions which can be attributed to CH₃CH₂OCH₂CH₃ and CH₃CH₂OCH₂CH₂ respectively. The only explanation for formation of these two ether products is that they originate from two different ethoxide species, one incorporating an O-18, the other O-16.
The acid and base sites on the surface of alumina can be pictured according to scheme 2 (3).

\[ \text{OH} \quad \text{heat} \quad \text{(OH)}^+ \quad \text{O}^+ \]
\[ \text{Al} / \text{Al} \quad \rightarrow \quad \text{Al}^+ / \text{Al} \quad \text{or} \quad \text{Al} / \text{Al} \]
\[ \text{O} / \text{O} \quad \text{O} \quad \text{O} \]

The presence of the two alkoxide species can only be explained by considering that the ethanol reacts with the Lewis acid site, as suggested by Knozinger (1,2), and also reacts with the oxide of the basic site. These two mechanisms are shown in Scheme 3.

\[ \text{Et}^{18}\text{O}-\text{H} \quad \text{Et}^{18}\text{O}-\text{H} \quad \text{Et} \quad \text{Et} \]
\[ \downarrow \quad 18\text{O} \quad \downarrow \quad 18\text{O} \quad 16\text{O} \quad + \quad \text{H}_2^{18}\text{O} \]
\[ \text{Al} / \text{Al} \quad \rightarrow \quad \text{Al} / \text{Al} \]
\[ \text{O} / \text{O} \quad \text{O} \quad \text{O} \]

In conclusion, using $^{18}$O-ethanol we have shown that ethanol reacts with the alumina surface to produce two alkoxide species. This novel technique is currently being applied more extensively to other catalytic systems.

Distillation fractions of a hydrotreated diesel fuel were analyzed for aromatic and saturate types by mass spectrometry using modified versions of the ASTM methods for hydrocarbon types in low olefinic gasoline (D2789) and in middle distillates (D2425). The diesel fuel had been distilled into nominal 10% volume fraction cuts. The first three boiling fractions were in the gasoline range and were, therefore, analyzed for hydrocarbon types using the low olefinic gasoline method. The seven higher boiling fractions were analyzed by the middle distillate method. These diesel range distillation cuts required separation into saturate and aromatic fractions prior to mass spectrometry type analysis. This was accomplished by open column chromatography using a modified version of ASTM D2549, in which only pentane and diethyl ether are used as elution solvents. Both type analysis methods were also modified by substituting a quadrupole mass spectrometer for a magnetic sector mass spectrometer. These data were required to determine whether fractionation would help in producing a diesel product which would meet the new California air control standards.

The mass spectral analysis showed that the total aromatic hydrocarbon content increased in the higher boiling fractions, while the saturate hydrocarbons generally decrease as demonstrated by figure 1. A more detailed review of these data showed that the polynuclear aromatic compounds significantly increased in the higher fractions, while the mononuclear aromatic compounds such as alkylbenzene and alkylindane actually decreased as shown in figure 2. These results are significant because the naphthalene, biphenyl, fluorene, and phenanthrene content, which make up the major polynuclear aromatic components, have been shown to correlate with diesel particulate emissions.

The individual saturate hydrocarbon types also show diverging trends with boiling range as seen in figure 3. While the paraffinic content increased as the boiling temperature increased, the one ring saturates decreased substantially. The two ring saturates remained relatively constant over the entire range and the higher ring saturates showed moderate increases at the upper part of the range.

The results of this study show that the individual hydrocarbon composition varies greatly along the boiling range of the hydrotreated diesel fuel. Since the polynuclear aromatic compounds for the diesel sample are concentrated in the higher boiling ranges, controlled distillation may be used to remove great proportions of these components which are known to be strong contributors to diesel particulate emissions.
Preliminary results indicated plasma desorption mass spectrometry (PDMS) might be an ideal ionization method for analyzing metalloporphyrins in petroleum and shale oil samples. Conventional analysis of metalloporphyrin content involves separation of the polar porphyrin components from the hydrocarbon constituents followed by ultraviolet absorption spectroscopic analysis. Analysis of metallogeoporphyrins provides a means for obtaining relative maturation values of petroleum and shale oil crudes. This paper describes the background studies necessary for investigation of the potential of PDMS in metallogeoporphyrin analysis.

A Bioion 20 (Applied Biosystems AB, Uppsala, Sweden) plasma desorption mass spectrometer was used in these studies. The samples were dissolved in a 50/50 tetrahydrofuran/acetone solution prior to electrospraying onto a nitrocellulose-coated mylar target. The samples were inserted into the Bioion sample carousel for mass analysis. The acceleration potential used for these studies was 18000 volts. The ETIO vanadylporphyrin standard was purchased from Midcentury Chemicals (Posen, IL). The purity was checked for significant impurities using isobutane chemical ionization - none were detected.

The quality of the PDMS spectrum for high and low levels of the ETIO vanadylporphyrin standard is shown in Figure 1. As can be seen, there is a significant change in signal-to-noise levels in going from 100 ppm to 1 ppm. Also when higher levels of ETIO vanadylporphyrin are present on the target, fragmentation can be observed. Figure 2 shows the intensity of the PDMS signal of both a 1 ppm and a 10 ppm vanadyl signal over eight successive two-hour intervals. The intensity of the (M+H)+ ion in the last two hour interval remains very strong in both graphs, showing very little decrease in the 10 ppm sample, and a decrease to the 30% level of the intensity of the initial two hour interval in the 1 ppm sample.

With a better understanding of the detection limits achievable in the analysis of a pure vanadyl geoporphyrin using PDMS, the next step was to spike a petroleum sample. The petroleum chosen was a Djeno crude which did not have any detectable metalloporphyrins by the conventional separation/ultraviolet absorption spectroscopic method. Figure 3a shows the PDMS spectrum of the spiked (ETIO vanadylporphyrin - 100 ppm) crude (electrosprayed with 50/50 THF/Acetone) with no sample preparation. Figure 3b is the PDMS spectrum of the same sample after undergoing a simple methanol extraction. Notice the considerable improvement in both intensity and signal-to-noise with this preliminary extraction. This analysis speaks to the detection limits of a metallogeoporphyrin where all of the porphyrin intensity results from one component. This is not the case for a real petroleum sample in which the intensity of the metallogeoporphyrins is spread over a number of different homologs.

Figure 4 shows the PDMS spectrum of a Wilmington crude which has been separated and purified using chromatography and characterized using UV absorption spectroscopy. A homologous series of DPEP vanadylgeoporphyrins can be observed (C_{20-24}) m/z 458 - 584 (C_{24} = m/z 528). These results indicate that PDMS is a viable addition to the methodologies presently being used for the analysis of metallogeoporphyrins. PDMS of the sample obtained from a simple methanol extraction scheme can provide an improved mass spectrum of the ETIO/DPEP metallogeoporphyrins in a petroleum crude oil.

SPECTRAL ANALYSIS BASED ON BIPOLAR TIME DOMAIN SAMPLING: A NEW MULTIPLEX METHOD FOR TIME-OF-FLIGHT MASS SPECTROMETRY

Michael A. May!, Alan G. MarshallII, and Hermann Wollnik
Departments of Chemistry! and Biochemistry!, The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210; II. Physikalisches Institut, Universität Giessen, Heinrich-Buff-Ring 6; 6300 Giessen, Germany.

We hereby introduce bipolar sampling as a novel, non-Fourier transform, multiplex technique for sampling and frequency-analyzing a signal consisting of a sum of exponentially damped sinusoids of different frequency. The method is illustrated by a hypothetical toroidal time-of-flight mass spectrometer, in which ionic mass is related to the rotational frequency of pulse-injected analyte ions confined to circulate around the toroid (Figure 1). Time-domain data are generated from the (induced) ion current recorded by each of two annular detector plates placed 180° apart at opposite ends of the torus (Figure 2). If successive maximal voltages from the two detectors are stored alternately as positive and negative data (vs. time) after a pulse of analyte ions is injected into the torus, then bipolar sampling effectively mass-separates ions by recording their passage across a given detector at different times.

Unlike Fourier transform sampling, in which the sum of all of the component frequencies is sampled at equally-spaced time increments, the present bipolar sampling records only the extrema of each (individually periodic) signal to yield a (non-equally spaced) time-domain data set in which each frequency component is detected individually. If analyte ions injected isoenergetically into a torus are constrained to execute circular trajectories, then ions of a given mass-to-charge ratio will travel at constant velocity as a coherent packet. The rotational frequency of each ion packet is given by Eq. 1:

$$v = \sqrt{\frac{qV}{2\pi^2m^2r^2}}$$

in which $v$ is the ion rotational (time-of-flight) frequency (Hz), $q$ is the ionic charge (C), $V$ is the ion accelerating voltage (V), and $r$ is the toroidal radius (m). For $V = 5000$ volts and $r = 0.5$ m, the rotational frequencies for singly charged ions of mass 1 to 100,000 u range between 312.664 kHz and 988.73 Hz, well within the range of commercially available analog-to-digital converters.

Recovery of the corresponding mass spectrum from the time domain data requires (non-FT) sequential pattern recognition of the individual frequency components. Figure 3 shows the decomposition of a computer-generated two-frequency time-domain signal into its individual components by use of a pattern recognition algorithm. For a more complex signal with five frequency components (not shown), bipolar sampling followed by pattern recognition afforded excellent component isolation (unit efficiency). Once each component is isolated, its characteristic parameters are estimated with high accuracy: rotational frequency ($10^{-12}$ relative error), mass-to-charge ratio ($10^{-18}$), amplitude ($10^{-4}$), and phase ($10^{-12}$). Predictably, the effect of Gaussian-distributed time-domain jitter on bipolar sampling was to degrade frequency component isolation/characterization. In summary, bipolar sampling is inherently efficient (2 data samples per cycle), achieves the multiplex advantage of FT analysis, requires minimal digital storage capacity, and yields excellent signal frequency accuracy in "zero-noise" simulations. [Work supported by N.S.F. (CHE-9021058) and The Ohio State University.]
High resolution mass spectra of heavy petroleum and synthetic fuel fractions are difficult to analyze because of the complexity of the sample composition. Each spectrum contains thousands of mass peaks even under low energy electron-impact ionization conditions where fragmentations of parent molecular ions are minimal. Complete identification of peaks at every mass in the spectrum is a complicated and time-consuming task, which can be effectively accomplished only with the help of a mainframe computer. The difficulties in data processing become acute in on-line LC-MS analysis where the high resolution mass spectral data are acquired throughout the LC separation, and data analysis of narrow elution regions are frequently needed.

In our efforts to develop on-line LC-MS techniques for the molecular characterization of heavy hydrocarbons, we realized the necessity of inventing a fast, simple, and reliable method to process the high resolution mass spectral data. We noticed that the "messy" appearance of petroleum mass spectra are mostly attributed to the presence of homologous series and isotopic peaks containing $^{13}$C. If these homologous series could be recognized without examining elemental compositions for every mass, the data reduction would be greatly simplified.

In early 1960's, Kendrick proposed a mass scale based on CH$_2$=14.00000 instead of 12C=12.00000 to express organic mass spectral data (1). The advantage of the Kendrick scale is that all compounds in a homologous series have the same mass defect (Table 1). Therefore, all mass peaks can be sorted and grouped into homologous series according to their unique Kendrick mass defect (KMD). However, using KMD alone to sort out homologous series is difficult if not impossible, because it would require better resolving power and less mass measurement error than current high resolution mass spectrometers can provide. Table 2 show a partial list of compound types commonly observed in hydrocarbon mixtures with KMD between -.1167 and -.1608. The mass differences between adjacent members are usually less than 10 millimass units (mmu) and in some cases, even less than 1 mmu. It is not uncommon for errors in accurate mass measurements to be greater than 5 or even 10 mmu. Apparently, additional steps would be needed before we can use KMD for sorting and grouping of compound types.

The compound types shown in Table 2 are in various nominal mass series, or $Z^*$, where $Z^*$ is defined as the difference of the remainder of nominal mass divided by 14 minus 14, i.e., mod(nominal mass/14) - 14. Table 3 shows a list of compound types with a nominal mass series of -6. The closest adjacent members are 3 mmu. Many of them are greater than 30 mmu. Thus, pre-sorting by nominal mass series facilitates the sorting based on KMD.

Based on these considerations, we developed a multiple sorting technique to process high resolution mass spectral data. Mass peaks with their accurate masses are first sorted by $Z^*$ into 14 groups. Within the same $Z^*$ group, the mass peaks are further sorted by their KMD and grouped into several homologous series. In the final step, the masses of the same homologous series are arranged in sequence to judge the quality of multiple sorting. Identification of compound types is carried out by matching the average value of KMD of the series with the stored KMD values of various compound types in the same $Z^*$ series. The final output of multiple sorting is shown in Figure 1.
The multiple sorting technique has several advantages. Compounds in a homologous series are grouped together. General formula of each group is determined from KHD. This procedure is much faster than determining elemental composition of individual mass peak and then sorting them out into groups. Since average KHD is used for each group, measurement errors associated with individual members of the group are compensated for by statistical averaging, resulting in a more reliable determination of molecular formulae. Carbon number distribution within a series can be easily determined once the core structure is identified. Consequently, a computer program is much simpler in structure and works much faster than conventional data processing programs for high resolution mass spectrometry.

ADAPTATION OF A RANDOM INFORMATION PROCESSING PROGRAM FOR THE RAPID MANIPULATION OF GC/MS AND RELATED DATA

John M. Halket and Steve Down
HD Science Limited, 4a Bessell Lane, Stapleford, Nottingham NG9 7BX, UK

The mass spectrometry professional is confronted with an overwhelming array of data including chemical names, synonyms, Chemical Abstracts Registry Numbers, formulae, mass spectra, instrumental parameters, GC retention indices, literature references and abstracts. He is also required to prepare letters, reports, data sheets and even invoices all in a limited time. The increasing availability of low cost instruments and variety of computers, data sources and software only adds to this problem.

The present paper describes the adaptation of an inexpensive IBM PC-compatible personal information management program (PIM) to help the busy spectroscopist or any scientist to store, retrieve and manipulate such random data with a minimum of effort, thereby improving efficiency. The PIM program allows fields and records to be entered and searched immediately with a minimum number of single-letter commands. Every piece of information is searchable. Since many mass spectroscopists desire relatively small databases of, say, 400 pollutants, 200 steroid derivatives or 150 specialized references and abstracts, rather than many thousands of items, they can be held in memory. This allows searching and retrieval to be almost instantaneous even with a floppy disk system.

A personal overview of the data is maintained during a search by display of a DYNAMIC SEARCH ARRAY (Figure 1). Data sets are represented on screen by small squares which can be short notes or multi-page documents. When a search string is typed, character by character, squares not containing the string disappear from the array to show how many hits remain (Figure 1b). These can be examined at any stage after all or part of the string has been keyed.

![Diagram](image_url)

**Figure 1**: Example of DYNAMIC ARRAY during search. (a) squares represent records of data held in memory, dots represent space available in memory for further records, (b) reduction after search string entry; remaining squares represent those records containing the desired string

The relatively small number of data sets held in memory means that the names of compounds can be rapidly found by typing unusual letter combinations even from the middle of a word. Often name location
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

in databases is problematic as the typed name must correspond exactly with that stored. This problem is eliminated.

The method allows, for example, an eight peak index of mass spectra to be extended to larger numbers of peaks. Any number of GC retention indices or other parameters can easily be added. A further novel feature is the addition of graphics characters to give line diagrams. A typical mass spectral record for a derivatized amino acid is shown in Fig. 2.

Figure 2: Example of mass spectral data record for cystine tetra-TMS derivative showing mol. wt. (mw), mol. formula, GC retention index (r), key ions (k), Chemical Abstracts Registry Number (cas), selected ions (m), relative abundances, line diagram mass spectrum together with parent compound details.

Similarly, databases of full literature references and abstracts can be stored and searched easily to retrieve all abstracts on a specific analyte or matrix and/or by a given author. Such data sets can be held in memory even when other programs such as a word-processor or spreadsheet are in use. Instant switching without exiting and instant data transfer between programs is possible, reports can be written and printed out and where a suitable modem is present, stored telephone numbers can be dialled. A single file may be up to 10 megabytes in size and data is retrieved on the bench-top at up to 300 kilobytes/second.

In conclusion, a commercial PIM program has been adapted to store scientific data in a readily accessible environment. Preliminary results show that such software can be very useful in real lab situations and assists the busy mass spectrometry professional to maintain control over the many different types of data encountered daily. The increasing memory sizes available for personal computers will do much to encourage and develop the application of such RAM-resident techniques.
COMPUTER-ASSISTED ANALYSIS OF MS/MS DATA FOR THE DIFFERENTIATION OF FOOD-BORNE MICROBIAL CONTAMINANTS

*Mark J. Cole, Eric C. Hemenway, and Christie G. Enke
Department of Chemistry, Michigan State University
East Lansing, Michigan 48824

The ability to differentiate among food-borne microbial contaminants is of great concern to the food industry. Current accepted methodologies often have difficulties distinguishing many pathogenic species from non-pathogenic species. In addition, these methodologies require up to 7 days for results and do not always provide an acceptable level of reliability [1]. Phospholipid analysis by tandem mass spectrometry has shown promise for rapidly differentiating several food-borne contaminants that are difficult to distinguish using current accepted methods [2]. This work presents an exploration of computer-assisted techniques in the interpretation of phospholipid MS/MS data for the differentiation of microbial contaminants.

When phospholipids, ionized by fast atom bombardment, undergo CID, they fragment at specific points that are common to all classes of phospholipids. Positive phospholipid ions fragment to lose their polar head group as a neutral loss, while negative ion daughter scans of the phospholipid ions detected in the neutral loss scans provide the fatty acyl information on the individual phospholipid species. The resulting phospholipid MS/MS data forms a 4-dimensional data space in which each phospholipid class is represented by a 3-dimensional map consisting of the phospholipid masses from the characteristic neutral loss scans along the first dimension, the fatty acyl masses from the daughter spectra along the second dimension, and the relative intensities along the third dimension. This data space is shown in Figure 1. The triple quadrupole mass spectrometer can be automated to perform this extensive phospholipid screening in a few minutes, on a single sample [4].

For the cluster analysis, twenty neutral loss scans were collected for each of the 5 possible phospholipid classes known to occur in the particular set of organisms studied. Data from three or four replicates were analyzed for each microorganism. Filtering of the data was necessary to reduce the number of dimensions (features) used in the analysis, and was accomplished on three levels: 1) a peak must occur in a minimum of 50% of the neutral loss scans collected for each phospholipid class 2) the scans thus filtered are then averaged 3) a peak must occur in 100% of the averaged spectra within each set of replicates to be used as a feature in the cluster analysis. The similarity index of two organisms (or sets, or groups) is given by the position of the vertical lines connecting the elements to be compared. The higher the similarity index, the more data features within the particular phospholipid class they share in common, and the more closely related are the spectra. An example of a dendrogram for the analysis based on phosphatidylglycerol is shown in Figure 2. Phosphatidylglycerol provides a high degree of discrimination for the two Salmonella species over all of the other organisms. In addition, E. coli, C. freundii, and L. monocytogenes were readily distinguished from each other. S. abortetubae and S. enteritidis were moderately separated.

For spectral matching, averaged spectra produced for the cluster analysis experiments, for each organism in a replicate set, were averaged to produce a library spectrum for that organism. A reverse-library fit routine was used for searching. "Unknown" spectra for matching against the library spectra were the filtered, averaged spectra from single organisms. The average of these matches, for the analysis of phosphatidic acid in all replicates, is shown in Table 1. The term Δ in Table 1, is the difference between the match value to itself and the next highest value. The higher the value for Δ, the more discriminating is the phospholipid class for that particular organism, as shown in Figure 3.

Both cluster analysis and spectral matching were useful for determining which classes of phospholipids were most discriminating among the different organisms, and both appear capable of discriminating among the organisms tested. Spectral matching is easier to implement and does not require pruning to reduce the number of features, but cluster analysis appears to be more discriminating and provides more information such as most similar samples and parent-offspring relationships. Neither of these techniques are able to incorporate all of the information contained in the phospholipid MS/MS data set shown in Figure 1.

1. Private communication with Dr. Edward Richter, Silliker Laboratories of Ohio, Inc.
The phospholipid data space obtained by FAB/MS/MS. The masses of the phospholipids in each class are obtained by neutral loss scans specific for each class. The daughter spectrum of each phospholipid species provides the fatty acyl information.

ALGORITHMS FOR SEQUENCING PEPTIDES
FROM A VARIETY OF MASS SPECTRAL DATA

Marshall M. Siegel
American Cyanamid Co., Medical Research Division, Lederle Laboratories, Pearl River, NY 10965

SUMMARY

Algorithms for sequencing peptides have been written which can be applied to a variety of mass spectral data including high and low energy FAB MS/MS, high and low resolution FAB/MS and electrospray MS/MS. A unique feature of the algorithms is that all ions are considered to arise either as N- or C-terminus sequence ions or as non-sequence ions. Backtracking and feedback methods were used to enhance the speed of the algorithms. The numbers of amino acid residues in the generated sequences and the corresponding numbers of non-sequence ions were tracked for choosing the best scoring peptides.

ALGORITHM

A) DATA INPUT

Required input for the programs are: (i) observed spectrum: fragment ion masses and intensities, (ii) N-terminating group, (iii) C-terminating group, (iv) molecular weight of the peptide, (v) amino acid (aa) residue fragment ion tables, (vi) peptide scoring parameters, and, (vii) program control parameters. The aa residue fragment ion masses are divided into N- and C-terminal tables and each are expressed in two ways: (1) as aa residue fragment ion masses, and, (2) as mass changes upon fragmentation for each aa residue. The versatility of the programs originate from the fact that the aa residue fragment ion tables can be tailored to the type of data being analyzed and the list of amino acids considered. Customized tables were prepared for analyzing low and high energy FAB/MS and FAB/MS/MS data and for high resolution FAB/MS data. Also, these tables can be created to analyze data believed to originate from cleavage of all aa residues, of all individual and pairs of aa residues, of a selected list of any desired aa residues, etc. The computed peptides consistent with the input data were scored by peptide length, number of ion assignments per aa residue, number of unassigned ions, total ion current of assigned ions and by a weighted composite score.

B) SEQUENCING DETAILS

The sequencing can begin from either the N- or C-terminus and from either the high or low mass end, all being mathematically equivalent. For the following discussions, sequencing will be described from the N-terminus and from low to high mass.

1- Since fragment ions can arise from either the N- or C-terminus, all the experimentally observed fragment ion masses are mathematically recomputed as both N-terminus and C-terminus fragment ions where the C-terminus fragment ion masses are re-computed from the N-terminus side. Hence, all observed ions have two corresponding recomputed mass values, all expressed as N-terminus ions. All the possible recomputed ion masses, including the molecular weight of the peptide minus the mass of the C-terminating group, are sorted from lowest to highest mass after subtracting from each the mass of the N-terminating group. We refer to each of these masses as a "reconstructed ion mass (RIM)".

2- The lowest RIM mass value is searched in the appropriate N- or C-terminus aa residue fragment ion mass table for a match and the corresponding amino acid group is noted. All other fragment ions associated with this amino acid group are noted by searching the appropriate N- or C-terminating table of mass changes upon fragmentation and the matched masses are removed from the list of RIM values. This lowest RIM value is also considered to arise as a "bad ion", namely a non-sequence ion arising either from the peptide or from any other possible source.

3- Step 2 is repeated with the lowest mass value of the remaining RIM values until an amino acid sequence is found with a residue mass equal to the molecular weight of the peptide minus the N- and C-terminating groups, until the mass gap between the last assigned aa residue to a RIM value and the present RIM value is greater than the largest look-up mass in the aa residue fragment ion mass table, or the limits on the maximum number of aa residues or "bad ion" assignments has been exceeded. If a peptide sequence with the appropriate MW residue mass is determined, the sequence is stored as a possible answer if its weighted score exceeds the set lower limit.

4- BACKTRACKING- The last assigned aa residue or "bad ion" assignment is removed from the sequence list, the associated aa or "bad ion" RIM values are reincorporated into the list of unassigned RIM values, an alternate aa or "bad ion" assignment is considered and the sequence is extended as in Step 2. This backtracking procedure is continued until all possible combinations of assignments for aa's and "bad ions" are considered satisfying all the boundary conditions.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

**INPUT DATA**
1. Fragment ion masses
2. MW of peptide
3. Scoring and control parameters
4. C-terminating group
5. N-terminating group

**SPECTRAL RECONSTRUCTION**
1. Fragment ion masses recomputed as N- and C-terminus fragment ions
2. Re-express C-terminus fragment ions as N-terminus ions
3. Subtract N-terminating group mass from all ions

**FEEDBACK**
Partial sequences are now new N-terminating groups

**SEQUENCING**
Grow peptide from N-terminus/low to high mass using BACKTRACKING and LOOK-UP TABLES of aa residue fragment ions

**SOLUTIONS**
List of sequences satisfying boundary conditions

**C) POST-ANALYSIS**
For each peptide sequence solution, the unassigned fragment ions are analyzed for internal acyl fragment ions, internal immonium ions and for dehydration and loss of ammonia from the assigned ions. The scores for the peptide solutions are accordingly adjusted by the success of the post-analysis process. The list of sequence solutions are sorted, ordered from best to worst score and duplicates removed.

**D) FEEDBACK ANALYSIS**
Using the above described methodology, 40 fragment ions can be sequenced in about 20 minutes of CPU time. This time increases exponentially with increasing numbers of fragment ions because the backtrack method described above, but when feedback was incorporated into the algorithm the CPU time was dramatically reduced to less than 1 hour. The feedback process was incorporated in the following way. The above described backtrack method (Sections A-C) was implemented but instead of sequencing the whole peptide and all the fragment ions, only a partial peptide analysis is requested. In this way, for example, a peptide expected to have approximately 12 aa residues is sequenced to find all the first 5 aa residues consistent with the observed fragment ions. The mass of the N-terminating group plus the total mass of the aa residues for each partial solution is computed. These partial solutions are sorted and the duplicates removed. The remaining partial solutions were individually fed back into the backtrack routine (Sections A-C, above) with the only major change being that the masses of the partial solutions are now the N-terminating masses and the backtrack method proceeds to sequence all the RIM values greater than the mass of the N-terminating feedback mass.

**CONCLUSION**
The procedures described above were found to rapidly sequence peptides from a variety of low and high energy FAB mass spectral data. In all cases studied to date, the correct answer was always one of the top ten candidates. For multiply charged molecular ions studied by ES/MS/MS, the input spectral data were the observed ion masses and all possible multiple masses corresponding to all possible charge states. The score for the correct answer was very low because degenerate ions were used to generate the peptide sequences. Upon removing answers derived from degenerate ions, the ranking for the correct answer was very high. This exercise demonstrates that a more efficient procedure for sequencing multiply charged ES/MS/MS data may be to individually analyze each possible combination of charged species and then ranking all the answers.
Fast atom bombardment has become an important ionization technique in the analysis of biomolecules such as peptides and nucleotides and has allowed the determination of their primary structure. Reports have been published showing that the amino acid composition and sequence of unknown peptides can be determined from their FAB spectra. Computer algorithms have been developed to assist in the interpretation of peptide spectra which can be complex under the conditions used in FAB/LSIMS analyses. Although there are different approaches to the computerized or manual interpretation of FAB/LSIMS spectra, they all share a common difficulty which is the extraction of meaningful information from the spectrum. This is due to the fact that the spectra generated are heavily contaminated by background peaks which are produced by radiation damage of the matrix and the analyte by the high energy bombarding ion/atom beam. A FAB/LSIMS mass spectrum represents a quasi-continuum of peaks as illustrated in Figure 1a. The octapeptide, WRVFVHPF, analyzed in a glycerol matrix gives background peaks at every mass. The background intensities are distributed as a function of mass (decreasing with increasing mass) which makes it difficult to identify peaks that are related to the analyte. This “peak-at-every-mass” syndrome can be detrimental to computer algorithms that predict the mass of sequence ions and rely on the presence of specific ions in the spectrum for the determination of the probable sequences for the peptide.

In order to minimize the number of possible sequences in interpreting the spectrum while maintaining the structurally important information, preliminary treatment of the experimental spectrum is indispensable. The efficiency of any algorithm used for spectral interpretation is dependent on the filtering method used to remove the background from the spectrum. There are basically two approaches that can be used for background removal: I) direct subtraction of baseline using a threshold value, and II) use of an empirical method for background calculation and removal. Direct subtraction of background from a FAB/LSIMS spectrum is very difficult. This is due to the fact that the intensities of the background peaks vary with the mass. Furthermore, because the background peaks depend on the nature of the matrix and the analyte due to strong analyte-matrix interaction a simple subtraction is not practical. The use of an empirical method such as the one suggested by Ishikawa (1), although more efficient than direct subtraction, suffers from serious constraints related to the high number of residual peaks.

In seeking a background treatment method that would be objective, automatic, and concentrate useful information from FAB/LSIMS spectra, we have developed a compound-independent algorithm that removes background, without removing peaks of weak intensities due to the analyte, by calculating the frequency of peak intensities. The algorithm that is described here is based on the statistical assumption that the background signal is the one with the highest frequency in the mass spectrum. The algorithm developed is based on the following hypotheses: I) the background intensities are distributed as a function of mass, II) in a mass interval, the maximal number of peaks in a range of intensities (I± Al), determines the intensity of background. There are three major components to this algorithm. Section A controls the input data as a mass/Intensity list and calculates the number of intervals as a function of interval length defined by the user. Section B is an iterative procedure which evaluates and filters the background intensity for each interval according to hypothesis II. Finally, section C allows for the isotopic ratio correction if requested by the user. Isotopic peak correction may be made in order to minimize the total number of peaks remaining after the filtering procedure. The program “STRIP” was written in ANSI Fortran 77 and runs on the VAX-Station 2000 and 3100 (VMS 5.0 or later). The source program is transportable without modification to any computer having a Fortran compiler. The CPU time required for filtering a spectrum containing around 1500 mass peaks is approximately 1.5 seconds.

The algorithm has been applied to FAB/LSIMS spectra and an example of the results obtained is shown in Figure 1. The figure shows the LSIMS spectrum of the octapeptide WRVFVHPF (1a), the background that has been removed (1b) and the residual peaks (1c). It can be seen that most of the background peaks have been eliminated and that the useful spectral information has been substantially concentrated. The sequence ions present in the spectrum have been retained in the corrected spectrum (1c). Since the algorithm conducts a statistical treatment of the background and removes the peaks according to their intensity frequency, it is matrix independent and therefore can treat any type of matrix. This has been verified by comparison of the raw and treated spectra of bradykinin analyzed in glycerol and thioglycerol. These spectra have been found to be very similar in appearance indicating the universality of the approach. Interestingly, the treated spectrum obtained in glycerol showed the presence of more intense sequence ions.
It is also essential when using methods for background treatment that the algorithm removes most of the background signal while retaining small peaks that belong to the analyte. This aspect is especially important in the analysis of compounds like peptides where several sequence ions are of weak intensities. In order to demonstrate the S/N resolution of the new algorithm, Figure 2 shows an expanded portion of a raw FAB/LSIMS spectrum and the corresponding region after spectral treatment. It can easily be observed that the algorithm has excellent S/N resolution and that it can retain peaks that are only slightly above background signal, thus reducing the possibility of removing analyte peaks which are relatively weak.

In order to evaluate the overall efficiency of the new algorithm, the results obtained by this method and that of Ishikawa were compared for several spectra of peptides. Table 1 gives the number of total peaks in the spectra, the number of sequence ions observed before and after treatment and the percentage of spectral information enhancement. It can be observed that our method rejects on the average 90% of the peaks in the initial spectra compared to only 15% for the method of Ishikawa and that both approaches retain over 90% of the sequence ions. Therefore, the algorithm enhances the information by 1000% as compared to 25% for the method of Ishikawa which represents a significant improvement in the quality of information. Thus, the use of such a general background treatment and removal method can be extremely useful in the computerized analysis and characterization of biomolecules by desorption ionization techniques and also for other general applications requiring the elimination of similar background interferences.

Organic sulfonium salts exist as pre-charged species in the matrices normally used for fast atom bombardment mass spectrometry. Positive ion FAB mass spectra of the sulfonium salts exhibit the intact cation as the dominant species. Generally, the fragment ions produced in the spectra are of 30-40% relative abundance. Although other onium salts commonly exhibit rearrangement ions in their FAB mass spectra, the fragment ions produced from sulfonium salts are all products of simple cleavages. Cluster ions CAC* and CACAC* were also observed to occur in the spectra when higher concentrations of the sample in matrix were used. These cluster ions provided confirmation of the salt's molecular weight when beam-induced reduction reactions were suspected to be complicating the spectra. A single selenonium salt was also included in this study. The FAB mass spectra of a triphenylselenonium hexafluoroarsenate salt contained only the intact cation, and no fragmentation was observed (Figure 1). This the first report of a FAB mass spectrum of a selenonium salt.

Semiempirical calculations of the sulfonium salts were performed to determine gas phase stereostructures. MOPAC 5.0 calculations were used to determine the minimum energy structures of the cations. The bond lengths between the sulfur (with a localized charge) and any of the three groups bound to it are in the range of 1.73 to 1.80 Angstroms. These bond lengths are somewhat shorter than sulfur-carbon bond lengths typically found in neutral compounds. Though MOPAC calculations used as such can not predict the preferential cleavage of a substituent, in all of the eighteen different sulfonium salts calculated, the weaker bonds (longer) were cleaved more readily in their FAB mass spectra. Additionally, the MOPAC calculations show that the geometrical orientation of substituents depends directly on their identity. For example, the benzylidimethyl sulfonium salt exhibits a methyl-S-methyl angle of 143 degrees, whereas the methyl-S-benzyl angle is only 108 degrees. For aromatic sulfonium salts, the angles of the three substituents around the sulfur are all approximately equal, and the substituents are held far away from each other.

Positive ion FAB mass spectra were recorded using meta-nitrobenzyl alcohol as the matrix. This was found to be far superior over the more common glycerol matrix. The spectra indicate that cleavages of the sulfur to carbon bond were most common. Losses were typically associated with one or two phenyl groups for the aryl sulfonium salts, and alkyl groups for salts with these groups. Using higher concentrations of the salts in the matrix produces the cluster ions CAC* or CACAC*.

An intriguing example of the sulfonium salt FAB spectra is given in Figure 2. It is a doubly charged salt with a dication observed at m/z 278. The mass at m/z 701 is the cluster ion formed by two cations and one anion. Loss of a phenyl group and an anion from the cluster ion forms the fragment at m/z 479. A minimized stereostructure of the doubly charged salt as calculated by MOPAC is given in Figure 3.

The sulfonium salts presented here all provide excellent quality mass spectra. For singly charged salts, the intact cation is the dominant species in the spectra. Fragmentation of the salts is centered about simple cleavages of the sulfur-carbon bonds. Semiempirical calculations confirm the preferential breakage of weaker (longer) bonds which form the fragment ions observed in the spectra.

DEVELOPMENT OF ABSTRACT FACTOR ANALYSIS TOOLS IN A WORKSTATION ENVIRONMENT: THE ROLE OF SUBSTITUENT PROTON TRANSFER IN THE ORTHO EFFECT

Aubrey McIntosh and Jennifer Brodbelt
Department of Chemistry, University of Texas, Austin, TX 78712

Harrison has published a series of papers on the fragmentation pathways of benzoic acids and related compounds. In these studies, he mentions that proton donation by the o-amine and o-hydroxy substituents clearly account for exaggerated dehydration/decarboxylation ratios of those compounds. Curiously, the o-ido compound shows a similarly significant dehydration/decarboxylation ratio. Weisz, Andrzejewski and Mandelbaum demonstrated the significant involvement of substituents in the dehydration of 2-haloresorcinols under electron impact conditions. This suggests that the exceptionally high dehydration/decarboxylation of the o-ido benzoic acid may be mediated by proton donation from the iodo substituent. We are developing tools to predict these fragmentation patterns. In general, Hammett substituent effect correlations would be expected to predict these ratios.

Application of the Hammett substituent effect formalism has long been used in rational molecule design, quantitative structural activity relationship studies (QSAR) and explanation of mass spectrometry fragmentation patterns. The Hammett formalism has steadily evolved from the original correlations between pH values of substituted benzoic acids and target reaction rates. Saponification rates of methyl benzoates, and hydrolysis rates of benzyl chlorides were also used to correlate experimental values. Later studies separated the meta and para substituent values into different families of sigma values. Many studies have investigated the linear relationship between various sigma values and mass-mass spectrometry peak intensity ratios, NMR shift values, photo-ionization energies and other laboratory quantities. Experience with the Hammett formalism revealed that there were actually independent, additive effects. Saturated and aromatic molecules typically revealed these differences more clearly, and the strongest two effects are called field and resonance effects. Taft and others realized that a better form of the Hammett equation required inclusion of these effects in the equation.

$\ln \left( \frac{k}{k_0} \right) = C_F \cdot F + C_R \cdot R$

Swain and Lupton published a seminal work gathering the hundreds of lab values used for the various families of sigma values. By treating these with statistical methods, they defined field and resonance values, F and R, which represented the body of Hammett substituent constants. Linear transformations of this form are more easily recognized when they are represented as a rotation of a two dimensional object, such as a polygon made of the body of data points. Cursory analysis of the literature values for dehydration/decarboxylation values of substituted benzoic acids under various CIMS conditions suggested that there was indeed an underlying two dimensional linear transformation, where the classical one dimensional transformation is not present. We have developed abstract factor analysis tools to correlate substituent effects in mass spectral data.

Factor analysis is the tool of choice to determine how many dimensions are in fact necessary to represent a chemical problem to the limit of experimental error. The simplest form, abstract factor analysis, yields a set of numbers which describe the system, but which in themselves do not necessarily offer chemical insight. Target factor analysis is the more subjective area where actual chemical measurements, such as photoelectron spectral data, $^{13}C$MR shifts, proton affinities, Swain and Lupton F & R values or other measurements are identified as predicting the current laboratory data. Additional uses of factor analysis in chemistry include the identification of the number and spectra of absorbing species in UV-VIS spectroscopy, and identification and isolation of mass spectra from incompletely resolved gas chromatography - mass spectrometry chromatograms.

Recognizing the pivotal role of factor analysis to perform tasks in the mass spectrometry lab ranging
from the routine manipulation of mass spectrometry chromatogram data to the fundamental investigation of substituent effects and their mechanistic implications, we have developed computer software that runs in a highly interactive, mouse based graphically intensive environment. The library supporting this effort was modularly designed, and a portion is separately available as Real number and Matrix arithmetic applications. These applications incorporate correct management of significant digits, incorporation of comments and a prose text appendix to matrix data files. The overall emphasis in this library is ease of preparation, interpretation, and use of data sets by people. The initial use of factor analysis in our lab is the investigation of the ortho effect, beginning with the well studied hydrogen and methane chemical ionization mass spectra of ring substituted benzoic acids.

The central software is now finished, and benchmark studies are being performed on various literature data sets to gain experience. Surprisingly, this benchmark data is not from mass spectrometry. Carbon-13 NMR shifts are well studied, and to the first approximation the changes in the shifts upon substitution are additive. The chemical shift value appears to correlate with the Hammett substituent constants. Theoretical work, from second order perturbation theory, predicts that the chemical shift will correlate with the electron density at the nucleus. The shifts of the substituted carbon appear to vary with solution pH in a pattern consistent to the dehydration/decarboxylation ratio changes under chemical ionization mass spec. The NMR shifts for a family of substituted benzenes, including benzoic acids, was examined with the factor analysis software. This analysis gave good results. Although the literature benzoic acid data was sparse, and used hydrazine adducts and ammonium salts, shift values were easily assigned based on these predictions. The table below shows these rough predictions, and our assigned spectra. After the ambiguous assignments were resolved, the difference between lab values and the predicted values was typically within a ppm.

We have developed powerful, deeply interactive, environment to evaluate various linear models explaining substituent effects in mass spectrometry. This environment is a springboard toward applications as diverse as evaluating the origins of the ortho effect and developing spectral purification software.

Initial Predictions:

The benzene values were supplied in the original data sets, the others were fixed. The ortho compound was the hydrazine adduct. The benzene acid value is from Irk Jankowski. This is used as an initial guide to assign the shifts to data spectra.
Tandem mass spectrometry (MS/MS) has proven to be a powerful analytical tool for both complex mixture analysis and structure elucidation of unknown compounds.

We applied a newly designed instrument control language (ICL™) to the automation of a GC/MS/MS system of BEQ geometry (Fig. 1). Hybrid MS/MS instruments (BEQ, EBQ or EBEQ) combine the versatility of double focusing magnetic sector instruments (e.g. high resolution, high mass) with the simplicity of quadrupole instruments (ease of operation). However, since these two parts are based on significantly different physical principles, hybrid instruments require precise tuning and sophisticated coordination of their operations for optimum performance. Now, the new completely automated design of the BEQ makes this combination of the high resolution magnetic sector and the quadrupole mass analyzer far more routine than previous systems.

The ion source tuning and the setup of all control voltages within the quadrupole section (Fig. 1) are automatically optimized and implemented by routines implemented within the user interface (Fig. 2). Figure 3 displays an ICL routine written to automatically acquire the daughter ion MS/MS spectra of five different precursor ions. The chromatogram of this GC/MS/MS experiment is shown in Fig. 4. Other subroutines such as RETTIME and RETINI allow the automated precursor ion selection to be extended to quite complex samples with many selected precursors. The maximum switch-over-time between two precursors is less than 1 second. This allows the analyst to prepare mass menus with as many as 32 different precursor ions per time window, with each time window being less than 1 minute. Typical mass values monitored could range from 20 to 500 daltons. In addition, the flexible interface offers the user the option of selecting different MS/MS experiments within a given chromatographic run.

Thus, the application of ICL to the operation of a hybrid mass spectrometer of BEQ design combines the highest degree of analytical flexibility with simplicity and reproducibility of instrument operation.

INTRODUCTION

Quantitation of mass spectral data presents a wide range of computational requirements, including the proper handling of a large variety of data types, targetting protocols, calibration methods, report formats and even terminologies.

This paper describes a computer program, OpusQuan, which embraces all known types of quantitation calculations and which is conveniently driven by means of user defined forms for all input and output requirements.

Although designed to operate with a commercial data system, it has now been extended to accept input in the form of a generic ASCII peak list containing the minimum information of mass, retention time, and intensity.

GENERAL

Figure 1) shows the general relationship of OpusQuan to its processing environment.

- When used in conjunction with the commercial OPUS system, OpusQuan performs all the operations of chromatogram generation, peak detection and Integration, targetting and quantitative calculations. These operations are performed interactively, or in background (batch processing) mode with the Opus File Services (OFS) utility.

- When used independently to process ASCII peak lists, the parameter set is much smaller, as no peak detection is to be performed, but with no reduction in the targetting or calculation flexibility.

CONSIDERATIONS

A major step in the generalization of a quantitation package is to reduce to a manageable number the terms used to describe the various components in a quantitation mixture. Typically, reference is made to one, or more, of the following: Unknown; Analyte; Internal Standard; External Standard; Surrogate Standard; Recovery Standard; Standard Standard; Clean-up Standard; Retention Standard; etc.

OpusQuan 'knows' of only 3 component types, namely: Analyte; Standard; 'Super' Standard, but will apply the appropriate calculations to provide the conventionally accepted responses to all of the above. This is achieved by means of a self evident context within a table and the value of 2 parameters associated with each component. The hierarchy for Calibration and Quantitation calculations is depicted in Figure 2).
Historically, the calculations for any particular analyte have been defined by the type of standard(s) to which it is referenced, producing a seemingly large number of calibration and quantitation methods.

We believe that in essence there are in fact only 4 such methods, as illustrated in Figure 2).

Each analyte is referenced to one or more standards; these standards are not given special names. Instead, the method to be used is defined by 2 yes/no keywords.

Thus, for example, when calculating the recovery of surrogate standards, the surrogate standard becomes an 'analyte' and its internal standard becomes a 'standard'.

TARGETTING CRITERIA

OpusQuan locates targetted components on the basis of:

- A primary ion mass
- A Retention Time 'window'
- The relative abundance AND retention time of any number of additional ions

There are parameters for flagging, but still using, the response of components which may fall either the Relative Abundance or Retention Time alignment criteria.

The response of a component may optionally be defined to be the sum of the responses of all targetted ions, or simply the response of the Primary ion.

TOTALS

The total response of a homologous series may be reported, together with a 'maximum possible' amount, for any homolog falling the relative abundance criteria. This facility is particularly applicable to simple applications.

FORMS

All parameters and results for each analyte are stored in a database. The forms facility allows any item from this database to be displayed, and reported in a user specified position and format.

For example, one form may be designed to display selected parameters from the database on the basis of 1 row per analyte, whilst an alternative form could display all the parameters for an analyte on a 1 page per analyte basis.

CALIBRATION METHODS

The calibration methods available are:

- Curve Types: Mean; Linear; Exponential; Logarithmic; Quadratic; Inverse Quadratic; Piece-wise Linear.
- Origin Treatment: Force; Include; Ignore
Mass spectral libraries represent major time and resource investments for most laboratories. To change instruments usually means starting all over again, especially if these are made by different manufacturers. A new JCAMP-DX mass spectral data exchange file format is being developed in cooperation between Finnigan, VG, Hewlett-Packard and other manufacturers. It is capable of data exchange between different computer platforms. Unlike an older EPA format, the new JCAMP-DX is capable of exchanging a wide variety of data, including high resolution and high molecular weight mass spectra. It is also in an ASCII format, but file structure rules are not as strict as with the older EPA standard. All the necessary information for mass spectral libraries transfer is available in the new format and is therefore suitable for a library transport. We have recently acquired VG Analytical Autospec Q and succeeded in transferring the specialized toxicological (TX) and general purpose (GP) mass spectral libraries from Finnigan INCOS format to the VG OPUS format. The Finnigan INCOS library editor program (EDLB.MS) data were sent to a computer terminal screen through a short procedure. An IBM PC compatible computer was used as a terminal and was running a terminal emulation program (eg. Smarterm 240 or EM4010). The data were captured by the terminal emulation program into an ASCII file on a PC hard disk. An application program was written in Quick BASIC (GCMS.EXE, released to public domain) and was utilized to convert the data to a JCAMP-DX format in a new file. This program is also capable of reading/writing EPA and Finnigan ITDS data files and creating HPGL files for plotting on HP and compatible plotters or export to desktop publishing programs. JCAMP-DX files were sent from an IBM PC compatible microcomputer using the same terminal emulation program, utilizing the Kermit file transfer protocol. IBM PC compatible was connected through a RS-232C serial port to the DEC VAX station 3100 running VMS and VG OPUS software. The OPUS SPECBASE program is capable of reading in the JCAMP-DX ASCII file and converting the data to searchable libraries. (Both the GCMS.EXE program and mass spectral libraries are available from the author.)
Chemstation macros have been written for the transfer of S.I.M. or T.I.C. data from the Pascal 3.2 or UNIX-based MSD chemstations to a centralized Vax minicomputer. These macros are run during data acquisition, or postanalysis in a batch mode. The macros begin by sending the text string "START_OF_FILE XYZ" out the serial port of the chemstation (where XYZ are the user's initials). The time/abundance data for a given ion is then sent out the serial port, followed by the text string "END_OF_FILE".

On the Vax, BASIC programs are running continuously to read data being sent from any MSD chemstation connected via a serial port. Upon receipt of the string "START_OF_FILE" the BASIC program opens a file and stores the subsequent time/abundance data for a given ion to an ASCII file. The file is closed upon receipt of the string "END_OF_FILE". The time/abundance data in this initial file is then interpolated from the Hewlett Packard variable time intervals to a constant time interval format, required for the P.E. Nelson ACCESS*CHROM data files. Finally, the interpolated ASCII file is converted to the binary .RAW file type used in ACCESS*CHROM. This final file is stored in XYZ user's Vax directory. The original time and date of analysis are transferred with the raw data and are found in the sample name field of the final .RAW file.

Files created on the Vax by this procedure are sequentially numbered with the following format: XYZ_DATE_001.RAW. A list of files successfully transferred by this procedure is stored as an ASCII .LOG file in the user's directory. The final three digits of the Vax file are reset to 001, and a new .LOG file created, whenever two hours elapse between file transfers or if the initials of the user change.

**FLOWCHART OF MSD -> VAX DATA TRANSFER AND INTERPOLATION**

MSD

- MSD S.I.M. OR T.I.C. TIME/ABUNDANCE OUTPUT

VAX

- PROGRAM ON THE VAX READS AND STORES MSD DATA INTO THE ASCII FILE "XYZ_DATE_001.MSD".

- CONVERSION PROGRAM ON THE VAX CONVERTS AND INTERPOLATES "XYZ_DATE_001.MSD" FILE TO A "XYZ_DATE_001.RAX" ASCII FILE.

- COMMAND FILE ON THE VAX CONVERTS THE "XYZ_DATE_001 RAX" ASCII FILE INTO THE BINARY "XYZ_DATE_001.RAW" FILE. THE CONVERSION IS "LOGGED" AND THE TWO ASCII FILES DELETED.
DATA TRANSFER FROM A DEC PDP-11 BASED MS DATA STATION TO A MS-DOS PERSONAL COMPUTER.

The modern instrumentation for mass spectrometry is getting better and better, both considering the measurement hardware and the data stations. The software for data acquisition and reduction, as well as for the management of all the instrumental parameters allows nowadays a very easy operation of the machines. On the contrary, very little effort has been devoted to give the possibility to get good quality graphic presentation of data. Most MS data systems are equipped indeed with low density 9 pin matrix printers, and the software, usually, does not even provide the correct drivers for high quality laser printers or pen plotters.

We report here about the preparation of good quality graphic outputs from a NERMAG R3010 mass spectrometer equipped with a DEC PDP-11/73 based data station, using "KERMIT" to transfer files to an IBM compatible computer (Figure 1).

As the software of this machine (SIDAR) is not able to generate ASCII tables for chromatograms and spectra, we recovered them from the printer dump files generated on the disk when the printer is set off line, as these files can be handled as normal files. KERMIT can transfer the ASCII tables obtained to a personal computer. KERMIT can transfer binary files as well, but, of course, this can be useful only if a suitable software for their elaboration is available on the PC. The ASCII table can be then imported and elaborated using one of the powerful tools available for MS-DOS computers. In particular, the graphic output can be generated by the use of a simple spreadsheet (we used Borland Quattro Pro 1.0) or a presentation graphic program (we used Harvard Graphics 2.12). The main advantage of these programs is the possibility to customize
the format of the plot, also by text and graphic annotation. Moreover the final result can be sent to plotters or laser printers or exported to word processors such as Microsoft Word 5.

The method has been tested also on a VG 70-70E equipped with a DEC PDP-11/23 based data station. The software in this case is able to generate directly ASCII tables, but only for spectra, whereas it was not possible to handle chromatograms.

In Figures 2 and 3 are reported two examples of customized plots of one chromatogram and one spectrum, respectively.

USE OF A NETWORK-BASED LIMS SYSTEM TO AID IN
QUALITY ASSURANCE OF ENVIRONMENTAL GC/MS DATA

D. Thomas Terwilliger and Ann L. Behbehani, Computer Sciences Corporation
William L. Budde, U.S. Environmental Protection Agency
Cincinnati, Ohio 45268

The E.P.A. is responsible for analyzing, evaluating, and interpreting enormous quantities of environmental monitoring data, much of which is quantitative GC/MS analyses of hazardous substances. Samples are collected in the field and analysed for a known list of "target" compounds. This analysis procedure involves multi-level calibrations, use of surrogate and internal standard compounds, and a substantial level of additional QC. The goal of this procedure is to obtain a quantitative estimate of the amount of each "target" compound present in the original sample.

The data analysis process has been automated previously. GC/MS software is available to operate directly on laboratory instrument computers or attached PC's which processes data obtained by the instrumentation software. We have recently installed a PC-based Laboratory Information Management System (LIMS) to aid in further data evaluation and interpretation. The laboratory software performs all quantitation calculations, converts all results to the proper units, and performs all "bench-level" QC to aid the analyst in assessing data quality. The end result of this software is the creation of a data file according to the EPA Standard Format for Data Transmission of Laboratory Results (Dec. 1987) which can be transferred to a LIMS system or other central data repository. This file includes all final results together with sample documentation, intermediate values, and an assortment of flags and check fields necessary to prevent and/or detect unauthorized manipulation of data. This system allows the LIMS to replace most uses of instrument-generated hard-copy output.

The LIMS system is currently operational on our building-wide Local Area Network (LAN) so access is available to all laboratory personnel. This LAN connects most projects located throughout EPA's Cincinnati facility and is constantly being expanded. Currently there are nine separate network rings connected by a building-wide "backbone". There are also connections to other nearby EPA facilities in the Cincinnati area as well as provisions for accessing central EPA computers in Washington and Research Triangle Park, NC. This provides access to all necessary personnel from log-in clerks and GC/MS operators to lab managers and quality assurance officers. Clients could also be tied in to the system directly if desired.

The LIMS system provides full tracking of all samples analyzed from receipt to final dissemination of results. Samples are logged in by the clerk as they are received and assigned an order number which is used to track the sample throughout the laboratory. Tests are assigned and service groups identified. This allows the laboratory manager to have immediate access to the status of all samples currently being processed. Schedules are determined for each instrument based on numbers of samples and required due dates.

All instrumentation is being interfaced directly to the LIMS via the LAN so data can be transferred directly from the instrument data system to the LIMS. Prior to loading any data into the LIMS, it is essential that data be fully reviewed by the analyst. The above-mentioned software has been installed on all GC/MS systems to assist the analyst in this review and QC verification. Required laboratory QC might include duplicate analyses, use of matrix spiking solutions, addition of surrogate compounds to each sample, and periodic analyses of blanks, calibrations, and tuning compounds. Checks may also be made on peak areas and retention times of key compounds. In addition, all results must be compared to the valid calibration range and sample-wide parameters such as the elapsed time between sampling and analysis must be checked.
This software has been used in other laboratories for five years. It has been designed in a generic "method-independent" manner and will interface to most if not all commercially available GC/MS systems as well as some GC/EC systems. At the conclusion of this process the software transmits all results to the LIMS in the above mentioned EPA Standard Format. This avoids hand-transcription of results thus streamlining operations and preventing errors from occurring. We have also purchased software for inorganics instrumentation (AA, ICP, etc.), but this has not yet been tested. This software, like the GC/MS software, will automatically collect data from instruments, provide reports and QC checks, and produce a file in the EPA Standard Format.

A program has been written to transfer any instrument results presented in this Standard Format to our LIMS. It operates by reading the Standard Format File, parsing each line into a temporary data base, and then transferring the necessary fields into the appropriate places within the LIMS. All required completion flags must be set within the LIMS to indicate that the results have been entered. The initial version of this program is operational, but modifications are needed in order to capture all QC data and direct it to the appropriate place within the LIMS.

Programs are also available within the LIMS system to allow managers to review data and evaluate results. A wide variety of reports, each of which can be customized easily, can be generated. We are currently working on client reports for final results for one of the tests. Ultimately, all client reports will be generated directly on the LIMS.

Other functions within the LIMS maintain audit trails of all critical operations and make long-term assessments of laboratory QC. While the analyst will always perform all required bench-level QC, the LIMS will track long-term performance. This is useful for establishing control limits on key instrument parameters as well as monitoring laboratory performance and generating instrument control charts. The LIMS could also schedule instrument maintenance by using the above data. In addition, clients could be given direct access to the LIMS data so they could verify field QC automatically. As an example, two samples submitted as unrelated "unknowns" to the laboratory might in fact be aliquots of the same sample (field duplicates). The client could use the LIMS to calculate percent differences for each measured concentration thus verifying laboratory reproducibility. Other client uses might include the preparation of site evaluation reports and/or maps.

The LIMS also has administrative roles. It can provide management and clients with sample tracking reports as well as manage laboratory finances. Invoices can be prepared automatically and cost estimates generated for new work. Each test can be assigned a cost, and each client given a discount rate, so totals can be automatically computed.

Much work remains to be done. We are currently logging in all samples as received, and the GC/MS laboratories are almost ready to transfer all results to the LIMS using the above-mentioned software. We have just begun to define the QC requirements and set up data base structures to fulfill these needs. Other instrumentation, such as inorganic and biological analyses have yet to be interfaced.

The ultimate goal of this work is to provide a paper-free method of operation, where results can be evaluated quickly and accurately, and then transferred directly to clients in a timely manner. It is hoped that by use of the EPA Standard Format for Data Transmission, all EPA monitoring programs can be linked together with data being shared between them. State and Local agencies should also participate. This system is intended to serve as a prototype of how the above goals might be accomplished. We have already worked with the State of Ohio and hope to expand these contacts considerably in the future.
Sample Matrix Subtraction in Full-Scan Gas Chromatography/Mass Spectrometry

G. F. Holer; Organic Section, Public Health Laboratories
Arkansas Department of Health, Little Rock, Arkansas 72205

One function of our gas chromatography/mass spectrometry (GC/MS) laboratory is to identify analytes which have been detected by gas chromatographic systems. These GC systems usually use electron capture (EC) detectors, and the sensitivities of these detectors are obviously different than those of the mass spectrometer: non-electron-capturing species are not seen by the EC, but are seen by the mass spectrometer, and the response of electron-capturing species is proportionately greater with the EC than with the GC/MS. In addition, EC-GC conditions are frequently different from those of GC/MS, involving dissimilar columns and conditions. The result of all this is that it is difficult to correlate EC-GC peaks with GC/MS peaks.

Figure 1a shows a full-scan GC/MS chromatogram of a concentrated milk extract. The EC trace (not shown) of the same extract shows almost a flat baseline, with a few very small peaks. The GC/MS sees many fatty acids, which are not seen by the EC. The mass spectrometrist can waste time on these "matrix" peaks, which have nothing to do with the analytes he or she is asked to confirm or identify.

An important feature of the milk extracts is that the matrix peaks are part of the nature of the extract; they almost always show up on the GC/MS trace, though in varying proportions. It dawned on us that we could get rid of matrix peaks by subtracting their spectra from the corresponding spectra of a sample.

A computer program was written to subtract matrix peaks from a sample extract total-ion-current (TIC) chromatogram. The program subtracts spectral intensities of a blank matrix extract from those of a sample extract. Refer to Figures 1, 2, and 3. Figure 1a shows a TIC chromatogram of a milk extract containing six pesticides. Figure 2a shows a TIC chromatogram of a milk blank extract (no pesticides). Figures 1b and 2b are spectra of scan 415 of the TIC chromatograms shown in Figures 1a and 2a, respectively. Figure 3b is the spectrum of Figure 1b minus that of Figure 2b. The subtracted spectra are joined to create a new TIC chromatogram, shown in Figure 3a; note that only the pesticide peaks remain.

Spectral subtraction proceeds as follows. For each scan, the intensities of the matrix spectrum are subtracted from those of the sample spectrum. If the net is less than zero, it is set to zero. Figures 4a-4c compare the performance of matrix subtraction to that of background subtraction (part of the mass spectral data system). Figure 4a is the sum of spectra 841-846 (which is that of p,p'-DDE) from the TIC chromatogram shown in Figure 1a. Figure 4b is the spectrum obtained using background (i.e., on one side of the peak) subtraction. Figure 4c shows the sum of spectra 841-846 of the matrix-subtracted TIC chromatogram (Figure 3a).

It is important that the blank (matrix) concentration be greater than that of the sample (to make sure that the matrix intensities are larger than corresponding intensities of the sample, so that the net intensities will be set to zero). Figure 5a shows a matrix-subtracted TIC chromatogram using a matrix concentration equal to the sample concentration. Figure 5b shows a matrix-subtracted TIC chromatogram using a matrix concentration 1.5 times that of the sample concentration. Figure 5c shows a matrix-subtracted TIC chromatogram using a matrix concentration 3 times that of the sample concentration.

The computer program runs on an IBM-compatible PC, and uses Nermag’s Spectral 30 mass spectrometer data file format specifically.
Gelatin Films as Standards for Quantitative Molecular SIMS Analysis of Biological Tissue

Greg Gillen
Surface and Microanalysis Science Division
National Institute of Standards and Technology, Gaithersburg, MD 20899

Analysis of physiologically important molecules in biological tissue by secondary ion mass spectrometry (SIMS) has become an area of much interest in recent years. In any quantitative SIMS experiment, the presence of matrix effects requires the use of standards that have a matrix composition similar to that of the unknown. In the case of biological tissues, such standards are not generally available. One potential approach, often used for elemental analysis of biological tissue, is to use doped gelatin or Epon plastic as standards (1,2,3). Gelatin has several advantages; its elemental composition is similar to that of tissue, it is compatible with the high vacuum of the SIMS instrument, and it is easily doped with a variety of molecular species. This preliminary report addresses the potential use of gelatin films doped with molecular species as standards for organic SIMS of biological tissues. In particular, linearity and detection limits are explored for several different compound/gelatin standards. Finally, the feasibility of using gelatin films as standards for molecular imaging SIMS is discussed.

Two percent solutions of porcine gelatin A (Sigma) were prepared in distilled water at ~80°C. Stock solutions of analyte compounds were prepared and serial dilutions used to generate standards of various concentrations. Aliquots of the standard solutions were then added to the gelatin. Concentrations were calculated on the basis of dry weight for both the gelatin and analyte compounds. Compounds used in this study include acetylcholine, cocaine, epinephrine, methylene blue, tetrabutyl ammonium bromide and tetrapentyl ammonium bromide. Spin-cast doped gelatin film samples were prepared by depositing 1 drop of the gelatin/compound mixture (while still warm and not too viscous) onto a 1 cm$^2$ silicon wafer which was spinning at 12,000-15,000 rpm on a May Spinning Disk Aerosol Generator. Spin-casting of the gelatin solutions results in a homogeneous film which completely covers the substrate silicon. Film thicknesses, as measured with a surface profilometer, were found to be 30-50 nm. This was sufficiently thin to eliminate the need for charge compensation during SIMS analysis. All analyses were conducted in depth profile mode on a Cameca IMS-3F ion microscope using an 8.0 keV, 0.5 nA, Ar$^+$ primary ion beam rastered over an area of 500 μm x 500 μm with detection of positive secondary ions. With a typical analysis time of 1000 sec the primary ion dose exceeded 1x10$^{15}$ ions/cm$^2$, resulting in complete consumption/fragmentation of the analyte compounds. Working curves were constructed by taking the integrated areas under the decay curves, normalized to the matrix element carbon, and plotting them as a function of analyte concentration in units of grams of compound/grams gelatin matrix.

One of the most severe drawbacks in analyzing compounds in gelatin (and tissue) matrices is the presence of a discrete background arising from polyatomic cluster ions. This background can severely degrade detection limits for lower mass analyte compounds. The influence of this background can be seen in the mass spectrum shown in Figure 1 for a .1 gm/gm (10 wt %) acetylcholine/gelatin mixture. Even for a compound such as acetylcholine, which is considered to have a high ion yield, the detection limit range for the parent cation (m/z 146) was between .001 gm/gm (.1 wt%) and .01 gm/gm (1 wt%). Similar poor detection limits were obtained for other lower mass compounds such as epinephrine and tetrabutyl ammonium bromide.

In general, compounds with higher molecular weights gave better detection limits. Figure 2 shows the integrated signal for the protonated molecular ion of cocaine (m/z 304) vs. concentration. In this case, the detection limit was ~ 100 ppm. High secondary ion yield compounds, such as tetrabutyl and tetrapentyl ammonium bromide, gave detection limits of better than 10 ppm and linear response curves over several decades of concentration. Figure 3 shows the response of the tetrapentyl ammonium cation (m/z 298) vs. concentration (this particular data was acquired using a CCD camera in imaging mode as discussed below). A summary of the preliminary detection limit ranges for the various compounds studied is given in Table 1.

A major difficulty with the analysis of compounds in the gelatin matrix is that the precision is rather poor. Replicate analyses conducted on tetrapentyl ammonium bromide resulted in a typical standard deviation for a single measurement of 20-70%. Because the analytical signal decays rapidly in these experiments, missing the first few channels of the signal decay curve (where the signal is the highest), can introduce a significant error in the area calculation. This is a particular problem when using the ion microscope because there is a noticeable background when the primary ion beam is off the sample. This can result in appreciable damage to the sample between replicate analyses. The result is that initial count rates for the analyte compound generally decreased between subsequent analyses even though supposedly virgin areas of the sample were examined. Preliminary experiments with a ToF SIMS instrument would appear to be promising for improving this particular problem.
appear to give much more precise results. We are currently evaluating the relative merits of the two approaches.

It is interesting to note that there is a saturation in signal for the higher concentrations of the tetrapentyl ammonium bromide which is not seen for the cocaine (preformed molecular ion vs. protonated molecular ion). For tetrapentyl ammonium bromide, the fall off may be due to a higher probability for renutralization with increasing counter ion concentration (a similar saturation in signal has been observed for other tetraalkyl ammonim salts and methylene blue). The observation of molecular matrix effects suggests that care will have to be taken in the interpretation of quantitative data from real samples in which localized analyte molecular concentrations (or localized counter ion concentrations) may result in smaller secondary ion signals than from adjacent regions where the true concentration is actually lower. Clearly, it will be necessary to study these effects in more detail. A summary of preliminary detection limit ranges for the various compounds studied is given in Table 1.

In addition to bulk analysis, the homogeneity of the doped spin-cast films makes them ideal as standards for quantitative molecular imaging SIMS studies. As was shown in Figure 3, using a slow-scan CCD camera, a tetrapentyl/gelatin standard was analyzed using this imaging system as the primary detector. Signal intensities were determined by integrating the total secondary ion counts in each image. Because of its high linearity and high dynamic range, the CCD camera is ideally suited for these studies and linear working curves were obtained over a concentration range of $2 \times 10^{-5}$ gm/gm to .02 gm/gm.

STATIC SIMS ORGANIC SURFACE ANALYSIS OF ELECTRONIC-GRADE GLASSY MATERIALS

Bryan L. Bentz
David Sarnoff Research Center, CN 5300, Princeton, NJ 08543-5300

Static SIMS studies have been undertaken to probe the molecular structural composition of solid surfaces of several classes of glassy materials used in the electronics industry. Because of their unique thermal, electrical, and mechanical properties, glassy materials are widely used in this industry for a number of varied applications, such as panels in display devices and as dielectrics in integrated circuit metal systems.

Low dose SIMS experiments of these insulator-type materials were conducted using a picoampere level, 3 keV neutral primary beam (xenon) on the triple stage quadrupole-based static SIMS instrument developed at the David Sarnoff Research Center. Mass spectral data were acquired over a one minute accumulation time. Charging of the samples did not appear to be severe in our experiments.

1000Å films of methyl polysiloxane type spin-on-glasses (SOG), used in dielectric planarization schemes, were studied to determine the identity and quantity of organics in solid films prepared using various conditions of heat curing. The SOG, once deposited and cured, has electrical characteristics very much like SiO₂. Large differences in the apparent methyl (-CH₃) content of the films were observed by SIMS among films cured under different conditions. Additionally, we studied so-called plasma converted SOG films. Data illustrating some of our findings from these experiments are presented in the table shown below. The SIMS data suggest that the increase in film dielectric strength upon oxygen plasma treatment is related to an increase in the hydroxyl and carbon (hydrocarbon) content of the films.

Work using derivatization reagents is currently underway to investigate the extent of hydroxyl/silanol groups on the surface of spin-on-glasses. For example, Figure 1 presents static SIMS spectra showing the effect of exposing a film of cured spin-on-glass to vapor of hexamethyldisilazane (HMDS). Results obtained to date indicate that the monolayer surface sensitivity and molecular specificity of static Organic SIMS can be employed in surface derivatization schemes to characterize the surfaces of spin-on-glasses.

STATIC SIMS ANALYSIS OF SURFACE OF AN SOG FILM
POSITIVE ION DETECTION

Derivatization of Si-OH groups to form Si-O-Si(CH₃)₃
FAB/MS CHARACTERIZATION OF SULFONE ETHER DIAMINE PREPOLYMERS.
John M. Ballard, Hoechst Celanese Research Division, Summit, NJ 07901.

INTRODUCTION
Gel permeation chromatography of some sulfone ether diamine (SED) prepolymers showed that they were mixtures but the molecular weight estimations were not sufficiently accurate to enable the chemical composition of individual components to be determined. Low resolution FAB/MS has provided confirmation of the preparation of the synthetic objectives and larger oligomers.

EXPERIMENTAL
SED prepolymers (provided by Dr. E. Choe) were prepared by the condensation of an aromatic dihydroxy compound (A) with 4,4'-dichlorodiphenylsulfone (B) in a 1:2 molar ratio, followed by treatment with two equivalents of the sodium salt of m-aminophenol (C) to yield the prepolymer. Samples dissolved in m-nitrobenzyl alcohol were ionized by a xenon beam from an Ion Tech atom gun operated at 8keV and 1mA emission current. Positive ion mass spectra (m/z 400-4000/3.6 sec.) were recorded on a VG Trio-3 triple quadrupole mass spectrometer. CAD spectra were generated at a collision energy of 7eV using argon at a pressure of approximately 1 x 10^-9 barr.

RESULTS AND DISCUSSION
When the aromatic dihydroxy compound is 4,4'-biphenol, the synthetic objective (BPSED) has the structure (NH2)CB(AB)C(NH-) with mol.wt. 832.19 for n=1. The full-scan mass spectrum of "BPSED showed an ion series of diminishing intensity at m/z 434, 834, 1233 and 1632. The 400 dalton differences above m/z 834 correspond to the oligomeric series where n=2,3 and 4 respectively, due to incorporation of extra (AB) units. The ion at m/z 434 is assigned to the product where n=0 and indicates the presence of free 4,4'-dichlorodiphenylsulfone in the intermediate (not isolated) product. The data system had centroided some ions at [M+2H]^+ and some at [M+H]^+. However, when limited-scan spectra were acquired at a higher resolution in the MCA mode, the molecular ion regions at m/z 434, 834 and 1233 each gave isotopic profiles in which Peak A is due to the M^+ ion (Fig.1). The observed relative peak intensities are significantly different from those calculated using the given molecular formula. In each case, the observed isotopic pattern is a composite of overlapping patterns due to M^+ and [M+H]^+ ions. The patterns observed at the m/z 432, 832 and 1232 molecular ion regions can be approximated by M^+:[M+H]^+ ratios of 10:7, 5:4 and 5:6, respectively, (Table 1). Although the occurrence of oxidation and reduction processes during FAB/MS has been widely reported (1,2) there was no evidence of enhanced [M+2H]^+ abundance. Similar results were obtained from the prepolymers, 6F-BPASED and BPASED, synthesized using (4,4'-hexafluoro-isopropylidene)-diphenol and 4,4'-isopropyliddenediphenol, respectively as the aromatic dihydroxy compound. The high intensity of the M^+ ions observed here implies a relatively low ionisation potential for these prepolymers (3,4).

MS/MS Experiments
Because of the low absolute intensity of the molecular ion signal, quadrupole Q1 was fully deresolved in order to maximize the transmission of the molecular envelope into the collision cell; the parent ion was therefore a mixture of M^+ and [M+H]^+ together with some 12C and 13C isotopic contributions. CAD spectra were recorded in the MCA mode at a resolution of 200 (at m/z 912) in quadrupole Q3. The m/z 834 molecular ion region of BPSED gave four major ions at m/z 585, 494, 248 and 185 whose
assignments are consistent (within the constraints of low resolution) with the structure of the prepolymer (see Table 4). Similar results were obtained for BPASED and 6F-BPASED.

CONCLUSIONS

FAB/MS and MS/MS has proved effective for the characterization of low-to-medium molecular weight oligomeric mixtures of the type described. A fast-scanning data acquisition under low resolution to maximize signal intensity is adequate for most purposes. The following information can usually be derived: 1) whether the synthetic objective has been prepared, 2) whether intermediates are still present, and 3) whether competing side-reactions have occurred.

Abstract

Temperature programmed desorption mass spectrometry (TPD/MS) studies have been performed using organic compounds condensed on a heatable/coolable stainless steel probe in order to learn about their useful lifetimes and stabilities at temperatures and in vacuum environments typically used in fast atom bombardment mass spectrometry (FABMS) of organic samples. Glycerol, 3-nitrobenzyl alcohol, thioglycerol, triethanolamine, and a 3:1 mixture of dithiorthreitol and dithioerythritol ("magic bullet") were chosen for study since they are commonly used as matrix compounds in FABMS.

For all matrix compounds studied, molecular species (M^+ and [M + H]^+) desorb within a relatively narrow temperature range. The desorption peak temperature is unique for each matrix. For some matrix compounds, however, additional species desorb which can only be formed by the dehydrolysis or decomposition of the compound.

These results suggest that for each matrix compound used in FABMS an optimum useful temperature range can be defined. The ultimate performance of each matrix, however, may also be affected by the thermal stability, which varies widely for the compounds studied in this work.
Summary

In this study, several matrix compounds commonly used in FABMS analysis of organic compounds have been studied using TPD/MS. The TPD/MS technique (1,2) was used to obtain information on the stability and lifetime of these matrices under conditions similar to those used in FABMS analysis (3-5).

For some matrix compounds (for instance, glycerol, thioglycerol, and triethanolamine) dehydrolysis to form water and/or decomposition to form methanol and/or ethanol can be significant. This degradation can occur at the same temperature as that typically used in FABMS, thus interfering with the performance of the matrix. The degree of degradation can be ranked as follows:

glycerol = thioglycerol > triethanolamine > dithiothreitol/dithioerythritol
> nitrobenzyl alcohol

Thus, nitrobenzyl alcohol would be the best choice as a FABMS matrix material on the basis of its stability.

Both nitrobenzyl alcohol and thioglycerol desorb around ambient temperature (25-50°C). Glycerol and magic bullet desorb slightly above ambient temperature, while triethanolamine desorbs significantly above ambient temperature. This variability in the desorption temperatures implies that the optimum useful temperature range for each matrix compound is unique, and thus requires the ability to control the sample temperature.

THE MEASUREMENT OF WORK FUNCTIONS OF SEVERAL ALKALI ALUMINOSILICATES IN VARIOUS CHEMICAL ENVIRONMENTS

A. Patel, E. Reno, and D. Bombick
Department of Chemistry, Wright State University, Dayton, OH 45435

The immediate goal of this work was to determine the work functions of several alkali aluminosilicates in various chemical environments. These results will aid in our laboratory's long term objective of better understanding the nitrogen/phosphorus detector (NPD) used in gas chromatography. Presently, the mechanism of this detector is not clearly understood. Several key points about the detector include:

- the heart of the detector is a heated alkali aluminosilicate bead;
- the detector gives selective responses for nitrogen and phosphorus compounds;
- the flow rates of air and hydrogen are such that a true flame does not exist, and;
- the detector can detect both positive and negatively charged species.

The ionization mechanism of the NPD has yet to be fully established. Although a number of mechanisms have been proposed, they do not take into consideration all of the key points mentioned above. It is the opinion of our laboratory that the operation of the NPD is based primarily on empirical knowledge. We feel that if the mechanism of the detector was better understood improvements could be made to increase its sensitivity and selectivity.

Gas chromatographic results were obtained using a Varian 6000 gas chromatograph equipped with a NPD. The injection and column temperatures were optimized for each compound. The carrier gas flow rate was held constant at 30 mL/min of helium. The air flow rate was 180 mL/min and the hydrogen pressure was 17 psi. These conditions were determined to be the optimum for this particular NPD bead. The detector temperature was 300°C.

The work function measurements were made in a test chamber (constructed in-house) that was attached to a vacuum system. The alkali aluminosilicate was made by mixing 0.1 mole of an alkali sulfate with enough refractory cement (Dylon Industries, Grade C-10) to produce 10 grams of material. A slurry (in water) of this mixture was prepared and coated on a tungsten filament. A new filament with the same physical characteristics was used for each material. The size and shape of the coated filament was similar to those used in the NPD. An initial heating of the coated filament was done using a heat gun. Final conditioning consisted of spot-welding the coated filament to the leads of the test chamber and attaching the chamber to the vacuum system. After approximately 12 hours, the alkali aluminosilicate was conditioned by slowly heating the filament over a 4 hour period up to a temperature of 1000°C.

The emission current was measured at a pressure of 0.10 mtorr in the absence of any added sample and 220 mtorr in the presence of selected nitrogen and phosphorus compounds. The emission current was collected and measured using an electrometer. The temperature of the alkali aluminosilicate was measured using an infrared thermometer (Omega Engineering model OS1200-HAC-4-B) which was equipped with a close focus option. The emissivity was set at 0.90 which is typical of most ceramics having the same characteristics.

The following table contains an abbreviated list of nitrogen compounds used in both the NPD and the test chamber. Plotting emission current (i) as a function of 1/temperature should give a line with a slope related to the work function of the bead material. We do not make an attempt in this study to measure the work function exactly, instead we are interested in the relative changes in the slope of these plots. In this table the compounds have been normalized. The numbers in brackets under the NPD data are the response factors obtained at a bead temperature of 530°C and 675°C, respectively.

It is important to note that the relative changes in each experiment stays the same. This suggests that in both processes a similar change in work function occurs. This change, as indicated from the test chamber results, is a decrease in work function which would promote the generation of negatively charged species.

An interesting question arises concerning the need for the hydrogen/air environment for a response to be observed in the NPD. Obviously this environment is lacking in the test chamber.
under vacuum conditions. Comparing the absolute current produced at various bead temperatures suggests a possible explanation. The quantity of analyte present in the vacuum test chamber is approximately seven orders of magnitude higher than that introduced into the NPD. Even though this is true, the ion current produced in the NPD is several orders of magnitude higher than in the test chamber at approximately the same bead temperature. This suggests that the hydrogen/air environment may be necessary to promote gas phase decomposition of the analyte. In addition, the parallel behavior in work function changes indicates that ionization is most likely a surface process.

Phosphorus compounds behave differently than nitrogen compounds. From the following figure the curve for trimethyl phosphate (TMP) by itself in the test chamber indicates the work function actually increases. When air is introduced (bringing the total pressure up to 500 mtorr) the work function decreases. The behavior of phosphorus compounds in the NPD indicates a strong interaction with the surface of the alkali aluminosilicate bead even in the presence of an air/hydrogen environment. In the absence of this environment within the test chamber, phosphorus compounds may chemically alter the surface. Upon the addition of air, whatever process taking place is hindered. From this behavior we cannot rule out that decomposition of an analyte in the presence of air/hydrogen can take place on the surface of the alkali aluminosilicate material. These decomposition products may lower the work function which favors the formation of negatively charged species.

To date, our results indicate that the nitrogen/phosphorus compound may decompose either in the gas phase or on the surface of the hot bead. It appears that for most nitrogen compounds decomposition may most likely occur in the gas phase whereas for phosphorus compounds the surface plays a major role. For both nitrogen and phosphorus compounds the adsorption of decomposition products lowers the work function which favors the ionization of these species.

To date, our results indicate that the nitrogen/phosphorus compound may decompose either in the gas phase or on the surface of the hot bead. It appears that for most nitrogen compounds decomposition may most likely occur in the gas phase whereas for phosphorus compounds the surface plays a major role. For both nitrogen and phosphorus compounds the adsorption of decomposition products lowers the work function which favors the ionization of these species.
Reduction of Mass Bias Effects in Inductively Coupled Mass Spectrometer Systems

Inductively coupled plasma mass spectrometry (1,2) has become a widely used method for the determination of elemental concentrations in solutions. A wide range of elements may be covered by the technique, and detection limits in many cases are in the parts per trillion range by weight. Samples are introduced into an argon inductively coupled plasma as a fine aerosol, and ions produced in the plasma are transferred into an analysing mass spectrometer via an interface which normally consists of a series of pumps and apertures which are followed by a Bessel Box type energy analyser and matching optics. This arrangement is shown in figure 1.

Plotted on this diagram are the trajectories of ions of three different energies as calculated using SIMION (3). Energies of 0.5, 2, 12 volts have been chosen since those correspond to the energies of ions of mass 10, 40, 238 which are assumed to pass through the skimmer orifice with a velocity of $3 \times 10^5$ cm/sec. It can be seen that focusing of the ions of different energies varies considerably according to energy. This means that there is a substantial mass bias introduced by this form of transfer optics. A further effect which must be considered is the space charge spreading of the ion beam as it travels through the low voltage region of space behind the skimmer. Since all ions are travelling with approximately the same axial velocity, and transverse acceleration $\frac{e}{m}$ spreading will be greatest for those ions of lightest mass.

Again, this can be modelled by SIMION by calculating the space charge potential due to a column of charge emanating from the rear of the skimmer cone. The results of this calculation are shown in figure 2. Again the overall effect is to produce a significant mass bias for the transfer function into the mass analyser.

The object of the centre stop in the lens system is not only to function as the central part of the Bessel filter, but also to stop photons and neutral particles travelling into the collector region of the mass filter and producing an undesirable background signal. An arrangement which also produces the required blocking features is shown in figure 3.
The plasma/vacuum interface is treated as a conventional ion source (such as a duoplasmatron) and a conical acceleration electrode is used immediately behind the skimmer cone. A voltage of typically 2kV-ve is used on this element, whilst focusing and deflection are controlled by subsequent components of the ion optical system. Trajectories are shown again for ions having energies of 0.5, 2, 12 volts, and it can be seen that the chromatic properties of this transfer lens are very much better than those of figure 1. Space charge effects are also minimised using the high voltage transfer lens approach. Direct line of sight from the sampling interface into the quadrupole is avoided, whilst the central part of the ion beam, previously blocked off by the Bessel Box arrangement, is available for mass analysis. The resulting system has:

a) LOW MASS BIAS  
b) HIGH TRANSMISSION  
c) LOW BACKGROUND

The mass bias as a function of mass is shown in figure 4 and is compared with that of a Bessel Box type transfer system.

AUTOMATED ANALYSIS OF \(^{13}\text{N}\) and \(^{12}\text{C}\) FROM THE SAME SAMPLE: A New Interface for Stable Isotope Ratio MS

B. Fry\(^1\), F. J. Mersch\(^2\), W. A. Brand\(^3\),

\(^1\) Marine Biological Laboratories, Woods Hole, Mas 2543
\(^2\) Finnigan MAT, Barkhausenstr. 2, 2800 Bremen, Germany

The variation of isotope abundances in nature is small. For \(^{12}\text{C}\) and \(^{13}\text{N}\) in particular, any method to study this variation needs a measurement precision of the order of 0.1 permil (8-notation: 
\[ \delta = \left( \frac{R_{\text{Sample}}}{R_{\text{Reference}}} - 1 \right) \times 10^6 \].

For \(^{12}\text{C}\) this corresponds to \(10^{-4}\) at% or 1 ppm, for \(^{13}\text{N}\) the values are \(4\times10^{-8}\) at% or 0.4 ppm. Such precision can be obtained with specialised Isotope Ratio Mass Spectrometers. These offer simultaneous ion current detection with multiple Faraday cup assemblies, high current ion sources and gas switching with a "Changeover valve". For all isotope measurements samples must be converted to clean \(\text{CO}_2\) and \(\text{N}_2\) gas respectively. These sample gases are measured against reference \(\text{CO}_2\) and \(\text{N}_2\) gases of known isotopic composition. The latter are calibrated versus international standards.

Figure 1 shows a schematic overview of the interface for Carbon and Nitrogen analysis (CTBOX CN). Milligram size samples are combusted in a commercial CHN analyser. The product gases \(\text{CO}_2\), \(\text{H}_2\text{O}\) and \(\text{N}_2\) are swept into the interface without splitting. Automated cold traps designed for fast and reproducible temperature changes between -196°C and +150°C separate the gases from the Helium carrier and from each other. The CTBOX CN also acts as inlet system to the mass spectrometer. \(\text{N}_2\) and \(\text{CO}_2\) are measured from separate compartments with dedicated capillaries to the changeover valve. The latter has a new design with four ports. Each of the ports accepts a capillary from a gas reservoir. Two of the reservoirs contain the reference \(\text{CO}_2\) and \(\text{N}_2\) gases while the other two are connected to the CTBOX CN interface. Only one of the ports at a time may communicate gas to the MS, the other three being switched to the waste line pump.

Figure 1 Schematic outline of Trapping Interface CTBOX CN
The whole system is software controlled. Nitrogen and Carbon from a single combustion are analysed in sequence:

**Nitrogen:**
After trapping in the first N₂ trap with the aid of 5 Å Angstrom zeolite (Alltech) at -196°C the trap is heated to 90°C for quantitative release of N₂. PM2 measures the sample amount. The sample then is quantitatively transferred to the second volume (500µl) which is filled with a small amount of silica gel (Fischer). Depending on the previous PM2 reading the gas is measured from this small volume or it is back expanded into the volume between the two preceding valves after heating. For fast isotopic equilibration between the silica gel and the gas volume we added a mixing cycle by cooling and heating the trap one more time with different times and temperatures. Omitting this cycle leads to a measurable dependence of the δ-value upon signal height (=0.1 permil/nA). Care must be taken during all times that the absorbents in the N₂ traps are not contaminated with CO₂. Even small amounts will spoil the N₂ results due to the fact that CO⁺ formed from CO₂ in the ion source has a ²⁹/²⁸ ratio ≠600 permil different from natural abundance Nitrogen.

**Carbondioxide:**
CO₂ is first trapped from the Helium carrier stream in the first trap at liquid Nitrogen temperature together with water. After pumping He and heating the trap to -80°C CO₂ is distilled to the second trap where it's amount is measured after heating. This procedure ensures that no trace of CO₂ may enter the nitrogen trap. Depending on the PM1 reading, the CO₂ is either measured directly when the Nitrogen analysis is finished or it is further concentrated into the small volume cold trap (250µl) preceding the CO₂ capillary. From here, reexpansion is employed for intermediate size samples.

**Results:**
Figure 2 presents some of the data obtained with the CTBOX CN interface. Especially for small samples (<28µmol) the blank must be controlled precisely for good Nitrogen measurements. The results demonstrate that good agreement is observed for international standards between the expected and the observed values. Furthermore, this agreement is true independent of sample size (after blank correction) for samples in the lower µmol N and C range. Cross contamination between CO₂ and N₂ is negligible. CO₂ formation in the combustion is not observed.

DETECTION OF NONCOVALENT ENZYME-SUBSTRATE AND RECEPTOR-LIGAND COMPLEXES BY CONTINUOUS-INTRODUCTION ION SPRAY MASS SPECTROMETRY.

Jack Henion* and Yu-Tsyr Li, Drug Testing and Toxicology, New York State College of Veterinary Medicine, Cornell University, 925 Warren Drive, Ithaca, New York 14850 USA, and Bruce Ganem, Department of Chemistry, Baker Laboratory, Cornell University, Ithaca, New York 14853 USA

There are few methods known for detecting and identifying enzyme-substrate, receptor-ligand and antibody-antigen complexes whose weak, noncovalent interactions constitute the essential basis of molecular recognition in the biological world. We report the use of mass spectrometry (MS) to detect non-covalent enzyme-substrate and receptor-ligand complexes as their protonated, multiply charged species. The enzymatic reaction of egg-white lysozyme (HEWL, MW 14,305) with various substrates and the cytoplasmic receptor, FK binding protein (FKBP, MW 11,776 Da) with various drugs (FK506, MW 804 Da; rapamycin, MW 913 Da; cyclosporin A, MW 1202) were monitored using continuous introduction ion spray MS in real time under physiological conditions (HgO, pH 5.0, and 7.5, respectively) in aqueous acetate buffer. That the observed complexes were not anomalous aggregates resulting from the electrospray ionization process was supported by several lines of evidence. Results from on-line monitoring of the interaction of lysozyme and FKBP with carefully chosen substrates are described that demonstrate mass spectrometric detection of transient complexes. These studies suggest mass spectrometry may be a powerful tool for characterizing noncovalent enzyme-substrate and receptor-ligand complexes.

EXPERIMENTAL

All enzyme-substrate mixtures were introduced in 100% aqueous buffered solutions by continuous infusion of the sample (2μL/min) at ambient temperature through an ion spray interface. The mass spectrometer was a Sciex TAGA 6000E triple quadrupole system upgraded to an API III operated in the single MS mode. Enzyme-substrate ratios of lysozyme-NAG were typically 1:13.9 at a pH of 5.0, and receptor-ligand ratios were 1:1.6 for FKBP:drug at pH 7.5. The mass spectrometer was tuned and mass calibrated on the enzyme and receptor, respectively, and acquisition experiments utilized 2 sec scans with 10-20 scans summed.

RESULTS AND DISCUSSION

For the HEWL studies the substrates included NAG, NAG2, NAG3, NAG4, and NAG6 in addition to TACL in addition to mixtures of these. One, ten and sixty minute infusion experiments that studied the hydrolysis of NAG6 to NAG4 by HEWL clearly showed rapid hydrolysis of NAG6 with the production of NAG4. Both appeared as a complex with the (M+H)+ charge state of HEWL. Related studies with measurements taken 10 min after commencing the infusion experiments showed varying degrees of complex formation between HEWL and NAG4 showing the most abundant ion current signal as predicted from known solution behavior. When HEWL was mixed with TACL, a known inhibitor of the hydrolysis the HEWL-TACL complex was detected with significant reduction of the HEWL-NAG4 complex. Finally, when an equimolar mixture of NAG3 or NAG6 and TACL were subjected to the same experimental conditions, the HEWL-TACL complex predominated in each case further suggesting that an active site-directed interaction plays a role in the formation of the enzyme-substrate species detected in this work.

Additional competition experiments with an important receptor, FKBP and the immunosuppressive drugs, FK 506, rapamycin and cyclosporin A (CsA) were conducted. These experiments were carried out in the same manner as described for HEWL. A competition experiment in which FKBP was combined with equimolar amounts of FK 506 and rapamycin clearly showed the presence of both receptor-ligand complexes at m/z 1803.1 and 1821.0, respectively, in the ion spray mass spectrum (Figure 1). Peak integration revealed that the rapamycin complex was twice as abundant as the FK 506 complex, in striking agreement with known k4 values. This result indicates that noncovalently bound species with suitably high association constants can be detected directly in a complex mixture without prior chromatographic separation. Ion spray MS might thus simplify the characterization of such structures when either the host or guest MW is known.

1155
In a broader context, the use of MS to detect and identify molecular association complexes resulting from the interaction of charged macromolecules with their specific molecular ligands (or vice-versa) may find additional applications in two other classes of biologically important Noncovalent association complexes. The interactions of cell surface receptors with specific effector molecules and extracellular components play critical roles in signal transduction, cellular adhesiveness, and many other multicellular processes. Antibody-antigen recognition and aggregation phenomena are central to the function of the vertebrate immune system, and may likewise be amenable to study using antibody Fab fragments, single chain V_{L}/V_{H} and V_{H} antigen-binding proteins, as well as other, lower-MW immunoglobulins.

ACKNOWLEDGMENTS

This research was supported by a grant from the Cornell Biotechnology Program, which is sponsored by the New York State Science and Technology Foundation, a consortium of industries, the U.S. Army Research Office, and the National Science Foundation. We thank Professor Taichi Usui for providing NAQe and Professor Gustav Lienhard for providing TACL. We also thank Professor Stuart Schreiber (Harvard University) for providing generous samples of FKBP, FK 506, rapamycin and cyclosporin A.
Structural Characterization of Proteins using Open Tubular Liquid Chromatography Coupled with Electrospray Ionization on a Triple Quadrupole Mass Spectrometer

Patrick R. Griffin, Leroy E. Hood, and John R. Yates, III

California Institute of Technology, Division of Biology Pasadena, California 91125

The focus of the mass spectrometry group at Caltech has been the development of new approaches for the analysis of biomolecules. Presently in our laboratory we have three mass spectrometers; a triple quadrupole (Finnigan TSQ-700) with LSIMS and electrospray, a quadrupole Ion Trap with an electrospray ion source, and a time-of-flight instrument for matrix-assisted laser desorption mass spectrometry. We have developed methods for protein sequence analysis based on coupling liquid chromatography with electrospray ionization. The methodology presented in this paper offers a high sensitivity, high throughput strategy for analyzing the primary structure of proteins.

Using electrospray ionization on the TSQ-700 a strong signal is obtained when infusing a 5 pmol/ml solution of angiotensin. The same intense signal can be obtained when lowering the flow rate to as low as 100 nl/min allowing less material to be consumed during the analysis. For instance, scanning for 1 min at a flow rate of 1 μl/min consumes 5 pmol of sample (for a 5 pmol/μl solution). Scanning for 1 min at a flow rate of 100 nl/min consumes 500 fmol of sample (1 order of magnitude less material needed for analysis). To take advantage of this observation, we have been investigating the use of open tubular liquid chromatography coupled to electrospray tandem mass spectrometry. Using OTLC-MS, molecular masses of peptides could be recorded loading on as little as 100 fmol of sample. Isocratic OTLC allowed MS and MS/MS experiments to be performed on 500 fmol of a synthetic peptide in a single run. The methodology presented in this paper offers a high sensitivity, high throughput strategy for analyzing the primary structure of proteins.

C18 derivatized fused silica columns can be made using a stainless steel pressure vessel (Figure 1) and the following conditions.

1. Pass 500 μl of 6 N HCl through a 1 m x 50 μm length of fused silica capillary.
2. Pass dry N2 through the capillary for several minutes.
3. Pass 500 μl of a 5% solution of octyldecyltrichlorosilane in hexane through the capillary.
4. Pass 500 μl of hexane through the capillary.
5. Bake the column at 130 C for 1 h.
6. Pass 500 μl of 0.1% TFA through.
7. Load sample and wash with 200 μl of 0.1% TFA.

Shown in Figure 2 is the reconstructed ion chromatogram for the analysis of 100 fmol of angiotensin by OTLC-MS. 100 fmol of angiotensin was loaded onto a C18 derivatized fused silica capillary column and unbound material was washed off with 0.1% TFA. The peptide was then eluted isocratically with 10% acetonitrile in 0.1% TFA at a flow rate of 200 nl/min. The electrospray mass spectrum from this analysis is displayed in Figure 3.

The same experiment was performed on 500 fmol of a synthetic peptide of structure SPYVESEDAPPQK. The sample was then eluted isocratically into the electrospray ion source using 10% acetonitrile in 0.1% TFA at a flow rate of 250 nl/min. The peptide elutes over several scans thus allowing MS and MS/MS experiments to be performed with a single sample loading. The RIC from this analysis is shown in Figure 4. The electrospray ionization MS and MS/MS spectra are displayed in Figures 5 and 6, respectively.

OTLC-MS can be used for analyzing proteins as is demonstrated in Figure 7. The Reconstructed Ion Chromatogram is from an analysis of 2 pmol of a novel post synaptic neurotoxin, β-bungarotoxin, by OTLC-MS.

Characterization of Antibodies and Other Large Glycoproteins up to 200 kDa by Ionspray Mass Spectrometry

*Rong Feng, François Bouthillier, Yasuo Konishi and Miroslaw Cygler, National Research Council of Canada, Biotechnology Research Institute, 6100 Royalmount Avenue, Montreal, Quebec H4P 2R2, Canada

Antibodies (immunoglobulins) are a class of large biomolecules responsible for the functioning of the immune system. The average molecular weight (MW) of four intact IgG class monoclonal antibodies (Fig. 1), namely anti-(α1-antitrypsin) (148,484±4 Da), anti-(α1-acid glycoprotein) (149,599±12 Da), anti-(β-galactosidase) (two components, I 150,544±10 and II 151,496±17 Da) and anti-RNA (150,475±11 Da), were determined using an ionspray mass spectrometer (Sciex API III triple quadrupole MS). It is very likely that the MW differences between the experimental MWs and the estimated IgG sequence MW (~140 kDa) are mainly due to the sugar attachments on the Fc domains of the antibodies' heavy chains. Still under investigation is whether the MW difference of 952117 Da between the two components of anti-(β-galactosidase) (Fig. 1c) are caused by their difference in the sugar content or in the genetic coding of the polypeptide chains.

Chemical disintegration of the anti-RNA IgG by reducing the inter-chain disulfide bridges (S-S bonds) resulted in one pair of light chains and one pair of heavy chains (the two in each pair are identical). The determined MW of light chain (24,106.9±0.4 Da) and heavy chain (heterogeneous, 30% of 51,021.5±0.8 Da and 70% of 51,184.0±0.9 Da) not only revealed the sizes of the constituent chains, but also confirmed the average MW determined for the intact antibody. Collisionally activated dissociation (CAD) of the 150 kDa antibody ions, at both the ionspray interface region and the MS/MS collision chamber in Q2 region without MS-1 m/z separation, produced a charge distribution profile corresponding to the light chain (~24 kDa) (see Fig. 2 for the total ion CAD spectra of anti-(α1-acid glycoprotein) taken under different collision energies at Q2). Apparently, the collision energy intake in a quadrupole type instrument is sufficient for the CAD of multiply charged macro-molecular ions as high as 150 kDa. However, the heavy chain fragments were not observed; the reason is still not clear.

Although exactly equal moles of light (24.1 kDa) and heavy (51.1 kDa) chains were obtained upon reduction of the inter-chain disulfide bonds of the anti-RNA IgG, the observed MS signals for the light chain was >10 times bigger than those for the heavy chain. Reduction of the anti-RNA Fab fragment (47.6 kDa) from papain digestion also yielded equal moles of the intact light chain and the shortened heavy chain (23.5 kDa). The light chain, which was slightly heavier by now, however, again gave 9-fold stronger signals than the shortened heavy chain. Therefore, serious attention must be given to the relative sensitivities of the species in a mixture, if one is to use ionspray or electrospray technique for their quantitation.

Human serum transferrin (HST), a glycoprotein serving for iron transportation in blood, gave a MW of 79,556.8±1.7 Da (Fig. 3a). The value is 4,414 Da higher than the calculated sequence MW (75,142.9 Da), indicating the attachment of ~23 sugar units in this protein via post-translational modification. The charge distribution profile of HST is sharply different from that of bovine serum transferrin (BST; three components, I 78,030.5±1.8, II 78,326.8±3.3 and III ~78,609 Da, see Fig. 3b), implicating that the difference in glycosylation may affect protein charging efficiency in solution.

The single chain subunit of human α2-macroglobulin (a glycoprotein whose tetrameric aggregate serves as an inhibitor to nearly all endo-proteinases by trapping them inside the gigantic molecular cage) yielded a MW of 186,070±150 Da (Fig. 4a). This measured MW is 25.2 kDa higher than the sequence MW (160,837 Da, reduced form). Therefore, post-translational modifications make up 13.6% of the total protein mass, consistent with the previous biochemical studies.

Human complement C4, a glycoprotein and one of the key complement components responsible for the destruction of alien cells and viruses, gave a MW of 196,863±29 kDa (Fig. 4b), in agreement with the gel electrophoresis estimate (~200 kDa). The MW difference of 9.8 kDa between the observed whole MW and the preliminary sequence MW (~187,087 Da) reflects the sugar content of ~5% in this protein, in line with the reported value of ~7%.

The above studies demonstrate that ionspray MS is capable of accurate MW determination for macro-biomolecules up to 200 kDa. The MW difference between the experimental and sequence MW values can be used to determine the degree of post-translational modifications in a protein. MS/MS analysis is feasible for multi-charged macro-ions as large as 150 kDa. The relative sensitivities of the constituent components must be determined to quantitate proteins in a mixture.

Characterization of Oligodeoxynucleotide Conjugates by Electrospray Ionization Mass Spectrometry

John T. Stults and James C. Marsters
Genentech, Inc., 460 Point San Bruno Blvd., South San Francisco, CA 94080

Synthetic oligodeoxynucleotides are important components in many molecular biology experiments. They may be probes for cDNA hybridization experiments, primers for PCR reactions, or pieces of synthetic genes for site-directed mutagenesis studies. Oligomers that are conjugated to a labeling reagent, such as N-hydroxysuccinimide-biotin or fluoresceinyl-isothiocyanate, are now commonly used in many hybridization experiments for DNA detection, sequencing, and diagnostic applications. Also, nuclease resistant oligodeoxynucleotide analogs and derivatives containing cross-linking or cell-targeting moieties are under study as therapeutic agents. At present, few methods exist for assaying proper synthesis, deprotection, and conjugation of these molecules. Oligodeoxynucleotides are a class of molecules that, except for oligomers smaller than n=10, have only recently become amenable to routine analysis by mass spectrometry as a result of the introduction of new ionization techniques. Recent experiments have shown that oligodeoxynucleotides may be analyzed readily by electrospray ionization (ESI) mass spectrometry (1-3). In most cases, however, the quality of the spectra have been limited by the presence of sodium adducts of the molecular ion species. The sodium is introduced during the electrophoretic purification of the crude oligomers from aqueous buffer components. The adducts become a severe problem in the spectra of larger oligomers, where the number of added sodium atoms in each peak cannot be determined, or the resolving power of the instrumentation is insufficient to separate the different adduct peaks. In addition, the adducts spread the available ion current over several different peaks, thereby reducing the signal intensity.

We describe here a rapid means of improving the mass spectrum of oligonucleotides and their conjugates by replacement of sodium with ammonium ions to reduce adduct formation. These samples show greatly improved spectra by electrospray ionization and extend the useful mass range for analyzing oligodeoxynucleotides beyond 20 kDa.

**EXPERIMENTAL**

*Synthesis of oligodeoxynucleotides* -- Oligodeoxynucleotides were synthesized using H-phosphonate (Milligen Biosearch 8600 DNA Synthesizer) or phosphoramidite (Milligen 7500 DNA Synthesizer) methodologies. Reaction products were examined and purified by electrophoresis (10-15% polyacrylamide gel, 7 M urea, visualization by UV shadowing).

*Sample preparation for mass spectrometry* -- Purified oligomers (100 μl, ~5 OD260/ml) were treated with ammonium acetate (10 M, 34 μl), precipitated with 2.5 vol. cold ethanol, pelletted, and washed with cold 70% ethanol. This quantity is 1-2 nmol of a 30-mer. The precipitated oligomers were reconstituted in water to a concentration of 50-200 pmol/μl.

*Mass spectrometry* -- Immediately before analysis, a 10 μl aliquot of the oligomer was added to 5 μl of acetonitrile and 5 μl of buffer. The buffers used were 10 mM ammonium acetate or ammonium hydroxide. The samples were infused at 2 μl/min with a Harvard Apparatus syringe pump into the ionspray interface of a Sciex API III triple quadrupole mass spectrometer, operated in the negative ion mode.

**RESULTS**

The ESI mass spectrum of a typical 30-mer, before removal of sodium, is shown in Fig. 1. The inset is the largest peak expanded to show the individual sodium adduct ions. The peak at m/z 944.2 corresponds to [M-27H+17Na+]10+. The same oligomer, following ammonium precipitation, is shown in Fig. 2. The peaks are much sharper, and the largest peak in each cluster contains no sodium atoms. The charge distribution is changed only modestly from Fig. 1, with the [M-12H+]12+ peak as the most abundant ion.

Other conjugated oligomers also produce sharp, well separated peaks when analyzed by electrospray ionization mass spectrometry. Figure 3 shows the spectrum of a biotin-conjugated 20-mer. The largest peak in each cluster includes no sodium atoms. Electrospray ionization mass spectra of other oligomers as large as 77-mers have been obtained successfully following the
The ability to rapidly obtain masses accurate to ±1-2 Da for synthetic oligodeoxynucleotides of most sizes makes mass spectrometry a valuable tool for the nucleic acid chemist, just as it has become an established technique for analyzing synthetic peptides.

ELECTROSPRAY IONIZATION MASS SPECTROMETRY OF WATER AND HIGHLY CONDUCTIVE AQUEOUS SOLUTIONS. Swapan K. Chowdhury and Brian T. Chait, The Rockefeller University, New York, N.Y. 10021.

The electrospray ionization mass spectrometry of water, acidified water, and aqueous protein solutions not containing organic solvents and without nebulization has been investigated. Aqueous solutions are difficult to electrospray because they have high surface tensions and high conductivities. The high surface tensions (T) normally necessitate the use of high voltages (V) on the spray needle (V ~ T^{1/2}) causing corona discharge in ambient air and destabilization of the spray. It has been demonstrated in the present investigation that purely aqueous solutions can be electrosprayed by the use of sharpened capillary needle tips. The sharp tips allow electrospray of aqueous solutions to occur at reduced electric fields, thus avoiding corona discharge destabilization. This observation is in accord with the prediction of Smith, who points out that V ~ T^{1/2}/2ln(4h/r); where r = o.d. of the spray needle and h is the tip to counter electrode distance. Thus for a constant T and h (5 mm) a change of capillary o.d from 700 μm to 200 μm decreases the required onset potential (V) by a factor of 1.4. The spray conditions as a function of spray voltage and flow rate for the electrospray of water is given in Table 1.

The electrospray of water or water containing small amounts of acid or other electrolytes provides an intense source of large ionic clusters of water molecules. The cluster size can be controlled by varying the temperature of the capillary tube used to transport the ions produced by electrospray into the vacuum system of the mass spectrometer. Under one set of experimental conditions, the electrospray ionization mass spectrum of 1% aqueous acetic acid exhibits protonated water cluster ions containing from 6 to 52 water molecules. The cluster ions, H^+(H_2O)_n, with n=21, 28, 33, 35, 37, and 42 appear to have special stability. It has been postulated by many investigators that the (H_2O)_{21}H^+ ion has a special geometry: the pentagonal dodecahedron with the oxygen atoms of 20 water molecules situated at the corners and a H_2O ion trapped inside the dodecahedron cage. To our knowledge, unassisted electrospray ionization mass spectra of aqueous solutions without the addition of any organic solvent have not been previously reported in the literature.

The ability to electrospray aqueous protein solutions without organic solvents allows the mass spectrometric investigation of conformational changes of proteins in solution and the investigation of the role of solvent composition on the mass spectrometric sensitivity of protein ions. Shown in Fig. 3 are the electrospray ionization mass spectra of horse heart cytochrome c obtained from aqueous acetic acid solutions of pH 2.6 (Fig. 3a) and 3.8 (Fig. 3b). In the top spectrum, ions are produced with a single charge state distribution with charges ranging from 18 to 11. In contrast, the bottom spectrum (Fig. 3b) exhibits ions with two discrete distributions of charge states. One distribution (also observed in the top spectrum) centers around 14+ and the other ranges from 10+ to 7+, with 8+ being the most intense ion. The formation of two charge state distributions results from two different conformational states of horse cytochrome c. At the lower pH, the majority of the protein is in a highly charged unfolded state (Fig. 3a). When the pH is increased from 2.6 to 3.8 a large fraction of cytochrome c molecules converts to a tighter conformation that can hold on to a lower number of charges.

THE EFFECT OF DIFFERENT SOLVENT SYSTEMS ON THE ELECTROSPRAY IONIZATION OF PROTEINS AND GLYCOPROTEINS, AND THE SEPARATION OF PROTEINS USING PACKED SILICA COLUMNS.

*M.H. Allen, D.J. Grindstaff and M.L. Vestal, Vestec Corporation, 9299 Kirby Drive, Houston, TX.

We previously reported an approach to electrospray that requires no counterflowing gas (1), where the ion source and consequently electrospray chamber are maintained at approximately 250°C and 60°C respectively, to effect ionization and desolvation. Spectra from protein mixtures and modest sized proteins such as bovine serum albumin (BSA) at these source temperatures exhibit fully desolvated ions with no thermal decomposition.

This electrospray system is usually operated at a spray chamber temperature of 60°C which allows aqueous solutions to be sprayed with stable ion currents. We find heating the ion source of particular benefit when investigating compounds such as glycoproteins and proteins which have tight tertiary structures, for example bacterial proteases. Such species were found to be insoluble in organic solution (methanol or acetonitrile) at the levels of concentration required for analysis by electrospray (typically 1 to 300 ng/μL). Even when the sample was prepared in aqueous solution then further diluted in organic solvent the sample would precipitate out of solution at generally > 20% organic, whereupon the 100 micron silica line leading to the electrospray probe clogged. Better sensitivity was seen when 2 to 5% acetic acid was added to solution in preference to 0.1% TFA as generally a 25% loss in signal intensity was observed with TFA. However for ribonuclease B we also obtained excellent spectra when no acid was added to the aqueous solution.

The effect of chamber temperature on the electrospray signal generated from infusion at 5 μL/min of an aqueous solution, 5% acetic acid, of proteinase K (SIGMA Cat. No. P5056; Lot. 70H6838) is shown in Figure 1. An impurity measured at 25,206 daltons is seen at lower chamber temperatures (48 to 60°C), with very weak ions for proteinase K observed; too weak to perform a mass determination. However, on increasing the chamber temperature (> 65°C) the proteinase K becomes the predominant signal.

![Figure 1](image-url). Full scan electrospray mass spectra obtained from a 100ng/μL aqueous solution (5% acetic acid) of Proteinase K at a chamber temperatures of 50 and 78°C. Spectra were acquired at 9 secs/scan. Spectra shown are an average of 3 single scans. Determined molecular weight = 28,910.5 ±/− 5 daltons.
A similar but more dramatic increase in signal intensity was observed for the glycoprotein ribonuclease B and to a lesser extent the bacterial protease thermolysin. It is proposed that the presence of heat helps relax the protein structure sufficiently to ionize the basic residues protected in the tight tertiary structure of the bacterial proteases and also helps fully desolvate ions. It should be noted that myoglobin in aqueous solution, whilst requiring chamber temperatures of > 55°C, does not increase dramatically in signal intensity at elevated chamber temperatures, as shown in Figure 2.

**FIGURE 2.** A plot of intensity for the largest peak in the multiply charged envelope vs electrospray chamber temperature, for the compounds shown, when infused at a flow rate of 5 uL/min at the 100 ng/uL level in aqueous solution, 5% acetic acid.

It is suggested that the best conditions in our interface for "difficult" proteins with tight tertiary structures and glycoproteins such as ribonuclease B are a combination of an aqueous buffer system (5% acetic acid) and a higher than normal chamber temperature (70 to 80°C). Under these conditions the accuracy of molecular weight determination is often better than 0.01%.

This electrospray system is particularly suited to the separation of proteins using packed 320 micron i.d. silica columns. These columns require low flow rates, typically 3.0 to 10.0 microlitres/min, where the electrospray affords the highest sensitivity, especially in producing highly multiply charged ions from proteins such as cytochrome C and myoglobin, which require only low picomole quantities injected on column. A gradient separation of several peptides and proteins was achieved. A gradient from 100% aqueous (2% acetic acid) to 50/50 H₂O/ACN (2% acetic acid) was run using a 320 micron i.d. x 30 cm long packed silica column and a gas-assisted electrospray probe (2), which improved spray stability. Solvent delivery was performed by conventional SSI reciprocating pumps operating at 0.6 mL/min, with a pre-injector split to 10 uL/min passing through the column. Full scan spectra at 7 secs/scan were obtained from 6 picomole of myoglobin and cytochrome C injected (3uL) on column.

CZE and Nanoscale Capillary LC Coupled with Electrospray ionization Mass Spectrometry for the Analysis of Proteins

*M.A. Moseley, S.E. Unger, R.L. St. Claire III, S. Gardlik, and C. Serabji-Singh,

Bioanalysis and Biochemical Toxicology Sections,
Department of Drug Metabolism, Glaxo Research Institute,
5 Moore Drive, Research Triangle Park, NC 27709.

Electrospray ionization (ESI) has found two major roles in mass spectrometry. The ability of ESI to produce multiply-charged gas phase ions from labile analytes of high molecular weight, such as proteins, has attracted much attention. Less well appreciated is the facile manner in which ESI can be used for coupling mass spectrometry with liquid phase separation systems, including capillary zone electrophoresis (CZE) and liquid chromatography. The work here reported has used both features of ESI: the analysis of proteins via on-line separations with mass spectrometry.

An electrospray ionization interface (Analytica of Branford) has been used with a single quadrupole mass spectrometer (Nermag R1010ES). This system has been coupled with both capillary zone electrophoresis and nanoscale capillary LC systems fabricated in-house. The performance of the combined systems was evaluated via analysis of mixtures of different forms of cytochrome-C and myoglobin. These mixtures were analyzed using full scan data acquisition (m/z 500-2000), at the 2 to 4 pmole level (Figures 1 and 2).

The principle application of this research has been the characterization of the class of metabolic enzymes known as glutathione-S-transferase (GST), which detoxify electrophilic alkylating xenobiotics (mutagens, carcinogens, and other noxious chemicals). The presence of a variety of different isozymes of GST, each with differential, overlapping substrate specificity, allows aerobic organisms to detoxify a wide variety of reactive xenobiotics. The type and amount of the different isozymes of GST present in a given tissue (i.e. the isozyme pattern) will determine the sensitivity of the tissue towards the toxic effects of electrophilic compounds.

Nanoscale separation systems coupled with ESI/MS have proven to be capable of characterizing the GST isozyme pattern in tissue samples. Constant infusion of a crude mixture of GSTs from rabbit liver into the ESI/MS system gave a mass spectrum (Figure 3) containing two major components, identified as the alpha-1 (MW=25,650) and alpha-2 (MW=25,350) isozymes, along with at least four minor components (MWs from 24,000 to 26,000). Analysis of this mixture by CZE/ESI/MS resulted in the separation of the alpha-1 and alpha-2 isozymes. Application of nanoscale capillary LC/ESI/MS methodology to this rabbit liver GST sample gave seven distinct chromatographic peaks, all corresponding to GST isozymes with molecular weights between 25,000 and 26,000.

An electrospray ionization (ESI) source has been coupled to a magnetic sector mass spectrometer operated at acceleration potentials of 3 kV to 7kV. Analyses have been performed that demonstrate the determination of mass, charge state, and stable isotope distribution from high resolution mass analysis of multiply charged ions. Linked scan (constant B/E) analyses of the [MH]+, [M+2H]2+, [M+3H]3+, and [M+4H]4+ species have been obtained for several peptides to determine the feasibility of performing MS/MS experiments on the multiply charged ion species.

The ion acceleration region of the mass spectrometer consists of four lens elements arranged as a capillary (C), skimmer 1 (S1), and conical lens. The acceleration potential of the mass spectrometer is set by the potential of the S1 element. We have observed that the magnitude of the voltage difference between skimmer 1 and the capillary where the ions are entering the acceleration region can affect both the charge-state distribution of the ions and the extent of fragmentation. For example, when a capillary/skimmer potential of 10 V is used, the ESI mass spectrum of a polyethylene glycol (average M.W. = 2000) shows a mixture of predominantly doubly and triply charged species. If the capillary/skimmer potential difference is increased to > 300 V, the mass spectrum show only the singly charged species ([M+Na]+). In other experiments with the peptide bradykinin, it was observed that raising the capillary/skimmer potential difference causes extensive fragmentation. The fragment ions observed are consistent with a low-energy CID process.

Linked-scan (constant B/E) analysis can be performed for ions dissociating on the first field-free region of the mass spectrometer. This provides higher collision energies than obtained for the "in-source" (capillary/skimmer region) dissociation. Dissociation of the [M+2]2+ species from bradykinin shows characteristic side-chain fragmentations that are characteristic of high-energy CID processes. These fragment ions were not observed in the "in-source" fragmentation.

High-resolution electrospray ionization mass spectra indicate that it is possible to determine the relative isotope distribution for the molecular ion species with greater accuracy than FAB, due to the absence of a matrix compound in the electrospray ionization process. The reduction in chemical background provides better resolution for ESI-MS compared to FAB-MS and avoids chemical reactions with the FAB matrix (oxidation/reduction) that prevent the reliable determination of isotope distributions. ESI-MS shows the natural charge state for a cyclodextrin dimer that has a doubly charged cation, while the FAB mass spectrum shows a reduction to a singly charged species.
"Normal" ESI mass spectrum of poly(propylene glycol) Average M.W. ~2000u

Mass spectrum for a capillary/skimmer potential difference of 400 volts.
Electrospray ionization has proven phenomenally useful in the analysis of thermally labile polar molecules, especially for peptides and proteins. The development of this atmospheric ionization technique initially began on quadrupole instruments because of the lower voltages required in operation. Interfacing electrospray to high-voltage magnetic sector instruments requires reducing the pressure from atmospheric pressure (ionization) to high vacuum (ion acceleration) in a step-wise fashion in order to prevent corona discharges. We developed a simple single staged electrospray source based on the Fenn and Whitehouse design for a VG ZAB-E, in order to take advantage of the better mass accuracy, higher resolution and extended mass range of a high performance mass spectrometer. Having a similar electrospray interface for a Finnigan TSQ700, we can make a direct comparison of electrospray on a quadrupole and a magnetic sector mass spectrometer. Interfacing electrospray to the different instruments has relative merits. Parameters to consider include: mass range, sensitivity, resolution, mass accuracy, complexity of the source, and ease of operation.

- Mass Range - most biomolecules we have studied result in a distribution of multiply charged ions below 2000 m/z with a few biopolymers showing distributions up to 3500 m/z. The larger mass range is not necessarily a requirement for success in electrospray.

- Sensitivity - electrospray interfaced to a quadrupole or a magnetic sector instrument exhibits, for the most part, similar sensitivities. Array detection could be employed on the magnetic sector instrument which would increase the detection limits.

- Resolution - resolutions of 10000 have been observed with electrospray on a magnetic sector instrument. Higher resolution aids in mixture analysis. Shown below is the theoretical resolution for bovine insulin (mw 5733.5), lysozyme (mw 14305), and carbonic anhydrase (mw 29000). Included with each is a 25% impurity of the oxidized molecule. On the +5 ion for insulin, the resolution narrows the peak making the determination of the average mass more reasonable. For molecules in the 5000 mw range a resolution of 1000 should be sufficient. The lysozyme molecule shows that 300 and 1000 resolution is inadequate and shifts the mass measurement to higher mass because of the contribution of the oxidized species. For this mw range, a resolution of 2000 is adequate. Similarly for the +20 ion for carbonic anhydrase, the resolution of 5000 would result in reasonable mass accuracy.

- Mass Accuracy - Mass accuracy of 0.01% is achievable on the quadrupole which is equivalent to what is obtained on the magnetic sector instrument. However, it has been shown that 0.003% mass accuracy to 17000 u is possible on a magnetic sector instrument.

- Source Complexity and Ease of Operation - Pressure and source contamination are critical in the electrospray source and appear to have a more dramatic effect on the magnetic sector instrument.

Effect of Resolution on Bovine Insulin (+5) Ion

Effect of Resolution on Lysozyme (+10) Ion

Effect of Resolution on Carbonic Anhydrase (+20) Ion
An Electrospray Ionization Time-of-Flight mass spectrometer (ESPI-TOF-MS) has been designed and tested for the rapid analysis of biological compounds. The Electrospray Ion Source and the TOF mass filter together comprise an extremely powerful chemical analysis tool. The unlimited mass range of the TOF-MS allows detection of macromolecules beyond the reach of dispersive instruments. In addition, simultaneous mass detection and rapid scan speed make it an ideal ion detector for rapid chromatographic separation techniques such as microbore LC or CZE. The inherent simplicity in operating such an instrument may also appeal to biomedical researchers outside of mass spectrometry.

The application of several variants of ESPI-TOF-MS as they relate to the detection of biologically significant compounds is considered, with an emphasis placed upon maximizing the normally low duty cycle associated with "chopping" a CW ion beam. Extensive studies have been performed to determine the best method(s) to produce ion packets suitable for TOF mass filtering. In all cases, the goal was to maximize duty cycle while maintaining a marginally acceptable mass resolving power.

One method has been shown to be far superior in terms of enhancing the sensitivity of the ESPI-TOF instrument. With the appropriate selection of static and pulsed electric fields, a DC beam of Electrospray Ions has been stored and modulated to produce TOF spectra for compounds ranging from 100 - 1000 m/z. Ion sensitivity has been measured to be significantly greater than for traditional rastering or chopping approaches. Compromises in ion energy spread are minimized, and can be treated by further energy compensation.

DEVELOPMENT OF AN ELECTROSTATIC ION INJECTION DEVICE FOR FOURIER TRANSFORM ION CYCLOTRON RESONANCE STUDIES OF ELECTROSPRAYED IONS

E. L. Kerle1, M. V. Buchanan, K. D. Cook, and M. Shahgholi2
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6220

This group has recently dedicated considerable effort to the development of a simple electro spray ionization (ESI) interface for use with Fourier transform ion cyclotron resonance (FT-ICR) detection. This source incorporates the Fenn/Whitehouse type glass capillary ion transfer tube in a two-stage pressure reduction, capacitance -type molecular beam source. In this configuration, ion injection into the magnetic field and ion cell would be accomplished by direct injection oriented along the magnet's central axis in a manner analogous to that employed by Smalley et al.1. Studies in the past year emerged along two paths, i) determining the minimum parameters required for operation of the ESI-FT-ICR interface and ii) developing this “minimum interface” using a quadrupole mass spectrometer in an effort to further define the essential functional requirements of the interface.

In order to understand charged particle injection into the FT-ICR cell, an electron injection source was constructed as shown in Figure 1 and mounted to the right side of the FT-ICR vacuum chamber (see Figure 2). The motivation for injecting electrons from a distal source was threefold. First, the magnetic chaos at the end of the magnetic could be probed directly using a very light particle that cannot penetrate fields which are non-conducive to injection—especially at low energies. Secondly, this electron “test bench” would allow both visual and magnetic alignment of the ESI interface. Finally, the effect of vacuum chamber pressure could be crudely probed for the electrons traversing the chamber. After physical alignment of the source, it was found that electrons exiting the skimmer passed through the cell and struck the collector plate nearly a meter away without any detectable signal (using a picameter) striking the cell plates. This was found to be true even down to 5 eV electrons. Argon admitted to the right side of the FT-ICR vacuum system (as depicted in Figure 2) attenuated the electron signal detected at the collector plate by nearly 20% on going from 1 x 10⁻⁴ torr to 1 x 10⁻¹⁰ torr argon pressure.

Without altering the physical alignment of the vacuum system, a simple ESI interface was assembled and installed on the FT-ICR vacuum system depicted in Figure 2. A 300 µ borosilicate glass capillary having both ends vapor plated with gold was fitted to the standard 2 ½ conflat vacuum cross so that the exit from the capillary was held rigidly a few millimeters from the entrance to a 460 µ copper skimmer. The capillary skimmer region of the interface was pumped by a mechanical pump capable of maintaining approximately 0.300 torr. The exit from the skimmer was fitted with a large, three element tube lens. Pumping after the skimmer was provided by the right side of the differential FTMS-20GG vacuum system giving a pressure of nearly 1 x 10⁻⁴ torr in the right differentially pumped region and approximately 1 x 10⁻³ torr in the left. A 0.001 M NH₄⁺(OAc⁻) solution was electrosprayed into the system (positive ion mode) giving a steady 1 pA positive current detectable at the conductance limit plate at the center of the ion cell. A large current (approximately 0.6 pA) was detected at the right cell plate and no current (< 0.1 pA) was detected on the left cell plate or collector plate indicating that the ions were very defocused. No ions could be detected by FT-ICR in either cell region.

The ESI interface above was mounted onto an Extrel quadrupole mass spectrometer with the skimmer exit region pumped by a 700 IS⁺ cryopump. Ion transmission through the skimmer was found to improve with better pumping conductance behind the skimmer. This conductance was improved by decreasing exit dead volume and refining the larger, more restrictive tube lens with a more open tube lens/Elzing lens design. The capillary was placed in an X-Y tilt adjustable mount for more controllable placement of the capillary exit. Pumping in front of the skimmer was improved by placing the skimmer closer to the throat of the tee in which it was mounted. Initial studies using the quadrupole test system indicate that aggressive drying in the nozzle/capillary entrance region is required for transmission of ions. Further, preliminary data indicated that the width of the energy spread for ions emerging from the source is directly related to the amount of drying before entering the capillary. Various configurations of gas flow guides have been employed to bathe this region with warm N₂. It was found that more directed gas flow yielded improved performance.

Advanced Methods for Structural Characterization of Large Multiply Charged Ions: Obtaining Charge State Determination and Improved Sensitivity

Richard D. Smith, Alan L. Rockwood, and Harold R. Udseth
Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352

There is growing interest in obtaining structural information for large molecules by the methods of tandem mass spectrometry. Electrospray ionization (ESI) now allows the efficient production of high molecular weight ions having high charge states. The application of existing instrumental methods for this purpose encounters several problems. One is that the primary ion beam flux is, to a crude approximation, inversely related to the square of molecular weight for large molecules due to the number of charges on each ion, the width of the charge state distribution, and the limitations upon electrospray ion currents. Since the number of "useful" and desired fragmentation pathways increase approximately linearly with molecular weight, the sensitivity demands increase approximately with the inverse third power of molecular weight. A second problem for methods utilizing multiply charged parent ion is the necessity of determining the charge states of product ions from tandem experiments. The combination of these problems will grow dramatically with molecular weight, currently limits the application to high molecular weight biomolecules.

A solution to these problems, which we plan to investigate, is based upon the use of coincidence detection methods, an approach which exploits the fact that molecular ions for higher molecular weight compounds produced by ESI, and more importantly, their collision induced dissociation (CID) products will often be multiply charged.

A CID mass spectrum represents a summation of signals resulting from different dissociation processes occurring for molecular ions, each pathway characterized by different statistically determined (e.g., RRKM) frequency of occurrence. The basis of our approach will be to determine the product ions arising from CID of single parent ions. The number of different CID processes possible for a large polypeptide is very large. Complex dissociation processes can occur (particularly at higher collision energies), including side chain losses, sequential dissociation processes, and perhaps charge or proton transfer to the collision gas. The additional complications arising due to the range of possible product ion charge states arising from dissociation of a multiply charged parent ions adds an element of ambiguity that for large molecules generally precludes spectral interpretation unless the structure is already largely established.

Assume a molecular ion of mass M and charge Z. Both M and Z are known from interpretation of the ESI mass spectrum. Of interest is the situation where molecular ion internal energy does not greatly exceed that required for dissociation on the mass spectrometric time scale, so that more extensive dissociation processes are avoided. Here the most likely dissociation processes can be generalized by reactions [1]-[7].

\[
\begin{align*}
M^Z & \rightarrow m_a^x + m_b^y + m_c^z + m_d \\
M^Z & \rightarrow m_a^x + m_b \\
M^Z & \rightarrow m_a^x + m_b y^+ \\
M^Z & \rightarrow m_a^x + m_b y^+ + m_c \\
M^Z & \rightarrow m_a^x + m_b y^+ + nV + z^+ \\
M^Z & \rightarrow m_a^x + m_b y^+ + m_c z^+ + m_d
\end{align*}
\]

where \( m_a + m_b + m_c = M \), \( x + y + z = Z \), and \( y^+ \) and \( z^+ \) designate (undetected) charge loss. Each reaction may represent hundreds, or even thousands, of possible CID processes. It should also be noted that the individual neutral products (\( m_b \), \( m_c \), or \( m_d \)) may represent the sum of several smaller indicated neutral species. The vast majority of all CID processes of interest are expected to conform to these general reactions, unless excessive internal energy is deposited in the molecular ion (facilitating additional sequential dissociation steps).
An important feature of most CID processes for each multiply charged parent ions is the formation of more than one product ion. With the possible exception of simple cleavage to form "complementary ions" by reaction [3], the absence of charge state information prevents reliable assignment of peaks in the mass spectrum to specific CID processes. If product ions arising from individual CID events can be correlated, our evaluation has shown that interpretation and unambiguous charge state assignment becomes feasible in most cases. This is possible for two reasons: the fact that total mass and charge (of the parent) are known, and that ion charge is restricted to integral values.

The correlated detection of dissociation products can potentially yield enormous gains in sensitivity. Since detection is accomplished for single events, conventional problems related to resolution would rarely be significant; rather, temporal resolution is of significance along with m/z measurement accuracy. Since events at much less than one per second should be interpretable with confidence, sensitivity gains can be substantial. In addition, the problem of "spectral congestion", noted in our studies of large molecule CID² should largely be moot; i.e., different species having the same nominal m/z (but perhaps different charge) would be temporally resolved. Clearly this approach would yield an abundance of mechanistic information, otherwise quite difficult to obtain.

The coincidence detection approach could be implemented in several ways. One approach could involve a tandem instrument with a TOF second stage. At low ion flux (readily obtained for ESI), and with m/z selection in the first stage, each TOF spectrum would be limited to dissociation of only a few or (ideally) only one parent ion. Thus, TOF detection in this limit inherently provides coincidence detection, but at a substantial cost in terms of sensitivity (at least for conventional TOF methodologies) due to the low duty cycle. A much more powerful alternative might involve tandem double focusing sector instrumentation with an array detector. Such a detector must have both a wide m/z range for simultaneous detection, and provide for adequate temporal resolution to allow product correlation. We plan to investigate such correlated detection methods, as well as the ancillary issues related to data analysis and interpretation.

Peptide Fragmentation in $^{252}$Cf-PDMS

David M. Bunk* and Ronald D. Macfarlane
Department of Chemistry, Texas A&M University
College Station, Texas 77843

Recent investigations have indicated that the prompt, metastable fragmentation of peptides observed in $^{252}$Cf-PDMS provides sufficient information for effective peptide sequence analysis. Compared to other mass spectrometric methods used in peptide sequencing, the fragmentation of peptides observed in PDMS is unique, both in terms of the time scale of the fragmentation, and the amount of energy deposited in the parent molecule, inducing fragmentation. Therefore, we began a study of the fragmentation of peptides in PDMS, to characterize the factors that influence fragmentation, and to compare this fragmentation to that observed in other mass spectrometric methods.

Our initial examination of the fragmentation of peptides in PDMS used the nonapeptide bradykinin (RPPGFSPFR) as a model compound. The PD mass spectrum of bradykinin in Figure 1 was obtained by adsorbing approximately 250 pmol of the peptide onto a nitrocellulose matrix. The types of fragment ions observed in Figure 1 are very similar to those observed in MS/MS under high energy CID conditions: extensive $a_n$, $b_n$, $c_n+2$, $x_n$, $y_n+2$, and $z_n+1$, fragment ions as well as the higher energy $d_n$, $v_n$, and $w_n$ side-chain fragment ions.

To determine whether a charge-remote or a charge-induced fragmentation mechanism is taking place in the fragmentation of peptides by PDMS, analogs of bradykinin in which both the N- and C-terminal basic arginine residues were removed were analyzed. In the PD mass spectrum of des-arg$^9$ bradykinin, no C-terminal fragment ions were observed. This indicates that charge-remote fragmentation may be occurring because removal of the basic C-terminal arginine eliminated all C-terminal fragment ions. The PD mass spectrum of des-arg$^1$ bradykinin showed C-terminal fragment ion comparable to those seen in the spectrum of bradykinin, but also weak N-terminal fragment ions. The observation of N-terminal fragment ions in the spectrum of des-arg$^1$ bradykinin does not preclude a charge-remote fragmentation mechanism because the des-arg$^1$ bradykinin molecule still include a possible site for N-terminal protonation: the α-amino group of the N-terminal proline. When this N-terminal α-amino group was acetylated, the N-terminal fragment ions were
not observed in the PD mass spectrum, while the C-terminal fragment ions remained unaffected. Our interpretation of these results is that charge-remote fragmentation is prevalent in the PD mass spectra of peptides.

To examine the effect of the nature of the charge site on the fragmentation, we examined derivatives of bradykinin in which the N-terminal basic amino acid was altered. Figure 2 shows the results of this study. In this figure the relative intensities of N-terminal a_n series of fragment ions is plotted for four peptides with varying N-terminal charge-sites. The N-terminal triphenylphosphonium (TPP) derivative of bradykinin, with a fixed positive charge on the N-terminus yielded the most intense N-terminal fragment ions. The relative intensities of the N-terminal fragment ions of the arg^1, his^1, and lys^1 bradykinin analogs follow the same trend as the relative gas-phase basicities (1) of these amino acids: arg > his > lys.

The fragmentation observed in PDMS is not limited to small peptides. As Figure 3 shows, fragmentation of an amino acid chain is also observed in the PD mass spectra of small, native proteins such as ribonuclease A (M_r = 13,682.4)

![Figure 2](image)

LINKAGE POSITION DETERMINATION IN LITHIUM CATIONIZED DISACCHARIDES: TANDEM MASS SPECTROMETRY AND SEMIEMPIRICAL CALCULATIONS

G.E. Hofmeister, Z. Zhou, and J.A. Leary*
University of California, College of Chemistry, Berkeley, CA 94720

Fast atom bombardment ionization (FAB) in combination with tandem mass spectrometry of lithiated disaccharides is used to differentiate the linkage position of five isomeric sugars as well as investigating the gas phase mechanisms of various ion formation. In this study we show how the linkage position of different isomeric disaccharides can be distinguished when the monolithiated precursor undergoes collision induced dissociation (CID) after FAB ionization (Table 1). Deuterium and 18O labeling studies were used in combination with product and precursor ion scans which showed that reducing ring opening occurs followed by two-, three-, and four-carbon chain neutral losses via a retro-aldol rearrangement (Scheme 1). Carboxyl migration via keto-enol tautomerization is postulated as an isomerization process that occurs during CID, thus enabling specific cleavages for each different isomer. Semiempirical calculations of both the hemiacetal and hydroxy aldehyde forms support experimental data which indicates that the lithium ion is penta-coordinate between the two rings with the most stable structure giving a heat of formation of -406 kcal/mole (Figure 1).

GAS PHASE PROTON AFFINITY OF RIBONUCLEOSIDES BY FAST ATOM BOMBARDMENT MS/MS

Francesco Greco, Angelo Liguori, Giovanni Sindona* and Nicola Uccella
Dipartimento di Chimica Università della Calabria
1-87030 ARCAVACATA DI RENDE (CS)- Italy

The evaluation of the proton affinity (PA) of nucleic acid constituents in vacuo, provides data unaffected by the solvent effect thus enabling straightforward structural function correlations. The determination of the pK values of nucleotides has been widely investigated both theoretically and experimentally for its implication in the base-base recognition processes (1). The gas phase chemistry of the all set of proton bound heterodimers containing the four DNA nucleosides has provided information concerning the relative PA of the examined molecules in an hydrophobic environment (2). A recently proposed fab-bracketing approach (3) allowed the determination of their absolute PA values by applying the eq. 1, Where the unknown value of the nucleic acid component

\[ \text{PA}_N = \frac{\ln (k_{N/k_A1}) \cdot \text{PA}_{a2} - \ln (k_{N/k_A2}) \cdot \text{PA}_{a1}}{\ln (k_{N/k_A1}) - \ln (k_{N/k_A2})} \]  

(\text{PA}_N) can be determined from the known values of two reference amines (\text{PA}_{a2}, \text{PA}_{a1}) by means of the experimentally determined rate constants (k) for the unimolecular dissociations of a given proton-bound heterodimer. This method is sensitive to very small variation in the basicity properties of the examined molecules and has been therefore applied in the evaluation of the substituent effect on the absolute PA of nucleosides.

The PA's of ribonucleosides (N) and deoxyuridine (dU) have been determined as described above, using triethylamine and tripropylamine as reference compounds for G, A and C and pyrrolidine and piperidine for U and dU. The PA's of ribonucleosides (N) differ from those of the correspondent deoxyribonucleosides (dN) by 0.6-1.0 kcal/mole (table). This effect has to be associated to the lack or presence of an OH group in the 2' position of the sugar portion of the nucleoside. The lower basicity of ribonucleosides with respect to the deoxy analogs, already verified in solution (1), is associated to the electron withdrawing effect of the extra hydroxyl group which provides them an higher stability towards depurination. A deeper insight into the physical meaning of the observed PA differences (0.6-1.0 Kcal/mole) can be obtained from the unimolecular dissociations of the proton-bound dimers formed by ribo and deoxyribo nucleosides containing the same aglycone moiety. In the figure are reported the MIKE spectra of the species [dC+C]+ and [dG+G]+. The partitioning of the proton among the two interacting nucleosides always favor the formation of (dN+H)+ ions. Moreover the relative intensity of the daughter ions shows that the PA difference of the guanine containing nucleosides is lower than that of the cytosine analogs. The data reported in the table allow also to conclude that the relative basicity of the unmodified gaseous ribonucleosides follows the same order of the correspondent deoxy-analogs (3), i.e. G > A > C > U. The reliability of the proposed method is further evidenced by the results obtained with the pyrimidine containing nucleosides. The measured
proton affinities of deoxythymidine (dT) and uridine (U) differ from that of deoxyuridine (dU) by 0.6 and 1.0 kcal/mole, respectively.

It is possible, therefore, to evaluate selectively both the contribution of the methyl group in position 5 of the base and that of the hydroxyl function in position 2' of the sugar moiety.

The enhanced basicity of dT with respect to dU is due to the electron releasing effect exerted by the alkyl group adjacent to the amide function of the pyrimidine base. This result suggests, also, that the O4 represents the protonation site of both nucleosides in agreement with the chemistry of the same species in the condensed phase (1). The PA difference between dU and U is due to the electron withdrawing effect of the 2'-OH group and falls in the same range previously discussed for the purine nucleosides. The overall basicity enhancement of dT with respect to U (ΔPA=1.6 kcal/mole) has to be ascribed to the presence of the 5-CH3 group and to the lack of the 2'-OH function in the deoxythymidine molecule.

In conclusion the kinetic approach applied in the determination of the proton affinities of nucleosides enables the evaluation of PA differences of less than 1 Kcal/mole which can be correlated to the structure of the examined molecules.

OBJECTIVES. The dimeric indole alkaloids vincristine, VCR, vinblastine, VBL, and vindesine, VDS, are used in the chemotherapy of several neoplastic diseases. In Fig. 1, the substitutes, in the vindoline part, for VCR, VBL, and VDS, respectively are: \( R_1 \) COOCH\(_3\), COOC\(_3\)H, CONH\(_2\); \( R_2 \) COOCH\(_2\)CH\(_3\), OCOCH\(_3\), OCOCH\(_3\); OH; and \( R_3 \) CHO, CH\(_3\), CH\(_3\). The catharantine part is the same for all three compounds. Our objectives were to compare the collisional activation decomposition of these compounds using FAB and to select strategic ions for the subsequent search for metabolites in urine, serum and tissues.

METHODOLOGY. Matrix: glycerol. The VG Trio-3 triple quadrupole mass spectrometer was operated in static FAB mode using xenon at 8 kV and 1.2 mA. CAD conditions: nitrogen at 10\(^{-5}\) X 10\(^{-6}\) mtorr, 8-18 eV. Daughter spectra were obtained from 30 ions and parent spectra from 39 ions selected from various daughter ion spectra.

RESULTS AND DISCUSSION. We divided the FAB spectrum of VCR (Fig. 2) into two parts. The substituent-dependent ions, appearing at their respective masses, were almost identical for VCR and VBL, while vindesine yielded the same ions but usually of much lower intensities. The \((M + H)^+\) ions of VCR AND VBL are base peaks; VDS is intense (15%), but its base peak is at m/z=154. The other substituent-dependent ions, including the loss of water, methanol, the \( R_1 \) substituents and the loss of the catharantine moiety are present in all three vincas at approximately the same intensities (1-8%). In the substituent-independent group (m/z<500), the three compounds behave nearly identically, with intense (23-52%) peaks at m/z=144, 140, and 122, and a structurally and diagnostically interesting ion at m/z=355 (see later). The m/z=154 ion is intense in both VCR and VBL and is the base peak of VDS.

In the daughter spectrum of \((M + H)^+\) (Fig. 3) the substituent-independent ions, e.g., m/z 705 and 765, appear, as expected on the basis of energetic considerations, at higher intensities than in the straight FAB spectra. The daughter spectra of VBL and VDS show similar decomposition products, losing the \( R \) substituents. In Fig. 4 portions of the daughter ion spectra of the \((M + H)^+\) ion of VCR, the intense substituent-dependent ion at m/z=765, and an ion, selected as the vindoline marker, at m/z=555. The spectra are aligned to reveal a series of identical losses from the parent ions. The CAD processes A, B, C, etc., are the same for all three parents within the \( R \)-containing vindoline part of the molecules and correspond to the loss of \( \text{H}_2\text{O}, \text{C}_2\text{H}_4\text{O}_2, \text{C}_2\text{H}_2\text{O}_2, (\text{C}_2\text{H}_4\text{O}_2+\text{H}_2\text{O}), (\text{C}_2\text{H}_4\text{O}_2+\text{CH}_3\text{OH}), \text{C}_2\text{H}_2\text{O}_2+\text{C}_2\text{H}_2\text{O}_2, \) and 2 \( \text{X} \text{C}_2\text{H}_4\text{O}_2 \), respectively. It is noted that processes D, E, F, and G assume two-step decompositions.

Although of low intensity, m/z=555 is rich in information and is representative of the catharantine ring. Fig 5b shows the parent spectrum confirming that this ion directly originates from the molecular ion of VCR. It is noted here that parent ion spectra were obtained for all ions in the various daughter spectra to confirm their origins. Fig. 5a shows the daughter ion spectrum of the m/z=555 ion. The higher mass region of the spectrum has already been discussed (Fig.3). The ions with lower masses can also be derived from the structure of m/z=555 (Fig. 6). Ions at m/z 285, 122, and 108 also appear in the straight FAB spectrum of VCR, in fact, at rather higher intensities (Fig. 2).

Fig. 7 shows similar information for the m/z=353 ion. Fig 7b shows two parents. One is the molecular ion of VCR, the other is an original small impurity, one that turned out to be a vincain analog with an \( H \) instead of \( \text{CHO} \) on the 1-N in the vindoline ring. The m/z=355 ion can be used to explain the appearance of the m/z=144 and 224 ions in the daughter ion spectrum of vincristine and the m/z=130 ion appearing in straight FAB. In addition, the structure of the m/z=353 ions leads to the formation of a few ions, e.g., m/z 293 and 210, which are not directly relevant to our objectives. To complete the explanation of all important ions both in the straight FAB and daughter spectra of VCR, the structures of three additional ions, at m/z=140, 154 and 168, are shown in Fig. 1. None of these is substitute-dependent and all are of high abundance, in fact, the m/z=154 peak is the base peak for VDS.

Strategy for metabolite identification. If the m/z=555 ion is present, there are no metabolic changes involving R and 18 carbon substitutes. If m/z=353 is found, the metabolic process involved only the vindoline parts which contains the R substitutes. If m/z=355 is not found, the presence of m/z=140, 154, and 166 indicates metabolic changes on substituents on 16 or 18 carbons. If only m/z=130 and 144 are present, metabolic changes occurred on substituents on 4 carbon. To search for the \((M + H)^+\) ions of potential metabolites, find all parents of the markers and, in turn, look for the grandparents, etc. Finally, the interpretation of the ions in the daughter spectra of the ions thus found will help to confirm the identification of the metabolite(s).

CONCLUSIONS. (a) Apart from intense \((M + H)^+\) ions of VCR, VBL, and VDS, the substituent-dependent fragments were low, but measurable, intensity; (b) In the daughter ion mode, several substituent-independent ions were present in considerable intensities; (c) Representative ions were selected for the vindoline and catharantine portions; (d) Several selected ions will, in the parent ion mode, help to detect and identify metabolites in biological materials.

MULTIPLE STAGE MASS SPECTROMETRY IN THE STRUCTURAL CHARACTERIZATION OF ORGANOPHOSPHORUS COMPOUNDS

Loreen Zeller, Craig Claussen, John Farrell, Tuula Kulvalainen', Hilkka Kenttamaa, Department of Chemistry, Purdue University, West Lafayette, Indiana and 'Department of Chemistry, University of Helsinki, Helsinki, Finland.

Electron ionization of organophosphorus compounds often yields a number of small fragment ions, which complicates the interpretation of unknown compounds of this type. By performing sequential collision-induced dissociation, or multistage mass spectrometry, on the molecular ion and subsequent fragment ions, the fragmentation pattern can be simplified and information about the structure of the molecular ion may be obtained. Further information can be obtained by reacting the fragment ions with neutral molecules in ion-molecule reactions. In this work, we describe the use of multistage mass spectrometry combined with energy resolved CAD or hydrogen deuterium exchange in investigations of the structures of fragment ions common to many organophosphorus cations.

The fragment ion C₂H₄O₃P⁺ (m/z 109) is common to many organophosphorus esters. Four stable isomers of m/z 109 were generated from the dissociation of trimethyl phosphate, triethyl phosphate, trisopropyl phosphite and ethylene phosphonate. Upon CAD, each of these isomeric ions of m/z 109 fragment differently to give an energy resolved plot that is characteristic of that isomer (Figure 1). In Figure 2, the collisionally induced dissociation spectrum of m/z 109 obtained by CAD of the molecular ions of dimethyl chlorophenyl thiophosphate is compared to the CAD spectrum of the reference ion generated from trimethyl phosphate. The four isomer isomeric ions of m/z 109 can also be distinguished on the basis of the number of acidic protons they contain through the use of hydrogen deuterium exchange reactions: the dimethyl isomer does not undergo H/D exchange with deuterated ammonia, acetic acid or water, the ethyl isomer exchanges one hydrogen atom with deuterium, the cyclic ester exchanges two hydrogens and the vinyl isomer three.

Multistage mass spectrometry was also used to study the structures of other fragment ions from the molecular ions of organophosphorus compounds. By adjusting the conditions of CAD of the molecular ion of dimethyl chlorophenyl thiophosphate it is possible to fragment the molecular ion into only a few ions, including m/z 109 and 125. The structure of the fragment ion of m/z 125 produced from aromatic thioesters has been proposed to be that of the sulfur analog of the dimethyl isomer of m/z 109 (see figure 3). However, the CAD spectrum of the m/z 125 fragment ion produced from dimethyl chlorophenyl thiophosphate is markedly different from that of the sulfur analog and is virtually identical to that of the fragment ion of m/z 125 from 4-chlorotoluene (Figure 3). We conclude that the structure of the m/z 125 fragment ion of these pesticides contains the aromatic moiety rather than the heteroatom moiety. The observation of a homologous fragment of m/z 139 from the molecular ion of diethyl chlorophenyl thiophosphate under similar CAD conditions indicates that transfer of C₂H₄ to the aromatic portion of the molecule of the ethyl esters occurs. Compounds of similar structure but without the chlorine substituent also exhibit alkylene transfer to the aromatic ring portion of the ion. CAD of pesticide analogs ionized by protonation also produces product ions that, upon CAD, yield structurally characteristic information about the neutral molecules in a similar manner as described here for the molecular ions. Information obtained from CAD of the molecular ion and the fragments of the molecular ions of organophosphorus compounds can be used to characterize the structures of these compounds.

The dehydrobenzenes (o-, m-, and p-benzynes), 1 - 3, constitute a fascinating class of reactive organic intermediates that has inspired numerous experimental and theoretical studies. Ortho-benzyne has been extensively studied over the last forty years to establish its geometric and electronic structures, its chemical reactivity, and its thermodynamic properties. Recently, derivatives of para-benzyne have attracted considerable attention as potential bio-active intermediates in the DNA-cleaving action of calichemicins and esperimicins. A related system, the α,n-dehydrotoluenes (n = 2, 3, 4), 4 -6, have not been studied as intensively as the benzynes. α,3-Dehydrotoluene, however, has been proposed to be essential in the activity of the DNA cleaving necarzinostatin chromophore. Therefore, we have been studying the thermochemistry of the dehydrotoluenes and the benzynes in a flowing afterglow-triple quadrupole instrument and report here the absolute heats of formation of ortho-, meta-, and para-benzyne and α,2-, α,3-, and α,4-dehydrotoluene as derived from energy resolved collision-induced dissociation (CID) measurements.

We have recently demonstrated how collision-induced α-elimination reactions of halocarbonanions can be used to obtain carbene thermochemistry in a flowing afterglow-triple quadrupole instrument. We have now extended this approach to more remote (α,ω) eliminations to obtain thermochemistry for unsaturated compounds and diradicals. For the benzynes the procedure involves regiospecific generation of the chloropheny! anions in the gas phase followed by measurement of the activation energies for chloride loss upon collision activation. The measured activation energies can be combined with the heats of formation for CI' and the precursor chloroanions to give the heats of formation for the neutral products.

Meta- and para-chlorophenyl anions are readily generated in the gas phase from the reaction between fluoride ion and meta- and para-chlorophenyltrimethylsilane, respectively. The proton affinities of these anions were bracketed between furanide ion and hydroxide. Therefore, we assign the gas phase acidity, ΔH°acid, of the meta- and para- positions of chlorobenzene to be 390 ± 2 kcal mol⁻¹. Ortho-chlorophenyl anion is selectively prepared from the deprotonation of chlorobenzene by furanide ion. Bracketing experiments locate the ΔH°acid of the ortho-position of chlorobenzene to be 388 ± 2 kcal mol⁻¹. Each of these ions undergoes efficient CID to give chloride as the only product. The threshold energies found for chloride loss from the three chlorophenyl anions are 16, 24, and 35 kcal mol⁻¹ (± 3), respectively. The acidities and activation energies measured in this study can be combined with the literature thermochemistry for CI' and chlorobenzene to obtain absolute heats of formation for the isomeric benzynes: ΔH°f(ortho-benzyne) = 106 ± 3 kcal mol⁻¹, ΔH°f(meta-benzyne) = 116 ± 3 kcal mol⁻¹, and ΔH°f(para-benzyne) = 128 ± 3 kcal mol⁻¹. These results are summarized in table 1.

The same approach was used for the dehydrotoluenes. Deprotonation of ortho-, meta-, and para-chlorotoluenes gives ortho-, meta-, and para-chlorobenzyl anions which undergo efficient chloride loss upon CID to give α,2-, α,3-, and α,4-dehydrotoluene, respectively. The threshold energies obtained can be combined with literature values for meta- and para-chlorotoluene acidities and the bracketed acidity for ortho-chlorotoluene (ΔH°acid = 374 ± 3 kcal mol⁻¹) to give heats of formation for the dehydrotoluenes: ΔH°f(α,2-dehydrotoluene) = 106 ± 4 kcal mol⁻¹, ΔH°f(α,3-dehydrotoluene) = 96 ± 3 kcal mol⁻¹, and ΔH°f(α,4-dehydrotoluene) = 112 ± 4 kcal mol⁻¹. A notable result obtained here is that the isomer responsible for the

Table 1

Biological activity of the neocarzinostatin chromophore, \(\alpha,3\)-dehydrotoluene, is lowest in energy of the three dehydrotoluenes.

Other interesting thermochemical data can be derived from the measured heats of formation. For example, using the currently accepted value for a C-H bond dissociation energy in benzene, 110.9 ± 2.0 kcal mol\(^{-1}\), it is possible to calculate the C-H bond strengths for a phenyl radical. With the heats of formation reported here, the following C-H bond strengths are obtained: \(\Delta H_f(ortho-C_6H_4-H) = 80\) kcal mol\(^{-1}\), \(\Delta H_f(meta-C_6H_4-H) = 90\) kcal mol\(^{-1}\), and \(\Delta H_f(para-C_6H_4-H) = 102\) kcal mol\(^{-1}\), with all the C-H bonds in phenyl radical being weaker than the C-H bond in benzene. A similar calculation can be made for the dehydrotoluene system to give the C-H bond energies for benzyl radical. In this case, the ortho- and meta- C-H bond energies are nearly the same as that in benzene, while the meta carbon-hydrogen bond is 10 kcal mol\(^{-1}\) lower than a benzene C-H bond.

Finally, we have been able to prepare the distonic para-benzyne radical anion via CID on para-trimethylsilylphenyl anion. The ability to generate this and other remote radical anions provides a route to determining electronic properties for the neutral diradicals.

References

Beams of neutral molecules can be formed in the mass spectrometer by neutralization or dissociation of mass selected ions. Reionization of these neutrals leads to neutralization-reionization (NR) mass spectra which can reveal useful information on the structures of the mass-selected parent ion and the intermediate neutral species, as well as on the fragmentation mechanism(s) of the parent ion. These capabilities of neutralization-reionization mass spectrometry (NRMS) are illustrated here with specific examples.

**Ion Structures.** The collisionally activated dissociation (CAD) spectrum of protonated acetaldehyde shows prominent C$_2$H$_3$+ and OH$_2$+ fragments that are not observed in the corresponding NR spectrum (Figure 1). This is consistent with the presence of two structures in the C$_2$H$_5$O+ parent ion beam, namely the conventional CH$_3$CH=OH+ ion and the proton bound complex C$_2$H$_2$H+—OH$_2$, formed from the former via H rearrangement. The complex can yield C$_2$H$_3$+ and OH$_2$+ upon CAD, but decays into C$_2$H$_2$, H-, and OH$_2$ upon neutralization, thus disabling the formation of C$_2$H$_3$+ and OH$_2$+ after reionization.

![Figure 1](image)

**Neutral Structures.** NR spectra provide data on the stability of the neutrals accessed upon neutralization. E.g., that of figure 1B contains a significant recovered parent ion (m/z 45) showing...
that the radical CH$_3$CH-OH survives at least partly intact and must therefore have an appreciable barrier towards dissociation. The insignificant abundances of OH$^+$ (m/z 19) and C$_2$H$_5^+$ (m/z 27) in the NR spectrum further prove that the van der Waals complex C$_2$H$_5$H--OH$_2$ decomposes before it can be reionized (lifetime <<<0.11 μs).

A different radical, CIHCl$^-$, in which a light atom is surrounded by two heavy atoms, is hypervalent but nevertheless predicted by theory to be "vibrationally bound." CIHCl$^-$ can be formed in the gas phase by neutralization of CIHCl$^-$; upon reionization into anions no recovered CIHCl$^-$ is observed, indicating that CIHCl$^-$ is unstable in the time frame of the experiment (lifetime <<<0.2 μs). Similar conclusions were drawn by Holmes et al. from CIHCl$^-$ reionization into cations.

**Fragmentation Mechanisms.** Conventional MS/MS spectra contain only the ionic fragments from a specific parent ion. The simultaneously formed neutral fragments can be detected after reionization. From the resulting NR spectra knowledge is gained on the fragmentation mechanism(s) of the parent ion.

**Figure 2.** (A) CAD, He (ionic fragments) and (B) NR, He/O$_2$, spectra (neutral fragments after O$_2$ reionization) from protonated leu-enkephalin (Tyr-Gly-Gly-Phe-Leu).

Figures 2A and 2B show the ionic and neutral fragments, respectively, generated from the protonated pentapeptide leucine-enkephalin upon CAD. Despite the limited resolution in the NR spectrum, the neutral products from important N- and C-terminal fragmentations can be recognized: 131 Da (Leu residue) from MH$^+$-$\rightarrow$ b$_4$; 147 Da (Phe residue, largest neutral loss) from b$_4$-$\rightarrow$ b$_3$; 57 Da (Gly residue) from b$_3$-$\rightarrow$ b$_2$ (also from y$_4$-$\rightarrow$ y$_3$); 119 Da (Phe residue) from a$_4$-$\rightarrow$ b$_3$; and 135 Da (Tyr residue) from MH$^+$-$\rightarrow$ y$_4$ (+ CO). The absence of high mass peaks in the NR spectrum indicates that dipeptide or larger units are not eliminated directly from MH$^+$. The smaller backbone fragments are rather formed from the bigger via consecutive losses of single amino acid residues. Internal fragment ions are also observed in the CAD spectrum (e.g., m/z 205 and 177). These products do not originate by a rearrangement in which the N- and C-termini approach each other and are eliminated as a single piece because such a neutral fragment (351 Da) is not observed in the NR spectrum. Their formation must proceed through a stepwise mechanism: MH$^+$-$\rightarrow$ y$_4$-$\rightarrow$ y$_3$-$\rightarrow$ m/z 205 (loss of 131 Da) $\rightarrow$ m/z 177 (CO loss). Finally, the intense ions around m/z 90-92 and 106-108 in the NR spectrum can arise from losses of the aromatic side chains or from the further dissociation, after reionization, of eliminated phenylalanine and tyrosyl residues.
PHOTODISSOCIATION OF n-HEPTANE MOLECULAR ION: AN INVESTIGATION OF CONSECUTIVE REACTION IN REAL TIME

Joong Chul Choe*, Hun Young So**, and Myung Soo Kim
Department of Chemistry, Seoul National University, Seoul 151-742, Korea

Photodissociation (PD) of n-heptane molecular ion has been studied using the mass-analyzed ion kinetic energy spectrometry (MIKES). Even though competing consecutive reactions are usually invoked to explain mass spectral data, cases for direct investigation of consecutive reactions have been rare. For example, Baer and coworkers determined the rate constant for the secondary reaction in the consecutive reaction of halobutane molecular ion on a microsecond time scale using photoelectron-photoion coincidence technique.[1] Tandem mass spectrometry has been used for indirect identification of consecutive channels. In the present study, consecutive dissociation pathways have been observed in real time and rate constant for a consecutive reaction has been determined on a nanosecond time scale using the PD technique developed recently.[2]

The collision cell assembly of the ZAB-E mass spectrometer located in the second field free region was modified to produce an electric field of \(-5 \sim 5 \text{ kV/cm}\). The laser (Argon ion) beam was made to cross the ion beam at a position within the field. Then, analyzing the translational energy of daughter ions, time-resolved investigation of a consecutive reaction was possible. A time resolution of around 1 ns could be achieved. Charge exchange ionization (CS2/N2) was used to generate the molecular ion of n-heptane with a rather well defined internal energy.

Figure 1a shows a PD/MIKE spectrum for n-heptane molecular ion. Appearance of several peaks suggests that competing reactions participate in the PD of n-heptane molecular ion. Figure 1b shows a field-on PD/MIKE spectrum for n-heptane molecular ion, which was obtained with the applied voltage on the cell. Symmetric nature of the peaks with m/z 56, 57, 70, and 71 implies that the total dissociation rate constant of the photoexcited n-heptane molecular ion is larger than the maximum value \(k_m \sim 10^9 \text{s}^{-1}\) resolvable with the present instrument. On the other hand, the PD/MIKE signal for m/z 43 consists of two peaks designated as A and B in Fig. 1b. Moreover, the peak A is asymmetrically broadened and tails toward the peak B. Detailed analysis showed that this unexpected spectral feature resulted from the consecutive reaction 100+ → 71+ → 43+ under two assumptions: (1) The total rate constant is larger than \(k_m\). (2) The rate constant for the secondary reaction is smaller than \(k_m\).

In addition, several other consecutive channels could be identified, even though those were not as efficient as above: 100+ → 85+ → 43+, 100+ → 57+, and 100+ → 55+. Considerably broad rate constant distribution for the secondary reaction was obtained. This may be originated from the broad internal energy distribution of the intermediate ion due to the energy partitioning in the primary dissociation. Average rate constants for the consecutive

* Korea Basic Science Center, Seoul 135-280, Korea.

reaction determined were $(3.3 \pm 1.0) \times 10^7$ and $(1.88 \pm 1.3) \times 10^7 \text{s}^{-1}$ for PD at 488.0 and 514.5 nm, respectively. The PD channels of \( n \)-heptane molecular ion are shown as in Scheme 1. Based on rough estimations, the fragmentation pathways determined in this work including the consecutive reactions have been found to be in agreement with the statistical expectation.

MASS SPECTROMETRY OF BUCKMINSTERFULLERENE AND ITS CONGENERS

Purdue University, Chemistry Department, West Lafayette, Indiana 47907-1393

Abstract

It is well-known that a graphite vaporized by laser irradiation \(^1\) in a helium atmosphere yields ionized C\(_{60}\) and C\(_{70}\) in high abundance. It is also well-known that a high-power AC arc applied between graphite rods \(^2\) in a helium atmosphere produces macroscopic amount of buckminsterfullerene, C\(_{60}\), and its C\(_{70}\) analog in a few % yield. We now report our study on graphitic soot (product of the arcing process) using mass spectrometry. Extracts of graphitic soot are shown to contain, in addition to the well-known fullerenes C\(_{60}\) and C\(_{70}\), smaller quantities of much larger carbon clusters, up to C\(_{124}\). These compounds were detected by electron attachment and electron impact mass spectrometry (Figure 1). The relative stabilities of C\(_{60}\), C\(_{70}\), and C\(_{54}\) were investigated by charge exchange and collision activated dissociation experiments. The positively and negatively charged ions showed remarkable stability to fragmentation, although the reactions C\(_{70}\) \(^+\)\(\rightarrow\)C\(_{54}\)\(^+\) and C\(_{70}\) \(^-\)\(\rightarrow\)C\(_{54}\)\(^-\) provide evidence for interconversion of fullerenes. The data show the conspicuous absence of particular clusters.

Mass spectra of positive and negative ions derived from the fullerenes C\(_{60}\) and C\(_{70}\) show persistent satellite peaks. Differential evaporation into the mass spectrometer and changes in relative ion abundances with sample preparation suggest that the satellite ions are not generated in the mass spectrometer but correspond to four stable species with 14, 15, 16, and 17 additional mass units that are produced during the synthesis of the fullerenes or their extraction from graphitic soot. They are assigned as adducts of C\(_{60}\) and C\(_{70}\) containing CH\(_2\), CH\(_3\), O\(_2\), and OH, respectively. Collision activated dissociation of the (M+17)\(^+\) and (M+16)\(^+\) (M = C\(_{60}\), C\(_{70}\)) adducts yielded the respective ions of C\(_{60}\) and C\(_{70}\). Irradiation, using a mercury arc lamp, of mixtures of C\(_{60}\) and C\(_{70}\) increased the yields of the C\(_{60}\)+O and C\(_{70}\)+O adducts. In addition, products that corresponded to (C\(_{60}\)O + (CH\(_2\))\(_n\)) where n = 1,2,3,4,5, and (C\(_{70}\)O + (CH\(_2\))\(_n\)) where n = 1,2 occurred on irradiation of solutions of soot extracts (Figure 2). These compounds were absent upon irradiation of fullerene mixtures that were thoroughly washed with ether. Irradiation of the ether wash containing small amounts of C\(_{60}\) and C\(_{70}\) and the monoxides gave increased yields of C\(_{60}\)O and C\(_{70}\)O as well as C\(_{60}\)O\(_n\), where n = 2,3,4,5 and C\(_{70}\)O\(_n\), where n = 2 (Figure 3). These series of adducts are interpreted as products resulting from sequential cyclopropanations and epoxidations.

A variation of the arcing experiment was made using graphite electrodes with metallic inserts. Many low mass components were observed in the extract of the graphitic soot but none of the buckminsterfullerenes.

SURFACE-INDUCED DISSOCIATION OF DISTONIC RADICAL IONS

J.L. Jones and V.H. Wysocki
Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006

Distonic radical ions and their conventional counterparts have been extensively investigated both experimentally and theoretically. It was recently reported that low-energy gas-phase collisions can be used to differentiate between distonic ions and their conventional counterparts. We now report surface-induced dissociation results for distonic and conventional ions. The distonic ions investigated include \( \text{CH}_2(\text{CH}_2)_n\text{OH}^+ \) with \( n=0-2 \) and \( \text{CH}_2(\text{CH}_2)_n\text{NH}_3^+ \) with \( n=1-2 \). These ions were allowed to collide with the surface and their ion/surface collision behavior was compared with that of their conventional isomers \( \text{CH}_3(\text{CH}_2)_n\text{OH}^+ \) and \( \text{CH}_3(\text{CH}_2)_n\text{NH}_2^+ \). Deuterium-labelled distonic and conventional ions were also investigated, as was the influence of the nature of the surface (e.g. stainless steel, gold, ethanethiol and octadecanethiol on gold). The goals of the research are to determine the (i) surface-induced dissociation behavior of the distonic vs. conventional ions and (ii) the relative reactivity of the distonic vs. conventional ions toward H addition from surface-bound hydrocarbons.

With certain projectile ions, charge exchange can occur between the mass-selected projectile ion and surface adsorbates with the release of ionized adsorbates from the surface. Our data show that the use of a modified surface, consisting of a self-assembled monolayer film of ethanethiol on gold, drastically reduces the relative amount of charge transfer that occurs when polyatomic ions collide with the surface in the gas phase. This can be exemplified by ethanol and its distonic ion and in Figure 1 which compares an untreated gold surface (Fig.1a) with the ethanethiol modified gold surface (Fig.1b). These surfaces were used for the ion structure determination described below.

It was found that surface-induced dissociation spectra can be used to distinguish the distonic ions and their conventional counterparts. This can be seen in Figure 2 for ethanol and its distonic ion and in Figure 3 for ethylamine and its corresponding distonic ion. The distonic ions and their conventional isomers produce distinct spectra that indicate little isomerization. Some H addition does occur and can be seen in the fragmentation pattern in the spectra. Further studies will be required to determine whether these ions are the result of an initial neutralization followed by a proton transfer or if the distonic ions are reacting as radicals to abstract a hydrogen from surface-bound hydrocarbons.

We are developing methods for detecting volatile organics in water and soil samples. Our twofold goal is to develop rapid, fieldable screening procedures to identify contaminated samples that will require full analysis by EPA-approved methods, and to scope the utility of direct sampling MS for quantitating volatiles in the low ppb range.

The apparatus consists of a Finnigan ion trap mass spectrometer (ITMS) connected via an open-split interface with a purge device. The sample, contained in a standard 40 mL VOA vial, attaches to the purge device. The sample is sparged with helium at a flow rate of 100-150 mL/min. A portion of the purge gas flows into the ITMS through a restricting capillary. Mass spectra are obtained under El conditions.

Water standards were prepared by injecting a methanol stock solution into 25 mL of water that contains NaCl and Na2SO4 to simulate groundwater samples of interest to the U.S. Army Toxic and Hazardous Materials Agency (USATHAMA). Soil standards were prepared by spiking 5 g of soil with a stock solution. 25 mL of water were pipetted onto soil standards before purging.

To demonstrate the screening ability of direct-sampling ITMS, water standards containing the 34 volatiles on the EPA Target Compound List (TCL) at concentrations ranging from 1 ng/mL to 250 ng/mL were analyzed. Using data obtained from analyses of the individual components, most peaks in the mass spectrum of the mixture, shown in Figure 1, could be assigned to one or more TCL compounds. The goal of our screening procedure is "no false negatives"; i.e., all TCL volatiles present at or above quantitation limits must be detected. The fact that many of the ions occurring in the mixture spectrum are due to more than a single compound is not fatal for a procedure designed to eliminate uncontaminated samples from the queue for full-blown analysis. Eventually, the construction of a library with information about multiple ions observed for many compounds will lessen this interference effect. One problem with the screening procedure is that water-soluble ketones do not purge rapidly. Less soluble volatiles yield intensity vs. purge time profiles with an initial rapid rise followed by an exponential decay, reaching baseline intensity in 3 to 5 minutes. Purge profiles for the ketones rise to a low level and do not readily return to baseline, as Figure 2 shows. This behavior leads to higher detection limits for these compounds.

Mixtures of benzene, trichloroethene and tetrachloroethene ("BTT") spiked at 50 ppb(v) into a number of water and soil matrices were analyzed to evaluate direct-sampling ITMS for quantitation. Integrated purge profile areas for characteristic BTT ions in the samples were ratioed to the corresponding areas for BTT in water to give recoveries. Adjusting the pH of water samples over the pH=2 to pH=10 range had no significant effect on BTT recovery. A high organic content in the water, simulated with a potting soil leachate prepared by filtering a mixture of potting soil and water, did not interfere with BTT recovery. In general, soil samples reduced BTT recoveries, although some of this loss is associated with the spiking procedure rather than with the analysis. Soil types examined include a commercial potting soil, (mixture of sand and organic matter), Rocky Mountain Arsenal soil (sandy), a soil provided by USATHAMA (finely-divided clay), a local Oak Ridge soil, and a Knox county soil (mixed clay and organic matter). Precision of results for the various soils depended strongly on the uniformity of the samples. The three compounds also tended to purge differently relative to one another depending on soil composition. BTT recovery from the USATHAMA soil was lower than from other soils, indicating that this soil is the most adsorptive of those tested. We also evaluated different purge conditions for the USATHAMA soil. Heating the sample during the purge increased recovery slightly, while sonicating the sample had little effect. Allowing the sample to stand for 24 hours after adding water resulted in no significant loss of volatiles. In addition to the matrix comparison at 50 ppb(v), calibration curves constructed for BTT in water over the 1 to 1000 ppb(v) range were reasonably linear in the 1 to 100 ppb(v) range, but showed some deviation from linearity at higher concentrations because of space charging.

Direct sampling ITMS is useful for screening environmental samples for volatiles. Our results show that quantitation is feasible, despite some matrix effects. We plan to study other matrices and investigate alternative methods for troublesome compounds such as water-soluble ketones.

A new technique has been developed to extract volatile organic compounds from aqueous systems into the gas phase. Unlike the conventional purge-and-trap method with the bubble purger, the new technique disperses the liquid sample in a flowing carrier gas. The water sample is sprayed through a nozzle into an extraction chamber (Fig. 1), where the formation of tiny droplets increases the total surface area dramatically and accelerates the partitioning process of the dissolved compounds between the aqueous sample and the gas phase. The water pressure and flow required by the spray process can be provided either by a pump or by a pressurized sampling chamber. Fig. 2 shows a pump-driven spray extraction system schematically. In the system with the sampling chamber, compressed nitrogen is used to pressurize the chamber and as carrier gas for the extraction. The sampling chamber can be dipped into water and a "normally-open" spring-loaded valve at the bottom lets the liquid enter the chamber. Whenever pressure is applied, the spring-loaded valve closes and the system becomes ready to spray. An automated valve-operation sequence controls the entire spray extraction process.

The carrier gas enters the extractor at the top (Fig. 1) and travels down through the spray cone against the flight direction of the water droplets (counter-current). At the lower part of the chamber, the gas exits through the slot of the protected exit tube. After flowing down the chamber walls, the sprayed water sample exits the extractor through the drain tube at the sink shaped bottom. In order to prevent the carrier gas from leaving the chamber through this "wrong" exit, there is always a little residual water in the sink. The volume of this "rest" is monitored by a level sensor in the chamber. As soon as the water level exceeds a pre-defined mark, the signal of the level sensor is used to open the magnetic valve in the drain tube. The drain valve stays closed when the water level is below a marked height. The carrier gas enters an automatic gas preconcentrator, equipped with a Tenax sorption tube. Subsequently, the Tenax tube is heated and the desorbed gases are transferred into the GCMS. The Mobile Environmental GC-Mass Spectrometer "HEM" of Bruker-Franzen Analytik was used.

A mixture of volatile organic compounds (VOC) has been
used to test the response of the complete system. The test results as a diagram of the VOC concentration in water versus the GC peak area is depicted in Fig. 3. The linearity of the data points is remarkable. As a natural result of the extraction process, water vapor is also entering the sorption tube. In the experiments, the Tenax tube was "dry-purged" for 30s between the sampling and the desorption events, in order to prevent large amounts of water vapor from entering the GCMS. Experiments using the spray extractor / preconcentrator / MRM (2 min. of sampling, simple flow, 900ml of water) have shown, that compounds with relative low solubility in water (benzene, toluene etc.) can be detected in a concentration range as low as 10-30 ng/l. The spray extractor can also be operated as a stand-alone device. Extracted compounds can be captured in a Tenax tube mounted on the gas exit. They can then be analyzed separately.

The spray-and-trap method as a continuous monitoring technique can be applied to large-size water samples like industrial waste waters, river, lake and seawater in the simple flow mode: The water sample passes through the extractor only once. However, for small-volume samples, the circulation mode is recommended. A calibration of the sampler for each different mode is necessary.

Increased curvature of the surface (droplets!) leads to an increase of vapor pressure of the liquids (Kelvin equation): $P_{\text{mist}} = P_{\text{bulk}} \exp\left(\frac{2\gamma V_m l}{\pi r^2 T}\right)$. $V_m$ is the molar volume, $r$ the droplet radius and $\gamma$ the surface tension. This effect, supporting the extraction, is however small and becomes only remarkable at sub-micron sized water droplets.

The spray-and-trap method can be applied to solutions containing surfactants. Unlike in the bubble purger, the operation of the system is not blocked by a foam formation. Some effects of surfactants are observed in the quantitative analysis data from spray extraction (usually minor and compound dependent). Standard addition method is recommended to increase accuracy.

1) Patent applied for
The determination of specific organic chemicals in natural waters is of prime importance in the assessment of the environmental impact of waste liquid effluent discharges. Conventionally, these measurements are performed by discrete sampling of the waterbody followed by specific analysis at the Laboratory by methods such as gas chromatography and gas chromatography-mass spectrometry. While this process provides a considerable amount of useful data, it is comparatively slow and there is a real need for a method which is capable of direct determination of these substances in the field.

In conjunction with VG Gas Analysis Systems Ltd, this Laboratory has investigated the potential of membrane inlet mass spectrometry as a field method. This technique has previously been used by a number of workers to measure volatile organic chemicals in aqueous samples and is currently undergoing a resurgence in the United States. Beginning in 1985, we have carried out a number of field surveys of natural waters with a small portable mass spectrometer fitted with a membrane inlet, the VG “AquaPetra”. Originally, the system was transported to the banks of the river estuary by mobile van where the constituent parts were assembled. These included a pumping system to bring the estuarine water into the vicinity of the mass spectrometer so that it could be sampled by its own flow system. Using this apparatus, information on the concentrations of a number of organic chemicals in the estuarine water was obtained by monitoring up to 16 selected ions.

Although, this mode of operation did provide useful information, the system could only be used for continuous monitoring over a very restricted area. Consequently, more recent surveys have sought to extend the range of applicability by mounting the apparatus in a boat. Two surveys of this type have been carried out, the first on a relatively narrow waterway and the second on a wide estuary.

Typical results from these two surveys are shown in Figures 1 & 2, although these represent only a very small fraction of the data that was collected in each case. Figure 1 shows the results of continuously monitoring the m/z 78 ion, to represent benzene concentration, over a 16 kilometre stretch of the waterway at 2m (nominal) depth. At the beginning of the profile, the intensity of the ion is found to decrease over the first few kilometres. But at 8 kilometres, which represents the most industrialised part of the waterway, two distinct peaks are observed corresponding to discharges from petrochemical establishments. On completion of this profile, some depth profiling (0 - 7.5m) was carried out and this shows the water to be relatively well mixed at this point. The second example, Figure 2 shows a profiling run conducted in a large estuary for toluene using the m/z 92 ion to represent toluene concentration. The system was calibrated using a 100 ug/l toluene standard at both start and finish of the profiling work. After the first of these standards, a longitudinal profiling run (nominal depth 1m) was conducted over a 4 kilometre stretch of the estuary and this showed little evidence of the presence of toluene. On returning (at depths of between sub-surface and 1m), a submerged pipeline was passed and the toluene discharge from this was clearly discerned. This area was then criss-crossed to take other measurements of the toluene content of the water immediately surrounding this discharge. However, this process was complicated by the difficulty in ascertaining the relevant location since the discharge boil was only visible at intervals. Nevertheless, it was observed on a number of subsequent occasions and was monitored as is shown in the figure. The maximum toluene concentration observed in this work was approximately 20 ug/l.

Although only a small fraction of the data has been presented, the capability of membrane inlet mass spectrometry for the continuous monitoring of certain chemicals in water is clearly demonstrated. However, the high cost of the instrumentation, approximately £40,000 and its rather limited compound range, i.e to those substances of high aqueous volatility, have probably restricted its use to date.

DIRECT MEASUREMENT OF VOLATILE ORGANICS IN AIR USING AN ION TRAP MASS SPECTROMETER

Marcus B. Wise, Gregory B. Hurst, Cyril V. Thompson, Douglas L. Theobald, and Michael R. Guerin
Analytical Chemistry Division, Oak Ridge National Laboratory
P.O. Box 2008, MS-120
Oak Ridge, Tennessee 37831-6120

Introduction
Growing concern over indoor air pollution, occupational exposure to airborne toxics, excessive stack emissions, accidental spills, and other sources of emission which contribute to air contamination, has led to an increased need for fast, sensitive, and selective methods for the detection of trace organics in air. In response to this need, we have been working on the application of ion trap mass spectrometers to real-time, continuous monitoring of volatile organic compounds in air.

Experimental
All experiments were performed with a Finnigan MAT ITMS ion trap mass spectrometer equipped with an electropolished vacuum chamber and dual 330 L/sec turbomolecular pumps. A special sniffer probe was designed for direct air monitoring which includes an open/split capillary restrictor interface with a 2 L/min air sampling pump attached to the split vent. This pump provides active sampling at a high flow rate, while the open/split interface maintains the pressure inside the mass spectrometer at a tolerable level. Normally, the low mass cutoff for the ion trap is set at or above mass 35 in order to eliminate water and air ions from the cell. Under these conditions, either electron impact or chemical ionization (using a reagent such as isobutane) can be used to ionize the analytes. Typically, conventional full scan electron impact mass spectra are acquired and searched for the presence of characteristic ions which may correspond to the presence of target analytes. For greater confidence in the identification of an analyte, the ITMS may be operated in a selected ion storage MS/MS mode.

In order to establish the detection limits of the instrument, trace levels of volatile organics in air were generated using a syringe pump vapor generator. This device continuously meters a known volume of a dilute solution of volatile organics into a flowing air stream. The concentration of the analytes can be controlled by altering either the flow rate of the air or the amount of analyte metered into the air stream. Using this apparatus, reliable concentrations VOC's in air can be generated ranging from low ppb levels to greater than 10 ppm. Certified standards of volatile organics in nitrogen were also purchased and used to confirm the proper operation and calibration of the vapor generator.

Results and Discussion
An important aspect of successful direct air sampling with our ITMS is that the helium buffer gas (for the stabilization of ions in the cell) is added to the instrument through the air sampling probe instead of by means of a batch inlet. This improves the overall performance of the instrument in terms of resolution, reduced multiplier noise, and better detection limits as shown in Figure 1. In order to minimize dilution of the air sample with the helium, a pulsed valve is used to inject helium into the sampled air stream at a rate of approximately twice per second. Using a sniffer probe approximately 6 feet long in conjunction with the 2 L/sec air sampling pump, the response time of the ITMS is generally less than 5 seconds.

Under electron impact ionization conditions, the real-time detection limits for 30 different volatile organics in air have been found to range from approximately 2 ppb to 50 ppb (Table 1). Linear calibration curves have been generated over a 2-3 order of magnitude concentration range (without the use of the Automatic Gain Control software) indicating that quantification of target analytes is feasible at low ppb concentrations (Figure 2). Although extensive experiments have not yet been performed for a wide range of VOC's, preliminary experiments indicate that detection limits in the part-per-trillion range may be achieved for some compounds through the use of chemical ionization reagents.
Laboratory tests of the ITMS indicate that it can be configured for the real-time monitoring of volatile organic compounds at low ppb concentrations. Quantification is possible either by the addition of a standard to the sample or by comparison of instrument response with an external calibration curve. Electron impact ionization provides universal detection, while chemical ionization can be used for more selective ionization and in some cases improved detection limits. Further, the MS/MS capability of the ITMS provides an important added dimension to the identification of target analytes in complex samples. At this time, a fieldable version of the air monitoring ion trap is under construction and is scheduled for initial testing later this year.

DETECTION OF EXPLOSIVES RESIDUE
BY ION MOBILITY SPECTROMETRY

*Dean D. Fetterolf, FBI Laboratory, Forensic Science Research Unit, FBI Academy, Quantico, Virginia, 22135; Frederick W. Whitehurst, FBI Laboratory, Materials Analysis Unit, Washington, DC 20535.

The United States has been a prime target of international terrorism for at least two decades. The bombings of the U.S. Embassy and the U.S. Marine Barracks in Beirut in 1983, and the destruction of Pan American Flight 103 over Lockerbie, Scotland in 1989 are grim reminders of terrorism in recent years. These criminal acts have prompted the need for the development of new and innovative methods of explosives detection. As part of an ongoing research effort, the FBI Laboratory has been evaluating new technology and the innovative adaptation of existing technology for use in counterterrorism and counternarcotics investigations.

The widely varying (ppm to ppt) vapor pressures of explosives hidden in packages, luggage or on people requires extremely sensitive and selective detection methods. Laboratory studies have shown that explosive material can be transferred from contaminated hands to surfaces. Therefore, the sampling of particulate residue on surfaces offers a greater chance for detection of concealed explosives.

Three commercially available ion mobility spectrometers (IMS); an IONSCAN (Barringer Instruments, Inc., West Plainfield, NJ); a Phemto-Chem PC-110 (FCP, Inc., West Palm Beach, FL) and a briefcase sized Graseby PD-5 (Graseby Dynamics Ltd., Watford, Herts, England) are being evaluated for routine forensic applications.

The IONSCAN collects explosives residue on a membrane filter while the PC-110 uses a quartz wool preconcentrator tube. In both cases sample collection, thermal desorption, and analysis requires less than 30 seconds. The Graseby PD-5 is designed for direct air sampling and is therefore only sensitive to the more volatile nitrated ester explosives, ethyleneglycol dinitrate (EGDN) and nitroglycerine (NG).

Sampling procedures for examining packages, luggage and people for hidden explosives have been developed for each of the detectors. Laboratory evaluation of the IONSCAN system has determined the limits of detection for common explosives to be 50-600 pg. Figure 1 show the identification of a PETN based sheet explosive. The PC-100 IMS has a limit of detection of 0.03 ppt RDX vapor. From a saturated head space vapor, a 10 second air sample results in the detection of 20 fg RDX as shown in Figure 2. For the Graseby PD-5, 0.25 pounds of dynamite can readily be detected in a cardboard box from 10-12 feet after a "soak time" of 1 hr.

The IMS detectors have been employed in actual terrorist investigations. Following a domestic dispute, a local police agency asked the FBI Laboratory to identify homemade nitroglycerine in a basement prior to it being rendered safe. Using the Graseby PD-5 the NG was safely located and identified. In another incident, the PD-5 was used to assist the FBI and New York City Police Joint Terrorist Task Force in a narcoterrorist investigation by searching 1,300 rental storage lockers and 6 apartment buildings for dynamite.

The recent Middle East crisis heightened the world's awareness to the potential for terrorist attacks. In January, 1991 all three IMS detectors were employed by the FBI Laboratory to provided added security and to respond to potential terrorist threats during Superbowl XXV in Tampa, FL. Figure 3 shows the detection of RDX on the trunk of a car which had C-4 explosive hidden in it for testing and training of canines.

This is a publication of the Laboratory Division of the Federal Bureau of Investigation. The use of names of commercial manufacturers does not constitute or imply endorsement, recommendation or favoring.

DIRECT INTRODUCTION OF PESTICIDE-CONTAMINATED CROP SAMPLES TO A MASS SPECTROMETER VIA A PYROLYSIS PROBE

John P. Toth, Department of Food Science and Human Nutrition, University of Florida, Gainesville, FL
A. Peter Snyder, U.S. Army Chemical Research, Development and Engineering Center, Aberdeen, MD

Pyrolysis is an established method for introducing complex samples such as natural and synthetic polymers, commercial drug and pesticide formulations and intact microorganisms to a gas chromatograph or mass spectrometer. We are investigating the use of pyrolysis in conjunction with mass spectrometry for the detection of pesticide residues in crop matrices. The potential advantages of this approach are reduction of the amount of extraction and cleanup needed and the ability to detect unextractable bound residues.

We have chosen as representative pesticides four triazine compounds (fig. 1) used extensively in Florida agriculture. Simazine, atrazine and ametryn are herbicides used for the protection of citrus and other crops; cyromazine is an insecticide used for the protection of several minor crops including Chinese cabbage. Bok Choy Chinese cabbage was used as a representative matrix for cyromazine and orange peel was used for the three herbicides.

Data were obtained using a Sciex TAGA 6000 atmospheric pressure ionization (API) triple-quadrupole mass spectrometer. Samples were introduced to the mass spectrometer via a Pyroprobe Model 122 Controller equipped with a platinum coil desorption probe (Chemical Data Systems, Oxford, PA) ramped to 600°C at 240°C/min. 5-mg crop samples were spiked in situ with pesticide analytes at concentrations ranging from 400 ppm to 1 ppm.

Under these conditions, all four analytes evaporated from the probe without decomposition giving API mass spectra dominated by MH⁺ (fig. 2). Crop samples, on the other hand, underwent thermal degradation to volatile products of low molecular weight (fig. 3). Even in the absence of chromatographic separation, some temporal resolution of analytes and substrates was seen in spiked samples (fig. 4). Further enhancement of signal-to-noise was sought by obtaining CID daughter-ion spectra of MH⁺ for the four analytes. In each daughter ion spectrum three diagnostic ions were identified as XCNC(NH₂)NH⁺, CHNX⁺ and CH,N₂X⁺, where X=Cl for simazine and atrazine, X=SCH₃ for ametryn and X=NH₂ for cyromazine. Selected reaction monitoring for these three daughter ions permitted detection of low-ppm levels of each analyte in spiked crop samples (Table 1). Efforts are underway to lower these LOD’s by the introduction of chromatographic separation.

SELECTIVE DETECTION OF CHLORINE-CONTAINING COMPOUNDS IN A COMPLEX MIXTURE

Jeff Morre and Mehdi Moini

Department of Chemistry and Biochemistry, University of Texas at Austin, Austin TX 78712

Introduction

The addition of a reaction gas to a low pressure microwave-induced plasma (MIP) creates a reaction interface in which complex molecules are converted into small stable neutrals. For a given reaction gas used the molecules formed represent the elemental composition of the original analyte. In this study SO₂ has been used as a reaction gas for the selective detection of chlorine-containing compounds in a complex mixture, using capillary gas chromatography-microwave induced plasma-reaction interface mass spectrometry (GC-MIP-RIMS).

Experimental

The GC-MIP-RIMS apparatus is described before therefore only a brief description is given here. The GC-RIMS set-up consists of a Varian 3400 GC with a 30m DB-5 capillary column connected to a 4.5" long, 1/16" i.d. and 1/4" o.d. ceramic tube using conventional vacuum components. The ceramic tube extends through the microwave cavity. The other end of this ceramic tube is connected to a deactivated uncoated wide bore fused silica capillary which is used as a transfer line. The union on the column side of the ceramic tube was modified by adding a 1/16th inch stainless steel tubing to allow flow of the reaction gas into the ceramic tube using a leak valve. The detector was a Finnigan 4000 quadrupole mass spectrometer with INCOS, version 4.07.82, data system. The microwave chamber was powered by a 100 W, 2450 MHz power supply with a forward power of 80 W and a reverse power of 6 W. Helium was used as a carrier gas for the GC and the MIP.

Results and Discussion

Selectivity: When SO₂ was used as a reaction gas, carbon predominantly formed CO m/z 28 and CO₂ m/z 44. The chlorine primarily formed HCl m/z 36, plus some other minor components, e.g., SCI m/z 67 and SCI₂ m/z 102. At m/z 36 detection of chlorinated compounds was completely selective. This was demonstrated using dichlorobenzene and n-dodecane as the chlorinated and non-chlorinated compounds as shown in Figure 1.

Sensitivity: The GC-MIP-RIMS limits of detection for dichlorobenzene is 10 picograms on column with a S/N>3. This was achieved using single ion detection mode with 1000 ms scan time. The linear dynamic range of the calibration curve using dodecane as the internal standard is at least 4 orders of magnitude, as shown in Figure 2.
Applications in Environmental Studies A mixture of the PCB mix and several non-chlorinated compounds was used to show the selectivity for the chlorine-containing compounds in a complex mixture. The result is shown in Figure 3. As is shown m/z 36, HCl, is completely selective. After identifying the chlorinated peaks in the chromatogram of the complex mixture using the MIP-RIMS method, the experiment was repeated this time MIP was turned off and mass spectrum in the full scan mode were obtained. Figure 4 shows the mass spectra of one the identified PCBs.

Conclusion

The GC-MIP-RIMS method of chlorine detection can be used as a time saving analytical tool in the environmental testing industry. The setup allows the versatility of prescreening complex mixtures for chlorinated compounds. This is a valuable asset to the detection of PCBs, pesticides and other life threatening chlorinated compounds. Low limit of detection and wide dynamic range of the GC-MIP-RIMS, its minimal cost and its ease of operation make this setup an attractive analytical tool for the selective detection of chlorine-containing compounds and their identification in a complex mixture.

Analysis of Isomeric Alcohol Mixtures Using GC-Matrix Isolation-FTIR-MS

Eldon R. Baumeister, Liming Zhang, Christoph Klawun and *Charles L. Wilkins
Department of Chemistry,
University of California, Riverside
Riverside, CA 92521

INTRODUCTION

Isomeric alcohol mixtures are very important because of their use in various commercial manufacturing processes. The extent of carbon branching in isomeric alcohol mixtures determines their overall physical and chemical properties. Short chain alcohol mixtures are often used in plasticizer production. New legislation is requiring manufacturers to identify more specifically the constituents in their products, as well as in their products' precursors. For these reasons, the ability to separate and identify the individual constituents of commercial isomeric alcohol samples has recently become much more important.

Gas chromatography/matrix isolation infrared spectroscopy-mass spectroscopy (GC/MI-FTIR-MS) is a highly sensitive and specific technique that combines the capabilities of capillary column gas chromatography for separating components of complex mixtures with the high sensitivity and specificity of both matrix isolation infrared and mass spectrometric detection. This technique provides three distinct types of chemical information. First, the flame ionization detector provides retention times and quantitative information for each separated component of the complex mixture. Second, the matrix isolation Fourier transform infrared spectrometer provides functional group and isomer specific information. Third, molecular weight and fragmentation patterns are obtained from the mass selective detector. GC/MI-FTIR-MS is well suited for the analysis of isomeric alcohol mixtures. In this paper, application of this methodology to the analysis of two representative alcohol mixtures is described.

EXPERIMENTAL

The GC/MI-FTIR-MS instrument utilizes a Hewlett-Packard 5890 gas chromatograph with a 50:35:15 three way splitter to the IR, MS and FID, respectively. The matrix isolation Fourier transform infrared spectrometer used is a Mattson Instruments Cryolect 4800, while the mass spectrometer is a Hewlett-Packard 5970B mass selective detector. A 60m DB-wax column is used for the separations. Quantitative $^{13}$C NMR is also utilized.

RESULTS

The two samples analyzed are thought to contain only saturated, C-7 primary alcohol isomers. There are a total of 17 $\text{C}_7\text{H}_{16}\text{O}$ alcohol isomers. FID and $^{13}$C NMR data indicate the presence of more than 12 distinct isomers in each sample. Each sample contains only 7 components in sufficient concentration (>0.5%) to be simultaneously identified by IR, MS and FID. Six of the seven major components occur in both samples, although in varying relative concentrations. The individual mass and matrix-isolated infrared spectra have been recorded for all eight of the major components. Figure 1 shows the mass spectrum for 2,4-dimethylpentanol, component 2. A detailed analysis of both the mass and infrared spectra allows structure assignments to be made for each component. Table 1 shows the structural assignments for each component in order of elution (column 1), based upon the MS and MI-IR data alone, (columns 2 and 3), and the assignment based upon complimentary use of both the IR and MS data (column 4).

THE ATMOSPHERIC STABILITY OF POLYBROMINATED DIBENZOP-DIOXINS AND DIBENZOFURANS

C.C. Lutes, M.J. Charles and R.M. Kamens
Department of Environmental Sciences and Engineering
University of North Carolina at Chapel Hill
Chapel Hill, NC 27599

Introduction. Atmospheric emissions of polybrominated dibenzo-p-dioxins (PBDDs) and dibenzofurans (PBDFs) are likely to increase in the future due to the rising use of brominated organic compounds in consumer products and of incineration as a means of municipal waste disposal. Information on the atmospheric stability of PBDDs and PBDFs is thus needed for risk assessment since human exposure takes place through atmospheric transport and depositional processes. Previous laboratory studies of the photodegradation of PBDDs and PBDFs have shown rapid degradation in organic solution (for 2,3,7,8-tetrabrominated dibenzo-p-dioxin $t_{1/2} = 0.8$ min) but much slower degradation on quartz surfaces ($t_{1/2} = 32$ hours for 2,3,7,8-TBDD) (1). It is unknown whether these half-lives represent actual degradation rates in the ambient environment.

Experimental. In this study dilute emissions from the combustion (640-760°C) of polyurethane foam containing polybrominated diphenyl ethers (PBDPEs) were introduced into 25 m³ outdoor teflon film chambers and aged in the presence of sunlight. Important atmospheric variables such as temperature, particle size distributions, total solar radiation, and ozone concentration were monitored over the course of the experiment. Concentrations of tetra- and penta-brominated PBDDs and PBDFs were monitored by collecting and analyzing particulate and vapor phase samples. This analysis involved soxhlet extraction, the use of silica, florisor and carbon/celite columns to isolate PBDDs and PBDFs from other compounds and high resolution gas chromatography/high resolution mass spectrometry (Resolving Power = 10,000). Although PBDPEs can exhibit ions that interfere in the analysis of PBDFs, these compounds were not significant interferences in this work.

Results and Discussion. PBDDs and PBDFs partitioned primarily to the particulate phase ([particulate]/[particulate + vapor] = .95-.99). Particulate phase concentrations of PBDDs and PBDFs show no consistent evidence for degradation over periods of up to six hours under realistic atmospheric conditions (see Figure 1). This conclusion is supported both by an examination of the individual data points in view of their experimental variability, and by a statistical analysis of the change in concentration of analyte as a function of incident solar radiation. Though a photolytic production of TBDFs from PBDPEs has been demonstrated both in solution (2) and adsorbed onto filter surfaces, calculations predict that this process is unlikely to significantly influence observed concentrations in our chamber aging experiments. Therefore we believe that a photolytic degradation process for PBDDs and PBDFs, on realistic soot particle surfaces, if occurring, has a half life of at least three hours instead of several minutes as predicted by solution phase experiments.

1215
Figure 1: Stability of TBDD, TBDF, PeBDD and PeBDF on particulate phase material over 6 hours under warm temperature (39 - 30 C) and bright (1.0 - .22 langleys) sunlight (data is derived from the March 14, 1990 experiment).
A HIGH RESOLUTION MASS SPECTROMETRIC METHOD FOR THE DETERMINATION OF MONOBROMINATED POLYCHLORINATED DIBENZO-P-DIOXINS IN ENVIRONMENTAL SAMPLES

Lee Q. Huang¹, Huayl Tong², Anthony Paiva¹, Steve J. Monson², and Michael L. Gross²
¹Department of Analytical Chemistry, The Connecticut Agricultural Experiment Station, 123 Huntington Street, New Haven, CT 06511,
²Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

The analysis of environmental and biological samples for polychlorinated dibenzo-p-dioxins (PCDDs) has received considerable public and scientific attention during the past several decades because of their high toxicity. Recent findings of polybrominated dibenzo-p-dioxins (PBDDs) in some samples have also raised concern about their environmental impact. At the present time, very little is known about mixed bromo/chloro dioxins such as monobromopolychloro dibenzo-p-dioxins (BPCDDs), although structural considerations and biological activity of these compounds indicate that their toxicity is similar to that of PCDDs (ref. 1).

Mass Spectrometry (MS) has been the leading technique used in dioxin analysis, and MS methods for the analysis of PCDDs are well-established. Quantitative analysis of BPCDDs is, however, much more difficult than the methods for PCDDs in that: (1) very few standard compounds of BPCDDs are currently available for calibration and quantitation; (2) the levels of BPCDDs found in samples are a factor of ~30 times lower than those of PCDD counterparts as estimated in an early study (ref. 2); (3) there are many more possible isomers of BPCDDs than that of PCDDs, e.g., maximum possible BPCDD compounds of 198 for tetra- through octa- halogen substitution and 70 for tetra-group, as compared to only 49 PCDD isomers of tetra- through octa- substitution and 22 for tetra-group; (4) mass spectrometric responses of BPCDDs are a factor of 2-5 times lower than that of PCDDs, which requires higher sensitivity of an instrument for the analysis of BPCDDs (ref. 2); (5) the analysis of BPCDDs is more complicated due to the presence of large quantities of chloro analogues, which cannot be separated in cleanup procedures. Under such circumstances, the analytical method must have an extremely high sensitivity and specificity for the quantitative determination of BPCDDs.

In a recent study, a high resolution gas chromatographic/high resolution mass spectrometric method was developed for the determination of BPCDDs in environmental samples. The mass spectrometer was operated at high resolution (>10,000) in the selected ion monitoring mode with magnet switching among tetra- through octa- groups to achieve low or sub-ng sensitivity. Synthesized standard compounds of BPCDDs for tetra- through octa- congener groups were utilized for accurate measurement of the MS relative response factors for the first time. The mean values of RRFs (Table 1) ranged from 0.2 to 0.6 for BPCDDs, as compared to RRFs of close to unity for PCDDs. This finding indicates that previous quantitations for BPCDDs in the literature using PCDDs' RRFs of close to unity underestimated the levels of BPCDDs in the environment. Excellent linear calibration was achieved by using these standard compounds at different concentrations. Correlation coefficients of 0.9988, 0.9980, 0.9984, 0.9990, and 0.9992 were obtained for 2-Br-3,7,8-Cl₂DD, 2-Br-1,3,7,8-Cl₄DD, 2-Br-3,6,7,8,9-Cl₅DD, 1-Br-2,3,6,7,8,9-Cl₆DD, and 1-Br-2,3,4,6,7,8,9-Cl₇DD, respectively. The method detection limit was at low or sub-ng levels for BPCDDs. Accuracy greater than 80% and precision better than 10% were demonstrated with spiked samples. Flyash samples collected from several countries were analyzed for BPCDDs by this method, and substantial amounts of BPCDDs were detected in every sample. Preliminary identification of some BPCDD isomers that were detected in flyash is shown in Figure 1. Isomer specific determination, however, awaits further improvements of chromatographic techniques and availability of BPCDD standard compounds in the future.

APPLICATIONS OF MASS SPECTROMETRY TO THE IDENTIFICATION OF MUTAGENIC COMPOUNDS PRODUCED BY MONOCHLORAMINATION OFFULVIC ACID

*Rohini Kanniganti, M. Judith Charles, David Cozzie, Louise M. Ball, and J. Donald Johnson
Department of Environmental Sciences and Engineering
University of North Carolina at Chapel Hill
Chapel Hill, NC 27599

INTRODUCTION. Chlorination of drinking water that contains natural organics leads to the formation of mutagenic nonvolatile chlorinated compounds. These compounds include propenals, propanones, oxo-butenoic acids and hydroxy furanones. In view of the human health hazards posed by chlorine by-products, monochloramine has gained importance as a possible alternative disinfectant. However, information regarding the potential human health hazards associated with the use of monochloramine is very limited. Although several researchers have identified mutagenicity in monochloraminated humic and drinking waters, few have been able to identify products leading to this mutagenicity. The objective of this research was thus to identify compounds in the mutagenic extracts produced by the reaction of monochloramine and fulvic acid. Fulvic acid was chosen as a model compound since it represents approximately one half of the organics naturally present in drinking water sources.

METHODS. Monochloramine was prepared fresh by reacting ammonium chloride and sodium hypochlorite in a 3:1 molar ratio at pH 8.0. Monochloramine was reacted with fulvic acid at the desired Cl:C molar ratio at pH 8.0 over a period of 96 hours. Chlorination of fulvic acid was performed by reacting sodium hypochlorite with fulvic acid at a molar Cl:C ratio of 1:5. Extraction of the sample was by liquid-liquid extraction with diethyl ether. Extractions were performed at sample pH 2.0. The mutagenicity of the extracts was assayed in accordance with the standard plate incorporation assay by Maron and Ames (1983).

Results of preliminary experiments suggested that the mutagenic compounds were acidic and polar. We therefore derivatized mutagenic extracts with boron trifluoride (BF$_3$) in methanol because it methylates hydroxyl-, dihydroxyl-, carboxyl-, dicarboxyl- and aldehydic functional groups. Diethyl ether extracts were taken to dryness under a stream of N$_2$ gas and then redissolved in 250μL of methanol containing 14% (v/v) BF$_3$. The mixture was allowed to react for 12 hours in a 70°C mineral oil bath. The mixture was subsequently neutralized with 3mL of 2% (v/v) NaHCO$_3$, extracted twice with 250mL of hexane and concentrated under a stream of N$_2$ gas.

The derivatized extracts were then analyzed by using high resolution gas chromatography / mass spectrometry (HRGC/MS). The analyses were performed on a Hewlett Packard 5890 gas chromatograph interfaced with a VG70-25SEQ mass spectrometer (resolving power = 1,000 or 10,000; 10% valley definition). All experiments were conducted using a DB-5, 30-m-length, 0.25-mm-i.d., 0.25μm film fused silica capillary column. Experiments performed by full-scan mode were conducted using a GC temperature program of 50°C for 1 minute followed by a temperature rise of 2.5°C/min to 150°C and 5°C/min to 300°C. A temperature program of 50°C for 1 minute and a rise of 10°C/min to 300°C was used in analyses conducted by selected ion monitoring (SIM).

Full-scan mass spectra were acquired by using electron-ionization (EI) at an electron energy of 70eV, 200μamp trap current, 250°C source temperature and resolving power of 1,000. The magnet was scanned at 500-50 amu at 1 second/decade. Quantifications were performed by measuring the relative response of a specific ion of each of the compounds to the response of the m/z 334 ion of the internal standard, decaffluorobiphenyl (10ng/μL).

Selected ion monitoring analyses were performed under similar instrumental conditions as full-scan analyses except that a resolving power of 10,000 was used. The internal standard used was $^{13}$C$_6$ benzoic acid (50pg/μL) and the recovery standard for quantification of 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-furanone (MX) was anthracene d$_{10}$ (25pg/μL). MX quantification was based on a four point calibration curve constructed from the analysis of standard solutions that contained 50, 100, 250 or 500pg/μL of MX, and the internal and recovery standards. Semi-quantification of E-2-chloro-3-(dichloromethyl)-4-oxobutenoic acid (EMX), E-2-chloro-3(dichloromethyl)-butenedioic acid (ox-EMX) and mucoochloric acid was performed based on a relative response factor obtained from the analysis of a single standard solution of each analyte that containing 50pg/μL $^{13}$C$_6$ benzoic acid.
RESULTS AND DISCUSSION. Analyses in the GC/MS full-scan mode resulted in the analyses of forty-five short chain (C₅ - C₁₀) saturated and unsaturated aliphatic chlorinated compounds. The majority of these compounds were identified on the basis of their electron-ionization mass spectrum. The identities of di- and trichloroacetic acids, dichlorosuccinic acid and ox-EMX were confirmed by performing analyses on authentic standards. The products identified are all esters derived from the methylation of chlorinated alcohols, chlorinated aldehydes (which may also be dialcohols due to the nature of the derivatization) and chlorinated acids. About a third of the compounds identified, mostly acids, have previously been observed as chlorination by-products. Unique to this work are several alcohols which may be characteristic of monochloramination products. Of particular interest are the several alkenoic acids identified which may be of toxicological significance because of their structural similarity to the mutagenic open and oxidized forms of the potent mutagen, MX.

Selected ion monitoring analyses resulted in the identification and quantification of MX, and semi-quantification of EMX, ox-EMX and mucoccloric acid in monochloramination as well as in chlorination extracts. Chlorination produced at least twice as much of each of these compounds as monochloramination. MX, EMX and ox-EMX were found to contribute 11%, 26% and 2%, respectively to the mutagenic activity of the monochloramination extract.

CONCLUSIONS. Forty-eight compounds were identified in the mutagenic extracts of monochloraminated fulvic acid by HRGC/MS analyses. Of these, forty-four are novel to this work. The potent mutagen, MX and its tautomers EMX, ox-EMX were found to contribute 39% to the mutagenic activity of the monochloramination extract. The remainder of the activity may be explained by the several alkenoic acids identified as they are structurally similar to the open and oxidized forms of MX.

The development of tandem mass spectrometry for the determination of internal amino acid sequences in proteins will make a significant impact on the field of structural biology. The ability to directly analyze complex mixtures of peptides derived from proteolytic digests of proteins will increase the rate at which amino acid sequences can be determined. Limited structural information obtained from tandem mass spectrometry experiments on proteins can be used to design and synthesize deoxynucleotide probes for cloning the corresponding gene. An integrated high sensitivity, high throughput protein sequencing strategy based on tandem mass spectrometry would be ideal for the characterization of a large array of proteins such as those involved in transcriptional regulation. However, the amount of MS/MS sequence data derived from such a large scale analysis would require many hours for successful interpretation. Real time or near real time interpretation of the data would make such an approach a powerful tool for the molecular dissection of key biological processes.

The development of computer algorithms for the interpretation of mass spectral data has been a long standing goal (1-3). Early attempts at automated interpretation were hampered by insufficient computational power to provide solutions in a timely manner. This was particularly true for the determination of peptide amino acid sequences where a 10 residue peptide could have $10^{20}$ possible sequences. Computer technology has been evolving at a phenomenal rate with computer processor speeds doubling every 12-15 months. A consequence of these rapid technological advances is that computational approaches should no longer be constrained by processing speed.

We have developed two approaches for the interpretation of low energy MS/MS spectra of peptides. The first approach was designed for the interpretation of the singly charged mass spectra produced by MS/MS of peptides ionized by LSIMS. Peptides analyzed by this method are rich in fragment ions of type b- and y"-. The second computational approach has been optimized for the interpretation of mass spectra produced by MS/MS analysis of doubly charged peptide ions from electrospray ionization. In this type of mass spectrum y"- type ions are frequently the most abundant. Peptides derived from tryptic digests of proteins will consist predominately of doubly charged peptide ions. The fragmentation patterns of doubly charged these peptides are more consistent and easier to interpret than those of higher charge states.

LSIMS mass spectra were recorded as previously described on a Finnigan MAT (San Jose, CA) TSQ 700 triple quadrupole mass spectrometer equipped with a 20 keV conversion dynode and 40 keV cesium ion gun (4). Electrospray ionization mass spectra were recorded on the same mass spectrometer equipped with an electrospray ionization source. The molecular weights of peptides were recorded by scanning Q3 at a rate of 400 amu/sec over a mass range of 400 to 1600 throughout the HPLC gradient. Sequence analysis of peptides was performed during a second HPLC analysis by selecting the parent ion with a 6 amu wide window in Q1 and passing the ions into the collision cell which was filled with argon to a pressure of 5 mtorr. Collision energies were on the order of 20 to 50 eV. The fragment ions produced in Q2 were transmitted to Q3, which was scanned at 500 amu/sec over a mass range from 50 amu to the parent mass to record the fragment ion mass to charge ratios.

Under typical operating conditions a 3-6 dalton window in Q1 is used to select the parent ion.
This window will also pass the (M+H)\(^+\) \text{C}^{13}\text{ containing ions giving a cluster appearance to the parent ion region and the fragment ions. Fragment ions produced under low energy multiple collision conditions of the triple quadrupole are dominated by } b^-\text{ and } y^-\text{ type ions. Neutral losses of water and ammonia from } b\text{ ions are frequently observed and } a\text{ ions (b - 28) are also prevalent. Clusters of ions 17/18 and 28 daltons below another ion are frequently diagnostic for } b\text{ ions. } y^-\text{ ions can also be accompanied by neutral losses of water and ammonia. The MS/MS spectra of doubly charged peptides are often predominated by } y^-\text{ type ions and the neutral losses are of less intensity than observed in the singly charged MS/MS spectra produced by LSIMS. These sets of fragment ions are the major fragmentation pathways for peptides under low energy collisions and are the primary ions used for the identification of amino acid residues.}

The strategy used in the interpretation of LSIMS MS/MS spectra is to sequentially subtract the weights of each of the amino acids from the (M+H)\(^+\) ion and compare the predicted fragment ion with the mass spectrum. A score is generated on the basis of the intensity of the } b^-, b^-17, a^-\text{ and } y^-\text{ ions. The scores are then sorted to generate a list of partial sequences for the next subtraction cycle. If proline or histidine are found in the sequence the program checks for } b_ny^-n^-\text{ type ion series. The cycles continue on a particular amino acid sequence until subtraction of the mass of an amino acid leaves a difference between the predicted and observed (M+H)\(^+\) of less than 0.50 but more than -0.5. This sequence is saved for final scoring.}

A final score is calculated from three factors: the number of peaks in the mass spectrum (free acid and methyl ester, if used) accounted for in the mass spectrum, the average intensities of predicted fragment ions, and the continuity of sequence ion occurrences within a given fragmentation scheme. Any known sequence information can be provided to the program such as the presence or absence of amino acids, the extension directions (N to C, or C to N) and any known residues. The program also allows graphical analysis of the results obtained by comparison of the predicted fragments for a sequence with the mass spectrum.

A different computational approach was used for the interpretation of ESI MS/MS spectra. The mass spectral data is smoothed and ions below a set threshold are eliminated from the spectrum. The spectrum is then divided into sections of approximately 50 daltons each. The fragment ion of the greatest intensity in each section is identified and the boundaries are shifted to those ions classified as } y^-\text{ type ions. Amino acid sequences are then determined for the molecular weight differences between boundaries. Where continuous } y^-\text{ type ions have been found the differences between the ions will correspond to the weight of a single amino acid. In cases where the differences between boundaries correspond to two of three amino acids, all combinations corresponding to the weight difference are determined and their predicted fragment ions calculated. An average score based on predicted fragment ion intensity is calculated and the sequences sorted. The time required to interpret a mass spectrum is negligible. For each boundary determination the user can reject the determined boundary and choose another. Only the mass spectrum corresponding to the underivatized peptide is required for interpretation.}

In the methods described above no attempt has been made to differentiate Leu and Ile and Gln and Lys are differentiated on the basis of enzyme specificity or the chemical reactivity of the e-amino group of Lys. Computer aided interpretation of MS/MS spectra represents a promising approach for increasing the throughput of protein sequencing by tandem mass spectrometry.

MASS SPECTROMETRY IN CONTEXT. SOLVING STRUCTURAL PROBLEMS IN A NETWORKED MULTI-VENDOR ENVIRONMENT.

T.M. Halevy, K.A. Brinded and R.J. Dennis
Glaxo Group Research Limited, Greenford Road, Greenford, Middlesex, UB6 0HE, UK. M.G. Tucker, MGT Systems, 7 Akerman Close, Greenleys, Milton Keynes, Buckinghamshire, MK12 6AA, UK.

To function effectively and efficiently, within a large organisation, an analytical department offering a wide range of spectral techniques has to overcome numerous problems. These can be broadly categorised as follows:— management of sample throughput, handling data acquired from different spectral techniques with incompatible computer systems and data formats, review and storage of data is often restricted to 100% OEM systems, multiple paper transactions and only a few specialists capable of retrieval of data from multi-disciplined areas.

One solution to these problems is to base a system in the PC environment and utilize a PC local area network (LAN). Thereby using an operating system and software familiar to both Chemist’s and Analyst’s, whilst also making use of bulk storage devices such as optical disks possible. The objectives in implementing the system were to remove intra-company boundaries and enable the ‘pooling’ of analytical information for retrieval from any node on the network.

A Novell PC LAN was used along with a chemical structure database package to achieve the proposals outlined above. In the mass spectrometry laboratory, an EM4105 terminal emulator was used which provides a screen capture to file facility. The captured screen image is a mass spectrum which would normally be hardcopied and returned to the Chemist with an attached text report. The terminal emulation package can be setup to direct captured files automatically to shared networked areas specific to the instrument on which the data was acquired (see Figure 1).

This can also be indexed by date and so provides a reliable method of archiving.

![Diagram](image_url)

**Figure 1. File capture and management over the PC LAN**
The Chemist makes a request for analysis by entering information about the sample in the database. The Spectroscopist then identifies it as a new entry in the database and transfers the information as ASCII data to the spectrometer. After analysis, the spectrum/spectra is captured and converted to a metafile. The spectra from the sample, analytical conditions, date completed, files assigned for each spectroscopic technique and a brief text report can then be stored in the database for retrieval from any node on the PC LAN. The results can be displayed in a number of formats determined by which fields, in the database, are displayed in the report form, an example is shown in Figure 2.

The sample was analysed using Fast Atom Bombardment (FAB) MS. The molecular ion obtained is consistent with the proposed chemical structure.

The system described has been implemented and is in daily use. The likelihood of human transcription error has been greatly reduced. Two criteria of the system give the Spectroscopist more time to improve the quality of data produced:—no time is required for filing paper copies—all data and text report summaries are stored electronically together and secondly the responsibility for ‘backing up’ the File Server lies with personnel who maintain the PC LAN and not Spectroscopist’s. One negative aspect is that if there is a problem with the PC LAN, then the system grinds to a halt.

The implementation of this system has been met with enthusiasm by both Chemist’s and Spectroscopist’s. Its reliability is very good and in the future will enable us to seek a higher degree of integration allowing a higher degree of automation to follow.
COMPUTER-AIDED ASSEMBLY OF COMPLETE PROTEIN SEQUENCES FROM
THE PROBABLE (CID-MS DERIVED) SEQUENCES OF PROTEOLYTIC PEPTIDES.
A. Ghosh and K. Biemann, Department of Chemistry,
Massachusetts Institute of Technology, Cambridge, MA 02139.

INTRODUCTION:
The algorithm SEQPEP\(^1\), predicts sequences from the characteristic
fragments ions observed in the CID spectrum of the peptide, then ranks them
from a score of 1.0 (maximum) to 0.0 (minimum) by decreasing fit with the
input CID data. For example a score of 0.827 indicates that the sequence
accounts for 82.7% of the sum of all ion abundances of the input spectrum.
However, the highest ranking sequence is not necessarily the correct one,
mainly due to the possibility that certain combinations of one to four
amino acids have the same residue mass, i.e. are isobaric (R=156=GV). If
there is a peak in the spectrum that happens to fit a potential fragment
of the incorrect combination, than that sequence will have a higher score
than the correct one. In such instances it is then not possible to arrive
at the correct protein structure by using the highest scoring sequence of
each peptide.

The redundancy of information represented by the CID spectra of
peptides generated by two or more proteases with differing specificities
can be used to recognize the correct sequence even if it does not have the
highest SEQPEP score. This is because it is unlikely that the same
ambiguity exists in the spectra of peptides derived from very different
cleavage sites but partly representing the same region of the protein. The
corrected peptide sequences must then be assembled to the final protein
structure.

The process described above can be accomplished manually, but is
tedious and time consuming, hence is best done by using a computer. We
report here an algorithm, COMBSEQ, that does it automatically until the
final stage which is interactive to allow human inspection of ambiguous
situations (which are flagged). As an example we are using the output of
SEQPEP for the CID spectra of 30 peptides which were used to determine the
complete structure of glutaredoxin (Grx) isolated from rabbit bone marrow
(RBM) which had been deduced by manual correlation of the data\(^2\). The
peptides were produced by digestion of the protein with trypsin (11
peptides), Chymotrypsin (9), Endo Glu-C (8) and thermolysin treatment of
some tryptic peptides\(^2\).

PROCEDURE AND DISCUSSION:
The approach to the assembling of the peptides to the final protein
structure involves the following steps:

(a) First assume that the highest ranking sequence is the
    correct one.
(b) Use them to extend by overlaps.
(c) Obtain full overlap by substituting highest ranking sequence
    which does not overlap with a lower ranking sequence that does.
(d) Flag amino acid positions which may be ambiguous and
    needs human inspection and decisions.

The input data for COMBSEQ are the top scoring 20 sequence generated
by SEQPEP for each CID spectrum of 30 peptides produced by the above
described digests of RBM-Grx\(^2\).

COMBSEQ begins with the assumption that the highest scoring sequence
is the correct one, if it is at least compatible with the corresponding
enzyme specificity. This assumption does not hold for the C-terminal
peptide and in the final sequence the C-terminal amino acid should,
therefore, be scrutinized carefully. Each of the 30 peptides are searched
for greater than or equal to 2 amino acid overlaps with the 29 other
peptides. A set of 16 peptides resulted, of which 10 were unmodified and
the remaining 6 were overlapping combination of the other 20. Since the
molecular weights of the 20 highest scoring sequences for each peptide must
be identical, the ambiguities among the various possibilities are generally
due to isobaric combinations (e.g., AG=GA=Q=K or MA=AM=DS=SD or PSN=GL etc.). At this point COMBSEQ simply checks whether the mass of any of these peptides is a component (and that at least half the sequence matches) of any of the other 15. This isobaric match now results in 7 partial sequences.

At this point one has to remember that the sequences used even at this stage are not necessarily correct. The regions of ambiguity are revealed by the apparent lack of overlap between the C-terminal of one and N-terminal of another of the 7 partial sequences generated up to this point. If any of them indeed overlap then C-terminal of one must be isobaric with the N-terminal of the other. By matching the mass of all the C-termini (up to 4 amino acids) with that of all the other N-termini (also up to 4 amino acids), COMBSEQ recognizes that there is a pair which combine by overlapping (isobaric N-terminal & C-terminal match) as —CR=DSN--. This is confirmed by checking the input data which contain a number of sequences of lower scores beginning with CR--. One of them overlaps with other peptides and is therefore the correct one. A second such ambiguity --GNQX=GELL-- is resolved in the same way. These matches further reduces the total number of partial sequences to 5.

Two of these five partial sequences contain the same 18 amino acid sequence. The repeated occurrence of such a long sequence is very unlikely. Therefore COMBSEQ separates them in two sets of 5 partial sequences so that none of the sets have any common units.

For the final assembly of the two sets of 5 partial sequences COMBSEQ uses the molecular weights of larger peptides generated with a very specific enzyme but not sequenced by CID. In the case of RBM-Grx molecular weights of four endo Glu-C peptides were [(M+H)*]=1044.71, 1486.95, 3223.72 & 3953.06. Twelve of the possible 144 complete protein sequences were found matching at least three of these (M+H)* ions, but only one matched all the four (M+H)* ions and thus is most closely correct.

Up to this step the entire process is automatic. Now COMBSEQ goes into an interactive mode and displays for each possible sequence all positions where alternatives exist (by comparing it with all the 20 highest scoring sequences of SEQPEP for the 30 CID spectra), in a format that facilitates human intervention and inspection.

The ambiguous positions are corrected or reconfirmed from the peptide specificities and/or number of occurrence found for the particular position. For example; a sequence MDAA (positions 79-82) comes from one first ranked M, 1D, 3A and 2A, but there are 10 lower ranked sequences that have DCX and one DCI in this position. Since DCX or DCI (X=I or L) is isobaric with MDAA we replace MDAA with DCI after verifying I from d and w ions. Once all the ambiguous positions have been clarified and corrected, the final answer, the complete primary structure of protein, is obtained.

CONCLUSION:
An algorithm, COMBSEQ, has been written which assembles amino acid sequences of proteolytic peptides, derived from their CID spectra, to the complete primary structure of protein. The program is written in VAX-FORTRAN and requires 1-10 minutes to find the final complete sequence, reducing the time and effort to do manually.

ACKNOWLEDGEMENTS:
The authors are indebted to R.S. Johnson who determined the CID spectra and J. E. Biller for his help with the VAX-workstation. This work was supported by a grant from the National Institute of Health.

Over the course the last five years our laboratory has strived to institute a network system of mass spectrometry data systems. We have previously reported on our efforts to archive data from our VG 11-250J and Nermag Sider systems has been previously reported. This system allowed transfer of data between acquisition computers and an archival computer. Using a local area network (LAN), appropriate remote terminals can access software and data on each acquisition computer. In April 1990, three Kratos Mach 3 data workstations were acquired and placed on the network. These are being used to process data from two VG mass spectrometers as well as a Concept 1S mass spectrometer. Future plans are to process data from other instruments in the laboratory as well as data received from other laboratories. The installation of this workstation data system has been named a "universal" mass spectrometry laboratory system. This unwieldy title is used to distinguish it from the acquisition data systems which process data from only one mass spectrometer.

Having this "universal" system in the laboratory has provided several new capabilities to the laboratory. First, mass spectral data from different instruments can be processed on the same system without the need to go from one terminal to another. The data can also be archived to and retrieved from one system. Over several years, this means that the data from retired data systems can be accessed which is important under GLP guidelines and when plotting mass spectra for publication. Also, the software of the Mach 3 system can process data more efficiently than the older data systems. Analysis time for long GC/MS runs has been halved and the analysis of multichannel analysis (MCA) mass spectra of peptides has been reduced by two thirds.

Another advantage of the universal data system concept is the ability to analyze data produced at diverse geographical sites. The Wellcome Research Laboratories are situated in three separate buildings approximately one mile apart with mass spectrometers located in two of those sites. The need to analyze data at other sites can be achieved by use of the network and the Mach 3 universal system. Data produced in one building need not be reproduced in hardcopy form prior to discussion with chemists but can be shipped to the chemists location for viewing. This procedure saves time on the part of laboratory personnel who no longer have to plot or reprint data for the chemists. Also, BW sends out approximately 4200 samples per year for CI analysis to an outside facility. Presently, the data for each sample are returned as hard copy output via Federal Express which takes three days turnaround per sample set with samples being sent each working day. Using this procedure, no spectral enhancement can be done to elucidate small peaks nor can new mass chromatograms be plotted to verify coelution of ions to check for impurities. A new procedure is being instituted whereby the data are transmitted via phone-link to the Mach 3 system, converted, and plotted at BW. Such data can be reanalyzed if necessary. Also, the analysis of these data by the chemists without the intervention of mass spectrometry laboratory personnel is possible and is being considered.

As the laboratory grows we find that this system may be able to reduce the costs of purchasing new equipment and the number of extra terminals required in the laboratory. When new machines have been purchased in the past, extra terminals and sometimes data systems have been purchased with the mass spectrometer to facilitate data analysis. This is not necessary if the data can be transferred to the
universal system for analysis.

While the advantages listed above have made the universal system an attractive and valuable addition to our laboratory, we have encountered problems in its implementation. Most of these have had to do with the incompatibility of data formats from one machine to another. For instance, there is as yet no standard file structure for mass spectral data except for mass/intensity data, no provisions have been made for MCA data, MS/MS data, or single ion recorded data. Therefore conversion programs have to be written for each type of data from each machine. This has turned out to be a time consuming and costly procedure. We are in the process of writing conversion programs for the Nermag Sidar system at the present time. Other conversion programs for our VG equipment and Finnigan data systems were provided with the Mach 3 purchase. However, even these have required modification due to differences in the algorithms used for data acquisition and in the calibration procedures used by the various vendors. In order to analyze the converted data, changes had to be made in scan laws and/or scan functions to produce mass spectra that can be processed by the Mach 3 system. This has been accomplished for high and low resolution MCA data, but has not been implemented for linked scan data.

In regard to data conversion problems, mass spectrometer users must be trained to recognize that problems may exist in the use of a "universal" system and attempt to overcome them. The same training must be done for chemists who analyze their own data. We have found however that this extra effort is rewarded by the tremendous increase in speed and efficiency afforded by newer systems over systems five to ten years old.

Cost can be a problem in the purchase of a "universal" data system. These systems at present require data workstations which contain both computing power and resident software which requires both expensive hardware and expensive software licenses respectively (~$10,000/workstation). This is much more than the cost of two or three extra terminals per mass spectrometer for a conventional system (~$800/terminal) where no software license is needed.

The cost of a "universal" system can be lowered and some of its disadvantages can be overcome in the future by several steps. Faster and more powerful processors should become available as witnessed over the last twenty years. If these systems are adopted by the mass spectrometer vendors, then the cost for an equivalent amount computing power should be lowered. Also, the need for purchasing several workstations with their accompanying expensive software license can be eliminated by the institution of windowing in the host mass spectrometer data system environment. One fast, powerful processor could be used to analyze the data from any machine. This main processor could then be accessed from X-window terminals or other data systems running X-window software with all data manipulations being done on the main processor and viewed on the X-window device. This process is now being developed by several computer manufacturers and should be fully utilized by the mass spectrometer vendors. Finally, the vendors should agree on common data formats for all types of mass spectrometry data, and they should provide programs for conversion of their data to and from the standard file formats. With these changes the implementation of "universal" laboratory systems could become attractive to more laboratories.
A computer program called MacProMass has been written to assist protein chemists and mass spectrometrists in utilizing mass spectral data for peptide and protein structure analysis. The program runs on any Macintosh computer with 1 Mbyte of memory and a hard disk. Full advantage is taken of the Macintosh graphical user interface. Sequence data can be entered manually, pasted in from the clipboard, or imported from a text file. The main display is arranged such that any portion of a sequence in length up to 2000 residues can be readily located. For a user-selected portion of the sequence, values are calculated for monoisotopic and average mass, elemental composition, isoelectric point, HPLC index, surface free energy, and amino acid composition. Search routines are provided to locate portions of a sequence with a given mass, sequence, or amino acid composition. Mass values are calculated either for the protonated molecule or the molecule minus a proton. The m/z value can also be calculated for any number of charges. The theoretical isotope pattern can be calculated for any portion of the sequence.

The twenty common amino acids which are coded by DNA are permanently designated by the standard single letter code. The remaining six letters in the alphabet can be programmed by the user to have any composition which uses the elements C, H, N, O, S, P, F, Cl, Br, and I. Additionally, both the C-terminal and N-terminal groups can be programmed. A separate section of the program provides the means to easily calculate mass values for complicated multichain structures with multiple inter- and intra-chain linkages such as disulfide bonds. These connections are made using a clever graphical display that allows the user to simply draw in a bond of a selected type using the mouse. A list of several possible bond types is provided or the user may define his own. Thus, MacProMass can model almost any protein structure, real or imagined.

A number of routines are provided that greatly simplify data analysis. Mass spectral fragments can be calculated for any linear peptide up to 100 residues in length. The output can be in terms of a table arranged according to ion series or by increasing mass. The user can choose to use either the Roepstorff or Biemann nomenclature to designate ion series which may be numbered from either the N- or C-terminus. The user can select which ion series to include in the table choosing either the positive or negative ion mode. Default values can be set so that the user can customize the program to his particular needs. The fragment tables can be searched to identify particular ions in a spectrum either individually or in a group. Those values identified in a search are identified with bold face type. There is also a routine that will calculate possible fragments resulting from two bond cleavages (so called...
internal fragments). Values in the fragment tables can be adjusted to accommodate up to four charges.

The enzyme digest routine can be used to calculate the mass of peptides that result from enzymatic or chemical cleavage of a protein. The common enzyme and chemical cleavages are supported directly, and the user can create his own by defining the specificity of the cleaving reagent. The resulting list of peptides can be arranged according to position in the original sequence, mass, isoelectric point, HPLC index, or surface free energy value. For structures that contain inter- or intra-chain bonds, mass values are calculated for the linked fragments. For proteins that have disulfide bonds that are undefined, a routine is provided that finds all of the possible linked peptides that correspond to a given mass. This routine is very useful for determining the location of disulfide bonds. A second routine is provided to assist in analysis of protein variants that result from the substitution of a single amino acid residue. This routine systematically considers all of the single amino acid substitutions which will account for the mass difference between an observed mass in an enzyme digest mixture and those calculated based on the expected sequence.

A section called Hydrophobicity which is largely unrelated to mass spectrometry has been included as a convenience to protein chemists who do secondary structure analysis from primary sequence data. In addition to the Hopp & Woods, Kyte and Doolittle, and Engleman, Steitz and Goldman hydrophobicity scales, there are scales for antigenicity, chain flexibility and Chou Fasman secondary structure analysis.

In conclusion, MacProMass is a versatile, multifunctional, user friendly program that frees researchers from many of the tedious calculations involved in doing mass spectrometry on peptides and proteins.
Accurate Molecular Weight Determination from Near-symmetrical, Unsymmetrical, Broad or Inadequately Resolved Peaks

*Yasuo Konishi and Rong Feng, National Research Council of Canada, Biotechnology Research Institute, 6100 Royalmount Avenue, Montreal, Quebec, Canada H4P 2R2

Ionspray quadrupole mass spectrometer has been used to measure molecular weight (MW) of proteins. To assist the accuracy of MW determination, a polynomial curve fitting method was developed in the data analysis [1]. The method was applied successfully to bovine serum albumin, of which MW was estimated as 66,431.5 ± 1.3 Da by this method. Lately the sequence MW of the protein was corrected to 66,450.3 Da by discovering missing Tyr-156 [2].

API III ionspray mass spectrometer (SCIEX) used in this study was calibrated using polypropylene glycol. The calibration was corrected further using eq. 2 described below.

A polynomial curve fitting method is a modification of Gaussian curve fitting. Instead of Gaussian curve (eq. 1), natural logarithm of the curve (eq. 2) is used for the fitting.

\[ I = I_0 \exp\left\{-\frac{(x-H)^2}{2\sigma^2}\right\} \]  
\[ \ln(I) = A(x - \mu)^2 + B \]  

where \( x \) is the m/z value at each data point, \( \mu \) is m/z at the peak apex, \( \sigma \) is the peak width, and \( I_0/\sqrt{2\pi\sigma} \) is the peak height at the apex. The eq. 1 is converted to eq. 2, where the fitting is weighted by the logarithm of the intensity in eq. 2 being close to uniform fitting. Since the fitting with eq. 2 is sensitive to the peak shape, the fitting of commonly observed peak shapes, near-symmetrical, unsymmetrical and broad peaks, was examined.

Near-symmetrical monoisotope peaks of singly charged synthetic peptides were analyzed by fitting the top portion (> 50-70% of the maximum intensity) of the peak using eq. 2 (Fig. 1). The experiments were carried out with various synthetic peptides (MW 500 - 2000). The average MW error from 48 experiments was -2 ppm with a standard deviation of 46 ppm. The results suggest that average MW of many measurements is fairly accurate, although a single data has a large error. This is advantageous for MW determination of proteins, which provides average MW of many peaks in a single measurement.

Very often the peaks are not symmetrical in a mass spectrum. The applicability of eq. 2 to unsymmetrical peaks was examined by fitting nearly entire peak of doubly charged synthetic peptides (MW 800 - 2,500) (Fig. 2). The unsymmetry of these peaks is due to the unresolved isotope profile. The degree of the unsymmetry varies due to the different contribution of the isotope peaks in these peptides. The average MW error from 40 experiments was 22 ± 60 ppm. Although there is a systematic error, which overestimates the contribution of isotope profile, the average MW is fairly accurate.

Monoclonal antibodies (MW ~ 150,000) have shown broad peaks due to the heterogeneous glycosylation. Eq. 2 applied to these broad peaks of three monoclonal antibodies by fitting the top portion (> 50-70% of the maximum intensity) of the peaks. Average MW of monoclonal antibodies against α-1-antitrypsin and α-1-acid glycoprotein were determined as 148,484 ± 4 Da (precision 27 ppm) (Fig. 3) and 149,599 ± 12 Da (precision 80 ppm), respectively. Interestingly, monoclonal antibody against β-galactosidase showed two components with average MW of 150,544 ± 10 Da (precision 66 ppm) and 151,496 ± 17 Da (precision 112 ppm). Thus a high precision can be obtained for broad peaks of high molecular weight proteins using the polynomial curve fitting.

When peaks are not resolved to at least 50%, the overlap of the peaks shifts the peak apexes, which makes the experimental MW deviate from the true value. The peak shift was simulated using two Gaussian curves resolved partially. A correction table of the peak shift was obtained as a function of the resolution and the relative intensity of the peaks (Fig. 4). The method was applied to bovine serum apotransferrin (MW 78 kDa). The peak has an unresolved peak, which has additional 87 Da estimated from peak apex. With the peak shift correction, the MW difference was restored to 97, which indicates sulfate or phosphate adduct.

Quadrupole mass spectrometer has a low resolution, and near-symmetrical, unsymmetrical, broad and partially resolved peaks are observed commonly in the spectra. However, a simple data analysis by the polynomial curve fitting or the correction table gives accurate MW determination of proteins.

References:
Figure 1. Polynomial curve fitting of near-symmetrical peak. Raw data and curve fitting are shown with solid and dashed lines, respectively. Curve fitting was performed in logarithm scale in Fig. 1B. MWobs. of a synthetic peptide (MWcalc. 816.559) is 816.505 with an error of 0.054 (66 ppm).

Figure 2. Polynomial curve fitting of unsymmetrical peak. Raw data and curve fitting are shown with solid and dashed lines, respectively. Curve fitting was performed in logarithm scale in Fig. 2B. MWobs. of a synthetic peptide (MWcalc. 817.012) is 817.030 with an error of 0.018 (22 ppm).

Figure 3. Polynomial curve fitting of broad peaks. MW of monoclonal antibody against α1-antitrypsin was observed as 148,484 ± 4 Da (precision 27 ppm) by the curve fitting of five peaks with asterisk.

Figure 4. Apex shift of inadequately resolved peaks as a function of resolution and relative peak intensity. Total intensity of the two partially resolved peaks is normalized to 1.0. Resolution is defined as an intensity ratio between a peak apex and valley.
It has become apparent that computer manipulation of collision induced dissociation (CID) mass spectral data is required if the potential gain in peptide sequencing efficiency using mass spectrometry is to be realized. Two computer programs have been developed at the U of Washington - LUTEFISK and LEFSA - and are described here. The former program is designed to assist in the interpretation of low energy CID data of singly or multiply charged precursors; the latter incorporates both CID and gas phase sequence data in the structure determinations. LUTEFISK is conceptually similar to earlier algorithms in that partial sequences encompassing the C-terminus that account for the greatest number of ions present in a spectrum are extended until the molecular weight of the peptide is reached. Once this subsequecing procedure is finished, the list of completed sequences are assigned scores and ranked based on the fraction of product ion current that can be accounted for as either sequence-specific or non-sequence-specific ions. Of course, LUTEFISK concerns itself only with those ions associated with low energy collisions - predominantly b\textsubscript{n}, y\textsubscript{n}, and an occasional a\textsubscript{n}, all of which can lose 17 or 18 amu, or have multiple charges. It has also been necessary to allow for the absence of fragmentation between adjacent amino acids by allowing subsequences to be extended two amino acids at a time. Although the initial results depicted in Table I have shown that CID spectra of smaller peptides (MW < 2000) with few charges are readily interpreted, the program frequently produces a number of other sequences that account for the fragment ions equally well. For instance, the correct sequence for entry 7 of Table I (AQDFVQW) was assigned the third highest score, and the number in parenthesis indicates that there were eleven sequences of equal or greater score (i.e., there were many sequences with identical scores). Furthermore, fragmentations between adjacent amino acids may not always be observed in these spectra in which case LUTEFISK will identify the correct pair of amino acids; however, the sequence of these two amino acids remains uncertain.

Such problems can be resolved in a number of ways - manual Edman degradation followed by mass spectrometry, derivatization, assembly of probable sequences from overlapping peptides, etc. LEFSA is a program that incorporates both gas phase sequence data of peptide mixtures and CID spectra of those peptides in an attempt to resolve ambiguities that arise from either data set alone. The input for LEFSA is the molecular weight of the peptide, the CID m/z and abundance values, and a listing of amino acids found in each cycle of Edman degradation. From the molecular weight and the Edman data, a limited set of possible sequences is generated for each peptide. The sequences in this list are then scored according to how well they account for the CID fragmentations. Shown in Figure 1 are the amino acids found in each cycle of Edman degradation for a HPLC fraction of a tryptic digest of cytochrome c from yeast. This information plus the CID spectra of three of the peptides present in the mixture gave the results listed at the bottom of Figure 1. The correct sequences were ranked first for each peptide, but most noticeable was the wide range of scores for the sequences listed, none of which had identical scores. In addition, leucine and isoleucine could be differentiated, and there were no unsequenced pairs of amino acids. This is in contrast to what was found when only CID data was considered.

A very important characteristic of any analytical instrument is the range of analyte concentration over which the output signal shows a response that is linear with concentration. Almost from the relatively recent beginning of Electrospray Mass Spectrometry (ESMS) it has been realized that the dependence of ion current upon analyte concentration in the sample solution shows a rather abrupt change in slope at some critical value of that concentration. The reasons for this behaviour have never been clearly identified and are addressed here.

Figure 1 illustrates the phenomenon for the cyclic peptide Gramicidin S in a 1:1 water solvent. The analyte ion current is linear in concentration from 1 pg/μL to 10 ng/μL, four orders of magnitude. Then it shows a fairly abrupt decrease in slope to nearly zero, indicating saturation of some sort. This behavior is typical of all the species we have examined. The main differences from one species to another are (1) the value of the concentration at which the change in slope occurs and (2) the trend of the slope after the changes. For some species it actually turns negative showing a decrease in ion current with increasing analyte concentration. When the mass spectrum comprises number of peaks for a particular species, e.g. because of multiple charging, one should sum over those peaks to determine the total contribution to ion current for that species. In such cases we do not know how much multiplier response may be affected by the number of charges per ion. Consequently, the true contribution of multiply charged ions of each peak to the total ion current for that species is at best an approximation.

This change-in-slope has sometimes been attributed to a charge limitation. When analyte molecules in a droplet begin to outnumber charges on the droplet, further increases in concentration cannot increase the ion production. But this explanation doesn't stand up to close inspection. For example, plots like those of Fig. 1 for tetramethyl, tetrabutyl and tetraheptyl quarternary ammonium halides show that in each case the slope change occurs at the same weight per cent concentration of analyte corresponding to seven-fold change in molarity. Since the ions in each case are singly charged, smallest of these species should show a slope change at one seventh of the concentration of the largest, if charge limitation is the cause. More evidence that charge limitation cannot be the cause is shown in Fig. 2 which is the equivalent of Fig. 1 for Cyclosporin A (M = 1202), a cyclic peptide of nearly the same size as Gramicidin S (M = 1140). Although there are not enough data points to define the slope change point with any precision, it is clear that it occurs at a lower molar concentration for Cyclosporin than for Gramicidin. Moreover, mass analysis shows that most of the former ions are singly charged, whereas most of the latter are doubly charged. Shortage of charge cannot account for this difference.

An even more dramatic challenge to the charge limitation explanation is shown in Fig. 3. The solid curve is for tetrabutyl ammonium bromide in 1:1 water. The dashed curve is the same except that 2% acetic acid has been added, resulting in a shift of the slope change concentration of nearly two orders of magnitude! It turns out that addition of NaOH shifts the slope change concentration in the opposite direction, i.e. to a lower value than for the solid curve. To be remembered is that the solubility of ammonium salts generally increases with decreasing pH of the solvent. Also to be noted is that Cyclosporin is more insoluble in water and alcohol than in Gramicidin. We conclude that the slope change point in graphs like those of Figs. 1, 2 and 3 is most likely determined by the solubility of
the analyte. When the droplet liquid is saturated with analyte, addition of more, or removal of solvent, cannot increase its concentration.

Fig. 2

Fig. 3
Electrospray (ES) ionization is rapidly developing as a method to produce gas-phase ions from analyte species in solution for subsequent analysis by mass spectrometry (MS). The ES-MS combination has proven useful in the analysis of involatile, polar, and thermally labile compounds, especially high molecular weight biopolymers, and also serves to interface the mass spectrometer with a variety of liquid phase separation methods. While the detailed mechanism for ion evaporation or ion desorption is currently at issue, it has become clear that best ES-MS results, both in terms of sensitivity and detection limits, are achieved for compounds that are ions in solution. Species that are ionic in solution and have been analyzed by ES-MS include, for example, metal salts and organic salts. Compounds with functionalities that can be ionized via solution phase acid/base chemistry, such as carboxylic acids and amines, are also amenable to ES-MS. The latter category of compounds includes peptides and proteins which contain basic amino acid residues and oligonucleotides which contain acidic phosphate groups and are usually detected as the (M+H)+ and (M+nNa)+ species, respectively. Some polar molecules are also ionized efficiently by ES via attachment of ions other than a proton (e.g., Na+ or CH3COO−) that are present in the analyte solution.

Current and potential methods for preforming ions in solution for ES-MS can be divided into three broad categories, viz., chemical, electrochemical and photochemical methods. To date only the acid/base solution chemistry of an analyte has been exploited to preform ions. As a result, the applicability of ES ionization is currently limited to compounds that are ionic in solution or that can be ionized in solution (or in the desolvating droplets) by acid/base chemistry or by adduct formation. Several important classes of compounds, such as the polycyclic aromatic hydrocarbons (PAH's), cannot, at present, be analyzed using this technique. Additionally, the ions formed in solution via acid/base chemistry or adduct formation are limited in positive ion mode to cationized species and in negative ion mode to the deprotonated molecule or an adduct ion. Radical cations, M•+, and radical anions, M•−, which directly provide the molecular weight and might be of use in other mass spectrometric analyses, such as MS/MS, are typically not formed by ES ionization. In this paper, charge-transfer (CT) complexation and electrochemical reactions are demonstrated as means with which to form radical cations or anions in solution, both for compounds that display acid/base behavior and also for compounds that are otherwise not amenable to analysis by ES-MS. The data described in this paper were acquired on an ES/ion trap mass spectrometer combination that has been described in detail (1).

CT complexes are formed by electron transfer between an electron donor (D) and electron acceptor (A) as shown in equation 1

\[ D + A \rightarrow (D^+\cdot A^-) \rightarrow (D^+)^{\text{base}} + (A^-)^{\text{base}} \]  

Thus, this method can be used to form both radical cations and anions from species that undergo these reactions. Electron donors and acceptors are usually compounds of low ionization energy (IE) and compounds of high electron affinity (EA), relative to one another, respectively. Typical electron donors include PAH's and other aromatic species that contain electron-donating groups such as -OH, -OCH2, and -CH3. Common electron acceptors usually contain several electron withdrawing groups, such as -NO2, -CN, or halides. For example, the quinones chloranil (tetrahydro-p-benzoquinone) and 2,3-dicyano-1,4-benzoquinone (DDQ) are good acceptors. Figure 1 shows the positive and negative ion ES mass spectra obtained from a sample containing a mixture of the donor N,N',N'-tetramethyl-1,4-phénylenediamine (TMPD) and the acceptor DDQ. Without the addition of DDQ, the spectrum of TMPD shows the protonated molecule as the major ion. When DDQ is added, the radical cation is the ion observed. In negative ion mode, the molecular anionic species observed corresponds in mass to (DDQ+1)−. This observation suggests that the original molecular anion formed from DDQ by CT complexation with TMPD undergoes reactions in solution. The positive ion ES spectra of 2,3-benzanthracene in Figure 2 demonstrate that CT complexation can be used to ionize PAH type compounds which normally give no signal in ES-MS.

Electrochemistry can also be used to form ions in solution for ES. The setup used in these experiments, shown in Figure 3, consisted of an electrochemical LC detector in which both electrodes of the cell were floated at the high voltage necessary to promote ES. With this setup, no high voltage ES needle is required since the solution is charged in the cell. Figure 4 shows the electrochemically assisted ES spectra acquired for the perylene. When the voltage difference between the two electrodes in the cell is zero (Cell OFF) no signal is observed. However, when the two electrodes are offset by 1.5 V (Cell ON), the radical cation of perylene, formed by the electrochemical oxidation of the analyte within the cell, is observed.

In summary, both CT and electrochemistry are viable methods for preforming ions for ES-MS. The sensitivity and detection limits for these methods are comparable to those limits obtained for compounds analyzed using conventional ES techniques. In addition, both of these methods are potentially useful in on-line applications. Although both techniques will work for only a limited set of compounds, they do provide compound specific ionization, can be used to ionize nonpolar, neutral compounds, and also provide a means to form radical cations/anions via ES.

Is the Electrospray Mass Spectrum of Proteins Related to their Aqueous Solution Chemistry?

Roger Guevremont, K.W.M. Slu, J.C.Y. Le Blanc* and S.S. Berman, Institute for Environmental Chemistry, National Research Council of Canada, Montreal Road, Ottawa Ontario Canada K1A 0R9

The fundamental shape of the ion abundance profile observed in electrospray of proteins is controlled by the concentration of pre-formed ions in aqueous solution. An aqueous solution equilibrium model based on the pKa's of acidic and basic sites on proteins has been developed to account for the shape of the ion abundance profile in the electrospray mass spectrum. Monotonic functions such as mass spectrometric transmission efficiency may alter the centroid of the profile, but the basic factor that controls the ion abundance pattern is aqueous acid/base solution chemistry. Electrospray measurements were performed using a TAGA 6000E (SCIEX Inc., Thornhill, Ont. Canada) triple quadrupole mass spectrometer. To ensure reliable measurement of relative ion abundance data, the mass resolution was decreased from unit mass resolution to the extent that two or more measurements were taken near the apex of every peak. Samples were continuously infused at a rate of 20nL/mln through a 100μm ID stainless steel capillary held at 3.5kV. Stable operation of electrospray was achieved with the needle approximately 1.5 cm from the instrument orifice, and with a measured stable current of between 20 and 50 nA. Cytochrome c (horse heart, C-2506 type III) and myoglobin (horse skeletal muscle, M-0630) were obtained from Sigma Chemical Co. (St. Louis MO, USA). Cytochrome c samples (20 μg/ml) were prepared to cover various pH ranges; from pH 2.5 to 3.6 with HCl, from pH 2.8 to 3.5 with formic acid, and from pH 3.5 to 3.9 with acetic acid. Each of these cytochrome c solutions was diluted 1:1 with methanol. Similarly, three series of myoglobin solutions (20 μg/ml) were prepared; from pH 2.9 to 3.7 with HCl, from pH 2.7 to 3.3 with formic acid and from 3.2 to 3.6 with acetic acid. In turn, each solution was diluted 1:1 with methanol.

In aqueous solution the protonation of carboxylic acid groups controls the net charge on proteins in solutions below pH 5 [1]. The pKa's of the carboxylic acid groups in cytochrome c can be estimated. For example, assume that one of the carboxylic groups has a pKa of 3.9 (i.e. the pKa of the carboxylic group of aspartic acid) at the point wherein the mass to charge ratio of the cytochrome c ion has reached 1550. From this point, the protonation of each subsequent carboxylic acid will increase the net charge on the protein, increase the electrostatic repulsion on approaching protons, and therefore lower the pKa of each subsequent carboxylic group (e.g. cytochrome c, low ionic strength, each pKa is 0.086 [1,2] unit lower). On the basis of this simple array of pKa values, the abundance of the ions in aqueous solution is calculated. More refined models have been described [1]. A comparison of calculated and experimental abundance profiles are shown in Fig.1 and 2. The ion abundance pattern of myoglobin (Fig.2) is more complex than that of cytochrome c. Under some experimental conditions it appears to be a sum of two functions (i.e. two distinct tertiary structures which have unique sets of pKa values). Cytochrome c will also exhibit this dual function distribution in solutions containing little methanol and/or acid, but not under the experimental conditions used to collect the data in Figure 1.

The ion transmission efficiency of a quadrupole mass spectrometer is a function of mass. Previous estimates [3] of the transmission roll-off of a SCIEX TAGA instrument of this type have been as high as an order of magnitude per 200 m/z units. Fig.3 illustrates the ion abundance *envelope* for a set of experimental data for cytochrome c and a calculated profile using a solution pH 3.3. This profile was then modified by the transmission roll-off. With an estimated roll-off function of about a factor of 5 per 200 m/z units, the resulting profile matched the experimental data. The fundamental origin of the ion abundance profile observed in electrospray is controlled by the concentration of pre-formed ions in aqueous solution. Other monotonic exponential increasing, or decreasing, functions can shift this original pattern, nevertheless the abundance pattern observed in the mass spectrum retains the shape imposed by aqueous solution chemistry.

Obtaining Structural Information from Electrospray ionization-Mass Spectrometry at the Large Molecule Limit

Alan L. Rockwood, Joseph A. Loo, Harold R. Udseth, and Charles G. Edmonds, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352

A number of interesting challenges must be met if one is to obtain structural information from very large molecules. Molecular ions in predominantly low charge states, such as those produced by matrix-assisted laser desorption, are difficult to collisionally activate (unless collision energies are greatly increased) and one must ultimately rely on photoexcitation. The pulsed nature of the laser desorption and photodissociation processes makes this combination well suited for TOF methods, but appears to place experimental constraints upon resolution and m/z range. Additional pragmatic constraints arise, however, due to the inherent isotopic distribution and the actual molecular weight (MW) distribution of high molecular weight substances (due to small sequence variations). This and other sources of "peak splitting" lead to spectral congestion as revealed in the apparent "peak widths" of most mass spectra for biomolecules of MW > 30,000. In contrast, electrospray ionization (ESI) can produce highly charged molecular ions that can be efficiently activated by collisions regardless of MW if their charge state is sufficiently high. We have already obtained substantial sequence-related information for albumin molecular ions of ~66,000 MW. We propose a new approach, single molecule analysis by mass spectrometry (SMAMS), with the aim of allowing molecules in the megadalton range to be analyzed by their sequential dissociative processes. Ion cyclotron resonance (ICR) methods may provide an especially suitable approach for such studies due to the potential for high sensitivity and resolution for ions of high charge, the potential for high mass measurement accuracy and the ability to "re-use" ions. Our current plans for moving in this direction are summarized.

In ICR sensitivity is proportional to the number of charges in the cell. the practical sensitivity limit for analytical ICR instruments is presently ~10 charges. It matters not whether one has ten singly charged ions in the cell or a single ion with ten charges. Thus single ion detection should be readily achievable for ions containing more than ten charges. Electrospray readily generates ions containing tens or even hundreds of elementary charges. Therefore, single highly charged ions should be readily detected in ICR using detection technology presently available. Image current detection in ICR is non-destructive, so ions may be re-used for sequential reactions as has already been demonstrated by a number of investigators. If a single ion is followed through a set of sequential reactions (i.e., fragmentations) special advantages are obtained. These primarily have to do with a tremendous simplification of the spectra. There is no longer an ensemble of ions of slightly varying m/z (due to isotope distributions, etc.) but rather a single ion with single values for mass and charge. In SMAMS the requirements for resolution may be substantially reduced compared to conventional techniques. With only a single ion present in the trap, there are no interfering "isotope peaks" and the m/z of the ion can be confidentially assigned by knowing the centroid of the peak alone. Furthermore, when this ion fragments it must "choose" a single one of many possible fragmentation spectra. Thus, the dissociation spectrum is also very simple and could perhaps be interpreted in real time. This allows the possibility of a "real-time adaptive" strategy in which the results of the last dissociation event help guide conditions (such as re-excitation frequency) for the rest of the next sequential step. Perhaps the most significant (and least obvious) advantage of SMAMS is that it may relax the requirement for m/z accuracy. For example, suppose one can select conditions favoring the sequential loss of residues from the 3' end of a highly charged DNA ion, and one continues to observe the m/z of the larger fragment as the system undergoes sequential dissociations. In order to sequence the DNA one is only required to differentiate between the loss of adenine and thymine, a difference of nine daltons. Even allowing...
for as many as four deuterium substitutions on the leaving group, one would need only a five dalton specification for mass accuracy. A side benefit is that errors in sequence assignment are localized to single residues and do not propagate through the system. The feasibility of SMAMS depends in part upon the ability to degrade the system under study in a series of highly predictable steps. Some general strategies for achieving this are currently being explored, but more research is clearly needed into selective gas phase degradation processes.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830. This research has been supported internally by the Molecular Sciences Research Center and the Environmental and Molecular Sciences Laboratory at Pacific Northwest Laboratory.
Production of multiply charged molecular ions by electrospray ionization (ESI) has allowed mass spectrometry (MS) to obtain structural information for large proteins by collisionally activated dissociation (CAD) processes. CAD of intact molecular ions with subsequent MS\textsuperscript{n} (\(n \geq 2\)) analysis of the resulting product ion is potentially a more rapid and sensitive method for amino acid sequence analysis. On a triple quadrupole mass spectrometer, CAD of ESI-generated ions can be induced in the atmospheric pressure/vacuum interface or, more traditionally, in the collision quadrupole cell (Q2). Combining these two processes, dissociation of molecular ions in the interface region (with an elevated voltage difference between the nozzle and skimmer) and further dissociation of the product ions in Q2 (an MS/MS/MS experiment), provides an effective means for examining molecular regions unprobed by MS/MS and further confirmation of mass spectral assignments. In principle, nearly complete sequence information for relatively large species can be provided with such MS\textsuperscript{3} experiments, although the limitations of current instrumentation make interpretation of CAD mass spectra of multiply charged ions for true "unknowns" problematic. Tandem mass spectra of multiply charged ions are often dominated by several series of product ions with various charge states. For example, MS/MS of the (M+18H)\textsuperscript{+} molecular ion of human growth hormone (Mr 22 kD) yields b\textsubscript{n} sequence ions with 3+, 4+, and 5+ charge states. Deconvolution methods used for Mr measurements from ESI mass spectra can be applied to such product ion mass spectra.

Comparing data from samples with minor structural modifications can simplify the spectral interpretation procedure. Transferrin glycoproteins (Mr 78 kD) from various species have been examined by CAD, yielding significant sequence information (typically from the NH\textsubscript{2} terminus). Serum albumin proteins (Mr 66kD) from 10 different species (bovine, human, rat, horse, sheep, dog, goat, porcine, and guinea pig) have been examined by ESI-MS, MS/MS, and MS/MS/MS. The primary dissociation product ions assigned have low charge state (2+ to 5+) and are attributed to "b\textsubscript{n}" mode species from cleavage of the -CO-N- peptide backbone bonds. Particularly intense dissociation products originate from regions near residues \(n = 20-25\) from the NH\textsubscript{2}-terminus for parent ions of moderate charge (\(-50+\)). Collisionally activated dissociation mass spectra from porcine serum albumin, in contrast to the other albumins, also give prominent singly charged "y\textsubscript{n}" fragments formed from cleavages near the COOH-terminus. Tandem mass spectrometry of the multiply charged molecular ions, and of fragment species produced by dissociation in the interface produced similar "b\textsubscript{n}" species and served to confirm spectral assignments.

Protein structural factors, such as the presence of proline residues, can have dramatic effects on the collisional dissociation spectrum. Proline is unique among the common amino acids in that the side chain imposers rigid constraints on the N-C rotation. It has been previously observed in CAD mass spectra of (M+H)\textsuperscript{+} from small peptides that cleavage is sometimes favored on the NH\textsubscript{2}-terminal side of a proline bond. Dissociation of multiply charged ions of peptides and proteins under low energy collision conditions often show this enhanced fragmentation adjacent to a proline residue. For example, CAD of carbonic anhydrase (259 residues, Mr 29 kD) yields multiply charged products primarily in the vicinity of four proline residues near the COOH-terminus (residues 193, 199, 213, and 225). Bovine ubiquitin (Mr 8564) dissociates primarily between Glu(18)-Pro(19) to yield highly charged y\textsubscript{n} ions. The sequence for yeast ubiquitin involves a substitution of Ser for Pro(19). Dissociation products are more evenly distributed in the vicinity of residues 14-21.
Interpretation of such collisional dissociation spectra for "unknowns" is currently difficult due to the complexity of the spectra and the uncertainty of assignments for product ion charge states. With higher resolution methods (e.g., Fourier transform MS), charge state assignments from resolved isotopic peaks is possible. Such methods would largely circumvent the limitations of the present triple quadrupole methods, suggesting the potential for extension to even greater molecular weights.

MOLECULAR WEIGHT DETERMINATION OF DEUTERATED RIBOSOMAL PROTEINS BY ELECTROSPRAY IONIZATION

*Erol E. Gulcicek, Shida Shen, James G. Boyle, and Craig M. Whitehouse

New Haven, CT 06511

Electrospray ionization mass spectrometry (ESI MS) has become an invaluable research tool for its ability to determine the molecular weight of picomole concentrations of large and labile biomolecules. This paper presents how ESI MS can be used in conjunction with neutron scattering experiments for the structural determination of ribosomes.

Precise determination of percent deuteration of nonexchangeable protons in the specific ribosomal protein is necessary prior to costly neutron scattering experiments. Typically, this is determined using expensive, and time consuming contrast variation method which can consume up to micromole amounts of sample as opposed to the picomole concentrations typically used in ESI MS.

In neutron scattering experiments, after individual proteins are purified from the ribosome, all but few of the ribosomal proteins are deuterated, and added together with the RNA to reconstruct the ribosome. Since the neutron scattering intensity from the deuterium containing ribosomal proteins will vary from that of naturally occurring ribosomal proteins, the individual proteins can be selectively mapped on the ribosome by observing the neutron scattering angles and the intensity. One of the most widely studied ribosomes to date is the E. coli ribosome which consists of two subunits that has a total of 3 rRNA and 52 proteins. Although the molecular weight and structural sequence of each individual protein is studied very well, little is known about their functions in the ribosome. By spatially determining the subunits of the ribosome and in turn their complicated assembly of RNAs and proteins, neutron scattering can help to understand the functions of the individual components of the ribosome.

Fully deuterated, protonated and partially deuterated S4 ribosomal proteins from a 30S E. coli subunit were purified and diluted in 1:1 Methanol:Water solution in 0.1\mu g/\mu l concentration. The samples were introduced at 1\mu l/min flow rates (approx 4 pmoles/min) into an Analytica electrospray ionization source interfaced to an HP 5988 quadruple mass spectrometer (Figure 1). Figure 2 shows ESI mass spectrum of each of the three proteins taken in 2 minute scans (total of 8 to 10 pmoles of sample).

The S4 ribosomal protein has a theoretical monoisotopic mass of 23123.5 amu with 1279 nonexchangeable hydrogen sites in solution. In order to find the percent deuteration of the S4
protein, the molecular weight of all three protonated, deuterated, and partially deuterated proteins are compared to each other under the same experimental conditions. Table 1 summarizes the experimental results and compares these to the calculated results. From the synthesis, the partially deuterated ribosomal S4 protein was expected to be around 50%; indeed, the experimental results agree with the predicted percentage showing confidence not only in the purity of the protein but also confidence in using this number as an important parameter for the neutron scattering experiment.

The ESI mass spectra of Figure 2 were analyzed with the recently developed deconvolution computer program. The new algorithm greatly simplifies the deconvolution routine by, first, finding the coherence between the multiply charged peaks, and then, assigning the molecular weight of the macro molecule. The calculations do not assume the conventional proton adduct ion in finding the macro mass. All possible adduct ion masses are considered, and their intensity contributions to the respective macro masses are plotted in a three dimensional deconvolution spectrum.

**TABLE I**
CONFORMATIONAL CHANGES IN PROTEINS PROBED BY HYDROGEN EXCHANGE ELECTROSPRAY IONIZATION MASS SPECTROMETRY

Viswanatham Katta and Brian T. Chait
The Rockefeller University, New York, New York 10021.

When peptides and proteins are dissolved in solvents like D_2O, labile hydrogens exchange with deuteriums. The exchange rates differ widely between different labile hydrogens and are a strong function of pH (slowest at pH about 3). In small peptides, in the absence of high order structure, all the labile hydrogens are accessible to the solvents and, even for the slowly exchanging amide backbone hydrogens, the exchange is complete in minutes. The same is expected of proteins in unfolded conformations (denatured states). For proteins in tightly folded conformations (native states), some of the labile hydrogens are inaccessible to the solvent because they are buried in the hydrophobic core or involved in salt bridges and hydrogen bonds, and are not readily available for exchange. The rates of exchange of these hydrogens can differ by orders of magnitude depending on the conformation of protein in solution. Thus, native and denatured conformations exhibit different exchange kinetics. After a short interval of exchange, the folded and unfolded proteins will differ in the degree of deuterium incorporation that has occurred and end up with different molecular masses.

The availability and the effective pKs of the acidic and basic side chains are determined by the precise conformation that the protein assumes under the conditions of study. As a result tightly folded native states will have lower net positive charge than the denatured states in solution. The multiply charged ions observed in the positive electrospray ionization (ESI) spectra reflect, to some extent, the degree of protonation in solution. Thus, a combination of hydrogen exchange with electrospray ionization is a natural choice for probing conformational changes because different forms of proteins will exhibit different masses and charge distributions in their mass spectra.

Bovine ubiquitin, in its native form is a small, tightly folded protein (76 residues, molecular mass 8565, no disulfide bonds, 13 basic sites, 144 labile hydrogens) and is very resistant to denaturation. Figure 1 compares the ESI mass spectra of ubiquitin obtained (a) from a solution in which the protein is known to be in a tightly folded conformation (1% CH_3COOD in D_2O) and (b) from a solution in which the protein is known to be unfolded (1:1 CH_3OD:1% CH_3COOD in D_2O). The spectra were obtained about 20 minutes after dissolving the protein in the above solutions (temperature 23 °C). The spectrum obtained from the native protein shows a charge distribution centered at 8+ (range 9+ to 6+) and the measured mass indicated an exchange of only 89 hydrogens (i.e. 62% in 20 minutes). On the other hand the spectrum obtained from denatured ubiquitin showed a distribution centered at 10+ (range 13+ to 6+) and a mass indicative of an exchange of 131 hydrogens (i.e. 91% in 23 minutes). The exchanges were followed as a function of time. In the case of the folded protein the exchange slowed considerably after 90 minutes (103 exchanges) and only 130 exchanges even after a week. In the case of the unfolded protein, almost complete exchange (138 exchanges) was observed within 60 minutes.

The method was applied for probing other protein conformations and the results are tabulated in Table I. Chicken egg lysozyme (molecular mass 14305, four disulfide bonds, 19 basic sites, 255 labile hydrogens) showed a charge distribution centered at 10+ (range 11+ to 8+) and an exchange of only 62% in 30 minutes, suggesting that the protein is in native state in 1% acetic acid. The spectrum obtained from lysozyme in which the -S-S- bonds were reduced, showed a distribution centered at 15+ (range 19+ to 9+) and indicated an exchange of 96% of the 263 labile hydrogens, suggesting that the reduced protein is denatured in this solvent (1% acetic acid). Other proteins listed in the table could be analyzed only in the denatured states (greater than 94% exchange in 30 minutes). Ions produced from the native states could not be observed, presumably because the m/z values of the low charge states of these ions were beyond the range of our instrument (m/z 2000).

The results demonstrate that hydrogen exchange electrospray ionization mass spectrometry provides an effective new method for probing protein conformations in solution.

Simultaneous Determination SQ 28,555 and SQ 27,519 in Serum by High Performance Liquid Chromatography Combined with Ionspray Mass Spectrometry.

D. Wang-Iverson, E. Ivashkiv, M. Jamal and A.I. Cohen
Bristol-Myers Squibb Pharmaceutical Research Institute
New Brunswick, New Jersey 08903

SQ 28,555 is a second generation angiotensin converting enzyme (ACE) inhibitor and is currently under clinical investigation as a treatment for hypertension. It is a pro-drug which is hydrolyzed in vivo to its active form SQ 27,519. The purpose of this study was to develop a sensitive and specific assay for these two compounds based on ionspray LC/MS.

Initially, negative ion detection was attempted. Since both compounds contain a free carboxylic acid, they should exist as anions in solution at neutral pH. However, while negative ion spectra showed good sensitivity for SQ 27,519, poor results were obtained for SQ 28,555. The main difference between these two compounds is that the phosphinic acid is blocked in the pro-drug and free in the active compound. As a result, the use of (M+NH4)+ for each analyte was found to be a better overall choice. Such a cluster could be easily and reproducibly generated by maintaining a relatively low orifice potential of +45V. Spectra collected under these conditions showed predominant (M+NH4)+ species not only for the analytes, but also for the structural analogues that were used as internal standards.

Serum samples were prepared by liquid-liquid extraction using purified ethyl acetate. The dried extracts were dissolved in loading buffer and separations were carried out by gradient chromatography on a 2mm ID Deltabond C8 column. The column was operated at 60° C, which improved the chromatographic peak shape of SQ 27,519 by increasing the rate of cis-trans interconversion of the proline portion of the molecule. Column temperature had no effect on the chromatography of SQ 26,555 under these conditions. The flow rate was 300 μL/min with a 1 to 6 split introduced to the ionspray interface. All compounds eluted within six minutes and the total analysis time was ten minutes.

The serum extracts proved to be more contaminated than anticipated making low level quantification difficult. Daughter ion spectra were collected for the compounds and multiple reaction monitoring (MRM) experiments were analyzed. The daughter ions monitored for both compounds were (M+H)+ of SQ 27,519, representing the loss of NH3 from both compounds in addition to the loss of the blocking group from SQ 28,555. Some interference was still present in the SQ 27,519 channel, but the SQ 28,555 trace was clean. If a more specific reaction could have been generated for SQ 27,519, perhaps the interference would have been eliminated, but the molecule proved to quite stable. No hydrolysis of SQ 28,555 to SQ 27,519 was evident due to extraction or analysis conditions.

The system was linear from 5 ng/mL to 1000 ng/mL and validation data demonstrated good accuracy and reproducibility.

UTILIZATION OF THE HEATED NEBULIZER AND ION SPRAY INLETS FOR DRUG
METABOLISM STUDIES: A GENERAL STRATEGY FOR LC/MS ANALYSIS

Gerald C. DiDonato and Bethanne M. Warrack
The Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, New Jersey

The utilization of atmospheric pressure ionization LC/MS techniques such as ion spray and heated nebulizer interfaces, both found on an API III triple quadrupole mass spectrometer, provide complementary tools for the identification of metabolites of novel therapeutic agents. The first technique, ion spray, produces gas-phase ions for those species which exist as ions in solution. The absence of heat makes this an ideal means of analyzing phase II metabolites, such as glucuronide and glutathione conjugates. However, since ion spray works best with flow rates of under 100 μL/min, the eluent from a conventional bore column must be split 10:1 or 20:1 to be compatible with the inlet. The heated nebulizer inlet uses flash evaporation of the LC eluent without flow splitting, followed by chemical ionization. For compounds which are not strongly ionized in solution and are thermally stable and volatile, this inlet offers an excellent means of analysis.

We have found that utilization of both the ion spray and heated nebulizer interfaces offer the best approach to the unequivocal molecular weight and structural determination of metabolites in a complex biological matrix. Even with the flow splitting necessary to utilize ion spray in conjunction with conventional bore columns, the technique produces intact molecular ions for glucuronide conjugates 10-15 times more intense than molecular ions produced by the heated nebulizer probe. However, for the detection and structural elucidation of thermally stable phase I metabolites, such as hydroxylated products, the heated nebulizer inlet is the technique of choice since all of the chromatographic eluent is directed to the mass spectrometer. This enables detection and characterization of low-level metabolites.

This dual-approach strategy is illustrated in the analysis of the metabolites of compound A, shown in Figure 1. A water/acetonitrile gradient, using 0.1% TFA, was used as the mobile phase with a 3 cm C18 cartridge column at a flow rate of 1.0 mL/min. 10 μL of bile obtained from a bile-duct cannulated monkey that had been dosed with this compound was injected for analysis. The TIC produced via ion spray is shown in Figure 2. The reconstructed ion chromatogram for the (M+H)+ ion of hydroxylated glucuronide metabolite, m/z 729, and its oxidation product to the keto/aldehyde glucuronide metabolite present at m/z 727, is shown in Figure 3. Good reconstructed ion chromatograms are produced for the conjugates, even though the eluent is split 20:1 prior to mass spectrometric analysis. However, analysis of the glucuronide conjugates by the heated nebulizer inlet produces drastically reduced ion currents, as shown by the reconstructed ion chromatograms depicted in Figure 4. The mass spectrum of peak A produced by ion spray shows an intact (M+H)+ ion at m/z 727; the mass spectrum produced by the heated nebulizer inlet (Figure 5) shows no molecular ion, only the aglycone at m/z 553.

On the other hand, since all the eluent is directed to the mass spectrometer, the heated nebulizer inlet produces higher signal intensity for thermally stable phase I metabolites. Figure 6 compares the reconstructed ion chromatograms, corresponding to dihydroxylated metabolites at m/z 569, produced by the ion spray and heated nebulizer inlets. The ion current produced by the heated nebulizer for these metabolites is about 20 times more intense than the ion current produced by ion spray. Thus, the heated nebulizer is preferable for phase I metabolites, due to the increased signal intensity.

The results outlined above have led us to apply a general strategy to the API LC/MS analysis of metabolites. First, one LC/MS analysis is carried out in full scan mode using the ion spray inlet. This analysis provides unequivocal molecular weight data, even for minor component glucuronide conjugates. The analysis is repeated in daughter ion MS/MS mode using the heated nebulizer interface. Daughter ion spectra are acquired for all the (M+H)+ ions of the phase I metabolites as well as the (M+H)+ ions of the aglycones produced via thermal degradation.
Electrospray Tandem Mass Spectrometry of Polyether Ionophores
H. G. Fouda* and R. P. Schneider
Drug Metabolism Department
Central Research Division, Pfizer Inc., Groton, CT, 06340

Polyether ionophores are fermentation derived biologically active compounds with a unique ability to form stable complexes with alkaline or alkaline earth cations. They exert their biological activity by catalyzing an electroneutral cation-proton exchange across cell membranes, moving as undissociated acids in one direction and as neutral complexes in the other. Their usefulness as cardiovascular drugs has been evaluated but their commercial success is due to their wide utilization as anticoccidiosis agents in broiler chickens and as feed efficiency enhancers in cattle and sheep.

Pneumatically assisted electrospray mass spectrometry of polyether ionophores yield several molecular ion adducts. A specific metal adduct molecular ion can be obtained by the selective addition of one salt to the HPLC mobile phase. This approach can aid molecular weight determination of unknown ionophores and the investigation of their metal ion preference. By allowing the selected ion monitoring (SIM) of any of several possible molecular ions, analytical methods can be rendered more specific and interferences from matrix can easily be avoided. For example, selected ion monitoring of salinomycin residues can be based on either of the following ions: m/z 773 (I+Na)+, m/z 789 (I+K)+, or m/z 883 (I+Cs)+, depending on the salt added to the mobile phase. Detection limits in the low ppb range have been demonstrated.
Collision induced dissociation of the molecular ions provides additional structural information and enhanced specificity for trace analysis. The CID daughter spectrum of the ionophore maduramicin is shown in Figure 1. The sodium adduct molecular ion is dissociated to two fragments. The minor daughter is consistent with the neutral loss of a CO2 molecule from the molecular ion. The most abundant daughter is apparently initiated by an intramolecular proton transfer from the carboxylic acid to the hydroxy group of the β-hemiketal, and then followed by the concerted losses of water and carbon dioxide to produce a polyether olefin (1). Mild CID conditions provide additional evidence for dimer formation. In the divalent ionophore lasalocid, the CID of its dimer ion (2I + 2Na - 1)+ at m/z 1225 resulted in only a single daughter ion (I+Na)+ at m/z 613.

Electrospray Mass Spectrometry: A Study on some Aqueous Solutions of Metal Salts

This work was undertaken to answer a fundamental question in electrospray: Is there a correlation between the electrospray mass spectrum and aqueous solution chemistry? Our initial attempt was centred on well characterized proteins such as myoglobin and cytochrome c (Roger Guevremont, K.W.M. Siu, J.C.Y. Le Blanc and S.S. Berman; Is the Electrospray Mass Spectrum of Proteins Related to their Aqueous Solution Chemistry? ASMS 91). However, even for these proteins, not sufficient information on their solution equilibria is available for a rigorous evaluation.

We have chosen to work with aqueous solutions of metal salts because much information exists and some of it has been critically evaluated. In this first round, we opted to prepare our samples by simply dissolving known quantities of metal salts in water and avoiding the addition of any acids, bases or organic solvents. Electrospray mass spectra of 1-3 mM aqueous solutions of some 30 metal salts, mostly metal halides and nitrates, have been recorded to date. Most spectra are dominated by hydrated clusters of the metal ion, metal salt complexes and metal hydroxides. For example, for cadmium iodide, the predominant ions observed were \( \text{Cd}(\text{H}_2\text{O})_n^{+} \), \( \text{Cd}(\text{H}_2\text{O})_n^{+} \) and \( \text{Cd}^{+} \) (Fig. 1). Typically, the most intense ions measured were those that had \( n = 1 \) or 2, and \( n = 5, 6, \) or 7 for singly and doubly charged ions, respectively.

Formation constants of a large number of metal anion complexes are known and have been critically evaluated [1]. We were able to calculate equilibrium concentrations of metal complexes in aqueous solution by entering these constants, the total metal and anion concentrations as well as pH into the Fortran program, COMICS [2]. Good correlation was observed between response and calculated equilibrium concentration for ions of the same charge and type. Fig. 2 shows results of some doubly charged ions that have been studied. Correlation between ions of different charge and type was relatively poor. This was believed to be caused by differences in the effect of electrospray on them. For example, the singly/doubly charged response was always larger than calculated singly/doubly charged concentration. This could be attributed to the large difference in solvation energies between singly and doubly charged ions.

For ions of the same charge and type, e.g., \( \text{Cd}(\text{H}_2\text{O})_n^{+} \) and \( \text{Cd}(\text{H}_2\text{O})_n^{+} \), excellent agreement was obtained between the mass spectrometric response and the calculated solution concentration when the total chloride/iodide ratio was varied from 20/1 to 1/20 under constant cadmium concentration (Fig. 3). Another example is the comparison between \( \text{Ag}(\text{NH}_3)_2^{+} \) and \( \text{Ag}(\text{NH}_3)_2^{+} \); very good correlation was obtained between their relative response and relative solution concentration when ammonia concentration was increased from 0.1 to 20 mM in a 2mM silver nitrate solution (Fig. 4).

A COMPARISON OF THE FOUR SECTOR MS/MS SPECTRA OF MOLECULAR AND QUASI-MOLECULAR IONS OF THE CYCLIC PEPTIDE VALINOMYCIN FORMED USING EI, CI, FAB AND FD

*J. M. Curtis¹, C. D. Bradley¹, P. J. Derrick¹ and M. M. Sheil²

¹Warwick Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry, CV4 7AL, UK.
²Department of Chemistry, University of Wollongong, NSW, Australia.

Four sector mass spectrometry has been a successful tool in studying peptide ions of up to 2.5kDa, generally giving sufficient daughter ion mass accuracy to unambiguously assign peaks. To date, most work has employed FAB or LSIMS as the ionisation method. The present work follows an earlier study [1] in which the MIKES spectra of peptide ions formed by FD and FAB were compared. Dramatic differences were seen e.g. for the cyclic peptide beauvericin (RMM 783.4) the MIKES spectra of the [M+Na]⁺ ions formed by FD and FAB show different major fragmentation pathways. For the linear peptide bradykinin (RMM 1099.6) the MIKES spectra of [MH]⁺ ions formed by FAB and FD show great differences in the relative intensities of the fragment ions although the same fragments are seen.

The cyclic depsipeptide valinomycin (RMM 1110.6, structure shown in Fig. 1) was chosen for study since it is amenable to ionization by EI, CI, FAB and FD. The results are summarised below:

M⁺ ions are formed by field desorption (FD) and by electron impact (EI) using an electron energy of 70 eV. Both MS/MS spectra show the same dominant neutral loss of C₃H₇ involving a McLafferty rearrangement of valine (Val) or hydroxyisovaleric (HyV) acid residues. M⁺ ions, formed by EI fragment to a much greater extent which presumably reflects the much greater input of energy by the ionization process. A second dominant fragmentation forming [M-113]⁺ ions is seen in EI-MS/MS. This can be assigned to cleavage of the CH-O bond in the HyV or Lactic acid (Lac) residue and loss of Val-0 with transfer of two hydrogens to the charged fragment ie [M-(Val+O-2H)]⁺.

MH⁺ ions formed by either fast atom bombardment (FAB) or methane chemical ionisation (CI) give very similar MS/MS spectra. As with M⁺ ions, the spectrum is dominated by a single fragmentation, but in this case loss of 28 (presumably CO) is the major fragmentation instead of loss of 42 (C₃H₇) as seen for M⁺. MH⁺ ions formed by ammonia CI contain ~50% contribution from ¹³C isotopes of M⁺ resulting in an MS/MS spectrum containing ions from both EI and CI-MS/MS spectra. [M+NH₃]⁺ ions shows a major loss of NH₃ then similar fragmentation to [MH]⁺.

The most dramatic difference seen between similar adduct ions is for [M+Na]⁺ ions formed by FAB and FD (fig.1). FD-MS/MS gives a single dominant fragmentation of loss of 43 (C₃H₇), the isopropyl side-chain from Val and HyV residues. Much more extensive fragmentation is seen in the FAB-MS/MS spectra of [M+Na]⁺ ions, including major fragmentations forming [M+Na-(Val-Lac+O-2H)]⁺ and [M+Na-(HyVal)]⁺ ions. In addition, comparing the MS/MS spectra of [NH]⁺ and [M+Na]⁺ ions formed by FAB, the latter shows much greater fragmentation than the former, indicating that FAB ionisation results in more energetic [M+Na]⁺ ions than [NH]⁺ ions, possibly resulting in ring-opened structures and greater fragmentation. [M+K]⁺ ions formed by FAB show a similar degree of fragmentation to [M+Na]⁺ ions and the same two dominant fragmentations, although many different fragment ions are seen.
In conclusion, in the case of a large polyatomic ion such as valinomycin, the degree and nature of the fragmentation seen in the MS/MS spectra is dependent both on the ionization mode used and the type of adduct ion formed.

STUDIES OF THE EFFECT OF THE NATURE OF THE COLLISION GAS ON THE HIGH ENERGY CID OF PEPTIDES

J.Bordas-Nagy, D.Despeyroux and K.R.Jennings
University of Warwick, Department of Chemistry, Coventry, U.K.

High energy collision induced decomposition (CID) in tandem double focussing mass spectrometers has been proved to be a successful method for sequencing peptides containing up to 25 amino acid residues [1]. The major fragment ion types that are present in the high energy CID of peptides have been established. Usually helium is used as collision gas in these experiments. There have been some conference reports which compared the CID of peptides obtained by helium to that obtained by heavier gases, such as argon, xenon and nitrogen. These investigations found indications that CID spectra obtained by heavier gases may contain significantly different features than those obtained by helium collision gas. We carried out investigations on the Concept IIHH tandem double focussing mass spectrometer in our laboratory in which we compared the qualitative and quantitative characteristics of the CID spectra obtained with light (He) and heavier (Ar, Xe) collision gases as a function of molecular weight of peptide precursor molecules. Three groups of peptides were investigated in order to take into account that peptides belonging to these different groups show different fragmentation behaviour from each other as has been observed previously by Biemann and coworkers [2]. The results of these investigations are summarized below.

1. Peptides containing arginine at the C terminal end

The CID spectra of this type of peptides show the strongest dependence on the nature of the collision gas. The Ar CID contains mainly abundant w_n and v_n ions and some y_n ions. When He was used as collision gas the intensity of the w_n and v_n ions decreased significantly, ca ten-fold or more. The spectra still contain some abundant y_n ions, but they generally do not form a complete series. These effects were stronger for peptides of greater molecular mass. An example of these effects is shown in Figure 1.

2. Peptides containing arginine at the N-terminal end

The He and Ar CID spectra of these peptides have similar features. They contain mainly a_n and d_n ions. The fragment ion intensities are also comparable for the light and the heavier gases. The main differences are in the relative abundances of the a_n and d_n ions. Argon CID generally produces significantly more abundant d_n ions than He CID, and it also generates d_n ions corresponding to amino acid residues which have aromatic side chains while He does not. Above ca 1500 dalton molecular mass the abundance of fragment ions in the He CID spectra decreases rapidly with molecular mass, while that in the Ar CID spectra remains relatively unchanged up to a molecular mass of 2500 dalton.

3. Peptides containing no basic amino acid residue

The CID spectra of these peptides are not affected significantly by the nature of the collision gas. These spectra contain mainly b_n and y_n ions. These ion types usually form a complete or near complete series some members of which have strongly reduced abundances.
The abundances of the fragment ions are fairly similar for both the light and the heavier collision gases.

Figure 1. Comparison of the high energy CID spectra of pancreastatin peptide fragment [33-49] obtained with He and Ar collision gases

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

THE COMPLEMENTARY UTILITY OF ELECTROSPRAY TANDEM MS ON A TRIPLE QUADRUPOLE AND FAB TANDEM MS ON A FOUR-SECTOR INSTRUMENT

Mark F. Bean, Michael J. Huddleston, and Steven A. Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406.

Structural elucidation of unknown peptides and natural products presents unique mass spectrometric challenges. Although the high-energy CAD tandem MS proves to be the preferred technique in most cases, there are a number of situations where electrospray low-energy CAD may provide complementary useful information or even be the method of choice. Factors favoring the use of electrospray on a triple quadrupole are its excellent sensitivity, ease in rapid acquisition of many spectra from an infused mixture, versatility in terms of alternative scan modes, and simplicity of fragmentation for peptides (no side-chain cleavages and insignificant x- and z-type ions). These factors offset the method's lower resolution, poorer mass accuracy, inability to distinguish isomeric amino acids or establish disulfide-bond connectivity, and frequently incomplete sequence information for peptides when compared to high-energy CAD on a four-sector instrument.

The limit of analysis, defined as the minimum amount of sample for which a product-ion spectrum could be recorded with essentially the same analytically useful structural information obtainable from unlimited sample, was determined to be about 500 fmol by ESI/MS/MS (Fig. 1). This represents about 10-50 fold improvement over what we can do by FAB/MS/MS on the four-sector mass spectrometer with conventional electron multiplier detection. The mass range for CAD does not appear to be any better on the four-sector than on the triple quadrupole using ESI. Nearly complete sequence information was obtained by both methods for adrenocorticotrophic hormone fragment 18-39 \((M_r = 2464)\) (for ESI see Fig. 2), neither instrument was able to obtain fragmentation data from a peptide of \(M_r = 2307\), while only ESI/MS/MS was able to obtain any useful sequence data from a peptide of \(M_r = 1996\), and that, only from the triply-charged precursor (Fig. 3). In the case of a tryptic peptide of \(M_r = 1498\), ESI/MS/MS yielded more interpretable data and slightly better sequence coverage, while the four-sector data was able to clearly differentiate leucine isomers.

With proper technique, it should be possible to acquire informative MS/MS spectra consuming less than 5 pmol of sample.

Sequence information for ACTH derived from the doubly-charged parent complements and overlaps with that derived from the triply-charged parent (not shown). Together they provide sequence information for all but the N-terminal arginyl-proline. The presence of arginine is suggested by the immonium ion - ammonia at \(m/z\) 112.
Spectra of enzymatic digests of proteins are considerably more complicated when acquired by electrospray versus FAB ionization due to multiple charging. Nevertheless, the electrospray method lends itself to continuous infusion of small amounts of sample (<25 pmol/μl) at low flow rates (1 μl/min), so that MS/MS of all intense ions in the spectrum of a protein digest mixture can be acquired rapidly and in automated fashion with relatively little sample consumption. The resultant data may not equal the four-sector tandem mass spectra in terms of sequence completeness or structural detail, but a portion of the sequence is nearly always readily available. In the mapping of proteins of known structure, this ability allows rapid sequence confirmation and localization of post-translational modifications. In the case of sequencing peptides of unknown structure, the simplicity of the results and, more importantly, the clarity with which sequence direction can be determined, provide a convenient springboard for the interpretation of the more detailed, and more complex high-energy CAD data.

An example of the importance of high-energy CAD for detailed structural analysis is its ability to establish disulfide-bond linkages. High-energy CAD MS/MS on selected peaks in an unpurified thermolysin digest of TGF-α produced clear evidence that all three disulfide bonds were correctly formed. This is possible because high-energy CAD of disulfides produces unusually intense disulfide cleavage ions (Fig.4). The same is apparently not true for low-energy CAD. In contrast, an experiment that is particularly well-adapted to ESI/MS/MS on a triple quadrupole is the use of parent scans from the oxonium ion of N-acetyl hexosamine for specific detection of glycopeptides during LC/MS/MS of protein digests (see Huddleston, M. J. et al, this volume).
Tandem Mass Spectrometry (MS/MS) of Lithium-attachment Ions from Polyglycols.

R. P. Lattimer, The BF Goodrich Research and Development Center, Brecksville, Ohio 44141.

Earlier work from our laboratory investigated in some detail the MS/MS behavior of MH+ and MNa+ ions from linear poly(ethylene glycol), PEG, and poly(propylene glycol), PPG. The MH+ ions fragmented readily under low energy collisional activation (~50 eV), but the product ions formed were of relatively low mass; hence these were of limited value for chemical structure elucidation. The MNa+ ions, on the other hand, while generally quite intense, were found to be very stable towards cleavage of C-O and C-C bonds. Only very weak sodiated organic product ions were formed, even at a relatively high translational energy (3 keV), with collision gas air. Thus it was found that neither MH+ nor MNa+ ions were optimal for practical MS/MS analysis of polyglycols.

We have now carried out a detailed study of the MS/MS behavior of three glycol polymers (linear PEG, linear PPG, and an ethoxylated fatty alcohol) using a Finnigan MAT 95Q hybrid mass spectrometer of BEoQ geometry. Ionization was provided by fast atom bombardment (FAB). Collisional activation was carried out in the "collision octapole" at a relatively low translational energy (50 eV), with collision gas air. A principal thrust of this study was to investigate the analytical utility of MS/MS of lithium-attachment polyglycol ions. It was found that MLi+ ions provide a number of important advantages for practical MS/MS analysis as compared to the use of MH+ or MNa+ ions. First, MLi+ parent ions for polyglycols are generally much more intense than the corresponding MH+ ions. Second, MLi+ ions dissociate at low collision energies (~50 eV), in contrast to the much more stable MNa+ ions. Third, product ions are generally formed over the entire mass range for low molecular weight polyglycols. This feature is especially useful for analytical purposes, i.e., the chemical structure analysis of unknown polyol chemicals.

The MS/MS fragmentation mechanisms for MLi+ ions have been studied in some detail. Deuterium-labeled polyglycols were used to assist in this investigation. Product ion scans from MLi+ of linear PEG decamer (m/z 465) and PPG octamer (m/z 489) are attached as Figures 1 and 2, respectively. One thing that is immediately clear is that reasonably intense, characteristic fragment ions are observed throughout the entire mass range. Four ions series are marked (A, B, C, D). The most intense product ions are in the A series; these are lithiated, linear glycol oligomers (R = H for PEG and CH3 for PPG):

\[
\text{Li}[\text{H-(-O-CH}- \text{CHR}-)_{n} \text{OH}]^{+} \quad \text{PEG: m/z 44n + 25; PPG: m/z 58n + 25.}
\]

These ions are formed by internal hydrogen transfer reactions which likely proceed through six-membered ring intermediates (see scheme below for PEG). It is likely that lithium plays some specific role in facilitating these charge-site initiated rearrangements.

The B and C series ions are logically formed via charge-remote fragmentations (analogous to those described previously for MNa+ ions):  

- B series. Li[\text{H-(-O-CH}- \text{CHR}-)\text{-O-CH=CHR}]^{+} \quad \text{PEG: m/z 44(n+1) + 7; PPG: m/z 58(n+1) + 7.}

- C series. Li[\text{OCH-CHR-(-O-CH}_2\text{-CHR-)}_{n}\text{-OH}]^{+} \quad \text{PEG: m/z 44(n+1) + 23; PPG: m/z 58(n+1) + 23.}

The low mass D series ions are radical cations containing lithium. These evidently form via homolytic bond cleavages near chain ends.

The third compound studied was Neodol 25-7, an ethoxylated fatty alcohol:

\[
\text{C}_{m+2}\text{H}_{2m+1}\text{-O-(C}_2\text{H}_4\text{-O)-}_n\text{-H MW 14m + 44n + 18.}
\]

The pattern of MLi+ product ions is very similar to that observed for PEG (Figure 1). In fact, the four ion series noted for PEG (A, B, C, D) are also prominent for Neodol 25-7; these series are all derived from the PEG end of the molecule. A fifth prominent ion series (A') is derived from the alkyl end of the molecule: Li[C_{m+2}\text{H}_{2m+1}\text{-O-(C}_2\text{H}_4\text{-O)-}_n\text{-H}]^{+} \quad \text{m/z 14m + 44n + 23. In summary, MS/MS analysis of MLi+ ions from the ethoxylated aliphatic polymer (Neodol) proved to be quite useful for chemical structure elucidation. It appears that the lithiation / tandem mass spectrometry combination will be a very helpful tool in analyses of selected polar, low molecular weight polymeric materials.}

\[
\text{OCH-CH}_2\text{-O-(-O-CH}_2\text{-CH}_2\text{-O-)}_{n}\text{-OD}
\]

\[
\text{OCH-CH}_2\text{-O-(-O-CH}_2\text{-CH}_2\text{-O-)}_{n}\text{-OD}
\]

Product Ion Scan (FAB-MS/MS) of M Li+ 489 (propylene glycol octamer).
IMPROVED DETECTION LIMITS FOR MS/MS OF DNA-PAH ADDUCTS

Ronald L. Cerny and Michael L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304

Covalent bonding of chemical carcinogens to DNA is likely the first step in tumor formation. Polycyclic aromatic hydrocarbons (PAH) can be converted into electrophilic intermediates, which ultimately react with DNA, by either one-electron oxidation to form radical cations or by monoxygenation to produce diol epoxides. To ascertain the biological significance of these mechanisms, the structure of DNA-PAH adducts must first be determined.

FAB combined with tandem mass spectrometry can differentiate between isomeric forms of adducts formed between benzo[a]pyrene (BP) and DNA [1]. With direct probe introduction and scanning of MS-II (an electrostatic analyzer), the detection limit for these adducts is 100 ng on a Kratos MS-50 triple analyzer. Although this level is acceptable for in vitro studies where experimental parameters can be scaled up, detection limits in the pg range are required for in vivo studies of biological systems. These experiments are necessary to determine the actual significance of a proposed mechanism.

Improvement in both detection limit and in the quality of CAD spectra is obtained by using a VG ZAB-T, a Mattauch-Herzog like four-sector tandem mass spectrometer. Shown in Figure 1 are the CAD spectra of adducts formed between adenine (Ade) and dimethyl-benzanthracene (DMBA). The enhanced resolution of the four sector instrument allows differentiation between adducts formed at the C7-CH3 (upper) or C12-CH3 of DMBA (lower) by comparison of the relative abundances of two major fragment ions. CA of the Ade adduct involving the C7-CH3 of DMBA produces a more abundant ion of m/z 239 relative to 240; CA of the adduct formed at the C12-CH3 position of DMBA results in a more abundant ion of m/z 240. Because the resolution of the electrostatic analyser that serves as MS-II on the Kratos MS-50 Triple Analyzer is < 250, these two adducts could not be distinguished based upon their CA spectra of (M + H)⁺.

An example of the improvement in sensitivity is shown in Figure 2. The upper section is the CAD spectrum of 20 ng of a benz[a]pyrene adduct of guanine (Gua). It compares favorably with a reference spectrum of 2 ug of the adduct (lower section). This improvement in sensitivity may principally be due to the use of a Cs⁺ SIMS gun, operated at 25 keV above source potential, on the ZAB-T instead of a 6 keV FAB gun as outfitted on the MS-50 TA. Even with this improvement, the detection limit is still high. The spectrum of 20 ng contains several noise spikes of comparable intensity to the signals for the fragment ions, even though 15 scans were averaged to produce the CAD spectrum. It is evident that the means of detection is a limiting factor in the MS/MS analysis.

The ZAB-T is equipped with a 15 cm photodiode array for simultaneous detection over a variable mass range. The use of the array improves the detection limit for direct probe introduction of the BP-Gua adduct by two orders of magnitude. Figure 3 contains the partial CAD spectra obtained on 2 ng and 200 pg of the adduct. The spectra are the result averaging together several 3 second array integrations. The ion of m/z 248 is a matrix interference and points out that sensitivity is now limited by the ionization process rather than by the detection method.

Continued improvement in sensitivity is dependent on better parent ion production, both in efficiency and in selectivity. Since we have successfully obtained CAD spectra on 1 to 10 picomole samples of peptides by using continuous flow FAB, we feel that the technique holds promise for the analysis of PAH-DNA adducts. This technique is, however, still limited by matrix interferences, albeit at lower levels. We are, therefore, pursuing the use of other ionization methods, such as field desorption or laser desorption, to minimize the effects of chemical noise on detection limits.

DETERMINATION OF ISOTOPIC ENRICHMENTS USING TANDEM MASS SPECTROMETRY

Simon J. Gaskell, Ralph S. Orkiszewski, Kevin D. Ballard and Mark J. Raftery

Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030

The significance and utility of the isotope patterns observed in certain tandem mass spectrometric analyses have been appreciated for some time. Todd et al. (1), for example, recognized that the isotope patterns observed in the product ion spectra derived from precursor ions incorporating multiple isotopes reflected the elemental compositions of the precursor ions. Bozorgzadeh et al. (2) similarly noted that the elemental compositions of precursor ions can be determined from a comparison of the product ion spectra of $m_1^+$ and $(m_1 + 1)^+$. The particular value of observed isotope patterns in precursor ion spectra and constant neutral loss spectra was illustrated by Singleton et al. (3). The principles involved may be explicitly stated as follows. For a single fragmentation process, (i) a precursor ion scan defines the isotopic composition of the neutral fragment lost, and (ii) a constant neutral loss scan defines the isotopic composition of the product ion detected. These principles have hitherto been put to little practical use. Here we illustrate their application in three areas and indicate the need for caution in interpretation when isotope patterns are distorted by the occurrence of oxidation or reduction processes in concert with the ionization step.

(a) Determination of isotope enrichment in labeled compounds. Two particular advantages accrue from the application of tandem MS in this area. First, isotope incorporations may be determined even when the analyte is present in a mixture sufficiently complex to obscure the conventional mass spectrum. Second, judicious choice of tandem MS scans permits the determination of isotope enrichments in specific locations in the analyte structure. A simple example is provided by $[^3H_2]$platelet activating factor (1-O-[[H]4]hexadecyl-2-acetyl-sn-glycero-3-phosphocholine). Metastable decomposition of the protonated species (m/z 528) yields principally m/z 184, corresponding to the phosphocholine headgroup. A scan of precursors of m/z 184 then defines the isotopic composition (with enrichment of deuterium) of the substituted glycerol moiety whereas a constant neutral loss scan of 344 Dalton reflects the natural isotopic composition of the phosphocholine.

(b) Isotope patterns as an aid to spectral interpretation. During FAB/tandem MS analysis of the natural glutathione conjugate, leukotriene C4, scanning of precursors of m/z 308 (presumptively representing protonated glutathione) yielded an ion abundance pattern in the [M+H]^+ ion region (m/z 626-628) which reflected the natural isotopic composition of the lipid sub-structures of the precursor molecule. This correspondence thus substantiates the proposed fragmentation assignment. Observation of signals at m/z 625 and 624, however, provided evidence for the occurrence of one- and two-electron oxidation processes occurring in concert with FAB ionization. Distortion of the apparent isotope pattern attributable to reduction processes has been observed during FAB/tandem MS analysis of the glutathione conjugate of acetaminophen (Figure 1). When the FAB liquid matrix was glycerol, scanning of precursors of m/z 182 revealed the expected predominance of m/z 488, but m/z 490 was significantly more abundant than expected on the basis of naturally occurring abundance. When trifluoroacetic acid (TFA) was added to the liquid matrix, the relative abundances of m/z 488-490 corresponded to the expected isotope pattern, in keeping with the findings of Visenti et al. (4) concerning the suppression of reduction in the FAB matrix following addition of TFA.

(c) Applications in drug metabolism studies. We have previously described (5) the joint application of the twin ion technique and tandem MS in metabolism studies. Here we emphasize the interpretative value of isotope patterns imposed by the use of derivatization reagents of defined isotopic composition. FAB MS of the bis-methyl ester of S-butyl glutathione, prepared using methanol/[^3H_3]methanol (1/1), gave the spectrum shown in part in Figure 2. Since the analyte is a bis-carboxylic acid, a 1:2:1 isotope pattern is observed in the molecular ion region. Constant neutral loss scanning of either 143 or 146 Dalton, corresponding to loss of the methylated gamma-glutamyl moiety, collapses the isotope pattern to a 1:1 doublet (Figure 3). This strategy has been applied in the screening for glutathione conjugates derived from 2-furamide in rat bile, where the expected (and observed) pattern is complicated (but in a predictable fashion) by the use of a 1/1 mixture of unlabelled and $[^3C_1]$-labelled xenobiotic in the metabolism experiment.

MS/MS STUDIES OF PROTONATED AND ALKALI CATIONIZED ETHYLENE GLYCOLS

Steven L. Cohen, Vishwanatham Katta and Brian T. Chalt
The Rockefeller University, 1230 York Ave., New York, NY 10021

Fragmentation pathways of alkali cationized molecules frequently differ from those of the related protonated molecules. To explore these differences, we studied the metastable and collisionally activated dissociation, CAD, mass spectrometry of polyethylene glycol dimethyl ethers. These compounds, commonly referred to as the glymes, have the general formula \( \text{CH}_3(\text{OCH}_2\text{CH}_2)_n\text{OCH}_3 \). We investigated the protonated and cationized glymes of various sizes ranging from triglyme \((n=3)\) to nonaglyme \((n=9)\) and where the cations were \( \text{Li}^+, \text{Na}^+, \text{K}^+, \text{and Cs}^+ \).

The experimental conditions were as follows. MS/MS: B/E Link scan technique on a VG 7070E double focusing mass spectrometer. Ionization: FAB. Ion energy was 5 kV. CAD: Collision gases were argon or air, with parent ion attenuation at 50%. Alkali cations were from iodide salts.

Figures 1 and 2 show the metastable and CAD mass spectra of the \((M+H)^+\) ion of tetraglyme, respectively. In both spectra the fragmentation is dominated by cleavage of the C-O bond accompanied by a hydrogen rearrangement. The daughter ion yield under metastable conditions is 2%. Under CAD, the total yield of daughter ions doubled to 4.2%, this increase arising mainly from the enhancement of the \(m/z\) 103 and 59 ions. For comparison, Figures 3 and 4 show the CAD spectra of penta- and nonaglymes, respectively. The dominance of low mass peaks is clearly observed in these two spectra, a similar pattern as seen in the CAD of tetraglyme (Fig 2).

We believe that the main reasons for this dominant low mass pattern involve ion internal energies. Parent ions with a relatively high degree of internal energy would tend to undergo sequential fragmentations to smaller granddaughter ions. We note that the ion \(m/z\) 59, though a minor peak in the metastable spectrum, appears as the base peak in the prompt FAB spectra of the glymes (not shown). This suggests that the protonated glymes that are selected for metastable scanning, though energetically cooler than those undergoing prompt fragmentation, have sufficient internal energies to undergo sequential fragmentation. Collisional activation increases the chances of sequential fragmentation and the CAD results support this notion; the dominant low mass pattern shifts towards smaller fragments (i.e. \(m/z\) 103 and 59). Other factors for the low mass pattern may arise from the influences of dichromination of the proton within the glyme. Ion-dipole interactions between the proton and the \(-\text{CH}_2\text{OCH}_2-\) groups have been postulated by Kebarle.1 Stronger ion-dipole interactions occur more frequently towards the ends of the glyme chain where there can be optimal ion-dipole alignment (Fig. A). This ion-dipole stabilization may play a role in the fragmentation processes but it remains unclear what the influences of dichromination would be.

Cationized glymes exhibit different behavior from the protonated glymes. (We discuss here the sodium adducts; the other alkali cation adducts exhibited similar results.) Figure 5 shows the metastable spectrum of the \((M+Na)^+\) ion of tetraglyme. The spectrum is weak and the daughter ion yield is 0.08 %, lower than the protonated tetraglyme by a factor of twenty. This data suggests that the \((M+Na)^+\) ion is energetically cooler than the protonated ion. Coordination of the alkali cation by the \(-\text{CH}_2\text{OCH}_2-\) dipoles, resulting in a crown ether/sodium ion-like complex (formed in solution, prior to FAB desorption) (Fig. B) can serve to stabilize the \((M+Na)^+\) ion.

Upon collisional activation of the \((M+Na)^+\) of tetraglyme (Fig. 6), the daughter ion yield increased by a factor of seven over the yield from the pure metastable fragmentation. CAD has also dramatically increased the number of fragment ions observed. This high degree of uniform fragmentation was also observed for the larger nonaglyme \((M+Na)^+\) ion (Fig. 7).

Although the absolute daughter ion yields from CAD are smaller for \((M+Na)^+\) than \((M+H)^+\) ions and the CAD spectra from both of these ions are distinct, these differences diminished upon increasing the percent attenuation of \((M+Na)^+\) parent ions by the collision gas. In going from fifty to ninety percent attenuation, we found that the CAD daughter ion yield of the \((M+Na)^+\) of tetraglyme approaches the yields found for protonated tetraglyme and the fragmentation pattern becomes dominated by lower mass daughters, reminiscent of the dominant low mass peaks from CAD of the \((M+H)^+\) ion. The ion internal energies therefore appear to be the main properties influencing the nature and degree of fragmentation.

1270
Steranes are a class of organic compounds called biomarkers that retains the basic carbon skeletons of biological compounds through diagenesis and maturation during burial. The distributions of biomarkers can be used to assess source input, age, maturity, biodegradation and depositional environment of source rocks and oils. They can also be used for oil/oil and oil/rock correlation studies.

Conventionally, GC/MS is used to monitor the distributions of two principal biomarker types, namely, steranes and triterpanes. However, due to interferences from coeluting components, particularly in the case of steranes, certain GC/MS measurements can be difficult. Compromises are usually taken for determining the distributions of various types of steranes, such as the use of m/z 217 chromatogram for regular steranes, m/z 218 for isosteranes and m/z 259 for diasteranes. GC/MS/MS, which links molecular ion and characteristic fragment ions, provides a clean separation between homologous series of coeluting steranes (see below), eliminating many of the compromises necessitated by GC/MS for characterizing sterane distributions.

The use of normal geometry tandem sector instruments with a multiple reaction monitoring (MRM) technique was initially reported in the literature for the parent GC/MS/MS experiments[1]. Due to rather high kinetic energies (in keV) of daughter ions reaching the detector, reasonable sensitivities can be easily obtained without re-tuning the instrument. The use of a tandem quadrupole MS/MS, on the other hand, requires re-tuning of the instrument to achieve optimal sensitivities for the parent experiments. However, tandem quadrupole yields chromatographic peaks with baseline resolution while MRM yields raised baseline due to inadequate energy resolution inherent with a tandem sector instrument.

We used a Finnigan TSQ-46 tandem quadrupole instrument for the GC/MS/MS parent experiments. The first quadrupole (Q1) was used to monitor the molecular ions while the third quadrupole (Q3) was set to allow only the m/z 217 ion to pass through. The middle quadrupole was used for collimation. Figure 1 shows typical GC/MS/MS chromatograms for steranes in a phosphatic marine-source rock. The top four traces (A through D) are the selective GC/MS/MS measurements between the molecular ions and the m/z 217 ions for the C27 through C30 steranes, respectively. It can be seen that the GC/MS/MS technique can determine distribution of diasteranes, isosteranes and regular steranes for each carbon homologue without any interference due to coelution. The bottom trace (E) is the Integration of Traces A through D, which shows a similar elution pattern to that observed by GC/MS when monitoring only the m/z 217 ion.

The 217 ions observed in GC/MS and GC/MS/MS are the products of fragmentation from the molecular ions in different time frames. The m/z 217 ions detected by GC/MS occur in the ion source with fragmentation rates faster than $10^{-6}$ seconds, while those by GC/MS/MS in the region between the Q1 and the Q3 with rates of on the order of $10^{-5}$ seconds. However, for steranes of the sample set we studied both techniques yield highly comparable results. Figure 2 shows similarity by comparing a m/z 217 chromatogram from GC/MS with an integrated 217 chromatogram from GC/MS/MS measurements of a carbonate marine-source rock. Thus, the value of GC/MS/MS in the analysis of steranes does not lie in the ability to better determine routine sterane parameters employed in petroleum exploration applications, but rather in the ability to characterize steroidal hydrocarbon distributions which cannot be adequately determined by conventional GC/MS. Two of such opportunities were identified: (1) the ability to characterize distribution of C30 steranes, a marine-source indicator, and (2) the ability to characterize A-ring methyl steranes[1]. Neither of these compound classes, which carry important geochemical information regarding organic matter sources and facies, can be adequately measured using GC/MS.

FIGURE 3
COMPARABLE RESULTS ARE OBTAINED BY GC/MS AND GC/MS/MS
Time-of-Flight mass spectrometry (TOF-MS) has numerous advantages for the analysis of biomolecules, including virtually unlimited mass range (e.g., 274,800 Da) [1], high sensitivity (multichannel detection, high transmission), high speed, medium resolution (>20,000 demonstrated) [2], and relatively low cost. However, its capabilities for tandem MS have received little attention. Here, we describe a method for surface-induced dissociation (SID) [3] using an in-line collision device with a reflectron TOF instrument. We also demonstrate a novel method for combining matrix-assisted laser desorption [1] with continuous aqueous introduction for interfacing liquid-phase chromatographic techniques, such as capillary electrophoresis, to MS.

Ions from volatile samples are formed using 266 nm multi-photon ionization (MPI). For non-volatile biomolecules, aqueous sample solutions are introduced through a capillary directly into the ion source of the mass spectrometer; evaporative cooling results in a continuous flow of "ice" at the end of the capillary. Ions are laser desorbed from the ice matrix either directly (1.9 μm; 266 nm), or with two laser pulses (1.1, 1.9 μm neutral desorption; 266 nm MPI) from a single Nd:YAG laser with a double pulse option. For SID, ions are made to undergo collisions with a retractable stainless steel surface in the reflectron mirror. Collision energies are varied by adjusting both the position and voltage of the surface.

Ions are mass selected for dissociation using a pulsed deflection plate after the ion source; unit mass resolution at m/z 200 is obtained (Figure 1). This resolution increases with \( \sqrt{m} \) but is ultimately limited by the initial kinetic energy spread of the ions from the source as well as the rise time (and voltage) of the deflection pulse. Collision energies of the selected precursor ions can be continuously varied from 0 eV up to their acceleration energy. Most ions show extensive fragmentation with collision energies approaching 200 eV; above this, neutralization increases significantly, and desorption of secondary ions from the collision surface starts to occur. A typical breakdown graph of SID fragmentation of methyl-anlsole (Figure 2a) shows the expected fragmentation for this compound (80 eV SID spectrum Figure 2b). Daughter ion resolution of ~70 at m/z 100 (FWHH) is obtained with collision energies <100 eV.

![Figure 1: 266 nm MPI spectrum of Br-naphthalene (left), and with parent ion selection (m/z 208, right). Molecular ion region shown.](image)

Higher energy collisions produce extensive dissociation of even very stable ions, such as the molecular ion of phenanthrene (Figure 3). Surprisingly, abundant pick-up of species as large as C_{6}H_{9.4} by the molecular ion from the surface is observed. The source of this is most likely polyphenyl-ether diffusion pump oil used in our instrument. We observe no measurable shift in our flight times for these species, indicating that this process takes place spontaneously on the surface (<100 ns). Recent theoretical calculations indicate that such reactions can result from a single surface bounce (<1 ps) [4]. Fragmentation appears to be more extensive than that obtained by Cooks and coworkers [3] at the same collision energies, consistent with higher internal energy deposition obtained with our near normal collisions. Overall SID efficiencies of 7 - 15% are observed for most small molecules with 20-100 eV collisions. Preliminary SID spectra of peptides (Figure 4) indicate that efficiencies Preliminary SID spectra of peptides indicate that efficiencies of 30 - 50% are possible for these larger molecules.

Broad Spectrum Analysis of Alcohols for Delineating Plasticizer Contamination in Soils and Surface Water

J.V. Headley, D. Krause¹ and C. Swyngedouw¹

¹Environment Canada, Innovation Boulevard, Saskatchewan, S7N 3H5
²Chemex Labs Alberta Inc., 2021 - 41 Avenue N.E., Calgary, Alberta, T2E 6P2

In support of a monitoring program to delineate the extent of contamination by plasticizer at an industrial site a rapid analytical method was required for indicator compounds. GC/MS analysis employing EPA Method 8270 was not suitable as a single test for fingerprinting some sources. This was due in part to plasticizers containing multi-component mixtures of coeluting phthalate esters and adipates with poor diagnostic mass spectra.

The plasticizers investigated were suspected to contain various blends of: di(2-ethylhexyl)phthalate; tri(2-ethylhexyl)trimellitate; diisodecyl adipate isomers; diisodecyl phthalate isomers; diundecyl phthalate and dioctyldecyl phthalate. Preliminary tests conducted indicated a linear correlation between the levels of these components with detectable levels of C₇-C₁₁ alcohols in contaminated samples.

Indicator Compounds

This paper describes a GC/MS/FID strategy employing selected alcohols as indicator compounds for plasticizer contamination in soils and surface water. The indicator compounds selected for analysis occur as complex alcohol mixtures arising from the manufacturing process.

For example, the GC/MS total-ion profile of Blend #1 contained at least 8 isodecanol isomers. Another source of plasticizer, blend #2, coded as 810EE contained a mixture of 1-octanol and 1-decanol. A third blend contained a single component, 2-ethylhexanol. Conceptually, contamination of soil or surface water arising from these point sources could be distinguished from each other using the diagnostic alcohols as indicator compounds.

The analytical strategy selected for this monitoring program utilized a simple carbon disulfide solvent extraction procedure with off-line GC/FID quantitative analysis. GC/FID conditions were established to permit diagnostic identification of the three sources of plasticizer. Electron impact GC/MS analysis was reserved for secondary confirmations of phthalate esters as required. This strategy was required to: (a) reduce the response time between sampling and analysis and (b) minimize the cost of extensive analyses.

Extraction Procedures

Soil samples (10g) in 20 mL scintillation vials were agitated in water (8mL) to form a slurry which was extracted using carbon disulfide (5mL) for 5-10 minutes. The resulting mixture was allowed to settle for 10 min and 1 µL of the carbon disulfide fraction (middle layer) was analyzed directly without further cleanup. Poor recoveries below 5% were obtained using water only as the extraction medium. For some soils with noted organic matter, centrifugation was necessary to break up emulsions and facilitate separation of the carbon disulfide fraction from the extraction mixture. QA/QC data were obtained for the recovery of blends #1 - 3 using matrix spikes of soil samples covering the duration of the monitoring program. The recovery (for fortified levels at 40-300 µg/g) and method detection limits obtained for soil samples were 30-60% and 1 µg/g respectively.

Water samples (125 mL) were extracted in the sample containers with carbon disulfide (10 mL) for 5-10 minutes. The resulting mixture was allowed to settle, the carbon disulfide fraction transferred to a 20 mL scintillation vial and 8 mL of water added to suppress evaporation of the solvent. QA/QC data were obtained for the recovery of blends #1 - 3 using matrix spikes of water samples covering the duration of the monitoring program. The recovery (for fortified levels at 10-1000 µg/L) and method detection limit determined were 65-97% and 0.1 mg/L respectively.

Instrumental Procedures

The GC/MS/FID conditions utilized a Hewlett Packard 5996 GC/MSD equipped with TARGET software and a UNIX Chem Station. All confirmations were based on retention time data and electron impact data obtained for commercial standards.
of the indicator alcohols. GC/MS experimental conditions were established as per Method 8270 guidelines: 30m DB-5 column, i.d. 0.33mm, film thickness 0.25μm, helium carrier gas 1 mL/min, injector 280°C, transfer line 300°C, temperature program 150°C/5min 8 10°C/min - 280°C/7min. Off-line GC/FID conditions utilized a Shimadzu GC equipped with a 30m nukol column, i.d. 0.53mm, film thickness 0.5μm, helium carrier gas 6 mL/min, isothermal 120°C.

Quantification of the isodecanol isomers, blend #1, was performed using external standards and area summation of the isomers. Identification of real samples was facilitated by the diagnostic GC/FID fingerprints and GC/MS confirmations as required. Likewise, analysis of blend #2 in real samples was based on the presence of both 1-octanol and 1-decanol at relative concentrations of 1:1. GC/MS confirmation of the single alcohol in blend #3 was performed as required.

Conclusion
The GC/MS/FID strategy employing alcohols as indicator compounds provided diagnostic fingerprints of point sources. The strategy was found to be cost effective for delineating plasticizer contamination in a monitoring program. Actual samples from contaminated sites contained levels up to 1000 ppm. Appropriate dilutions were deemed necessary to minimize GC/MSD downtime and reduce the response time between sampling and analysis.

FRAGMENTIONS PRODUCED BY ION SOURCE REACTIONS
IN THE METHANE NEGATIVE ION CHEMICAL IONIZATION
MASS SPECTRA OF PHTHALATES

Elizabeth A. Stemmler and Jennifer A. Swift
Bowdoin College, Brunswick, ME 04011

Negative ions appearing at m/z values greater than M' are frequently observed in methane negative ion chemical ionization (NICI) mass spectra. Excluding ions produced by reactions involving neutral or ionized forms of \( \text{O}_2 \) or \( \text{H}_2\text{O} \), these ions have been attributed to radical-molecule or surface-assisted reactions that occur prior to electron capture ionization. In addition to ions appearing at m/z values above M', a few examples of fragment ions produced by such reactions have appeared in the literature.\(^1\)

The methane NICI mass spectra of phthalates show unusual fragment ions that correspond to \([\text{M-C}_n\text{H}_{2n-1}]^-'\) and \([\text{M-OC}_n\text{H}_{2n-1}]^-'\). For example, ions at \([\text{M-14}]^-'\) and \([\text{M-30}]^-'\) are observed in the NICI mass spectrum of dimethyl phthalate (see Figure 1). These ions are of interest because they can be used to differentiate ortho, meta, and para alkyl esters of phenyl dicarboxylic acids; however, the ions are unusual because their formation requires either a hydrogen addition or intramolecular hydrogen transfer.

The \([\text{M-14}]^-'\) and \([\text{M-30}]^-'\) fragment ions from dimethyl phthalate have been studied using deuteromethyl phthalate and \( \text{CD}_4 \) reagent gas. The spectrum of deuteromethyl phthalate shows ions that correspond to \([\text{M+H-CD}_4]^-'\) and \([\text{M+H-OCD}_3]^-'\) (see Figure 2A), indicating that a hydrogen addition has occurred, not an intramolecular hydrogen transfer. Using \( \text{CD}_4 \) as the reagent gas, the spectrum of dimethyl phthalate shows that the added hydrogen originates from the methane buffer gas (see Figure 2B). The spectra of dialkyl phthalates with longer alkyl groups \((n = 2-10)\) also show the \([\text{M+H-C}_n\text{H}_{2n-1}]^-'\) and \([\text{M+H-OC}_n\text{H}_{2n-1}]^-'\) ions. As the number of carbons increase, the \([\text{M+H-C}_n\text{H}_{2n-1}]^-'\) and \([\text{M+H-OC}_n\text{H}_{2n-1}]^-'\) relative abundance decreases.

Several mechanisms could explain formation of the \([\text{M+H-C}_n\text{H}_{2n-1}]^-'\) and \([\text{M+H-OC}_n\text{H}_{2n-1}]^-'\) ions. Noting that adduct ions at \([\text{M+H}]^-'\), \([\text{M+14}]^-'\), and \([\text{M+15}]^-'\) appear in the spectra, one possible mechanism would involve the fragmentation of adducted species following ionization. This mechanism has been demonstrated in studies of fragment ions from dicyanomethane derivatives of 9-fluorenone and benzophenone.\(^3\) Alternatively, the dialkyl phthalate may undergo a gas-phase or surface-catalyzed reduction to the corresponding monoaldehyde or conversion to the monocarboxylic acid (see Scheme I), with subsequent ionization by electron-capture. Other mechanisms could involve recombination processes, as proposed by Sears et al.\(^4\)

Initially, we attempted to determine if the reaction was gas-phase or surface-assisted. Previous studies have shown that tailing ion chromatographic peak shapes, incomplete incorporation of labelled reagent gases, and a decrease in relative abundance with ion source pressure are observed for ions production involving an initial surface-assisted reaction. The spectrum of dimethyl phthalate in \( \text{CD}_4 \) showed high incorporation of deuterium. Tailing chromatographic peak shapes
were not observed. The most revealing information came from pressure studies, which showed an increase in the relative abundance of [M+H-CH4]⁺ and [M+H-OCH3]⁺ ions with ion source pressure (see Figure 3). In contrast, an increase in \( M' \) would be expected for a surface-assisted reaction. The observed behavior could be explained by an ion-molecule reaction between \( M' \) and CH4; however, experiments on a FTICR instrument showed no evidence for such a reaction. A second explanation would involve a gas-phase radical reaction. In the source, radicals are lost primarily by diffusion to the walls; recombination and flow out of the source are minor loss mechanisms. As the ion source pressure is increased, the concentration of radicals is expected to increase. Thus, the observed changes with pressure could be explained by a reaction involving gas-phase radicals.

![Scheme 1](image)

To determine if radicals were involved in formation of the [M+H-CH4]⁺ and [M+H-OCH3]⁺ ions, an emission current study was carried out. As the emission current increased, the relative abundance of the unusual ions increased. The observed change depended upon sample concentration and CH4 pressure; however, at low pressures and sample concentrations, the ratio of unusual ions/M' increased linearly with emission current. To further verify that radicals were involved in ion formation, nitric oxide was added to trap H- and CH3 radicals. Upon addition of 1% NO the abundance of the [M+H-OCH3]⁺ and [M+CH3]⁺ ions dropped dramatically. The [M+H-CH4]⁺ ion was still observed; however, its intensity also decreased with higher percentages (27%) of NO. To determine if CH3 or H radicals were involved, the spectrum of dimethyl phthalate was measured using H2 and D2 as buffer gases. While the adduct ions at [M+14]⁺ and [M+15]⁺ were not observed, the [M+H-CH3]⁺ and [M+H-OCH3]⁺ ions were still present, indicating that H radicals were involved.

Under conditions that promote formation of these unusual ions (high ion source pressure, emission current) the methane NICI mass spectra can be used to differentiate phthalates, isophthalates, and terephthalates. The terephthalates (alkyl esters of para-dicarboxylic acids) show only a molecular ion, the isophthalates (meta isomers) show the [M+H-OCH3H2n+1]⁺ ion, while the phthalates show the m/z 148 ion, [M+H-C6H2n-1]⁺, and [M+H-OCH3H2n+1]⁺ ion.

INTRODUCTION

The accurate measurement and determination of volatile organic compounds in the field requires a device which is sensitive, versatile, and easily maintained. Additionally, the device should be able to provide real time monitoring of the air being analyzed. An instrument that is not commercially available as an ambient air analysis device but does have many of the above mentioned attributes is based upon ion trap technology (1-2). A number of research groups are currently evaluating similar instrumentation for volatile organic compound analysis in ambient air (3-6). The ion trap may be operated in a variety of modes including mass-selective storage and MS/MS (7-8).

R. G. Orth and coworkers presented a paper at the 1989 EPA/APCA symposium with preliminary data obtained using the ion trap mass spectrometer (ITMS) for ambient air analysis (9). This evaluation is an extension of the initial work utilizing different operational modes and interface. The evaluation included the determination of the detection limits of the ITMS for several compounds in calibrated mixtures sampled directly. A second evaluation of air samples was performed with the ITMS.

EXPERIMENTAL

The sample introduction system consisted of a fine metering valve and a heated transfer line. An uncoated megabore (~3 meter) capillary column is used as a transfer line. The samples were introduced through a fine metering valve to control the flow rate into the device. The static pressure of sample in the device was generally 1x10^4 torr while the total pressure in the ion trap was in the 10^-5 torr range. The difference in total pressure was due to the addition of helium (added co-axially to the sample inlet stream). The samples analyzed for this analysis include a NBS aromatic standard (10 ppm and 250 ppb). Certified standards from Scott Specialty Gas of a mixture containing the aliphatic compounds (1 ppb to 10 ppm) listed in Table 1. Two air samples were collected in one liter summa vessels and were analyzed.

RESULTS AND DISCUSSION

The air standard containing chlorobenzene was admitted directly into the ITMS. The majority of the sample is N2, which makes it is difficult to detect the ppm to ppb level constituents of interest (the partial pressure of the compounds of interest is on the order of 3x10^-5 torr). To accomplish the detection at these trace levels, the device is operated in mass-selective storage mode.

The detection limits for both EI/MS and EI/MS/MS mode of operation are summarized in Table 1. The detection limits for the aromatic compounds are very conservative and are based upon data obtained from the 250 ppb and 10 ppm standards. The detection limits for the aliphatic compounds are based upon data obtained from standards ranging in concentration from 1 ppb to 10 ppm. The detection limits for all the aromatic compounds examined should be able to be improved to the low ppb to sub ppb regime. Three compounds in the mixture were unable to be quantified using the current experimental arrangement. Future work will include heating the metering valve and optimization of the data system which should allow for the quantifiable detection of all the components.

In the identification of benzene (C6H6) from one air sample, interferent compounds present make the mass spectrometric identification very difficult. The ions at m/z 77 can arise from a number of sources, but the ion at m/z 79 can arise from fewer sources such as protonated benzene or from hydrocarbons. Figure 1a shows the mass spectrum that results when the m/z ions 79 have been selectively retained. This is followed by CID of the m/z 79 ions of protonated benzene shown in Figure 1b. The fragments are typical for protonated benzene based upon knowledge of mass spectrometric fragmentation. Three components of the sample were identified by using EI/MS/MS analysis. This sample also contained ions associated with hydrocarbons which were not identified.

CONCLUSIONS

The ITMS from this evaluation has distinct promise as an analytical tool for the determination of trace organics in ambient air. The simple interface which samples air directly was shown to have detection limits in a complex background at the ppb to sub-ppb (carbon tetrachloride) levels for selected compounds. This
The limit is once again conservative and probably can be extended with improvements in the interface and data system utilized for this evaluation. The ITMS was able to identify and confirm the components of standard mixtures and samples to the ppb region using EI/MS/MS. The small size of devices based upon ion trap technology (ITD and ITS40) indicates that the device may be miniaturized to a size that would be easily transportable. Although near real time analysis was realized with this study, it should be possible with a properly designed interface and data system to obtain real time analysis.

COMPARISON OF IONIZATION MODES FOR HPLC/PARTICLE BEAM/MASS SPECTROMETER INSTRUMENTATION

B. Mason Hughes and David E. McKenzie
Environmental Sciences Center
Monsanto Company
St. Louis, Missouri 63167.

Introduction

During December 1990 the Environmental Sciences Center (ESC) participated in an EPA-sponsored round robin on the analysis of benzidine and substituted benzidines using HPLC/particle beam/mass spectrometer instrumentation. That study required the electron impact analysis of blind Quality Control solutions containing benzidine, 3,3'-Cl-benzidine, 3,3'-(CH₃)-benzidine, and 3,3'-(CH₂O)₂-benzidine using ESC's recently-assembled HPLC/MS system. The same set of samples was also analyzed using methane chemical ionization. This paper compares these two modes of ionization for the quantitative analysis of this class of target compounds.

Background

New EPA methods incorporate the use of a particle beam interface for the analysis of unsubstituted and substituted benzidines.

\[ R = H \text{ for benzidine} \]
\[ = \text{Cl for } 3,3'\text{-Cl}-\text{benzidine} \]
\[ = \text{CH₃ for } 3,3'\text{-} (\text{CH₃})\text{-benzidine} \]
\[ = \text{OCH₃ for } 3,3'\text{-} (\text{CH₂O})₂\text{-benzidine} \]

This class of compounds produces large amounts of \( M^+ \) ions using 70 eV ionization and \( MH^+ \) ions using methane chemical ionization reagent ions.

\[ (\text{CH}_₃, \text{C}_2\text{H}_₅, \text{C}_₆\text{H}_{₁₅}) + X \rightarrow \text{XH}^+ + (\text{C}_₆\text{H}_{₅}, \text{C}_₆\text{H}_{₁₃}, \text{etc.}) \]

A recently-assembled system, consisting of HP-1090 HPLC with diode array detector, HP-5987 quadrupole mass spectrometer system, Vestec particle beam interface, and ESC-designed interface between the momentum separator and the EI/CI ion source, was used in this study.

Experimental

The interface between the momentum separator and EI/CI ion source consisted of a pyrex tube which inserted into the IV solids probe inlet of the ion source. Methane CI reagent gas was introduced concentric to the particle beam. Figure 1 compares the HPLC/MS chromatograms obtained under these two modes of ionization.

The following conditions were used in these analyses:

- HPLC flow rate: 1.0 mL/min.
- Gradient: 25% Acetonitrile for 1.0 min.; linear ramp to 70% Acetonitrile at 19 min.
- Injection Volume: 20 μL
- LC Column: B&J 4.6 mm x 15 cm., C₁₈, 5 micron
- No post column addition of acetonitrile was used and masses between 62 and 500 amu were scanned.

The major difference between these conditions and those of EPA's Draft Method 553 was that Method 553 suggests the use of an injection volume of 5 μL and the use of a C₁₈ LC column.
Results

The chromatograms shown in Figure 1 were obtained from the electron impact and chemical ionization analysis of a 50 μg/mL calibration standard. The Draft Method 553 requires: 1) at least a 25% valley between the dimethyl- and dimethoxy-benzidines, 2) no severe tailing, and 3) a signal/noise ratio greater than 3/1.

Calibration. External standards were used for calibration for both modes of ionization. The responses of the $M^+$ ions for electron impact, and (M+H)$^+$ ions for chemical ionization were used to construct calibration curves. Hewlett-Packard's Aquarius quantitation and identification package was used for all data reduction. Figures 2 and 3 show the calibration curves generated for this study. For all of the reported results, second order responses were assumed and the data in these two figures were used to generate a quadratic response curve upon which all blind sample concentrations are based.

Analyses. Figures 4 and 5 summarize the results of blind sample analyses using EI and CI modes. The CI data exhibit more spread than the EI data. This may be due to the lack of the use of an internal standard to correct for long term changes in instrument response.

If the % of correct value is calculated for each analyte at each concentration, the usefulness of these two modes of ionization for quantitative analysis of these target compounds can be compared. Performing this calculation yields an overall average for the % of correct value of 92.2 % for electron impact and 99.5 % for chemical ionization. The standard deviations (SDs) for these two sets of 52 data points for each mode of ionization yields a SD of 10.6 % for electron impact and 23.7 % for chemical ionization. Finally, the minimum % of correct value for electron impact was 70.4 % and the maximum value was 126.2 %. This compares with 70.2 % and 164.6 % for chemical ionization.

Conclusions

Major conclusions drawn from this study are that: 1) these four target compounds can be quantified with precision and accuracy between 10 and 30% using these two modes of ionization, 2) sensitivities are comparable using the two modes, 3) signal-to-noise is slightly higher for the chemical ionization mode, 4) second order calibration curves fit the calibration data better than first order curves, and 5) chemical ionization provides important additional information such as (M+W+1)$^+$ which may become important when analyzing unknown formulations and complex mixtures using HPLC/MS instrumentation.

A quantitative method for the determination of benzidines and nitrogen containing pesticides in water was developed using reversed phase liquid chromatography/particle beam/mass spectrometry (LC/PB/MS) and liquid-solid extraction (EPA Method 553; SW-846 8325). An interlaboratory study on the LC/MS portion of this method has been completed using five different types of particle beam interfaces from thirteen different laboratories. Quantitation over a 5 to 100 ng/l range for four benzidine compounds (benzidine – BZ, dimethoxybenzidine – MB, dimethylbenzidine – LB, and dichlorobenzidine – CB) was performed and the precision and accuracy for two levels (10 and 100 μg/l) are shown below.

SINGLE ANALYST PRECISION

OVER-ALL LABORATORY PRECISION

OVER-ALL LABORATORY ACCURACY
Three different extraction schemes (liquid-liquid extraction, C18 liquid-solid cartridges, and experimental neutral polystyrene divinylbenzene extraction disks - NPSDVB) were evaluated for this method. Average recovery from one liter of reagent water is shown below. Recoveries were 80 to 110% and precision for 6 to 7 replicate analyses was better than 10% for most compounds. This results in method detection limits of 2 to 25 µg/l.

On-line trace enrichment coupled with LC/PB/MS gave even lower detection limits. By extracting 100 - 500 ml of water on-line and back-flushing the entire sample onto the analytical column, 10 - 50 fold increases in method detection limits can be achieved. This will allow the analysis benzidines and nitrogen containing pesticides in particulate free water, such as drinking water, at 0.1 - 0.5 µg/l levels.

In all cases, quantitative analysis was performed using second order external calibration. The use of isotopically labeled internal standards, used in conventional GC/MS, appears to linearize the calibration curves when the ratio of analyte to coeluting labeled internal standard is plotted versus amount of analyte injected. This only appears to work with coeluting components. Thus, the use of internal standards for quantitative analysis in LC/PB/MS is limited by the need to have one internal standard for each analyte of interest. However, external calibration (as shown in the interlab study) produced acceptable accuracy and precision when sufficient quality control procedures were used. This coupled with the extraction schemes described above gives a method for the quantitative determination of benzidines and nitrogen containing pesticides in water by LC/PB/MS.
A NEW TECHNIQUE FOR THE ANALYSIS OF VOLATILE AND SEMI-VOLATILE ORGANICS

Santford Overton, John J. Manura
Chris W. Baker and John N. Manos
Scientific Instrument Services, Inc.
1027 Old York Road
Ringoes, New Jersey 08551

A new accessory for the thermal desorption and direct thermal analysis of samples into a Gas Chromatograph has just been introduced by Scientific Instrument Services, Inc. This new instrument is the combined effort of Scientific Instrument Services and Rutgers University, Center for Advanced Food Technology (CAFT), who have jointly applied for patents on the Short Path Thermal Desorption System and technique.

The Short Path Thermal Desorption System (Fig. 1) permits the analysis of volatile and semi-volatile compounds by desorbing the samples directly into the GC injection port. The instrument, which attaches to the injection port of a GC, is used for the qualitative and quantitative determination of volatile and semi-volatile organic compounds present in air or compounds which can be easily purged from solid and liquid samples. The system was designed to function in two operational modes. In the thermal desorption technique, samples are sparged with carrier gas which is then passed through glass-lined stainless steel (GLT) desorption tubes packed with an adsorbent resin and/or activated carbon which traps the volatile and semi-volatile organic components. The adsorbent traps which are fitted with a syringe needle, are subsequently thermally desorbed directly into the GC injection port for separation and determination. In an alternate technique termed direct thermal analysis, solid samples of low moisture content are placed directly into the GLT desorption tube where they can be heated and purged to direct the outgassed organic compounds directly into the GC. This permits the samples thereon to be injected, heated, and desorbed directly into the injection port via the shortest path possible.

The Short Path Thermal Desorption System consists of an Electronics Control Unit and a Desorption Unit which mounts directly on top of the GC injection port. The unit is easily movable and transferable since no mounting bolts or hardware are needed for installation. Due to its novel, inert short path of sample flow, this new system overcomes the disadvantages of other desorption systems by eliminating long transfer lines, thereby providing for the optimum delivery of sample to the GC resulting in increased sensitivity. Labile samples are not lost or destroyed in hot transfer lines and no "memory effects" occur due to contamination of transfer lines since each sample analyzed constitutes a new independent pneumatic circuit. The technique is fully compatible with capillary and packed column operation and may be used with all types of GC detectors including systems interfaced to mass spectrometers or Fourier transform infrared spectrometers. Parameters such as temperature and desorption time are accurately controlled.
controlled via a digital electronic control module. Samples can be ballistically heated throughout the temperature range of ambient to 350°C. Features such as auto-injection of sample and carrier gas flow control are accomplished using precision pneumatic circuitry.

Samples such as volatile and semi-volatile organics in air, flavors and fragrances in foods and cosmetics, manufacturing chemical residues in pharmaceuticals, volatiles in packaging materials and building products, and aromatic residues in Forensic arson samples are just a few of the applications for which this technique has been utilized. Additionally the technique has been applied for specific applications such as the detection of benzene and chlorinated hydrocarbons in food and other manufactured products, the identification of natural occurring insect attractants in plants, the identification of flavors in black pepper and other spices, and the identification of volatile contaminants in commercial shipping containers. The technique eliminates the need for solvent extractions in many analyses.
Integration of Methods for Measuring Human and Wildlife Exposures to Pollutants

In spite of extensive characterization of environmental pollution, our knowledge of the levels of exposure of humans and wildlife to pollution has lagged and we know even less about the health effects of pollution. One important observation complicates this situation: the toxicity of complex mixtures is poorly understood yet it is precisely these complex mixtures that are typically discharged into the air, water, and soil. Furthermore, what constitutes toxicity is not often well defined. An interdisciplinary approach is called for which integrates the data from chemical analyses with various measures of biological endpoints. We have found it useful to have an array of mass spectrometric techniques at our disposal in addressing these issues.

Urinary Mercapturic Acid Indicators of Exposure: GC/electron capture MS

The appearance of mercapturic acid conjugates in urine may serve as a useful indicator of exposure to numerous xenobiotic chemicals. Conventional GC/electron capture MS of esterified urine extracts has found limited success owing to the extensive fragmentation of these compounds. In contrast, we have found that GC/electron capture ionization of pentafluorobenzyl esters of mercapturic acid conjugates yields sensitive (~1 ppb) detection of a variety of conjugates in urine with minimal sample clean up. Our experiments have demonstrated the formation of several isomeric conjugates in the urine of model animals exposed to 4-vinylcyclohexene. The mercapturic acid conjugate of 4-hydroxy-2-nonenal is excreted in the urine of rats exposed to CCl4. This reactive aldehyde is a product of peroxidative damage of membrane lipids that results from oxidative stress.

Synthesis of α,ω-mercapturic acid standards is straightforward, and the use of these stable isotope labelled internal standards allows for easy quantification. The electron capture spectra of all mercapturic acid conjugates studied to date yield a peak at m/z 128 which is often the base peak. This peak arises from the N-acetylcysteine moiety, and allows these conjugates to be more readily detected in urine extracts. Recent experiments have demonstrated that mercapturic acid derivatives not amenable to GC separation can be detected using negative continuous-flow FAB ionization.

Incineration of Chlorinated Solvents: GC/MS and Laser Desorption MS

As part of a study of the incineration chemistry of chlorinated solvents such as trichloroethylene, we designed and built a laser desorption time-of-flight mass spectrometer for the direct analysis of soot. The instrument is capable of single step desorption and ionization using either Nd:YAG (λ = 266 nm) or CO2 (λ = 10.6 μm)
lasers. The 266 nm harmonic can also be Raman-shifted to yield 239 or 299 nm radiation to vary the selectivity of ionization.

Single step ultraviolet (266 nm) laser desorption/ionization of compounds adsorbed onto soot particles allows for a rapid screening of soot for polycyclic aromatic hydrocarbons (PAHs) because of the enhanced efficiency of 2-photon resonant ionization relative to non-resonant photoionization of aliphatic and monoaromatic constituents. Some photodissociation has been observed in these single shot experiments, but this is markedly reduced when infrared desorption is used followed by ultraviolet photoionization of the desorbed neutrals.

The ability to screen soot samples for PAHs allows us to select combustion experiments for which the combustion gases are trapped on sorbent tubes (Carbotrap CO). Splits of the extracts are characterized using GC/MS, and aliquots are distributed to collaborators who measure biological endpoints using cell culture and lung airway explant techniques.

Petroleum Marker Compounds Discharged from Oil Recovery Operations

An important issue surrounding coastal oil drilling is the discharge of produced water from these activities and the potential risk to marine wildlife. It is particularly important to distinguish the inputs which arise from oil recovery activities from seeps which occur naturally in coastal waters.

Routine processing of GC/MS data typically yields a complex array of mostly indistinct hydrocarbons. However, petroleum geochemists have used extracted ion current profiles of characteristic biomarker compounds to characterize petroleum source rock. In conjunction with a group studying the population ecology of marine wildlife, we have applied this organic geochemical methodology to the characterization of crude oil produced water and marine sediments taken from the Santa Barbara channel off the coast of California. Our initial results suggest that the relative amounts of saturated, monoaromatic, and triaromatic steranes are indicators of biodegradation and can be used to assess the efficacy of secondary treatment of produced water as well as to distinguish weathered inputs from natural seeps from recent discharges of produced water. We are currently performing analyses of mussels collected in the vicinity of a produced water outfall to determine whether this methodology can be used to measure the exposure of marine organisms to produced water constituents.
We have determined operating conditions for ion trap GC/MS systems which minimize the common problems associated with unstable quantitative precision and inaccuracy in the analysis of volatile organic chemicals (VOC) in water. Our research has illustrated the important contribution of ion trap helium pressure and water/methanol background concentrations common with purge-and-trap sample introductions. Concurrent developments with capillary columns (J&W Scientific), liquid sample concentrators (Tekmar Company), and capillary jet separation interfaces (SGE) have in combination significantly advanced the use of ion trap mass spectrometry for ultra-trace VOAs.

A specially designed all glass-lined stainless steel capillary jet separator interface has been developed to maintain the helium pressure required for an ion trap mass spectrometer. Figure 1 shows the proper working range of input and output flow rates for this interface with actual data from our three development systems. By use of interchangeable collector jets, both low flow (5-10 ml/min) and high flow (10-20 ml/min) chromatographic systems are accommodated. At the optimum of 1.3 ml/min output flow rate, the jet separator efficiency has been measured to be 43-54% for all USEPA regulated VOCs. The common matrix background of aqueous samples and analytical standards has been studied using an ITMS to elucidate the possible ion-molecule reactions affecting response factor stability and detection limit. Under conditions of high flow (18 ml/min) using a megabore (0.53mm) 75M VOA column, the co-elution and resultant ion-molecule reaction products of exogenous water and methanol are illustrated in Figure 2. An example of the deleterious effects caused by excessive water and methanol levels is shown in Figure 3 for chloroethane. By operating the extended length megabore VOA column at high flow rates, sufficient backpressure can be achieved to lower the partial pressure of water and methanol during desorption of the chemical trap. In series with the transfer line of the purge-and-trap, a novel thermo-electric condensation trap has been implemented to further reduce the water and methanol levels entering the chromatographic system. By the combination of these techniques, our measurements have shown a 60-75% reduction of this background. At this level, the ion trap mass analyzer can then be set for an effective RF cut-off at m/z 32 to exclude the residual amounts.

It is by the combination of partial pressure suppression, condensation and mass exclusion, that now yield a reproducible operating condition for the analysis of VOCs at sub-ppb levels. Figure 4 illustrates the improved statistical precision based on response factors for the early eluting VOCs (0.5 to 20 ug/L). While calibrating as high as 20 ug/L, our studies have shown MDLs at or below 0.05 ug/L for the USEPA 524.2 analytes. Figure 5 illustrates the high resolution chromatographic results achievable using the capillary jet separator as an interface. By use of these advances, it is currently possible to operate the ion trap mass spectrometer for higher sensitivity, below the quantitation range of USEPA method 524.2 to levels approaching 0.001 ug/L.
ITMS™ Experiments Uncover Fundamental Reaction Principles

As an example, the common quantitative instability of the purgeable gases with all mass spectrometers, can in part, be explained by the understanding of ion molecule chemistry as shown here for Chloroethane reacting with high levels of exogenous water and methanol.

\[
\begin{align*}

\text{m/z} & 45
\end{align*}
\]

Figure 3.

Improved Response Factor Precision for VOC "Purgeable Gases"

The best statistical precision for the early eluting gases results from the combined use of extended length VOA capillary columns with sub-ambient initial temperature, high flow capillary jet separation interfacing, and the water background reduction provided by the Tekmar 2000 LSC with Moisture Control Module.

Figure 4.

Total Ion Chromatogram for a 5.0 ug/L 524.2 VOC Standard

Figure 5.
Atmospheric pressure chemical ionization mass spectrometry makes possible the detection of several atmospheric species at concentrations down to or even below the 1 part per quadrillion level. The number of species for which such measurements are possible is, however, small. The only species measurable with this sensitivity are those which either have very high proton affinities (or low ionization potentials) or those which are very acidic (or have high electron affinities) in the positive and negative spectra respectively. Sulfuric acid is an example of one of these species for which such sensitive measurements are possible. Figure 1 shows a recent measurement of the atmospheric gas phase concentration of H$_2$SO$_4$ as a function of time of day during April 20, 1991 made at Cheeka Peak Research Station near Neah Bay, Washington. If somewhat less alkaline or acidic species are to be measured, they must normally be present at higher concentrations. These species may then be measured by insuring that the ion/neutral reaction time is short enough so that the ions of interest will not be significantly removed by higher proton affinity or more acidic species in the positive and negative spectra respectively. Even when this condition can be insured using normal chemical ionization methods, there still remains a great deal of uncertainty surrounding the initial ionization process. Typically, chemical ionization of the species of interest is accomplished through reactions with several often unknown initial ion species and involves a multiplicity of unknown exothermicities and reaction rate constants. Thus, the number of ions formed from a trace species of interest is in general not a well known or characterized function of its concentration. Instead the ions of interest may depend in part on the number and concentration of other trace species present. If highly exothermic reactions are involved in the chemical ionization of the species of interest, the reaction may result in the formation of daughter or fragment ions making the measurement even more difficult. In order to simplify the reaction schemes leading to the ionization of a product ion of interest, dilute mixtures of reactive gases such as benzene have been added to the chemical ionization buffer gas. As a result, a single known initial reactant ion can be formed (such as C$_6$H$_8$•*), thus considerably reducing the number of reactions leading to the product ion of interest.

Several uncertainties, however, remain: 1) do the radical or metastable species formed in the ionization process itself interfere with the measurement, 2) does the relatively large reactive buffer gas component sometimes used to control the initial reactant ion identity have secondary effects on either the ion or neutral chemistry, and 3) how does one prevent the removal of product ions of interest by the formation of still more stable ion species?

The present concept of controlled high pressure selected ion chemical ionization mass spectrometry (HPSICI/MS) promises to remove the above uncertainties and the associated measurement problems for a wide variety of difficult-to-measure species. This is accomplished using a variety of techniques (many of which are quite new) to independently control the ion formation process, neutral species preparation, the ion/neutral reaction environment, and ion sampling and analysis techniques. Production of a single initial ion species is accomplished by the addition of reactive buffer gas additives in an isolated ionization region of the measurement apparatus. Thus interferences from metastable and radical species as well as those from buffer gas additives (if they pose a problem), are removed from the chemical ionization region. The preparation of neutral species of interest can be accomplished by: titrating the species into the parent species of a more stable ion (ex. titration of the atmospheric hydroxyl radical into sulfuric acid$^6$, gas chromatographic separation (ex. GC separation of dimethylsulfide, and beta-caryophyllene)$^7$, or any other appropriate separation or enhancement technique. Control of the ion/neutral reaction environment includes variation of temperature pressure and the addition of reactive species that assist in forming more stable product ions (ex. SO$_2$ measurement using the SO$_2$•- product ion)$^8$. Finally, the sampling and analysis of reactant and product ions may involve collisionally inducted dissociation prior to analysis$^9$, followed by MS or MS/MS analysis.
As a result of these chemical ionization control techniques, GC/HPSICI/MS has been used at concentrations down to and even slightly below 1 pptv (part per trillion). Titration assisted HPSICI/MS has been successfully used down to the low ppq (part per quadrillion) concentration range, and direct HPSICI/MS has proven to be applicable down to and even below the 1 ppqv concentration range.

Figure 1. Gas phase sulfuric acid concentration in molecules/cm$^3$ as a function of time of day measured on April 20, 1991. The large diurnal variation in sulfuric acid concentration results because its formation is dependent on a photolysis product (OH).
MEASUREMENT OF ELECTRON CONCENTRATIONS IN THE LOWER ATMOSPHERE BY CHEMICAL RELEASE MASS SPECTROMETRY

A.A. Viggiano, J.O. Ballenthin, R.A. Morris, and J.F. Paulson
Phillips Laboratory/LID, Hanscom AFB MA 01731-5000

Introduction
The measurement of electron density throughout the mesosphere has proven to be a challenging problem. Both in-situ measurements and remote sensing techniques have been plagued by the very low electron densities involved (10^{-2} to 10^{4} \text{ cm}^{-3}). In addition, in-situ techniques are beset with the effects of the fast motion of rocket probes through regions of varying pressure (0.01 to 1 Torr), which results in transitional flow past the probes. This in turn is very difficult to model.

We have developed a new measurement technique which has alleviated some of the typical electron measurement problems. The technique involves releasing SF_6 in front of a negative ion mass spectrometer. Electrons are converted to SF_6^- and SF_5^-, and the ratio of electrons to negative ions is measured by measuring the ratio of the SF_6^- plus SF_5^- ion signals to the sum of all other negative ion signals. When combined with modelling of the neutral flowfields surrounding the rocket probe, the technique shows promise of being able to measure electron densities down to 0.04 electrons cm^{-3}.

Technique
The technique involves releasing a controlled amount of SF_6 in front of a rocket borne mass spectrometer. SF_6 is known to attach electrons rapidly to form SF_6^- and SF_5^- with a rate constant on the order of 10^{-7} \text{ cm}^{3}\text{ s}^{-1}. The branching ratio between these two channels is known to depend on the temperature and the kinetic energy of electrons but the rate constant is independent of temperature. Other ions in the atmospheric altitude range of interest (40-90 km) will not react with SF_6 under the conditions of the release, nor will SF_6^- or SF_5^- react appreciably with the ambient neutrals. Table 1 shows the relevant chemistry and the time scales of the various processes. The time scale for electron attachment is extremely short, orders of magnitude shorter than that for any ion chemistry that might take place. This enables an SF_6 release rate to be chosen such that all electrons are converted to SF_6^- and SF_5^- without any interfering ion chemistry occurring. The fraction of negative charge in the form of electrons is then just the ratio of the sum of the SF_6^- and SF_5^- ion signals to the total ion signal. The electron concentration is put on an absolute basis by separately measuring the total positive ion concentration realizing that the total positive and negative charge concentrations are equal.

The flight conditions were chosen as follows. The injector effuses SF_6 at a rate of 6 \times 10^{-3} \text{ standard cm}^{3}\text{ s}^{-1} in order to maintain an SF_6 gas concentration of 1 \times 10^{11} \text{ cm}^{-3}. The spacing between the injector and the entrance to the mass spectrometer was chosen to allow at least five electron-SF_6 attachment time constants to ensure complete electron attachment. Neutral gas and ions are drawn into the mass spectrometer, where the ions are separated according to their mass to charge ratio and counted with a channel electron multiplier. The interior of the mass spectrometer is maintained at high vacuum with a liquid helium cooled cryopump. The
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

mass spectrometer was capable of measuring molecular species of up to 175 amu and had mass resolution of 75. The SF₆ release was started on the downleg part of the rocket flight at an altitude of 85 km. A experimental problem occurred shortly thereafter, and only data at 85 km was obtained.

Results

The negative ion composition at 85 km before and after the SF₆ release is shown in Table 2. The effect of the SF₆ release is evidenced by the two percentages at mass 146. Before the release no atmospheric source of mass 146 was detected; after the release nearly 17% of the negative ion signal came from SF₆. Comparing the ratio of mass 146 ions to the sum of all other ions and estimating the unperturbed ambient ion density at 3000 ions cm⁻³ yields an estimated 500 electrons cm⁻³. This compares favorably with modelled electron densities for quiet mid-latitude daytime conditions. With the count rate observed, the instrument has a detection limit of 0.04 electrons cm⁻³ in accord with the preflight estimate. Therefore although the instrument failed shortly after the SF₆ release began, the feasibility of the technique has been demonstrated.

Mass Spectrometric Measurements of the Space Shuttle Environment

Donald E. Hunton
Geophysics Directorate, PL/LID
USAF Phillips Laboratory
Hanscom AFB, MA 01731

Mass spectrometry is a valuable diagnostic for determining the identities and concentrations of gaseous contaminants in the Space Shuttle environment (1). These contaminants arise from surface outgassing, payload venting, cabin leakage, thruster firings, and other spacecraft system operations. Water vapor is one of the most important gaseous contaminant species. Because water adheres strongly to surfaces, the time decay of water concentration in the shuttle environment is slower than for many other gases, and its concentration is larger.

We have measured water vapor concentrations in the payload bay (along with many other neutral and positively charged species) on two shuttle flights. The first time was on the fourth flight of the Shuttle (STS-4) in the summer of 1982, and the second was on the recently-completed STS-39 flight of Discovery from April 28 to May 6, 1991. These two data sets provide an opportunity to compare water concentrations and time dependencies under the differing circumstances of the two flights.

The instruments on both flights were essentially identical, compact quadrupole spectrometers. They were mounted in a fixed position in the payload bay with a viewing direction perpendicular to the long axis of the shuttle and slightly above horizontal over the right wing.

The water vapor data from STS-4, which have been discussed previously (2), are shown in Fig. 1. The water signal (in instrumental units) is plotted in the top panel and the instrument temperature is plotted below. The strong correlation between temperature and water concentration is due to an increased surface outgassing rate at higher temperatures. Although not as clear from the figure, the absolute amounts of water (i.e. concentration at one temperature) also decreases somewhat as a function of time.

Analogous data from the recent STS-39 flight are shown in Fig. 2. These very preliminary data were recorded by hand during the flight, and should only be used to indicate broad trends in water concentration. The water concentration is plotted in raw telemetry volts, which is a logarithmic scale where each volt change represents a factor of ten in actual concentration. The two temperatures plotted in the lower panel are for the mass spectrometer sensor (under thermal blankets) and the payload structure near the instrument (exposed).

Many of the same trends appear that were observed in 1982. Increases in temperature again lead to increases in water concentration, as seen at Mission Elapsed Time (MET) 80-100. The overall decrease in water signal as a function of time through the flight is clearer than in the earlier data.

Two different instrumental units for the water signal were intentionally used to avoid direct comparisons between the two data sets until after post-flight calibrations of the STS-39 instrument. However, a preliminary look at the pre-flight calibrations suggests that the STS-39 water concentrations were approximately as large as during STS-4. This is surprising, given that the tiles on Columbia were not treated with water repellant before STS-4 and the orbiter was rained on just before launch. STS-39 should have been a much drier flight.
A possible explanation lies in the fact that STS-39 flew at a lower altitude than STS-4 (260 km vs 305 km), and that May 1991 is closer to solar maximum than July 1982 was. For both of these reasons, the atmospheric density during STS-39 may have been significantly higher at the orbiter altitude than during the earlier flight. As the orbiter moves through the atmosphere at high velocity, a "plow cloud" of gas forms on the ram side of the vehicle which may be a factor of ten more dense than the ambient atmosphere. Even if the outgassing rate from the STS-39 surfaces was lower than STS-4, that outgassing flux could have been collisionally "trapped" within a higher density plow cloud, leading to longer residence times of water molecules near the shuttle and a correspondingly higher pressure.

References

The Giotto spacecraft flew by comet Halley on the night of 13/14 March 1986 at a closest approach distance of about 600 km. One of the instruments on board the spinning spacecraft was the Ion Mass Spectrometer (IMS), designed to measure the composition and three-dimensional velocity distributions of ions in the Halley coma. This paper discusses the design of the IMS and some of the results obtained at the comet.

The wide range of plasma conditions anticipated, as well as the very short time available for measurements (because of the 68 km/s flyby speed) required some unique design solutions for this mass spectrometer. The instrument consists of two sensors. The High Energy Range Spectrometer (HERS) was optimized for measuring the solar wind interaction with the comet and the hot, outer portion of the coma. At the entrance to the sensor the ions are first reflected by an electrostatic mirror which compresses the 60 degree external field of view into 30 degrees internal to the sensor. The mirror also helps keep the dust particles from entering the instrument. A pair of grids then pre-accelerate or decelerate the ions to the velocity necessary to pass through the 120° sector magnet constant momentum filter. The magnet has symmetrically placed entrance and exit slits, which results in unity magnification. The magnet exit slit is also the entrance slit of an electrostatic deflector with a field that is non-uniform in a plane normal to the entrance slit. Since all ions enter this deflector with a single momentum set by the magnet, different mass/charge results in different velocity (and thus energy). Mass/charge is therefore separated along the deflector. The symmetry of the magnetic momentum filter results in angles being preserved from entrance to exit slits. Thus mass/charge is imaged along one direction of the deflector exit plane and incident angle along the perpendicular direction. A two-dimensional microchannel plate detects the ions at this exit. The instrument design allowed mass/charge ranges 2-4 amu/e, 12-26 amu/e, 16-34 amu/e and protons only to be measured over an energy range from 10 eV/e to a mass dependent upper limit of ~4keV/e.

The second sensor, the High Intensity Spectrometer (HIS) was optimized for the denser and cooler plasma of the inner coma. In this sensor, two independent detector systems allow, separately, high angular resolution in the relative velocity direction, and good mass resolution in the range 12-56 amu/e. The energy and angles are measured with an electrostatic quadrupole analyzer, while the mass analyzer uses a permanent magnet between two quadrupole lenses to image ions onto a linear array of channeltrons. The design gave a mass/charge range of 12 - 56 amu/e from 300 eV/e to 1500 eV/e in energy.

The instrument performed well during the comet encounter. Analysis of the returned data gave some expected as well as unexpected results. As anticipated, most of the coma is dominated by ions resulting from the dissociation, ionization, and subsequent ion-molecule reactions of the chief constituent water. The surprises included the higher than anticipated amount of C+ and the lower than expected level of nitrogen. The plasma dynamics observed was also quite interesting: the weak bow shock observed (at around 1 million km from the nucleus) apparently resulted more from the mass loading of the solar wind by the newly born picked up ions than from the presence of the nucleus as an obstacle. These pickup ions were also scattered in phase space by a host of plasma waves, more so than theory had previously predicted. At about 4000 km from the nucleus a sharp boundary was found (sometimes called the ionopause or contact surface) which separated, on the inside, the relatively cold (~300K) nucleus-dominated and almost stagnant ion population from the hotter, flowing comet-solar wind mixture on the outside. A population of fast ions was observed streaming inward near this boundary, postulated to result from charge exchange of pickup ions to neutrals in the outer coma and then again back to ions as the neutrals enter the dense region of the inner coma.

(Supported in part by a contract with the US National Aeronautics and Space Administration.)

Interstellar gas clouds and circumstellar envelopes are the largest known chemical factories in the universe. A part of the chemistry in these environments is driven by ionizing radiation which initiates ion chemistry directed toward the growth of ions and molecules in the gas phase. Infrared and radio-astronomers have observed many different ions and molecules in these environments and chemical models have been proposed and developed by astrophysicists in order to account for their abundance. The laboratory ion chemist obtains information about the kinetics and product distributions for individual ion/molecule reactions and these provide the basis for the identification of the plausible chemical networks which are responsible for the growth of ions and molecules by ion chemistry.

The newest molecules which have been identified in circumstellar and interstellar environments are largely carbonaceous, highly or completely unsaturated and chain-like, and, it should be noted, all are carbenes. They include dicarbenes such as :CCCCC:, radical carbenes such as :CCCCCCCCH:, carbenes with two H-atoms at one end such as :CCCH₂ and :CCCHH₂, and carbenes with one terminal heteroatom such as :CCCO, :CCCS and :CCCCSi. Also, there now is direct evidence for the cyclic carbenes (silenes) c:-C₃H₃, c:-C₂H, and c:-SiC₄, and indirect evidence for sheets of carbon atoms in the form of free or bound PAH molecules and as grains of graphite, and hollow cages of carbon atoms from the fullerene family of molecules, such as C₆₀, also have been proposed to be present. Many of the observed and postulated carbon species occur in similar circumstellar or interstellar regions and so are expected to share a common chemistry.

Of course both neutral and ion chemistry may contribute to the gas-phase growth of molecules in an ionized medium and they do so in a cooperative fashion with ion chemistry becoming relati-
very more important at lower temperature and higher levels of ionization. Ions produced by ion-
molecule reactions need to be neutralized to produce molecules and the desired bonding must be pre-
served in the neutralization step. Such neutralization may occur, for example, by charge transfer and
proton transfer or recombination with electrons. Laboratory investigations and other considerations in-
dicate that the formation of interstellar and circumstellar carbonaceous molecules by ion chemistry may
occur in the following manner:

\[ \text{:C}_n \text{ from C}_n \text{H}^+ \] and \[ \text{:C}_n \text{H from C}_n \text{H}_2^+ \]: Association of carbon ions with carbon-chain mole-
cules and the subsequent hydrogenation of the carbonaceous adduct ions in sequential reactions with
\( \text{H}_2 \) (which stop at \( \text{C}_n \text{H}_2^+ \)) or by chain-lengthening reactions with \( \text{C}_n \text{H}_2, \text{C}_n \text{H}_4 \) and \( \text{C}_n \text{H}_6^+ \).

\[ \text{:C}_n \text{H}_2 \text{ from C}_n \text{H}_2^+ : \] \( \text{H}_2 \) adds to \( \text{C}_n \text{H}^+ \) to give \( \text{I-C}_n \text{H}_2^+ \). \( \text{C}_n \text{H}^+ \) reacts with \( \text{CH}_4 \) to produce
\( \text{C}_n \text{H}_2^+ \), and \( \text{CH}_2^+ \) reacts with \( \text{C}_n \text{H} \) to produce \( \text{C}_n \text{H}_3^+ \). Also possible are homologous series of reactions of
the type \( \text{C}_n \text{H}_n^+ + \text{CH}_4 \) and \( \text{CH}_2^+ + \text{C}_n \text{H}_6 \) leading to even and odd carbon chains of the type \( \text{:C}_n \text{H}^+ \).

\[ \text{:C}_n \text{X from XC}_n \text{H}^+ \text{ where X=O,S and S}: \] By the transfer of an X-atom from a molecule XY
to \( \text{:C}_n \text{H}^+ \) or simply by the addition of \( \text{:CX} \) molecules to \( \text{:C}_n \text{H}^+ \), by C-H insertion of an atomic ion X- into
\( \text{C}_n \text{H}_2 \) or by the C-H insertion of the atom X or molecule \( \text{:CX} \) into \( \text{C}_n \text{H}_2^+ \).

\( \text{c-}\text{:C}_n \text{H}_2, \text{c-}\text{:C}_n \text{H and c-}\text{:SiC}_2 \) from their protonated cyclic (or linear) forms: \( \text{c-}\text{C}_n \text{H}_2^+ \) can
be formed from \( \text{C}_n \text{H}^+ + \text{CH}_4 \) or \( \text{CH}_2^+ + \text{C}_n \text{H}_2 \) but the result of its recombination with electrons is uncer-
tain. The situation is similar for \( \text{c-}\text{:C}_n \) and \( \text{c-}\text{SiC}_2 \). Other possibilities exist for the formation of
\( \text{c-}\text{:C}_n \text{R}_1 \text{R}_2 \) where \( \text{R}_1=\text{H}, \text{CN}, \text{CH}_2 \text{CN} \) and \( \text{C}_n \text{CN} \).

**Benzene, naphthalene, PAH and sheets of carbon:** Reactions of \( \text{CH}_2 \text{CCH} \) and
\( \text{H}_2 \text{CCCH}_2 \) with their ions produce protonated benzene. Ionized benzene reacting with \( \text{C}_n \text{H}_2 \) produces
ionized naphthalene. Further reactions with \( \text{C}_n \) or \( \text{C}_2 \) units may form larger PAH molecules and possibly
graphite, the end member of the PAH series.

**Saucers and cages of carbon:** "Clamping" with C or \( \text{C}_2 \) units in sequential PAH-forming
reactions could introduce curvature to produce carbon saucers and ultimately the cage-like molecules
known as fullerenes.
Quantitative Aspects of LC/Particle Beam/MS

J. G. Wilkes and W. E. Wentworth, Chemistry Department, University of Houston-University Park, Houston, Texas 77204-5502

M. L. Vestal, Vestec Corporation, 9299 Kirby Drive, Houston, Texas 77054

The task of mating High Performance Liquid Chromatography (HPLC) with Electron Impact Mass Spectrometry (EI/MS) has been accomplished by means of designs which first produce an aerosol from the liquid mobile phase and then dry the aerosol droplets to their non-volatile residues. The resulting particles are carried into a jet separator in which the large momentum particles are segregated from the low momentum molecular species and are injected as a beam into a Gas Chromatography EI/MS ion source. Spectra obtained are library searchable.

Quantitation is possible with LC/MS data but suffers from: non-linearity of response; "Carrier effects" which inappropriately enhance response for co-eluting substances (such as deuterated internal standards); day-to-day instability of response which necessitates either the use of internal standards or frequent recalibration; and huge variations in sensitivity depending on the mobile phase flow rate.

The work reported here was divided into two parts. Part I dealt with the effort to use an internal standard in a particular project and to define the conditions under which it would (or would not) improve the accuracy of determinations. The conclusions were that the compound chosen, though very dissimilar to the target compounds of the analysis, served as an excellent internal standard for a target compound which eluted in the same portion of the LC gradient, but was no help at all for correcting the determination of a compound which eluted in a different solvent mixture. First and second order calibration curves were also constructed and their usefulness compared.

Part II involved modification of several of the elements of the system to improve Limits of Detection, linearity, and chromatographic fidelity. Significant changes were made to the vaporizer/nebulizer, the spray chamber, the jet separator, and the ion source. Quantitative figures of merit were measured and presented in tabular form to demonstrate the effects of each design change on the system performance. The design changes made great differences in the innate sensitivity of the system for medium and large concentration components but did not materially improve detection limits for the small particles produced from trace components. Addition of a semi-volatile salt, ammonium acetate, to the LC mobile phase dramatically lowered detection limits and permitted the new designs to demonstrate excellent figures of merit. This is an example of the positive use of "carrier effects" because the ammonium acetate was removed with much of the solvent vapors in a diffusion cell prior to the jet separator. Thus very little of it was transmitted through the jet separator and into the mass spectrometer; the spectra were not adversely affected. The fact that a semi-volatile buffer can so dramatically increase transmission of smaller particles to the source implies that the major place where they are lost is not by discrimination in the
jet separator but earlier, probably at the time when the aerosol transport system is first being set up.

The new ion source has combination EI and CI capability. A simplified diagram of this source is shown below.

![Particle Beam/Mass Spectrometry Ion Source](image)

This work demonstrated the practicality of particle beam sample introduction into the relatively high pressure region of a CI source. For benzidine the CI detection limit was found to be about 200 pg/s compared to a best case EI detection limit of less than 100 pg/s. Without the ammonium acetate buffer typical detection limits were over 2000 pg/s.
Chemical Ionisation combined with Particle Beam LCMS for magnetic sector mass spectrometers.

M.R. Green, R.H. Bateman, C. Lewis and P.A. Bott

Fisons Plc., VG Analytical, Floats Road, Wythenshawe, Manchester, M23 9LE, England.

Particle Beam LCMS has proven to be a useful technique for a wide range of compounds of medium to low volatility and polarity. Many compounds may be ionised directly by electron impact giving readily interpretable or library searchable spectra for nanogram quantitation levels. However, the ability to ionise the particle beam by chemical ionisation opens up the possibility of studying compounds which give little molecular weight information by El.

In the El mode of operation the particle beam is transported from the final skimmer to the ion source without the need for any guidance of the beam. Any nebulising gas or solvent remaining after the two-stage momentum separator is pumped away. For CI operation a gas-tight source is required to give good chemical ionisation conditions at reasonable reagent gas flow rates. Therefore, a sealing arrangement is required between the particle beam interface and the source. Due to the relatively high gas pressures resulting in high gas flows, both from the particle beam and the CI reagent gas, electrical discharges may occur on magnetic sector mass spectrometers with accelerating voltages of several kilovolts.

A tube was constructed to form a transfer line from the exit of the second skimmer to the source. The internal diameter of this is 2mm which allows all of the particle beam to enter the source without attenuation. To maintain molecular flow and prevent electrical discharge two pumping holes were added to the tube near to the momentum separator, but pumped by the source diffusion pump. This arrangement allowed the mass spectrometer to be operated at 8000V accelerating voltage with a good CI plasma, and the particle beam interface in operation.

Data was obtained for several compounds to test the quality of the CI arrangement. Figure 1 shows the El spectrum and library spectrum for the insecticide carbofuran, using 50ng of sample. The molecular ion peak at 221 Da is typically only 6% of the base peak at 164Da. This compound readily loses CH3NHCO to yield the benzofuranol ion at 164Da. Figure 2 is the CI mass spectrum obtained from 50ng of carbofuran using methane as reagent gas. The spectrum clearly shows the pseudomolecular ion (222 Da) together with the C2H5 adduct at 250Da. Also the benzofuranol ion is protonated (165 Da) and its C2H5 adduct is observed at 193Da.

Good quality CI data can readily be obtained under CI conditions using a particle beam interface or magnetic sector mass spectrometers utilising the full instrument sensitivity at full accelerating voltage.
Figure 1 50ng CARBOFURAN FULL SCAN EI

Figure 2 50ng CARBOFURAN, METHANE CI
THE DEVELOPMENT OF AN ADVANCED, HIGH SENSITIVITY BENCHTOP LC/GC/MS SYSTEM

D. S. RICHARDS
VG MASSLAB LTD

Until now, particle beam LC/GC/MS systems have been large, floor standing instruments, whilst bench top units have been dedicated to either GC/MS or LC/MS units. Many existing LC/MS systems are difficult to operate and all exhibit poor sensitivity. For example detection limits of 5-500ng in EI operation have been reported by Northington and co-workers (1990).

The poor performance of existing systems may be attributed to their "add on" design philosophy which results in unnecessarily long interfaces.

This paper describes the first benchtop, particle beam LC/GC/MS to use a complete system design approach to permit both the LC and GC interfaces to remain connected during operation in either mode. For probe work the particle beam interface is easily removed and the probe installed. The design provides a close coupled LC interface which improves sample throughput. The differential pumping of the interface is carried out using two ports per chamber in order to achieve balanced gas flow dynamics. This alone results in a doubling of sensitivity.

Detection limits for the particle beam interface below 5ng for EI+ mass spectrometer operation have been demonstrated. Indeed, full, library searchable spectra are routinely obtained from samples of 5ng. Excellent performance has also been observed in CI+ and CI- modes of operation. The CI results are presented together with EI spectra and detection limits for a variety of compounds.

Volatility Enhancement of Nonvolatile Solutes by the Combination of a Heated Target and a Solvent-Depleted Particle Beam

*Edward W. Sheehan, Suhas Ketkar, and Ross C. Willoughby
Extrel Corporation, 575 Epsilon Dr., Pittsburgh, PA 15238

The introduction of solute into a mass spectrometer in the form of a solvent depleted solute particle beam has been of great interest the last 2-3 years. There have been observations that the temperature of the source plays an important role in the vaporization of the solute. For example, Jones et al.\(^1\) noted, that using a particle beam interface, that polystyrene oligomers of n=11 (mass 1202) and below were effectively vaporized and observed in the total ion chromatogram at a source temperature of 200 °C. While if the source temperature was increased to 315 °C, oligomers out to n=20 were observed in the total ion chromatograph.

One important performance characteristic of the particle beam interface is the observed volatility enhancement over other solid sample introduction techniques. One explanation for these results is related to the extremely small particle size generated with the thermal concentric nebulizer compared to other aerosol generation techniques. It is thought that the addition of surface energy in the aerosol generation process enhances the volatility of less volatile solute. Another explanation could relate to increased surface area per mass of an aerosol requires that more solute is at or near a surface. Since evaporation is a surface phenomena, the probability of forming intact gas phase solute molecules increases with increased surface area and the probability of thermal degradation decreases.

According to the First Law of Thermodynamics, the change in state (solid => vapor) is independent of path. One can separate the energy required to change a solid into a vapor, into a heat and work function. Heat is potentially destructive leading to the generation of pyrolysis products, while work (e.g. the increase in surface area of the sample) in turn increases the chance that the majority of solute molecules will be closer to the surface, thus increasing their chance of vaporization.

Solute vaporization on a flat surface such as a solids probe or on a moving belt requires heat to be transported from a heated surface, across the sample, to the surface of the sample. The solute trapped on the inside of the sample layer may be exposed to significant amounts of heat, potentially causing pyrolysis. The particle beam sample introduction; however, will result in the sample being transported directly to the heated surface with plenty of surface area for evaporation to occur. The more surface area associated with the sample, the greater the volatility enhancement. Electron micrograph measurements have shown thermal aerosols to have a much smaller average diameter than pneumatic aerosols.\(^2\)

A quadrupole mass spectrometer (differently pumped) equipped with a particle beam LC/MS interface (ThermaBeam, a thermal concentric nebulizer) from Extrel Corporation (Pittsburgh, PA) was used.

The present study was undertaken to study the effects of impacting solute particles on heated targets to enhanced the volatility of organic compounds. Three configurations were evaluated:

1. An ion source without a heated target.
2. A prototype heated target consisting of a 1/2-inch probe with a ribbon of nichrome (0.125-inch wide, by 0.325-inch long, by 0.01-inch thick). A DC current was passed through the ribbon until it glowed slightly red. The current was control with a variable transformer.
3. The DCI probe was a standard DCI probe for an ELQ-400 from Vacuumeetrics, Corp. (Ventura, CA). A current of 3 amps. was passed through the platinun wire.
The source temperature for all three configurations was 300 °C. The liquid chromatograph was operated at 0.5 ml/min. The mobile phase consisted of water and methanol (1/1) for all compounds except the C-60 and C-70 fullerenes (Buckyballs). The mobile phase consisted of toluene and methanol (1/1). The ThermaBeam LC/MS interface was optimized to give a 10/1 signal/noise from the flow injection of 5 ng (10ng/1μl) caffeine.

Conclusion The use of heated targets showed that intact molecular species could be formed and be subsequently ionized. There was no enhancement of the volatility of low molecular weight volatile compounds (e.g. caffeine and benzidine) but there was a 2-3X increase in the volatility and less pyrolysis fragments of relatively high molecular nonvolatile compounds.

EVALUATION OF A PARTICLE-BEAM LIQUID CHROMATOGRAPH/MASS SPECTROMETER

*D.S. Weinberg, R. E. Adams, and M.L. Manier
Southern Research Institute, Birmingham, AL 35205

An Extrel, Inc. (Pittsburgh, PA) Thermabeam particle-beam interface was connected to a Micromeritics, Inc. (Norcross, GA) liquid chromatograph and a VG Instruments, Inc. (Danvers, MA) high-resolution mass spectrometer. The connection to the mass spectrometer was made through the port previously used to install a moving-belt interface on the mass spectrometer. No modifications other than the use of an additional rubber o-ring and longer screws were needed to mate the two instruments.

Standard solutions of caffeine in methanol (3.41 pg/µL to 55.8 ng/µL) were prepared by serial dilution with each succeeding standard containing one-half of the concentration of caffeine in the previous solution. In addition, caffeine standards containing a constant concentration of an internal standard (theophylline or carbazole) were prepared. One series of standards contained 90.9 ng/µL of theophylline and from 11.1 pg/µL to 90.9 ng/µL of caffeine, and another series contained 20.3 ng/µL of carbazole and from 3.10 pg/µL to 50.7 ng/µL of caffeine.

Twenty-five µL injections of the standard solutions were made. The liquid chromatograph was operated isocratically using methanol at 0.4 mL/min. Under these conditions, there is no separation of caffeine, theophylline, or carbazole. Consequently, in this study, the liquid chromatograph serves only to introduce the sample to the particle-beam separator, and the method has the characteristics of flow injection. The mass spectrometer was operated in the electron-impact mode. The resolution was 5000 (2% valley) in the full scan (m/z 40 to 700) or selected-ion monitoring (SIM) mode. The scan rate was 2 s/decade in the full-scan mode and the cycle time was 1 s in the SIM mode.

Although the scan range extends over a wide range, exact mass measurements of the molecular ions of caffeine and theophylline gave excellent results, the deviation for caffeine (194.08038) being -7.5 ppm and that for theophylline (180.06485) being 0.7 ppm. The results of the analyses are listed in Tables 1, 2, and 3. Examination of Table 1 reveals that a good linear response is obtained for full scan (4.44 to 2272 ng of injected caffeine) or SIM (1.11 to 284 ng of injected caffeine) analyses. Lower amounts were not measured because theophylline contains an impurity that produces an interference in the m/z 194.0804 channel.

Examination of Table 2 shows that good linear response (77.4 pg to 1268 ng of injected caffeine) and a lower detection were obtained when carbazole was substituted for theophylline. However, for an injected mass of caffeine of 317 ng or greater, the area of the peak produced by the injected mass of 508 ng of carbazole was significantly reduced. Therefore, carbazole could not be used for internal standard calculations at high caffeine concentrations.

Examination of Table 3 reveals that although the linear response of caffeine in the absence of an internal standard is fairly good (% RSD = 31.2) over the wide range of injected mass of (85.1 pg to 1395 ng, a range factor of 16,385), there is a clear trend toward a reduction in the calculated response factor as the concentration of caffeine decreases. This supports the suggestion that as the concentration of an analyte decreases, the size of the particles produced in the interface decreases, and that the smaller particles are more readily pumped away and lost than larger particles. This effect is not as prevalent in the other runs because the constant high concentration of coeluting internal standard tends to maintain a more constant particle size as the concentration of the analyte decreases.

*RF = 428; Relative standard deviation = 31.2%.
Two major deficiencies of the particle beam (PB) interface have become apparent: 1) transport efficiency of analytes through the particle beam interface has been determined to be as low as 12% [1]; 2) transport efficiency is a function of analyte concentration, decreasing at low analyte concentration, which results in non-linear calibration curves. Both of these deficiencies can be corrected through the use of "carriers", compounds added to the eluent to enhance the transport efficiency of the analytes through a wide dynamic range. Ammonium acetate [2] has been employed as a mobile phase additive to improve analyte transport, as has the isotopically labelled analog of the analyte of interest [3].

In the present work the structural similarity between a class of analyte and a generic "carrier" is exploited to enhance the transport efficiency of a number of compounds within the class through the PB interface. For the phenylurea herbicides, diuron, linuron, and neburon, 2.9 ng/μL of phenylurea (PHU) is added as the carrier pre-column to the mobile of 68% acetonitrile/32% water. The calibration curves for diuron in Figure 1 show that without the PHU carrier a non-linear curve is obtained (a), but with the PHU carrier (b) the curve is linear. The Hewlett-Packard 5988A mass spectrometer is operated in methane enhanced negative ion selected ion monitoring (SIM) mode. The detection limit for diuron improves from 2 ng on-column without the PHU carrier to 160 pg on-column in the presence of the PHU carrier.
For the chloroalkoxy acid herbicides phenylacetic acid (PAA) was used as the generic carrier for the compounds 2,4-D, 2,4,5-T, and Silvex. Using 1.7 ng/μL PAA in the mobile phase of 70% methanol and 30% aqueous 1% acetic acid produced the linear calibration curves shown in Figure 3. The detection limit for 2,4-D was 1000 pg injected on-column when the mass spectrometer was operated in methane enhanced negative ion SIM. The pH of the injected herbicide solution must be adjusted to 2.8 to assure that the herbicides are in the neutral acid form.
PARTICLE BEAM LC/MS INTERFACED TO HIGH-FLOW-RATE, HIGH-WATER-CONTENT SEPARATIONS
R.J. Seymour, Rhone-Poulenc Ag Company, Research Triangle Park, NC, 27709

Introduction

The particle beam LC/MS interface is usually limited to mobile phase flow rates of 0.8 mL/min or less depending on the design. Also, the sensitivity is adversely affected when the amount of water in the mobile phase is greater than about 50%. Stream splitting and narrow bore columns have been used to overcome the problem of high flow rates. Post-column addition of strong organic solvent has been used to improve sensitivity when the mobile phase water content is high. The technique presented here is an alternative to those solutions and has the advantage of not splitting away or diluting the analyte and can be used with standard sized columns at relatively high flow rates.

How the trap and transfer technique works

A diagram of the peak trap and transfer device is shown below. A sample is chromatographed using the mobile phase supplied by Pump #1. This mobile phase may have a relatively high flow rate and water content as required by the chromatographic separation. When there are no peaks to be sent to the particle beam interface, the effluent passes from the UV detector through the six port valve to waste. A second pump delivers strong organic solvent, typically methanol or acetonitrile, to the particle beam interface via the trap column at a flow rate which is compatible with the interface. When a peak of interest is detected by the UV detector, the six port valve is switched such that the peak is passed onto the trap column while the mobile phase from Pump #2 goes directly to the particle beam interface. When the peak has passed completely onto the trap column, the valve is switched back to the initial position causing the peak to be flushed from the trap by the strong organic mobile phase from Pump #2. This stream, now containing the analyte, is directed to the particle beam interface and mass spectrometer where the mass spectrum of the peak is obtained.

Identification of an Herbicide Impurity

A small impurity peak eluting just before a large active ingredient peak in an herbicide sample needed to be identified. A flow rate of 3.0 mL/min and a mobile phase containing 87% water with 1% acetic acid/13% acetonitrile was required to separate this pair of peaks in less than about 20 minutes on a Whatman Partisil column (25 x 0.46 cm, 10m). A narrow bore column and other mobile phases were tried but did not separate these peaks adequately. Therefore, to obtain a spectrum of the impurity peak, it was necessary to use the peak transfer technique. The small impurity peak was trapped on a 3 cm Brownlee C-8 column. It was then flushed from the trap with 100% acetonitrile at 0.8 mL/min. This served to refocus the peak and transfer it to the particle beam interface. The impurity was identified from the NBS Library as 2,4-dichlorophenoxyacetic acid or 2,4-D.
Confirmation of a Sugarcane Extract Residue

Sometimes a peak needs to be identified without changing a given set of chromatographic conditions. A peak observed in a sugarcane residue method was thought to be acetyl sulphanilamide. This needed to be confirmed by LC/MS. The residue method used a mobile phase containing 89% aqueous ammonium acetate and 11% acetonitrile at 1.0 mL/min. The column used was a B&J OD5 (25 x 0.46 cm, 5m). Figure 6 shows the ion chromatogram obtained when the peak of interest was transferred to the particle beam from the trap column using a stream of 100% acetonitrile at 0.8 mL/min. The identity of the residue peak was confirmed by comparison of the retention time and mass spectrum obtained to that of a standard reference material.

Instrumentation used

- VG Trio-2 quadrupole MS with VG particle beam interface
- Hitachi L-6200 low pressure gradient HPLC pump (Pump #1)
- Waters M6000A HPLC isocratic pump (Pump #2)
- Waters 990+ Diode Array UV detector with high pressure cell
- Rheodyne 7000 six port valve (Have also used two 7125 injector valves in a slightly different configuration)
Development and Application of Phase-System Switching Techniques used for Particle Beam-Liquid Chromatography/Mass Spectrometry

Jill Guthrie, Gil Radolovic
Midwest Research Institute, 425 Volker Boulevard, Kansas City, MO, 64110

Introduction

The liquid chromatographic conditions required to successfully separate mixtures of highly polar compounds typically include mobile phases composed of over 50% water at flow rates of 1 ml/min or greater. However, sensitivity routinely decreases for many compounds when performing particle beam LC/MS under these conditions.

Loss of sensitivity can be minimized when performing particle beam LC/MS by using phase-system switching techniques such as coupled column chromatography (CCC). Coupled column chromatography has been used routinely in the past by liquid chromatographers, but it has been only recently that the benefits of it have been applied to LC/MS technology (1).

In the CCC technique, the LC peak of interest is diverted or "heart-cut" onto a secondary trapping column as it elutes from the primary chromatography column. After the peak has been isolated on the secondary column, phase-system switching is then performed using a multi-port valve and an auxiliary pump. The analyte is flushed from the secondary column into the particle beam interface with solvents and flow rates which are more compatible with the PB-LC/MS system.

MRI has designed a CCC PB-LC/MS system and has successfully applied the technology to the identification of polar constituents present in commercial pesticides, drug formulations, and grains.

Experimental

Certain characteristics of the primary LC chromatography are necessary for successful heart-cutting. Peak resolution in the vicinity of the peak of interest should be optimized in order to allow selective heart-cutting of only the peak of interest from the chromatogram. In addition, the retention time of the peak of interest should be reproducible, because retention times are used to determine the times for heart-cutting.

Any standard LC column can be used with its appropriate flow rate for the primary column. Common LC solvents such as water, methanol, and acetonitrile can be used to develop the chromatography. Although not applied in this work, it has also been shown that non-volatile buffer systems can be used (2).

The secondary trapping column should retain the heart-cut as a narrow band on the front of the column in order to avoid peak broadening. The solvent and the flow rate used to flush the secondary column should be compatible with the particle beam interface. A volatile buffer such as ammonium acetate can be added to the flushing solvent.

Results

The CCC PB-LC/MS system developed was used to isolate constituents of a methanolic flax seed extract and obtain spectra for them. The primary chromatography separation developed, required a linear methanol/water gradient beginning at 100% water and ending with 100% methanol in 60 minutes to resolve the very polar constituents of the extracts.

In order to evaluate the performance of the CCC PB-LC/MS system, a flax seed extract was spiked with 50 ng/ul each of five phenolic acids commonly found in cereal grains (Figure 1). 20 ul of this spiked sample were injected onto the primary LC column and the phenolic acid peaks were heart-cut. Each heart-cut LC peak resulted in a full scan PB-LC/MS peak with a minimum signal-to-noise ratio of 10 to 1 (Figure 2).
Detection and identification of the phenolic acids would have been difficult without the ability to heart-cut the selected peaks of interest which eluted in the early portion of the LC separation.

ADVANTAGES OF PARTICLE-BEAM SAMPLE INTRODUCTION FOR ANALYSIS OF THERMALLY SENSITIVE NATURAL PRODUCTS BY MASS SPECTROMETRY

William F. Haddon and Leslie A. Harden, Western Regional Research Center, USDA 800 Buchanan St., Albany, CA. 94710

Introduction. The particle beam (P/B) liquid interface developed by Willoughby, Winkler and Browner utilizes a combined aerosol generator-nebulizer and momentum separator to produce a stream of solute particles which are subsequently ionized following their impact on the surface of the ion source. The P/B separator provides a desirable interface for liquid chromatography in that mass spectra (EI, CI and LSIMS) can be obtained under conditions which allow direct comparison to literature and library spectra for many compounds. Additionally, the P/B enrichment device extends the lower limit of volatility below that of GC and direct probe analysis methods.

We report here the electron ionization (EI) mass spectra of a series of condensation products between dimedone and substituted phenyl benzopyrans for which markedly superior spectra were obtained by direct liquid introduction using a commercially available P/B enrichment interface.

Results. Figure 1 lists four compounds which posed difficulties for direct introduction probe (DIP) analysis because of their thermal instability. Figure 2 shows the problem of obtaining a structurally representative EI mass spectrum of IV using an "in source" DIP. The molecular ion of IV was present only transiently at scan 21, along with structurally significant fragment ions at 273 and 274 daltons. Ions arising from thermal decomposition dominate the spectra following scan 21 and these non-representative spectra comprise the bulk of the volatilization profile; the spectrum at scan 26 contains no measurable molecular ion, and structurally diagnostic peaks have been lost below more abundant ions, such as the 257d peak, which apparently arises from thermal decomposition prior to volatilization.

Figure 3 shows the EI spectra obtained from about 500 ng of the same compound, IV, introduced via the particle beam interface using chloroform as solvent. The nebulizer tip was at 160 deg C, the desolvation temperature was 95 deg., and the ion source temperature was 180 deg. The molecular ion (502d) is prominent over the full range of the flow injection for P/B sample introduction. The only significant fragment ions we observe are the direct cleavage and McLafferty rearrangement ions at 273 and 274d respectively. In contrast to the DIP spectra, the P/B spectra are useful for assignment of molecular structure. The slightly lower molecular ion abundance of the P/B EI spectrum probably reflects the use of the quadrupole vs. magnetic analyzer.

Compounds I-III behaved similarly for direct probe analysis, showing extensive decomposition. In all cases P/B sample introduction yielded suitable EI spectra routinely. With the DIP improved results could be obtained by careful control of source temperature and heating rate. Figure 4 illustrates the improvement in the EI spectrum of IV using a faster DIP heating rate.

Discussion. The improved spectra of thermally sensitive compounds by P/B sample introduction probably reflects a relatively higher rate of heat transfer to the sample surface compared to the DIP. There is evidence for the importance of rapid heating in the literature in previous studies by Friedman et al. in which the activation energies for competing thermal decomposition and volatilization processes for thyrotrop releasing hormone (TRH, pyrolidinonecarboxylamide-His-Pro-NH₂) were shown to be different. For TRH, thermal decomposition proceeds with lower activation energy compared to volatilization; thus the volatilization process will predominate at higher sample temperature.

For the experimental conditions used in this work, the P/B aerosol generator should produce a narrowly-distributed range of particle sizes with an average of about 100 μm. diameter. For a roughly Gaussian distribution of sample in the 15 ul injection volume (see TIC curve of Figure 3), the sample concentration over the central portion of the curve is about 350 ng for a 500 ng injection. Aerosol formation should yield about 1.4 x 10⁷ droplets, assuming minimal recombination in the desolvation region, resulting in particle thickness of about 0.4 μm, based on spherical particles and complete removal of solvent. In comparison, a 10 ng sample deposited on the direct probe will have a sample thickness about two orders of magnitude lower, roughly 0.025 μm.
Thus the high temperature of the ion source probably accounts for the rapid heating rate for impacting particles rather than increased surface area or reduced sample thickness compared to the DIP. Of course very high heating rates can be achieved on a direct probe, for example by use of Curie-point probes. The advantage of P/B sample introduction is that the rate of heating the sample, which is determined largely by the impact surface temperature, and the rate of sample consumption, which is determined by the LC peak width or flow injection volume, are independently established. This independence of heating rate and rate of sample consumption allows spectra to be recorded at acceptably slow scan rates on the mass spectrometer even when the heating rate must be increased to minimize the effect of thermal decomposition. Of course molecular ion abundances are significantly reduced with increased temperature in many cases, and this factor will limit the utility of the spectra for some compounds.

Conclusions. For thermally sensitive natural product samples, introduction into the mass spectrometer directly in liquid solution via a particle beam interface can produce superior spectra compared to measurements with an in source direct probe. Using a high temperature for the impact surface, where volatilization occurs, will lead to improved spectra in cases where competing thermal decomposition reactions have lower activation energy.

Acknowledgement. Drs. L. Jurd and C. Elliger, WRRC, provided samples used in the work.

Analysis of Some Derivatives of Steviol by Particle Beam LC/MS

Extracts of the plant Stevia rebaudiana are used in several countries as sweeteners. The major sweet compounds are the ent-kaurene glycosides stevioside and rebaudioside A. In addition another structurally related sweet glycoside, rubusoside, is found in a sweet tea product consumed in the People's Republic of China. These compounds all contain a common aglycone, steviol.

Steviol (I), when metabolically activated has been found to be mutagenic and a number of these in vitro metabolites have been identified and studied (1) by GC/MS and GC/MS/MS. In addition another study (2) has characterized steviol and its metabolites by DCI/MS using ammonia and dimethyl ether as reagent gases.

In the current work a series of analogs of steviol was separated by reversed phase HPLC and analysed via the Particle Beam LC/MS interface in order to evaluate the suitability of this technique for the study of steviol metabolism.

**Experimental:** Steviol, a series of its in vitro metabolites, and their methyl esters were prepared as described previously (1). The compounds were chromatographed using a HP 1090L HPLC on a 250mm x 2.1mm Hypersil C-18 column with the following gradient system: solvent A- 0.01M NH4Ac (pH 3.5), solvent B- ACN:0.01M NH4Ac (80:20), Initial-(A:B) 50:50 to 40:60 at 6 min, to 25:75 at 10 min, to 20:80 at 12 min, then hold to 20 min. The flow rate was 0.4 mL/min. The eluting compounds were first passed through a diode array detector (220 nm) connected in tandem with the particle beam LC/MS interface. The MS were obtained with a HP 5989A LC/MS under the following conditions: El mode- scan 60-400; Ammonia PCI mode- scan 100-500, source pressure 0.8 torr; Ammonia NCI mode- scan 120-500, source pressure 0.8 torr; Methane PCI mode- scan 100-500, source pressure 1.0 torr; Dimethyl Ether PCI mode- scan 140-500, source pressure 1.4 torr. In all modes the source temperature was held at 275 C, the desolvation chamber temperature was 55 C and the helium gas flow was set to 60 psi.

**Results and Discussion:** The chromatographic system developed is capable of resolving all of the derivatives with the exception of dehydrosteviol A and B and their corresponding methyl esters. The chromatogram shown in II is typical of the results obtained for an 8 uL injection of a mixture containing approximately 100 ng/component/uL of 14 compounds. The UV chromatogram is shown below it (III). Because most of these compounds show poor UV absorbance (with exception of the 15-oxosteviol), the use of LC/MS proves to be a superior detection method at low concentrations. In general most of the compounds studied showed a detection limit of ca. 100 ng on column under El and PCI (methane and ammonia reagent gases) conditions. The methyl esters gave slightly better results. The use of dimethyl ether as a reagent gas in PCI was also investigated and detection limits were only half those of ammonia or methane. The spectra obtained for these compounds were found to be consistent with those reported earlier (1,2). A clear advantage in using LC/MS for the routine analysis of these compounds is that derivatization to enhance volatility is not required to obtain useful detection limits. Indeed, the slight improvement in sensitivity for the methyl esters could be due as much to their eluting at a higher organic solvent concentration (3) as it could be to any enhancement in their volatility.

AN INVESTIGATION OF ION ABUNDANCE ENHANCEMENTS FOR THE PARTICLE BEAM LC/MS ANALYSIS OF ETHYLENETHIOUREA (ETU) IN FOOD SAMPLES

S. Bajic, *D.R. Doerge and *C.J. Miles.

VG BioTech, Tudor Rd., Altrincham, Cheshire, WA14 5RZ, UK.
*Dept. Environ. Biochem., University of Hawaii, Honolulu, HI 96822, USA.

It is well known (1) that particle beam LC/MS interfaces inherently display ion abundance enhancement effects where the intensity response for a particular compound is typically enhanced by the presence of a coeluting compound. This coelution effect is detrimental when using isotope-labelled internal standards for quantitative analyses of target compounds since there is no rule of thumb method for predicting the contribution to the target response due to coelution.

Recently we demonstrated the use of particle beam LC/MS for the identification and quantification of ethylenethiourea (ETU), a fungicide metabolite and probable human carcinogen, in spiked and natural food samples with detection limits of 5ppb in the crop (2).

Figure 1 shows the on-column, PB LC/MS detection of 10(±5)ppb ETU in a papaya extract and the simultaneous internal standard response for 10ng of 13C ETU. At these low levels of detection (1-10ng ETU), and for comparable amounts of target and internal standard, it was reported that the effects of coelution in the VG LINC™ PB LC/MS interface were in fact negligible. In this communication, we present some data on the ion abundance enhancement of ETU for varying amounts of selected internal standards and a range of interface desolvation chamber temperatures.

All data were obtained from 10μl loop injections using a VG LINC™ PB LC/MS interface incorporating a Hildebrand grid nebulizer and a mobile phase composition of 50% CH3CN/water at 0.5ml/min. Unless otherwise stated, the desolvation chamber temperature (measured in the gas flow) was maintained at 30°C. MS measurements were made using a VG TRIO-2000 quadrupole system operating in positive ion El mode with a source temperature of 200°C and scanning the mass range 70-300amu in 1 second. ETU response was determined by the area under the chromatogram peak for the molecular ion m/z = 102 (m/z = 103 for the 13C-ETU internal standard). All data points are averages of 3 determinations (RSD ≤ 10%).

Figure 2 shows the coelution enhancement of 10ng of native 12C ETU due to the addition of increasing amounts of 13C ETU internal standard. Here, the enhancement factor is simply the ratio of the 12C response with internal standard to the 12C response with no internal standard. From a similar analysis, Figure 3 shows the coelution enhancement of 10ng of 12C ETU by the addition of increasing amounts of aminotriazole (MW = 84). From these enhancement relationships, it is seen that for comparable amounts of native compound and internal standard (in this case for 13C ETU and aminotriazole additions of ≤ 25ng) the coelution enhancement is negligible, as was previously reported (2). However, as the amount of internal standard is increased beyond 25ng, the enhancement factor increases dramatically such that the response to 10ng of native 12C ETU is enhanced by a factor of 14 by the addition of 500ng of 13C ETU. In addition to this internal standard concentration dependence, it appears that the enhancement is also dependent on the coeluting compound where it is seen that 13C ETU has an approximately 4 times greater enhancement effect than aminotriazole for 500ng additions.

During the course of these measurements it was observed that the desolvation chamber temperature had a strong influence on the reproducibility of these data. Figure 4 shows the effect of desolvation chamber temperature on the enhancement factor for 10ng of 12C ETU coeluting with 50ng of 13C ETU. Thus, it is seen that, under these
coeluting conditions, the enhancement factor increases approximately 4-fold as the temperature is increased from 25 to 50°C.

In the context of quantitative PB LC/MS analyses, these results serve to illustrate the need for careful calibration for the choice of internal standard, concentration and experimental conditions.

Surfactant Analysis by Ion Chromatography/
Particle Beam Mass Spectrometry

James N. Alexander, Chad J. Quinn. Rohm and Haas Company, Research Laboratoires, Spring House, PA 19477

Introduction:
Ion chromatography/mass spectrometry (IC/MS) has been investigated, using the particle beam interface, as an analytical technique for the analysis of anionic and nonionic surfactants. Ion pair chromatography is an excellent technique for separating hydrophobic anions. The surfactants were separated on a hydrophobic resin-based column utilizing acetonitrile as the organic modifier and ammonium hydroxide as the ion pair reagent. Most ion pair reagents are non-volatile, therefore, the use of ammonium hydroxide makes this technique compatible with the mass spectrometer. A main advantage of this technique is that co-eluting surfactants can be identified, whereas, with conductivity and UV detection this is difficult.

IC/MS was used to detect and identify surfactants in commercial laundry detergents and shampoos. Analyses were performed using both electron (EI) and chemical ionization (CI). Methane CI readily produced protonated molecular ions on some surfactants, and combined with structural information obtained from EI analyses, identification of alkylbenzene sulfonates and alkylphenol polyethoxylates is possible. Alkyl sulfates also produced molecular ions using negative ion analyses and were used to confirm their presence in shampoos and detergents.

Experimental Conditions:
The experiments were performed on a Hewlett Packard (HP) 5988 quadrupole mass spectrometer. The HP particle beam LC/MS interface was used to couple the mass spectrometer to a HP Model 1090 high-performance liquid chromatograph. The instrument was operated in the full scan mode for all experiments.

The surfactants were separated on a Polymer Laboratories PLRP-S (5 micron packing, 100 Å pore size, 15 cm x 4.6 mm ID) column. The separations were performed using a gradient method. The flow rate was 0.5 mL/min and the injection volume was 20 microliters. Mobile phase A was 5% acetonitrile, 10 mM ammonium hydroxide and mobile phase B was 95% acetonitrile, 10 mM ammonium hydroxide. The gradient conditions are listed below.

The following parameter settings were used for the mass spectrometer. The source temperature and pressure were 275 °C and 0.8 torr (methane), respectively. The electron multiplier was 2300 kV and the scan range was 65 - 900 daltons. The
following parameter settings were used for the particle beam interface. The desolvation chamber was set at 65 °C. The nebulizer helium pressure was 30 psi and the capillary position was extended approximately 0.9 mm.

Results and Discussion:
Anionic and nonionic surfactants are widely used in industry. Many chromatographic techniques have been used to separate and determine surfactants in a variety of samples. Today, high performance liquid chromatography (HPLC) and ion chromatography (IC) are the leading techniques used for surfactant analysis. Most often surfactant identifications are made by comparing retention times to standards. However, similar surfactants can co-elute and make identifications difficult when using UV or conductivity detection. Using IC/MS (particle beam interface) we were able to identify co-eluting surfactants by their mass spectra. We applied this chromatographic technique for the analysis of ionic and nonionic surfactants in laundry detergents and shampoos.

Both EI and Cl ionization techniques were employed with methane as the reagent gas. Negative Cl produced characteristic mass spectra for the alkyl sulfates. The negative charged parent ions were present for each of the alkyl sulfates from C_{10} to C_{16}. In most cases the base peak in the negative ion mass spectra was the loss of oxygen. Positive Cl produced protonated molecular ions with little fragmentation for the alkylbenzenesulfonates from C_{10} to C_{13}. Additional structural information was obtained by EI analyses of the alkyl sulfates and alkylbenzenesulfonates. EI analysis of the alkyl sulfates produced mass spectra with the classical low mass hydrocarbon ion series. With these characteristic mass spectra and retention time comparisons of standards we analyzed Vidal Sassoon shampoo and Ultra Tide laundry detergent.

Negative ion and EI analyses of Vidal Sassoon shampoo showed that the C_{12}, C_{14} and C_{16} alkyl sulfates were present. No presence of alkylbenzenesulfonates was observed. The analyses of Ultra Tide confirmed the presence of C_{14} and C_{16} alkyl sulfates and the linear C_{12} alkylbenzenesulfonate. The C_{14} alkyl sulfate and the linear C_{12} alkylbenzenesulfonate co-elute under these chromatographic conditions. With EI and Cl mass spectra, interpretation of the co-eluted peaks was possible, allowing for the determination of the presence of both the sulfates and the sulfonate.

Positive Cl was also useful for identifying nonionic surfactants specifically Triton X-100. Positive Cl generated molecular ions thus allowing the various homologs to be identified. We did not observe this surfactant in either the laundry detergent or shampoo.

Conclusion:
Particle beam ion chromatography mass spectrometry has proven it's ability to generate characteristic mass spectra for the identification of ionic and nonionic surfactants. Employing EI and CI, both positive and negative ion detection, the characterization and identification of surfactants in commercial laundry detergents and shampoos was possible.
Quantification of Tryptophan and Kynurenine Pathway Metabolites by Particle Beam-LC Negative Chemical Ionization-MS

Section on Analytical Biochemistry, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

The kynurenine pathway is the major route of tryptophan metabolism producing a number of intermediates which may be pharmacologically active in the central nervous system (1). Renewed interest in the kynurenines has resulted in the need for improved methods for quantifying them in biological fluids and tissues. A number of liquid chromatographic methods with UV absorbance, fluorescence, or electrochemical detection and gas chromatographic methods with electron capture or mass spectrometric detection have been described (2). Particle beam-LC/MS is particularly well suited to analyses of chemically similar compounds in complex aqueous matrices. Mass analysis provides additional specificity to quantification as well as the ability to use stable isotope labeled analogs as internal standards or as tracers in biological systems.

We have developed a method for the quantification of L-tryptophan (TRP) and its metabolites L-kynurenine (KYN), 3-hydroxykynurenine (3HK), 3-hydroxyanthranilic acid (3HAA), quinolinic acid (QA), kynurenic acid (KA), anthranilic acid (AA), and xanthurenic acid (XA). These compounds contain multiple functional groups but each contains at least one carboxyl function. All of the above were quantitatively esterified with pentafluorobenzyl bromide to increase electron capturing ability and enhance negative chemical ionization (NCI) mass spectrometric response.

Samples of a mixed standard solution in 1 M HCl were freeze-dried and each was derivatized with 80 µL PFB-Br (5% v/v in acetonitrile) and 20 µL diisopropylethylamine, at 70°C for 15 minutes (3). Derivatized samples were taken to dryness under a stream of nitrogen and reconstituted in acetonitrile. The resulting solutions were transferred to autosampler vials and analyzed by LC/MS.

Liquid chromatography was carried out on a HP 1050 series LC system equipped with a 5 µm ODS Hypersil column, 100 mm x 2.1 mm id at a flow rate of 0.4 mL/min. Gradient elution was used. A mixed mobile phase (28% 0.1 M ammonium acetate:32% methanol:40% acetonitrile adjusted to pH 5 with acetic acid) was maintained for 6.5 minutes to maximize separation of KYN and TRP, followed by a linear gradient to 100% acetonitrile at 16.5 min to 20 min. A post-run of 10 min was used to allow the column to re-equilibrate with the initial mobile phase.

LC eluent was introduced into the mass spectrometer via a HP 59980B Particle Beam Interface. Helium nebulized pressure was 50 psi and interface temperature maintained at 48°C. NCI-MS was performed on a HP 5999 mass spectrometer with methane as reagent gas with source pressure of 1 torr. Source and quadrupole temperatures were 250°C and 100°C, respectively. Spectra of the PFB derivatives of tryptophan and metabolites were obtained by scanning from m/z 100 to 800 at 0.40 scans/sec. All spectra exhibit prominent [M - PFB]~ ions. These characteristic ions dominate the NCI spectra of the derivatives except for that of 3HK (exhibits substantial fragmentation).

18O labeled isotopomers of QA, KYN, TRP, KA, 3HAA, AA, 3HK, and XA were prepared by exchange in 1 M HCl/H2[18O] at 70°C for 24 hours. Samples of each preparation were combined, derivatized, and analyzed by LC/MS. Oxygen exchange of QA gave primarily m/z 354 representing exchange of all four carboxylate oxygens. 18O-QA was not detected. TRP, KA, 3HAA, AA, and XA had predominantly [18O]3 ions; both carboxylate oxygens were exchanged. KYN and 3HK produced primarily the [16O]3 isotopomers with exchange of the ketone group as well as the carboxylate oxygens. Most conveniently, as has been reported previously (4), [16O]2, [16O]3, or [18O]4 labeled...
Isotopomers retained their isotope label upon derivatization and exhibited prominent \([M - PFB]^-\) ions in their NCI spectra. Thus, a useful internal standard for each target analyte was readily prepared.

A series of samples containing the PFB derivatives of QA, KYN, TRP, KA, 3HAA, AA, and 3HK in acetonitrile were analyzed by LC/MS monitoring ions corresponding to \([M - PFB]^-\). Signal:noise for 25 pg injected ranged from 100:1 for TRP to 4:1 for 3HK. The PFB derivative of 3HK shows significant fragmentation and may not be particularly well suited to NCI quantification.

Results are summarized in Table 1. The LC method provided adequate resolution with peak widths of a half minute. Derivatization with pentafluorobenzyl bromide allowed detection of these compounds by NCI mass spectrometry with sensitivities in the mid picogram range.

A particle beam interface was constructed after the design of Extrel's ThermaBeam™ interface (Extrel Corp., Pittsburgh, PA) and retrofitted to a Finnigan 4021 quadrupole mass spectrometer equipped with a Teknivent Vector II data system (Teknivent Corp, Maryland Heights, MO.). This instrument is currently used in structure elucidation studies in Drug Metabolism Research. Extrel's particle beam design was chosen because we believe it is superior in performance to other commercially available particle beam interfaces. Permission to use this design was obtained from Extrel.

The objective was to provide: 1) an LC/MS screening tool that would provide superior structural information than thermospray spectra and 2) an interface that would also easily adapt to existing chromatographic separations developed off-line. Particle beam LC/MS was chosen because it is capable of electron impact, chemical ionization, and other desorption ionization techniques without the limitations of flow rate and mobile phase compositions encountered with electrospray and thermospray. This paper focuses primarily on chemical ionization applications sometimes utilizing a heated target to assist in the formation of molecular ions from involatile biological conjugates such as estrone glucuronide, estrone sulfate, androsterone glucuronide, 8-hydroxyquinoline glucuronide, and s-(N-methylcarbamoyl) glutathione.

The momentum separator and nebulizer were directly coupled to the 4 inch conflat flange on the left side of the Finnigan 4021. A bridge was constructed for chemical ionization which tees the CI gas directly after the momentum separator. There were no other modifications to the basic mass spectrometer making this a very easy retrofit. The Finnigan ion volume design allows for a DCI probe to be inserted through the front probe lock. This proved to be an important feature since we found it necessary to have a heated target in order to see molecular ions from some of the conjugates.

Using caffeine as the test compound it was determined that it was possible to obtain a reasonable spectra from 500 pg flow injected with 100 % methanol as the mobile phase flowing at 0.5 mL per min operating in the electron impact mode. This represents roughly a factor of 10 increase in sensitivity over any commercially available system.

Figures 1 and 2 are PCI ammonia spectra of s-(N-methylcarbamoyl) glutathione (SMG) with the heated target off, then on respectively. Notice the total absence of the pseudomolecular ion at m/z 365 in the target off spectrum. The presence of the heated target produces the pseudomolecular ion as a major ion. A comparison was made between data obtained via heated target particle beam and direct probe LSIMS of SMG. It was found that while the pseudomolecular ion was produced via LSIMS, it was necessary to perform MS/MS to obtain the same degree of structural information that was present in the PCI data.

The various conjugates were attempted via either positive or negative chemical ionization (ammonia moderating gas). The mobile phase was 50/50 water-methanol flowing at 0.5 mL per min. Optimization of the interface temperatures was accomplished first with caffeine, then with the individual compounds of interest to determine the best heated target temperature (if it was necessary). The actual temperature of the heated target is not known, only the voltage and current required to see the molecular ion of the more difficult species. Typically, these values were 4 volts drawing 0.1 amps of current. It was found that not all of the conjugates required the heated target to see the molecular ion.
Particle beam LC/MS is just beginning to reveal that it has applications for thermally labile compounds that in the past would have to be derivatized and run via a static probe technique such as LSIMS or FD. In fact, work has been done coupling particle beam with both LSIMS$^1$ and FD$^2$. The current developments in electrospray also show promise in analyzing compounds of similar nature with greater sensitivity, however particle beam unlike electrospray is capable of performing on-line analysis at "real world" flow rates making it possible to match LC conditions without the need for flow splitting. Therefore, enhanced sensitivity of electrospray may well indeed be offset by the need to split flow in order to achieve sample introduction rates in the microliters per minute range. For example if one were to split 0.5 mL/min to 1 uL/min, the resultant loss in sample delivered to the mass spectrometer (e.g. 1/500) would translate detection limits via electrospray in the 500 pg range to 250 ng via particle beam. Some of the data presented herein was collected at or lower than this figure.

Although micro LC is easily coupled with electrospray the sample capacity is limited and is virtually of no practical use when working with crude biological matrices such as urine.

Particle Beam/MS Analysis of Naturally Occurring Aromatic Acids and Phenols

Aromatic acids and phenols, such as vanillyl and syringic acid, occur naturally in water and provide the building blocks for the lignins produced by vascular plants. As such, they are excellent molecular markers for natural water with a terrestrial source component. By analyzing the CuO oxidation products of lignins and dissolved humic materials, the macromolecular material has been correlated to specific types of vascular plants, i.e. gymnosperms versus angiosperms (e.g. Hedges and Ertel 1982, Ertel et al. 1986). CuO oxidation produces the single-ring aromatic acid and phenolic compounds mentioned above. Typically, these compounds are derivitized prior to analysis to form the more volatile alkylated silyl or methyl ethers which facilitates analysis by gas chromatography. However, silylation produces unstable derivatives and introduces appreciable amounts of contamination and methylation of the acidic and phenolic oxygens with diazomethane involves a mutagenic precursor. Furthermore, derivatization is time consuming with inherent losses of analytes due to the additional analytical step. Thus, direct analysis of these analytes, such as by HPLC/particle beam/MS, would eliminate the added analytical workup as well as the drawbacks described above.

Spectra of a series of substituted aromatic acids and phenols are presented here as introduced by the particle beam (PB) versus the gas chromatographic (GC) interface. Compounds intended for gas chromatographic introduction were derivitized by diazomethane prior to injection. The compounds analyzed were as follows: (a) phenolic methoxylated benzaldehydes vanillyl, syringaldehyde, and ethyl vanillyl (utility as a surrogate for recovery purposes); (b) phenolic methoxylated benzoic acids vanillic acid, syringic acid, p-coumaric acid, and ferulic acid; phenolic methoxylated acetophenones acetovanillone and acetosyringone; and (d) vanillyl alcohol. Vanillyl alcohol was not completely derivatized; thus, the GC spectrum is shown for the non-derivatized form. Sensitivity was roughly 10 to 100 times less for PB introduced compounds.

All spectra are well characterized by two or three fairly intense ions, including the molecular ion. Vanillyl alcohol is the only compound for which a direct comparison (both underivatized) may be made of PB versus GC effect on fragmentation patterns. The molecular ion is much larger in the PB spectra with a neutral loss of hydroxy apparent versus a loss of water for the GC spectra. Mid-range fragments (C7H7O+ m/z 107, and C6H5O+, m/z 93) are present in both spectra, although at different intensities. The aldehydes, except ethyl vanillyl, exhibit base peaks of either the M+ or (M-H)+ ion, with significant losses of CHO and CH3. Ethyl vanillyl, on the other hand, is dominated by the loss of 29, which may be a combined loss of CHO and C2H5. Loss of 28, most likely CO, was also noted for both its PB and GC spectra. PB and GC spectra for acetovanillone and acetosyringone were virtually identical in character, with base peaks attributed to the loss of CH3, molecular ions ranging from 38 to 57%, and loss of the acetyl group accounting for ions ranging in intensity of 10 to 31%. In both PB and GC spectra for the four acids, molecular ions dominated, with the exception of the GC spectra of p-Coumaric acid where loss of the methoxy group dominated. Losses of hydroxyl or methoxyl groups and COOH and COOCH3 were the mode for the PB and GC spectra, respectively.

Comparison of Thermospray and Particle Beam LC-MS for the Analysis of Triglycerides in Cooking Oils

Yang, Y-P and Vestal, Christina H.*. Vestec Corporation, Houston, TX

INTRODUCTION

Earlier work (1,2) has shown that Thermospray™ LC-MS is an effective tool for on-line identification of triglycerides separated by reversed-phase HPLC. Despite this success there remain some problems for which the information provided by Thermospray is not sufficient. Triglycerides with no carbon-carbon double bond often do not produce an observable protonated molecular ion using the Thermospray filament-on mode of operation required by the organic mobile phase. Those containing at least one C=C double bond always yield some protonated molecular ions and simple fragmentations which allow the masses of the three fatty acid components to be unambiguously determined. More recently, we have applied Particle Beam LC-MS to this problem and an improved LC method for Thermospray analysis to obtain detectable molecular ions for both the saturated and unsaturated triglycerides as well as structurally significant fragmentation. The resulting LC-MS techniques have been applied to analysis of a variety of commercial cooking oils to both identify and quantify the triglycerides present.

EXPERIMENTAL

Liquid Chromatography/Mass Spectrometry was performed using a Waters 600MS Multisolvent delivery system coupled to a Vestec 201 Dedicated Thermospray-Particle Beam Mass Spectrometer with an on-line UV detector at 215nm and connected to a Compaq 386 computer via a Teknivent Vector One interface. The LC column was an Alltech Spherisorb ODS-2, 4.6mm x 25cm, and 5 micron particle size. Samples were run isocratically using 52/30/18 acetonitrile/isopropanol (with 0.005M ammonium acetate)/hexane. Flow rate was 1.0 mL/min. All of the cooking oils were dissolved (50/50 v/v) in hexane prior to injection. The injection volume was 10 microliters. In this work we ran the following commercial cooking oils: "Mazola" Corn Oil, "Kroger" Vegetable Oil, "Wesson" Sunflower Oil, "Heart Beat" Canola Oil, and "Pompeian" Olive Oil which were labeled "no cholesterol" and "low saturated fat present" by the manufacturers. The experiments were done using Thermospray (TS) positive ion and filament-on mode of ionization and Particle Beam (PB)-EI at 20 eV.

RESULTS AND DISCUSSION

Figure 1 shows the TS (a) and the PB-EI (b) mass spectra of the standard tripalmitin (PPP) which is a completely saturated triglyceride. Both of the spectra gave a base peak at m/z 551 (PP⁺) and 39% of ammonium adduct at m/z 824 of PPP in TS and 1% of molecular ion M⁺ at m/z 806 in PB-EI. Saturated triglycerides do not produce observable molecular ions without some ammonium acetate buffer present in the mobile phase, and it also enhances the sensitivity without losing the chromatographic performance. The PB-EI spectrum at 20 eV of tripalmitin also consisted of several strong peaks at m/z 239 and 313 which are related to palmitic acid and monopalmitin with a loss of an OH group or water. The common fatty acids of triglycerides present in the cooking oils mentioned above are listed in Table I. Figure 2 shows the PB-EI total ion chromatogram (a) and the on-line UV trace at 215nm (b) for the analysis of "Heart Beat" Canola Oil. The TS- and PB-EI spectra of the peak at 7.7 minutes are shown in Figure 3 which consisted of common peaks at m/z 597 (LL⁺), 599 (OL⁺), and 601 (OL⁺) and other peaks at m/z 95, 108, 260, 262, 337, and 878 for PB-EI and 879 and 896 for TS. It determines the molecular weight of 878 daltons and three fatty acid components of oleic (O), linoleic (L), and linolenic (U) of this triglyceride which is present in "Heart Beat" Canola Oil. Four other cooking oils also show a peak at around 7.5 minutes with MW 878, but only have a single ion at m/z 599. It indicates the presence of trilinolein (LLL) in these cooking oils. It was also found a small amount of triglycerides of behenic acid (C22H43COOH) present in "Wesson" Sunflower Oil. The TS spectrum at 16.3 minutes of this triglyceride is shown in Figure 4 which consisted of a base peak at m/z 939 (MH⁺) and intense peaks at m/z 899 (LL⁺) and 659 (LB⁺). Unfortunately, it did not give a good PB-EI spectrum.

CONCLUSIONS

Thermospray and Particle Beam LC-MS with buffer present in the mobile phase is a powerful tool for on-line confirmation and identification of triglycerides separated by reversed-phase HPLC. The amount of unsaturated and saturated triglycerides present in cooking oil agrees with the manufacturers' values shown in Table II.

THERMOSPRAY AND PARTICLE BEAM LC-MS, COMPARATIVE STUDY FOR SOME SESQUITERPENE LACTONES FROM ACROPTILON REPENS.

Leslie A. Harden, Kenneth L. Stevens, and William F. Haddon, Western Regional Research Center, USDA 800 Buchanan St., Albany, CA. 94706.

Introduction. Sesquiterpene lactones occurring in Russian knapweed (Acroptilon repens L.) have been implicated in the nervous system disorder in horses known as equine nigropallidal encephalomalacia. Identification of these natural products from complex mixtures has in the past been aided by use of the mass spectrometer only after their isolation as pure compounds.

With the advent of practical LC/MS interfaces, the mass spectrometer can provide information to the natural products chemist that allows target compound analysis and structure elucidation of unknowns in complex mixtures. In this study we targeted the compounds previously isolated from Russian knapweed, repin, acroptilin, and centaurepensin. We compared particle beam (P/B) El, positive and negative ion Cl, as well as positive and negative ion thermospray (TSP) spectra for these sesquiterpene lactones and applied this information to the analysis of a plant extract from Russian Knapweed.

Experimental. All analyses were carried out with an Extrel C-50/400 quadrupole mass spectrometer equipped with TSP and P/B supplied by that manufacturer. The sample introduction and chromatography were performed on a Waters 600E HPLC equipped with an Analytichem C-18, 4mm x 15cm, column with 4.5 um packing.

Initial evaluation P/B (El, methane Cl, and ammonia Cl) and TSP were performed by sample introduction of individual compounds via flow injection without chromatography. The mobile phase in the P/B experiments was acetonitrile at 0.6mL/min. System temperatures for Cl in degrees centigrade were: P/B desolvation chamber=83, P/B control=125, P/B tip=192, MS source=210. For the TSP experiments 29% acetonitrile, 71% 0.1 M ammonium acetate in water was used at 1.2mL/min. Relevant temperatures in degrees centigrade were: source block=207, TSP probe control=127, and TSP probe tip=204.

Chromatographic TSP studies were performed on a mixture of repin, acroptilin, and centaurepensin as well as an extract from Acroptilon repens using an isocratic mobile phase of 29% acetonitrile, 71% 0.1M ammonium acetate in water.

Results. Of the three target analytes, the sensitivity was least for centaurepensin. Detection in the P/B mode was achieved at 1ug with negative ion ammonia Cl (Figures 1-3). Negative, molecular ion, ammonium adducts were seen down to 250ng for this compound when flow injected in the TSP mode (Figures 4-6).

Molecular ion abundances and sensitivity for the target analytes appeared to be enhanced with negative ion detection versus positive ion detection for both P/B, with Cl, and TSP ionization. Analysis of the knapweed extract, illustrated by single ion current plots (Figures 7 and 8), reveals an apparent mixture of components at the location of centaurepensin elution in the chromatography scheme utilized.

Discussion. Comparison of the spectra derived in the LC-MS analyses of the known compounds and the plant extract in this study demonstrate the utility of this hyphenated technique in providing useful information to the natural products chemist. In this case revealing a mixture of components that would not be recognized without additional separation. In addition this technique promises to provide additional information on the character of unidentified constituents in complex mixtures.

APPLICATION OF LC/MS TO THE STUDY OF CHELATORS IN MIXED HAZARDOUS WASTES

J.A. Campbell, R.B. Lucke, and S. Clauss, Advanced Organic-Analytical Methods Development Group, Pacific Northwest Laboratory, Richland, WA 99352

Chelators, such as ethylenediaminetetraacetic acid (EDTA), citric acid, and N-(2-hydroxyethyl)ethylenediaminetriacetic acid (HEDTA) have been used to complex radionuclides in mixed hazardous wastes (MHW). These organoradionuclides are potentially more environmentally hazardous than either radionuclides or chelators alone due to their enhanced mobility through the soil and possible deposition into the ground water. In addition, many of the chelators can't be analyzed by either gas chromatography (GC) or gas chromatography/mass spectrometry (GC/MS), accepted EPA techniques, without first being derivatized. Derivatization, however, may require extra sample handling, may give low or variable recoveries, and often requires the use of hazardous reagents. As a result, we have evaluated liquid chromatography/mass spectrometry (LC/MS) utilizing the HP 5988A LC/MS as a potential technique for analyzing chelators and chelator fragments. We have examined both the free acids and Cu complexes of several chelators and chelator fragments by LC/MS.

Both thermospray and particle-beam LC/MS interfaces are available in our laboratory. The chromatographic system for both particle-beam and thermospray was a HP Model 1090 equipped with a ternary solvent delivery system, a variable volume sample injector, an auto sampler, and a column bypass valve. The HP Model 5988A particle-beam and thermospray interfaces and mass spectrometer were used in this study. For the thermospray studies, the source temperature was typically 300° C and the stem temperature was 90° C. The mobile phase was 0.1M ammonium acetate. The free acids (not complexed) were analyzed using flow injection techniques. Separation of the copper complexes of EDTA and HEDTA was accomplished using RP2 Lichrosorb column with ammonium acetate as the buffer at a flow rate of 1 ml/min. Several chelators were also analyzed by direct injection techniques in methanol and particle-beam LC/MS.

Figure 1a is the thermospray LC/MS mass spectrum of HEDTA (MW 278). The base peak is m/z 261. This is probably the result of protonation to form m/z 279 and then loss of water to form m/z 261. The ion m/z 261 could also be the protonated lactam, but then one would expect an addition of 18 as the ammonium adduct at m/z 278. Figure 1b is the mass spectrum of ethylenediaminetriacetic acid (ED3A), a decomposition product of HEDTA. The ion m/z 217 is probably the protonated lactone and 234 is (M+18). The formation of lactones and lactams was also noted by Toste (1) in the GC/MS analysis of methylated derivatives of several of the chelators.

The mass spectra of various chelators obtained by particle-beam LC/MS showed extensive fragmentation; the chelators could not be unambiguously identified based on the spectra.

A LC method for the separation of chelators and chelator fragments utilizing Cu complexation, reverse phase, ion-pair chromatography has been developed by W.R. Grace and modified by our group. As a result, we have examined several Cu complexed chelators by LC/MS. Figure 2a is the total ion chromatogram of a mixture of Cu(EDTA) and Cu(HEDTA). Figure 2b and 2c are mass spectra of the complexed chelators. It is interesting to note that the mass spectrum of Cu(HEDTA) is similar to the mass spectrum of ED3A. Cu may be facilitating electron transfer and subsequent reduction. Further studies are underway to determine the role of copper.

Thermospray LC/MS can be utilized to identify the chelators and the complexed chelators and chelator fragments. Particle-beam LC/MS, however, may have limited application, due to extensive fragmentation.

Accurate Mass Determinations By Thermospray LC/MS

Walter Davidson, Roger Dinallo, Keith McKellop, Gordon Hansen
Boehringer Ingelheim Pharmaceuticals Inc., R & D Center, Ridgefield, CT 06877

Accurate mass determination in conjunction with thermospray ionization has been investigated. Modifications to instrument hardware and improved methods of calibration permit us to obtain resolution and stability comparable to standard EI performance. Measurement accuracy of better than 7 ppm for low level components separated by HPLC and better than 2 ppm for samples introduced directly into the mass spectrometer was achieved.

The instrument was fitted with an improved vaporizer insert, having a replaceable sapphire orifice, which greatly improved ion beam stability. The mass spectrometer was also modified by the addition of a cryopump to the source housing. This lowered both source and analyzer pressures which greatly enhanced resolution and sensitivity (Table 1). Large systematic errors in mass assignment were observed when operating with current controlled magnetic scanning. These errors were greatly reduced by operation with field controlled magnetic scanning (Fig. 1).

The remaining systematic errors (in field control) were further characterized. It was most convenient to perform this experiment using perfluorokerosene and EI ionization. A modified reference file of ions separated by 40-50 amu was constructed to simulate the use of polyethylene glycol oligomers (separation of 44 amu) as internal reference ions in TSP operation. The remaining PFK ions were treated as unknowns by the data analysis software. Two hundred scans were averaged to largely eliminate random statistical errors. The remaining systematic errors were used to derive a mathematical correction formula:

$$M_{corr} = M_{meas} + \left(0.038 \frac{|M_{meas} - M_{ref}|}{M_{meas}}\right)$$

where $M_{corr}$ is the calculated exact mass of the unknown, $M_{meas}$ is mass of the unknown reported by the instrument (DS90) software, and $M_{ref}$ is the mass of the nearest internal reference ion. This formula was found to be accurate over the mass range 500-1000 and independent of scan rate.

Several test compounds were analyzed and the correction formula was applied to the average of about 30 scans. As shown in Table 2, excellent results were obtained.

A Kratos MS25RFA mass spectrometer equipped with a thermospray interface was employed for these experiments. The LC system consisted of an ABI SF400 pump and SF757 UV detector having a high pressure in-line flowcell. An additional SF400 pump was connected via a low dead volume tee to permit post-column addition of internal standard calibrant. The standard EI source was used for the PFK experiments. A Vacumetrics 33060 LN$_2$ cryopump was added to the ion source housing by removing the glass plate and adding an aluminum adapter plate constructed in-house. A Vestec VT146014R vaporizer tip having a replaceable sapphire orifice was installed. This required use of an insulator over the entire enclosed length of the insert and wrapping of its thermocouple wires to prevent high voltage discharge.

Test compounds were injected into a 0.1 ml/min flow of 50% acetonitrile in water with 0.015% PEG 200-400 (1:1). Make-up flow was 1.0 ml/min of 0.3 M ammonium acetate. A WISP auto injector was employed to inject 0.5 ml of sample solution containing 100 ug of test compound. This was sufficient to produce a strong signal for several minutes. Approximately 30 scans were averaged for each analysis.
The mass spectrometer was operated at 10 000 resolution (10% valley) with a scan rate of 10 sec/decade. The instrument was scanned from m/z 600 to 120 for the test compounds and 400 to 120 for the LC/MS experiment. Field controlled magnetic scanning was performed, except as noted.

SENSITIVE DETECTION OF DIHYDROXY ARACHIDONIC ACIDS FROM HUMAN POLYMORPHONUCLEAR LEUKOCYTES (PMNLs) BY THERMOSPRAY LC/MS

H.Y. Kim and D. D. Hassell
Section of Analytical Chemistry, LCS, DICBR, NIAAA
Building 10, Room 3C-102, 9000 Rockville Pike, Bethesda, MD 20892

Human PMNLs are known to metabolize arachidonic acid to leukotrienes and 5(S),15(S)-, 8(S),15(S)- and 5(S),12(S)-dihydroxyeicosatetraenoic acid (diHETE) by various lipoxygenase reactions. Leukotriene B₄ (LTB₄), one of the main dihydroxy compounds produced by PMNLs, induces chemokinesis, chemotaxis, aggregation and degranulation of human PMNLs and has been implicated as a potential mediator of allergy and inflammation. While 8,15-diHETE also exerts a chemotactic effect upon PMNLs, 5,12-diHETE antagonizes some of the LTB₄ effects. Measurements of these compounds are typically made using an HPLC/UV technique. However, this technique is not adequate for the analysis of many biological samples, since its detection limit is usually above the ng range and these compounds are generally present only in nanomolar concentrations.

In our laboratory, these hydroxy compounds were measured by thermospray LC/MS after pentafluorobenzyl (PFB) derivatization. As demonstrated in Figure 1, subnanogram quantities of PFB derivatives of leukotriene B₄ and various diHETE standards can be easily detected. Approximately 250 pg of diHETEs were separated using reverse phase HPLC (C-18, 2.1 mm x 10 cm, 5µ) with a mobile phase of 0.1M ammonium acetate/acetonitrile (40/60) and a flow rate of 1 mL/min. They were then detected in an on-line fashion by a negative ion mode-thermospray technique in either a discharge-on or filament-on condition. The source and vaporizer tip control temperatures were maintained at 250 and 75°C, respectively. With this technique, 50-100 pg of dihydroxy compounds can be quantified after HPLC separation.

Using ¹³C₂-LTB₄ as an internal standard, the production of leukotriene B₄, as well as other diHETEs, was measured from PMNL preparations. Whole blood was obtained from normal volunteers and PMNLs were separated using a Histopaque density gradient method. Recovered PMNLs were washed with phosphate buffered saline and resuspended in the same buffer. Their capacity to produce these hydroxy compounds was determined after stimulation with the calcium ionophore A23187. The metabolites were extracted with ethylacetate in the presence of 2 ng of ¹³C₂-LTB₄ as an internal standard. The result obtained from 1x10⁶ purified PMNLs (corresponding to approximately 5 mL of whole blood) is shown in Figure 2. For this particular experiment, in order to better separate 8,15- and 5,15-diHETE, an ODS column with 3µ particle size (4.6 mm x 7.5 cm) was employed with the same mobile phase described above. The PMNLs were observed to produce LTB₄ and 8,15-, 5,15- and 5,12-diHETE, and the levels of these compounds varied between individual blood samples. This was presumably due to individual variation in the content of precursor arachidonic acid as well as in the sensitivity of the PMNLs to stimulation. However, production of approximately 1-5 ng of these compounds was estimated with reference to the internal standard. Typically, this level of products could not be analyzed by UV detection either before or after derivatization.

This technique was employed in order to investigate the effect of ethanol on the production of these dihydroxy compounds. The purified PMNLs were preincubated with 0.01-0.2% ethanol for 10 min prior to the stimulation by A23187. The levels of 5,15-diHETE, LTB₄ and 5,12-diHETE were measured by thermospray LC/MS after PFB-derivatization. As shown in Table 1, no difference was found in their production. However, it is possible that changes in their production could be observed following a longer period of preincubation of PMNLs with ethanol.
Figure 1. Separation and detection of standard diHETEs (approximately 250 ng each).

THERMOSPRAY LC/MS ANALYSIS FOR CONTAMINANTS IN L-TRYPTOPHAN SUPPLEMENTS

W.J. Driskell¹, R.H. Hill Jr.¹, S.R. Sirimanne¹, L.L. Needham¹, and S.W. Page²
Center for Environmental Health and Injury Control, Centers for Disease Control¹, Atlanta, GA 30333; Centers for Food Safety and Applied Nutrition, Food and Drug Administration², Washington, D.C. 20204

At the end of 1989 a new fatal disease called eosinophilia-myalgia syndrome (EMS) appeared in America and West Germany. Epidemiological investigations traced the cause to an unknown contaminant in L-tryptophan (LT) dietary supplement tablets (1-3). High performance liquid chromatography (HPLC) analysis with UV detection found more than 50 contaminants in the LT material. Many of the contaminants were present in less than parts per million levels.

One approach to identifying these contaminants was analysis with thermospray LC-MS or LC-MS/MS. These analyses were performed with the Finnigan TSQ-70 triple quadrupole mass spectrometer with the thermospray interface and the Waters 600 liquid chromatography system with an online Waters 490 UV detector. Elution was by a water and acetonitrile linear gradient that contained 0.1% trifluoroacetic acid (TFA). Both discharge ionization at 0.5 kV and buffer ionization were used. The thermospray vaporizer was set at 120 C and the block was set at 240 C. For MS/MS analyses, the collision gas was argon; the collision cell pressure was 1.3 millitorr; and the collision offset was -10 V.

Thermospray was useful in attempting to identify some of the more concentrated contaminants but was not sensitive enough to detect many of the lower concentration contaminants. The four most prominent UV detectable contaminants present in LT tablets at concentrations between 10 and 200 ppm were easily detected and LC-MS/MS spectra were obtained. These compounds are varieties of indole-tryptophan conjugates with molecular weights between 300 and 400 amu; it is unlikely that they are EMS causative agents since they are present in all the LT lots including those not associated with EMS cases. Thermospray was useful in identifying the LT contaminant 1-methyl-1,2,3,4-tetrahydro-beta-carboline-3-carboxylic acid (MCCA), which was not case related but was of interest because it is a breakdown product of a compound that was case related (see below). Thermospray was used to identify two other contaminants, 5-chloro-LT and 5-hydroxy-LT, neither were EMS case related.

Of the many contaminants found in the LT preparations, the only one that had a marked association with EMS cases was identified as 1,1'-ethylidenbis[L-tryptophan] (ETB), also known as "peak 97" and "peak E" (4,5). EBT is formed during the LT manufacturing process probably by the reaction of 2 LT molecules with an acetaldehyde molecule. Because EBT is thermolabile, breaking down in the thermospray ion source mainly to LT and a small amount of MCCA, thermospray was only of limited use in identifying EBT. Atmospheric pressure ionization (API) LC-MS analysis provided much more useful information in the identification of EBT because the 435 m/z MH+ ion was prominent in
the EBT spectrum. API LC-MS was between 10 and 100 times more sensitive for many of the LT contaminants than thermospray.

Bacitracin, a 1420 amu antibiotic bacterial peptide that under certain culture conditions is synthesized by the bacterial strain used in the production of LT, is a suspected LT contaminant. The thermospray limit of detection for bacitracin was about 5 ppm in spiked LT samples using a narrow scan window and a 20 kV dynode detector. We were not able to detect bacitracin in the LT material by thermospray.

Since no extensive sample preparation was done before LC-MS analysis, a very large amount of LT entered the ion source each run. Thermospray proved to be very rugged and reliable under these conditions, requiring only weekly ion source cleaning.

INTRODUCTION

Sulfonamides are an important class of antibacterial agents used in veterinary practice. Sulfonamides are fed to cattle for prophylactic and therapeutic purposes. Residues from sulfonamides have been found in cows' milk as well as edible animal tissues. A recent study implies that sulfamethazine may be a thyroid carcinogen.¹ Various analytical methods have been developed for the analysis of sulfonamide residues in milk.²-⁴ Liquid chromatography/mass spectrometry has been utilized for the determination of sulfadiazine in biological fluids and for the analysis of sulfonamide residues in meat.⁵,⁶ Combined high-performance liquid chromatography/thermospray mass spectrometry (HPLC/TSMS) is used in this study for the analysis of sulfamethazine (SMZ), sulfamerazine (SMR) and sulfadiazine (SDZ).

EXPERIMENTAL

An ISCO LC-5000 syringe pump was connected to a Rheodyne 7125 injector equipped with a 20 µl loop. A Phase-Sep Spherisorb S5 ODS2 (150 x 4.6 mm) column, preceded by a Brownlee RP-18 New Guard column (15 x 3.2 mm), connected the injector directly to a Delsi Nermag RIO-10C mass spectrometer. The mobile phase was 0.1 M ammonium formate in an 80% water/20% acetonitrile mixture pumped at 1.1 ml/min. The mass spectral analyses were performed in the positive ion, "filament/discharge off" and "repeller off" mode. The control temperature and the block temperature were set at 130°C and 150°C, respectively. Full scans of m/z 125 - m/z 300 were acquired for the standard solution and scans of m/z 225 - m/z 300 were acquired for the blank and fortified milk samples.

Standard solutions of SMZ, SMR and SDZ (ICN Pharmaceuticals) were prepared at a concentration of 1.0 mg/ml in mobile phase. Milk was fortified by the addition of 100 µl each of the standard solutions to 10 ml of milk to yield a final concentration of 10 ppm. The milk used was whole milk purchased locally. Both the blank milk and the fortified milk samples were mixed 50/50 with mobile phase before injection.

RESULTS AND DISCUSSION

The structures of the three sulfonamides are shown in Figure 1. Good separation was obtained when a 5 ppm mixture of the three standards was analyzed by HPLC/TSMS. The base peaks in the TS mass spectra of the three standards corresponded to the [MH]+ ions for the individual compounds.

No evidence of sulfonamide residues was present in an unspiked milk sample analyzed by HPLC/TSMS. There was a strong early signal due to the milk components. Figure 2 displays the HPLC mass chromatogram and ion traces for a 10 ppm fortified milk sample. The ion traces represent the [MH]+ ions of each compound. Good resolution is still achieved for the three standards along with a well resolved early peak due to the milk matrix.

CONCLUSION

The utility of HPLC/TSMS for the quick analysis of sulfamethazine and two other sulfonamides in milk has been demonstrated. The technique may also prove useful for analysis of other sulfonamides. Detection limits were not at optimum levels in this study. By experimenting with various extraction techniques, selected ion monitoring or selected reaction monitoring, the detection limits for sulfonamides by HPLC/TSMS should be improved significantly.

UTILITY OF HPLC-TSMS FOR THE ANALYSIS OF THE ANTITUBERCULOSIS DRUGS ACONIAZIDE AND ISONIAZID

E.B. Hanson, Jr., J. Bloom, H.C. Thompson, Jr., and W.A. Korfmacher; Food and Drug Administration, National Center for Lexicological Research, Jefferson, AR 72079

BACKGROUND

Since 1952 the drug of choice for the treatment of tuberculosis (TB) in humans has been isoniazid (INH). Because INH can cause severe side effects there has been a search for less toxic drugs (1). Aconiazide (ACON), is the isonicotinylhydrazone of 2-formylphenoxyacetic acid. ACON has been reported to provide antituberculosis activity both in animals and humans equivalent to that of INH and has demonstrated a much lower toxicity (2). Presently, animal toxicological studies of ACON are being performed at the FDA's NCTR and analytical procedures for the analysis of ACON and INH in aqueous solution and rat plasma are needed to support these studies.

EXPERIMENTAL

ACON solutions were prepared at about 1 mg/ml by dissolving a weighed amount of the powder into an appropriate volume of 1% aqueous sodium bicarbonate (w/v).

Mass spectral analyses were performed using a Finnigan MAT TSQ 70 triple stage quadrupole mass spectrometer equipped with a Finnigan MAT thermospray controller and source. The mobile phase was maintained at a flow rate of 1.25 ml/min by an Isco LC-5000 syringe pump. Typically, the vaporizer was set to 105°C with a block (zero) setting of 220°C.

HPLC was achieved for ACON using a Beckman ODS analytical column. The mobile phase was 600 ml water and 400 ml methanol to which was added 5 grams of ammonium formate. For the analysis of INH in rat plasma a Beckman CN analytical column was used and the mobile phase was 650 ml of water and 350 ml methanol which also contained 5 grams of ammonium formate. Typically, 20 µl aliquots of sample were injected on column using a Rheodyne model 7125 injector.

Formation of the isonicotinylhydrazone of verataldehyde (3,4-dimethoxybenzaldehyde) in rat plasma was achieved using a modification of a previously reported procedure (3). A 250 µl aliquot of rat plasma spiked with 10 ppm INH was mixed with 50 µl of a 1.5% methanolic solution of verataldehyde and 100 µl of a 10% aqueous solution of trifluoroacetic acid with a vortex mixer for 1 min. The samples were then centrifuged at about 2000 rpm for 10 minutes and the supernatant analyzed by HPLC-TSMS.

RESULTS AND DISCUSSION

Figure 1 shows the results from the HPLC-TSMS analysis of a freshly prepared aqueous aconiazide solution. The large peak in the RIC in Figure 1 is due to ACON. The TS mass spectrum obtained for this peak showed an ion at m/z 300.
which is consistent with the \([M+H]^+\) ion for ACON; the spectrum showed a base peak at m/z 138 which can be attributed to fragmentation at the C-N bond of the ACON molecule.

Figure 2 shows the mass chromatograms from the analysis of an old aconiazide solution. The RIC in Figure 2 shows that the sample contains three major components; these HPLC peaks are labeled 1 to 3. Peak 1 is identified as ACON because its retention time and its TS mass spectrum match those of the standard material. Peak 2 is identified as 2-formylphenoxyacetic acid (2-FPAA) because its TS mass spectrum (consisting mainly of peaks at m/z 180 and m/z 198) and HPLC retention time match those of authentic 2-FPAA. The TS mass spectrum for HPLC peak 3 includes at least two components which are only partially resolved; one of the components is INH since the TS mass spectrum for peak 3 includes a strong peak at m/z 138, which is the \([M+H]^+\) ion for INH. In addition, this TS mass spectral response and HPLC retention time match those of authentic INH. The other component of peak 3 has not been identified, but the TS mass spectral data for this compound includes ions at m/z 142, m/z 156, and m/z 169.

In addition, there are at least two other minor components that were observed in the HPLC-TSMS analysis of the aged ACON solution shown in Figure 2. One of these components corresponds to the HPLC peak labeled 4, and has a TS mass spectrum consisting of a base peak at m/z 200 with no additional ions of significance. The other component is labeled 5 and has a TS mass spectrum which includes a base peak at m/z 227 with no other ions of significance.

The HPLC-TSMS mass chromatogram of a 1 mg/ml INH equivalent standard solution reacted to form the isonicotinylhydrazone of veratadehyde shows two major peaks eluting at 5.5 and 9 minutes and are attributed to excess veratadehyde and its isonicotinylhydrazone, respectively. The TS mass spectrum of the 5.5 minute peak showed a base peak at m/z 167 and was consistent with veratadehyde. The second peak seen at 9 minutes gave a TS mass spectrum showing essentially only the base peak at m/z 286 consistent with the isonicotinylhydrazone of veratadehyde.

Figure 3 shows the HPLC-TSMS analysis of a rat plasma sample which was spiked with 10 ppm INH, reacted to form the isonicotinylhydrazone, and analyzed by HPLC-TSMS. The peak seen at 9 minutes is identified as the isonicotinylhydrazone of veratadehyde because its retention time and the resulting mass spectrum obtained was identical with that obtained from the standard INH-veratadehyde analysis.

**CONCLUSIONS**

This study demonstrates HPLC-TSMS to be very useful for the analysis and characterization of the antituberculosis drugs aconiazide and isoniazid in aqueous solutions and in rat plasma samples.

Diethylamine Cluster Ion Artifacts Observed During Thermospray LC/MS/MS
A. P. Breau and M. D. Lantz; Lilly Research Laboratories
Indianapolis, IN 46285

Introduction: Diethylamine is often used as an additive in the mobile phases for reverse phase HPLC separation in order to enhance peak shape (reduce tailing) and adjust pH. The volatility of diethylamine makes it an ideal additive for thermospray liquid chromatography/mass spectrometry applications (LC/MS). Initial attempts to characterize the degradation products of nizatidine (Figure 1) by thermospray LC/MS utilized a mobile phase containing diethylamine that was successfully employed for the UV detection of the drug and its nitrous acid degradation products. The resulting thermospray spectra of the first eluting peak did not produce ions that could be interpreted as products of nizatidine. The spectra contained series of peaks separated by 171 mass units and all of the major ions had a molecular weight greater than the molecular weight of nizatidine. These peaks were analyzed by LC/MS/MS in a triple stage quadrupole mass spectrometer.

The daughter ion collisional induced dissociation (CID) spectra of each of the major ions in the first eluting peak produced a common daughter ion at m/z=74. An examination of the mobile phase components suggested that protonated diethylamine (M+H ion of 74 amu) might be involved. Subsequent reanalysis of the nizatidine reaction products with the same mobile phase minus the diethylamine component produced spectra that could be readily assignable as related to nizatidine. Apparently under the thermospray ion source conditions, diethylamine reacted with the components to form a series of cluster ions.

Methods: Reaction Conditions Nizatidine (2.5 g, 7.55 mmole) and sodium nitrite (2.1 g, 30.4 mmole) were added with stirring to water (760 ml) at 37 C in a 3-neck flask. Hydrochloric acid (20 ml of 1N) was added until pH 3.63 was achieved. The solution was stirred for 3 hours at 37°C. Ammonium sulfamate (4.33 g, 38.0 mmole) was added to consume the excess nitrous acid. The solution was lyophilized and stored at approximately -20°C. LC/MS Twenty five microliters (50 ug) of the sample dissolved in mobile phase was injected through a Rheodyne injector onto a 15 cm, 5 micron, Jones ODS reverse phase HPLC column. The mobile phase consisted of 760 ml of an 0.1 M ammonium acetate buffer (adjusted to pH 7.5 with glacial acetic acid) and 215 ml methanol. The diethylamine containing mobile phase had 1 ml of DEA added to the aforementioned mobile phase. The isocratic separation was achieved by pumping mobile phase at a flow rate of 1 ml/min through the column using a Waters 600-MS HPLC pump with Silk software. The HPLC eluent was delivered to a Nermag R 30-10 triple stage quadrupole mass spectrometer equipped with a Nermag thermospray ion source. The ion source block temperature was maintained at 223°C with a probe tip temperature of 206°C and a repeller voltage of 150 eV. LC/MS/MS The Thermospray ionization conditions were identical to the conditions listed above in the LC/MS method. A Nermag R 30-10 triple quadrupole mass spectrometer was operated with Q1 filtering the desired daughter ion. The second quadrupole, Q2, was set as an rf only collision cell that was maintained with a gas collision pressure of 2.5 x 10-2 torr Argon. The third quadrupole, Q3, scanned the collision induced dissociation fragments at a rate of 1 scan/second. The accelerating potential of the collision was increased by -40 eV to increase the internal energy of the isolated daughter in order to enhance the collision process.

Results and Discussion: The LC/MS analysis of nizatidine nitrosation reaction products using a diethylamine containing mobile phase produced four major peaks in the LC chromatogram (Figure 2). Spectra from the major peak revealed ions that did not seem related to the structure of nizatidine (Figure 3). These ions appeared in distinct groups in the spectra that were separated by 171 mass units. In the subsequent LC/MS/MS analyses, the daughter ion at 74 amu was consistently observed (Figure 4). Since no fragment of 74 mass units could be readily attributed to a nizatidine substructure the possibility of artifact formation was investigated. An examination of the mobile phase components suggested that protonated diethylamine was involved in the formation of the observed ions. Reanalysis of the nitrosation reaction products without diethylamine present in the mobile phase produced an LC/MS chromatogram with four major peaks that were considerably different than the original analysis. The nizatidine degradation product found in the analysis without diethylamine but at the same retention time as the “polymer” peak had a mass of 187 amu. A reaction with the acid moiety of this product and diethylamine may account for the observed 171 mass unit increments observed in some of the diethylamine containing spectra (Figure 5).

APPLICATIONS OF THERMOSPRAY LC/MS AND TANDEM MASS SPECTROMETRY
IN THE CHARACTERIZATION OF NUCLEOSIDES

H.K. Jajoo, S.M. Bennett, D.M. Kornhauser, P.S. Lietman and R.J. Cotter*, Division of Clinical Pharmacology, Department of Medicine, and Department of Pharmacology and Molecular Sciences, The Johns Hopkins University School of Medicine, Baltimore MD 21205.

More that 80 different nucleosides are presently known in RNA and DNA. They can undergo chemical changes and adduct formation on exposure to certain toxins and carcinogens (1). A number of nucleoside analogs also possess activity against replication of viruses and are thus chemotherapeutic agents (2). Hence it is desirable to have a method available for analysis of nucleosides with high sensitivity and specificity. In this study we report the thermospray mass spectral data on a number of nucleosides. Since thermospray ionization does not provide extensive fragmentation, tandem mass spectrometry was used in combination with thermospray to obtain structural information.

MATERIALS AND METHODS

Materials

The nucleosides were purchased from Sigma Chemical Co. (St. Louis, MO). Fluorothymidine (FLT) was provided by American Cyanamid (Pearl River, NJ). All other chemicals were reagent grade and solvents were HPLC grade.

Thermospray Mass Spectrometry

Mass spectral data were obtained on a VG Trio-3 triple quadrupole mass spectrometer. The HPLC effluent was introduced in the ion source of the mass spectrometer through a heated capillary. The HPLC system consisted of a Hitachi L-6200 pump, and a Valco C6W injector. The mobile phase was Methanol:0.01 M ammonium acetate (20:80; v/v) at a flow rate of 1 ml/min. Direct loop injections were used for obtaining the spectra. Thermospray conditions were optimized for adenosine by proper selection of capillary temperature, source temperature and voltage of the repeller electrode.

Tandem Mass Spectrometry

Tandem mass spectrometric data were obtained by selection of the protonated molecular ion of the nucleoside through the first quadrupole (Q1), and allowing it to undergo collision aided decomposition with Argon in the collision cell, which is an RF only quadrupole (Q2). The ions from the collision cell were mass analyzed by quadrupole (Q3) and were detected on a photomultiplier detector at 400 volts. The collision gas pressure and collision energy were optimized to obtain maximum fragmentation. The collision cell gas pressure was 5.0 E-6 torr and collision energy was 30 eV.

RESULTS AND DISCUSSION

Thermospray mass spectra of nucleosides gave intense pseudo-molecular (MH⁺) ions together with structurally informative fragment ions. The pseudomolecular ions were subjected to collision aided dissociation (CAD), and the mass spectra of the products gave daughter ions corresponding to the nucleic acid base (BH₂⁺) and sugar (S⁺). The relative intensities of the major ions observed in the CAD/MS spectra of the pseudo-molecular ions of the nucleosides are shown in figure 1.

(a) Ribonucleosides

Thermospray mass spectra were obtained on 3 ribonucleosides adenosine, cytosine and uridine. The thermospray mass spectrum of ribonucleosides showed that the protonated molecular ion MH⁺ was the base peak in the spectrum and that there was very little fragmentation corresponding to the BH₂⁺ ions for the nucleic acid base in the nucleoside. The MS/MS spectrum of the protonated molecular ions showed the BH₂⁺ ion as the base peak, and an ion at m/z 133 corresponding to the sugar (S⁺) in addition to the protonated molecular ion.
(b) Deoxyribonucleosides

Thermospray mass spectra were obtained on three deoxyribonucleosides 2'-deoxy adenosine (2DA), 2'-deoxycytidine (2DC) and thymidine (TYM). Protonated molecular ions were base peaks in the spectrum except for thymidine in which the BH$_2^+$ ion at m/z 127 was the base peak. The S' ions were observed at m/z 117 except in 2DC. The CAD mass spectrum of Thymidine had a base peak at m/z 127 (BH$_2^+$) and also ions at m/z 117 (S') and 243 (MH$^+$).

(c) Dideoxyribonucleosides

Thermospray mass spectral data were obtained on four dideoxyribonucleosides dideoxyadenosine (DDA), dideoxycytidine (DDC), 3'-deoxythymidine (3DT) and dideoxyuridine (DDU). The thermospray mass spectra of DDU and 3DT showed excessive fragmentation and the base peak in their spectra was S' ion at m/z 101. The thermospray mass spectrum of DDC showed the protonated molecular ion at m/z 212 as the base peak together with an ion at m/z 112 (BH$_2^+$). The CAD mass spectra of the protonated molecular ion of DDC at m/z 212 showed the BH$_2^+$ ion at m/z 112 as the base peak and also ions at m/z 101 (S') and 212 (MH$^+$).

(d) 3'-substituted nucleosides

Thermospray mass spectra were obtained on two 3'-substituted anti-AIDS nucleosides 3'-azidothymidine (AZT) and 3'-fluorothymidine (FLT). Both of these nucleosides showed MH$^+$ ions as the base peak in their spectrum. The thermospray mass spectrum of AZT showed ions at m/z 127 (BH$_2^+$), 285 (MNH$^+$) in addition to the protonated molecular ion at m/z 268, which was also the base peak in the spectrum. The CAD mass spectra of protonated molecular ion of AZT at m/z 268 showed BH$_2^+$ ion at m/z 127 as the base peak together with ions at m/z 142 (S') and 268 (MH$^+$). Thermospray mass spectrum of Fluorothymidine (Figure 2a) showed MH$^+$ ion as the base peak at m/z 245, together with ion at m/z 262 corresponding to the MNH$^+$ ion. The CAD mass spectrum of MH$^+$ ion of FLT at m/z 245 (Figure 2b) showed BH$_2^+$ ion at m/z 127 as the base peak together with ions at m/z 119 (S') and 245 (MH$^+$). In summary, the CAD mass spectra of nucleosides show S' peaks, characteristic of the sugar part of the nucleosides and BH$_2^+$ peaks characteristics of the nucleic acid base.

THE DIRECT ANALYSIS OF DRUG CONJUGATES USING LC-MS

J. Maltas, J. Ayrton, P. Dow, B.A. Duncan, A.J. Harris and G. Harrison
Department of Drug Metabolism, Glaxo Group Research Ltd
Greenford, Middlesex, England

Introduction
In our experience, conjugated drug metabolites often undergo extensive breakdown in the thermospray (TSP) interface, presumed to be due to the thermal instability of such compounds. In an attempt to overcome this problem we have modified our methodoloy to allow the use of lower temperatures on the TSP interface and thus improve the yield of pseudo-molecular ions of the intact conjugated drug or metabolite. Additional data, not presented here, has also demonstrated increased sensitivity by adopting this strategy. Two Glaxo compounds, GR50360 and GR55721, are used to exemplify the benefits accruing from our approach for the analysis of conjugates.

GR50360

GR55721

Methods
The metabolites of GR50360 were purified from samples of rat, dog and human urine. Deuterated-GR50360 was used to assist in these studies. The metabolite of GR55721 was prepared by incubation with rat liver S9 fraction and purified by solid-phase extraction.

Reversed-phase chromatography was performed on a C8 column using mobile phases consisting of methanol and water each containing ammonium acetate (0.02M) at a flow rate of 0.5ml/min. Methanol containing ammonium acetate (0.02M) was added post-column at the same flow rate.

Mass spectrometric analysis was carried out using a Finnigan 4500 instrument fitted with a Finnigan thermospray interface, including the discharge ionisation facility.

Results
1. Metabolites of GR50360
Analysis of two prominent metabolites using full scan, positive ion monitoring gave the following spectra:-

METABOLITE A

METABOLITE B
The ions at m/z433 and 293 are the respective ammoniated cations of the two conjugates. The ion at m/z196, base peak for metabolite A, is equivalent to the protonated cation of GR50360 and arises as a result of the thermal breakdown of the conjugates during the thermospray process. Additional data from negative ion monitoring allowed the molecular weights to be assigned as 415 and 275 and the following structures to be proposed:

The structure for the carbamoyl glucuronide was supported by the discharge ionisation spectrum which showed fragments at m/z222 and 240, characteristic of the presence of a carbamate function on GR50360.

2. Metabolite of GR55721

TSP analysis of the major in-vitro metabolite of GR55721 gave the following spectrum:

The spectrum shows a strong protonated molecular cation at m/z519 and a weak thermal fragment ion at m/z246. This data is characteristic of a glutathione conjugate of GR55721, molecular weight 518.

Conclusions

1. Post-column addition of methanol permits the use of lower temperatures on the TSP interface.
2. The use of lower TSP temperatures reduces the extent to which thermally sensitive compounds undergo thermal degradation.
3. Routine use of the modified approach has resulted in greater success in determining the identities of conjugated drug metabolites.
4. It has also been observed, during these and other studies, that enhanced TSP sensitivity is obtained using high proportions of methanol, typically greater than 60%, in the mobile phase.
5. The use of post-column addition of methanol permits the consistent use of methanol in proportions greater than 50%. This in turn significantly reduces the effect of gradient elution on the TSP performance.
The practical use of Thermospray (TSP) HPLC-MS for the analysis of prostaglandins (PGs) and other eicosanoids in biological matrices is dampened by its low structural information and high detection limits (DLs). Derivatization has been used in order to lower DLs as well as to obtain functional information (1-4). Methoximation of oxo groups afford no significant improvement in DLs due to the extensive solvolysis and adsorption of the derivatives in the hot interface. Despite this, these derivatives could be of interest to obtain functional and structural information (5). Methoxime derivatives of prostaglandins with keto groups show spectra with important signals derived from the loss of the methoxiamine group (2). In contrast, methoximes from aldehyde groups show preferently losses of CH$_3$OH (3) and this behavior allows these two oxo groups to be differentiated. Methoximes could also be of interest in the analysis of compounds showing liquid-phase equilibria implying an oxo group (4).

In the analysis of prostaglandin F$_2$-$\alpha$ (PGF), 6-oxo-PGF$_2$-$\alpha$ (6KF), 2,3-dinor-6KF (DKF) and some of their chemical derivatives (Fig.1), some analytically important fragmentation derived signals were observed. In addition, these three prostanoids, bearing in common a 1,3 dihydroxy moiety in the cyclopentane structure, show important chromatographic and spectrometric differences.

**EXPERIMENTAL**

- Methylation and methoximation were carried out as described (3). No purification was performed prior to chromatography.
- A 0.1 M ammonium acetate (AMAC) buffer (pH 4, formic acid) was used for TSP. The mobile phase consisted of AMAC/MeOH or AMAC/ACN mixtures. LC flow-rate was 1 ml/min.
- Chromatography was carried out on 5 micron (15x0.4 cm) or 3 micron (6x0.46 cm) Spherisorb ODS-2 reverse phase columns.
- Mass spectrometer.- A Hewlett Packard (HP) 5988A quadrupole instrument provided with a TSP source and interface (also from HP) was used. Spectra were recorded at 3 different source temperatures (200, 250 and 300 °C). In the filament on mode, electron energy was set at 250 V. The TSP interface temperature was normally adjusted at 110 °C.

**RESULTS AND DISCUSSION**

**MASS SPECTRA.**- The TSP spectra of these compounds are dominated by signals that can be described by:

\[
[M-H+xBA+(H$_2$NOCH$_3$)$_n$]-n(H$_2$O)]^+ \quad \text{(positive ion mode)} \\
[M-H+xBA-(H$_2$NOCH$_3$)$_n$]-n(H$_2$O)]^- \quad \text{(negative ion mode)}
\]

where M is the prostagland molecule and B and A a base and an acid from the eluent buffer, respectively. The integer n ranges from 0 to 3 or 4 and x,y (y is only applied for methoximated derivatives) from 0 to 1. Ion assignments can be made taking in account the MW shift between the compounds assayed and the spectra obtained in different TSP buffers. The relative abundances of these ions are dependent on the particular structure as well as on source and interface temperatures and eluent composition.

The differences observed in the spectra of these compounds (Table I) point to the formation of different ion structures. It is known that 6KF and DKF show various equilibrium forms in solution derived from the nucleophilic attack of
the C9 hydroxy group to the ketone (Fig 1). The presence of these structures in the gas phase as the more stable ionic species is in agreement with the different base peaks observed for the prostanoids assayed (Table I). The [M+H-HjX]+ base peak of some of these compounds can be explained by the formation of a stabilized cation from II.

(b) Ion source temperature 200-250 °C.

**FRAGMENTATION IONS.** These prostanoids show ions implying a loss of 44 amu which cannot be explained as derived from water losses and/or adduct formation with solvent components. The TSP spectra of C9 and C11 deuterated PGFs, obtained from reduction of PGD2 and PGE2, indicate the fragmentation derived ions are mainly due to the loss of the C10-C11 moiety of the structure.

In addition, the TSP mass spectrum of methoximated 6KF shows a group of ions that could be formed from a fragment of MW 267 amu. These ions are not observed in the spectra of PFG or non derivatized 6KF and can be explained for the fragmentation a to the methoxime group with elimination of a methanol molecule. The extension of these fragmentation processes depends on the composition of the eluent. Although in methanol based eluents abundant fragmentation derived ions are formed, in those based on acetonitrile these signals are of low abundance.

**CHROMATOGRAPHY.** The liquid phase equilibria of DKF (I-III in Fig.2) direct its particular chromatographic behavior and complicate its analysis by TSP. The substitution of the oxo group for the oxime makes more difficult the formation of cyclic equilibrium forms and results in narrower HPLC peaks. Some peak broadening can be observed that can not be correlated with different equilibrium forms or methoxime hydrolysis during chromatography and can be seen in the HPLC-UV profiles. This effect is mainly due to adsorption processes implying hydrolysis or ammoniolysis of the MO group in the hot interface or on the surface of the ion source. Ions like [M+H]+ or [M+NH4]+ show narrow chromatographic signals; unlike this, ions derived from losses of methoximamine, as [M+NH4-CH3ONH2]+, show broad signals. As these ions are carrying the major part of the total ion current due to the derivative, DLs focussing in [M+H]+ and [M+NH4]+ ions are higher than expected for this derivative (DLs of 20 ng for DKFMO and 1 ng for DKFMEMO vs 200 pg for POFME).

THE CHARACTERIZATION OF A MIXTURE OF SURFACTANTS USING THERMOSPRAY LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

JOHNNY D. REYNOLDS*, DAVID STUBBS, AND MICHAEL BARRINGER
CIBA-GEIGY CORPORATION, P.O. BOX 18300, GREENSBORO, NC 27419

INTRODUCTION
Surfactant materials are often used as additives to alter the properties and/or the performance of final products. Analytical characterization of these additives is very difficult because of the varying degree of polymerization and concentrations present. The characterization process becomes even more complicated when the additives are blends of multiple surfactant components.

EXPERIMENTAL
The experimental system (Figure 1) was operated in one of two modes, a column mode (switches S1 and S2 in position A) or a loop-injection mode (switches S1 and S2 in position B). A Rheodyne 7125 injector (I) was used in the loop-injection mode. All LC/MS data were collected under the following conditions unless otherwise noted: 1) Waters 600 MS System Pump (W1) operated at 0.5 ml/min to deliver 55:45 0.002M NH₄OAc in H₂O (pH adjusted to 3.0 with TFAA):ACN; 2) Waters Column Oven (W2) was operated at 35°C using a Spherisorb NH₂ column (100 x 3 mm with 3 μm particles) from Keystone Scientific; 3) Waters UV Detector (W3) was operated at 275 nm with output to the TSQ-700 MS instrument; 4) Waters 590 MS Post-Column Pump (W4) was operated at 0.4 ml/min to deliver 0.005 M NH₄OAc in 80/20 MeOH:H₂O; and 5) Finnigan TSQ-700 MS (TSQ) was operated at a source temperature of 180°C, at a TSP vaporizer temperature of 90°C, and in both the +/− TSP modes. In all cases, 25 μg of sample was injected on column.

SURFACANT COMPONENTS
The sample contains cationic (ethoxylated tallowamine; Aₙ, Bₙ, and Cₙ; where n = 2x; Table I), anionic (ethoxylated alkyl-phenol sulfates; Dₙ, Eₙ, and Fₙ), and nonionic (ethoxylated alkyl-phenols; Gₙ and Hₙ; and polyethylene glycol; Iₙ) surfactant components. All components were detected as indicated (Table I); note that the nonionic components were detected as NH₄⁺ adducts.

LC/UV RESULTS
Initially a weak anion exchange liquid chromatography system using a sodium phosphate buffer system was employed to achieve separation of the surfactant components based upon each component's acidity (Figure 2). Elution times were predicted to increase in the order: cationic, nonionic, and anionic. The data illustrate the separation of four major chromatographic peaks (I-IV). With minor adjustments, the buffer system was converted to an ammonium acetate buffer system for MS compatibility reasons (Figure 3).

LC/UV/TSP MS RESULTS
Reconstructed ion chromatograms illustrate the separation of each component (Figure 3). The first chromatographic peak (I) corresponds to the cationic component which contains three major series of tallowamine ions (Aₙ, Bₙ, and Cₙ; Table I; Figure 4 illustrates a typical mass spectrum). The second chromatographic peak (II) corresponds to the nonionic component which actually contains two series of ethoxylated alkyl-phenol ions (Gₙ and Hₙ; Table I) and polyethylene glycol ions (Iₙ; Table I). The third chromatographic peak (III) corresponds to one anionic component which contains a series of ethoxylated alkyl-phenol sulfate ions (Dₙ; Table I). The fourth chromatographic peak (IV) corresponds to a second anionic component which contains two series of ethoxylated alkyl-phenol sulfate ions (Eₙ and Fₙ; Table I). The series of ions corresponding to Dₙ and Eₙ are empirically equivalent, however the proposed structures are consistent with the elution order of the components based on expected acidities. MS/MS experiments have not yielded any useful data to distinguish these two series of ions.

LC/UV/TSP MS OPTIMIZATION
For all series of ions, increasing the discharge voltage caused an increase in the background level, and an overall decrease in the signal/noise ratio for the ions in each series. The TSP vaporizer temperature optimized at 90°C for all ions in each series. The source temperature (Figure 5) and post column buffer concentration (Figure 6) optimization varied for each surfactant component.

A COMPARISON OF LC/MS TECHNIQUES FOR PHARMACEUTICAL ANALYSIS

Bethanne M. Warrack, Mark S. Bolgar, and Gerald C. DiDonato
Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ

INTRODUCTION

The development of a variety of interfaces for LC/MS offers the analyst a choice of methodologies for characterizing multicomponent samples. A comparison of heated nebulizer atmospheric pressure ionization and ion spray atmospheric pressure ionization using a Sciex API III mass spectrometer, and continuous flow FAB (CF-FAB) using a VG ZAB-HF mass spectrometer for the analysis of pharmaceutical samples is presented. The sensitivity and selectivity of each of these techniques is evaluated for several classes of drugs.

EXPERIMENTAL

Continuous flow FAB spectra were obtained using a VG universal FAB ion source and probe. Flow rates of 5 μl/min into the source were used. Mobile phases contained water and CH3CN, with 5% glycerol. Heated nebulizer atmospheric pressure ionization and ion spray spectra were obtained on a Sciex API III mass spectrometer. Zero grade air was used as the nebulization gas for heated nebulizer atmospheric pressure chemical ionization. Ultra high purity nitrogen was used as the nebulization gas for ion spray. Collisions were 40 eV with argon.

RESULTS

Benzazepine Calcium Entry Blockers are amenable to all three techniques with limits of detection in the low picogram range. The CF-FAB interface provides the lowest limit of detection--50 pg for full scans, and less than 10 pg for SIM experiments. Full scan spectra can be obtained on 100 pg using either the heated nebulizer or ion spray interface. Ion spray SIM and selected reaction monitoring (SRM) experiments have a limit of detection of 50 pg. Ion spray full scan daughter ion spectra require 5 ng of compound.

The CF-FAB mass spectra of mycosamine containing Polyene Antifungals, such as amphotericin, exhibit intense pseudomolecular ions. The full scan limit of detection using this interface is 500 pg. Ion spray mass spectra are similar, but the limit of detection is 2.5 ng. No pseudomolecular ions are observed when the heated nebulizer interface is used.

The ion spray interface provides intense pseudomolecular ions for the analysis of thermally labile Monobactam Antibiotics, such as aztreonam. In the negative ion mode, the full scan limit of detection is 500 pg. Using CF-FAB in the positive ion mode, 5 ng are required for full scan spectra. As would be expected for thermally labile compounds, only thermal decomposition products are present in positive or negative ion spectra obtained with the heated nebulizer interface.

Decalin ring containing Cholesterol Lowering Agents, such as pravastatin and lovastatin, exist as either carboxylic acids or pro-drug lactones. For analysis of the lactone forms, both CF-FAB and heated nebulizer spectra exhibit intense pseudomolecular ions with limits of detection of 500 pg. Structurally informative full scan daughter ion spectra are obtained with 4 ng. The ion spray spectra of these neutral molecules show only (M+NH4)+ at levels of 50 ng.

For the carboxylic acid forms, the lowest limits of detections (500 pg) are obtained by ion spray or CF-FAB. Less than 250 pg can be detected using SIM. Ion spray full scan daughter ion spectra require 10 ng of compound. Limits of detection using the heated nebulizer interface are 100 ng for full scan and 5 ng for SIM.

An Improved Atmospheric Pressure Ionization Interface for LC/MS on a Bench-Top Mass Spectrometer.

Timothy Wachs and Jack Henion, Drug Testing and Toxicology, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Although our goal of performing routine LC/MS on a small bench-top mass spectrometer has been demonstrated [1,2], the sensitivity of our first system was compromised by the limited pumping speed. Sensitivity of the atmospheric pressure ionization interface can be increased by increasing the diameter of the sampling orifice and/or skimmer. Although this allows more ions to enter the system, it also places a heavier gas burden on the pumping system. Thus for a simple interface, a very high pumping speed is need. The pumping capacity can be reduced (along with the cost) if one or more stages are added to the interface that permit separation of ions from the neutral gas.

Rather than increasing the pumping speed of the high vacuum analyzer region of our system, we have chosen to increase the ratio of ions to neutral gas molecules in an intermediate rough pumped region. An RF-only quadrupole lens system was selected as the method for transmitting the ions to the mass analyzer while reducing the amount neutral gas entering the analyzer. A diagram of this instrument is shown in Fig 1. The mass spectrometer is a Hewlett-Packard 5790 MSD that has an enlarged analyzer housing and a 330 L/sec turbomolecular pump. All of the ion optics were removed with the exception of the mass analyzer quadrupole and the detector. The ions that enter the analyzer are confined by an RF-only quadrupole lens system that is capacitively coupled to the mass analyzer quadrupole by butting the two sets of rods together separated by 0.001 in mylar spacers.

The ions entering the analyzer in the previous version of this system [3] exited the skimmer of the heated capillary/skimmer [4] interface. In our latest system an intermediate RF-only quadrupole stage has been added. This lens is directly connected to the other RF-only quadrupole via copper/nylon feed-thrus. (Capacitive coupling was also tried but little difference in performance was noticed between the two methods.) This region is pumped with a inexpensive rough pump. Pressures are indicated on Fig 1 for the various regions.

Although the new system demonstrates a sensitivity increase of a factor of 3-5, problems were encountered when the instrument was scanned over more than several amu or when SIM was attempted. The problem was traced to what we believe may be a charging phenomenon. The quadrupole was referenced to ground through a resistor network. When a slight positive voltage was applied to the quadrupole, the system then worked normally. The voltage required seems to have some dependence on the scan rate. This is being studied further.

In order to increase the rate of removal of gas from the intermediate region, a quadrupole was constructed from mesh instead of solid rods. A decrease in sensitivity of a factor of 4 was observed with the mesh rods. Obviously more studies need to be done on both the effects of pressure in this intermediate region as well as the actual quadrupole construction.

LC/MS runs with the new system on a mixture of pesticides at the 50 ng per component level at 3.4 sec scan over the mass range of 10 to 450 demonstrate the utility of the instrument. SIM experiments with LSD at the 250 pg level from a 1 x 100 mm LC column show a factor of 5 fold increase in sensitivity over the previous system. An LOD of 100 pg is now possible. The additional stage can also provide CID type spectra by increasing the potential on the skimmer, although not with the same sensitivity as that which occurs between the capillary and skimmer.

HPLC/MS FOR THE DETERMINATION OF AMINOGLYCOSIDES USING ATMOSPHERIC PRESSURE IONIZATION

Lee McLaughlin and Jack Henion, Drug Testing and Toxicology, Cornell University
925 Warren Dr., Ithaca, NY 14850

As part of a regulatory effort for determining aminoglycoside residues in tissues and milk of livestock, the U.S. Food and Drug Administration (FDA) requires confirmatory methods based on mass spectrometry. Because of their polar, basic nature and thermal lability in some cases, these compounds cannot be determined directly by GC/MS. However, methods based on HPLC/MS and HPLC/MS/MS could provide direct, on-line identification of these drugs in complex biological matrices. Existing HPLC methods for their determination in animal tissues employ fluorescence detection of derivatized analytes (1). There are few reports of aminoglycoside determinations by HPLC/MS. Considering the nature of these analytes, the unique features of the ion spray HPLC/MS interface make it worth investigating for this application.

Most reported HPLC methods are based on some form of ion chromatography, ion pairing or ion exchange for example, because the aminoglycosides are difficult to retain in the reversed-phase mode, even with an entirely aqueous eluent (2). The majority of reported conditions are not well-suited for use with the ion spray interface due to the presence of high concentrations of non-volatile buffers and alkali salts. Samain et al. have reported the use of volatile acids such as pentafluoropropionic acid (PFPA) as ion pairing agents to separate aminoglycosides in the reversed-phase mode (2). Here we explore this approach for determining aminoglycosides by ion spray LC/MS. The HPLC method is also compatible with a commercial pulsed amperometric detector. Data are presented for six priority compounds: spectinomycin, hygromycin B, streptomycin, dihydrostreptomycin, gentamicin C, and neomycin B in selected ion monitoring (SIM) and selected reaction monitoring (SRM) modes of operation.

EXPERIMENTAL

Separations were developed using a Gradient Pump Module and PAD 4500i pulsed amperometric detector ( Dionex Corp.) on a Spherisorb ODS-2, 4.6 mm i.d. x 100 mm column at a flow rate of 1 mL/min. HPLC/MS work was done with a Spherisorb ODS-2, 2 mm i.d. x 100 mm column at a flow rate of 200 µL/min using a Waters Model 510 pump. Mobile phases consisted of 8% acetonitrile (ACN) in 20 mM PFPA for isocratic separation of four of the analytes and 22% ACN in 20 mM PFPA for isocratic separation of gentamicin and neomycin. Column effluent was split with a PEEK tee such that 20-40 µL/min reached the ion spray interface that was maintained at 3.4 kV. The mass spectrometer, a Sciex TAGA 6000E upgraded to an API III, was used in the positive ion mode. Collision-induced dissociation (CID) experiments were accomplished with argon at 180 x 10^12 atom/cm² and collision energies of 76 eV (laboratory frame). Control bovine kidney was fortified at the 20 ppm level with four of the analytes and extracted using the matrix solid phase dispersion (MSPD) technique (3) with modifications for this class of compounds (4). Analytes were eluted from the MSPD column with 1 mL water and 8 mL 0.1 N sulfuric acid. An aliquot of the 9-mL eluate was concentrated by a factor of 4, neutralized with ammonium hydroxide, and 10 µL injected onto the HPLC column.

RESULTS AND DISCUSSION

Although increasing concentrations of PFPA in the mobile phase were found to decrease ion spray response, a concentration of at least 10 mM is necessary for adequate chromatographic resolution and 20 mM provided the best separation efficiency on the Spherisorb ODS-2 column. The gentamicin C components and neomycin B are more highly retained than the other four analytes and cannot be eluted unless a gradient program is used. Here, we have used two separate isocratic methods. Improvements are needed with respect to resolution of the gentamicin C components and peak tailing of the gentamicins and neomycin B.

Under these conditions doubly charged ions predominated for all analytes except spectinomycin for which singly charged ions were observed. The mass spectra exhibit high chemical noise especially at the relatively low m/z of the doubly charged ions. Extracted ion current profiles from ion spray LC/MS in SIM mode for four analytes are shown in Figure 1. Confirmation is accomplished by LC/MS/MS in the SRM mode. CID spectra of all
compounds except spectinomycin and hygromycin B contain at least three abundant product ions which can be monitored for confirmation. The detection limit for dihydrostreptomycin by LC/MS/MS SRM was found to be approximately 5 ng injected on-column. Results for gentamicin and neomycin with LC/MS/MS SRM are shown in Figure 2. A bovine kidney extract fortified at 20 ppm of spectinomycin, hygromycin B, streptomycin, and dihydrostreptomycin was analyzed by LC/MS/MS in the SRM mode and no matrix interferences were observed at this level. See Figure 3. This concentration corresponds to injection of 40 ng of analyte on-column assuming total extraction recovery. Given detection limits of approximately 5 ng for this method, it should be possible to reach the desired low to sub-ppm levels in bovine kidney by further concentration of the 9-mL MSPD eluate and by increasing extraction recovery.

ACKNOWLEDGEMENTS

The authors thank the U.S. FDA for funding this work under agreement # FD-U-000577-02 and Dionex Corp. for the generous loan of the pulsed amperometry system. Mr. Mark Mercer and Dr. Phillip Kljak are acknowledged for many helpful discussions.

REFERENCES

Antibiotics are commonly used for the prevention and treatment of disease in farmed animals raised in crowded conditions. A major concern is that residues of these compounds may be present in the final food product if proper withdrawal times for treated animals have not been strictly enforced. Tolerance levels (typically 100 ppb (ng/g)) must be enforced through monitoring programs.

Immunoassay techniques are ideal for the routine screening of food products for antibiotics. However, instrumental methods of analysis are usually required for confirmation, especially in a regulatory situation, since immunoassays are often subject to false positives. Legal cases usually demand a spectroscopic proof of identity, with mass spectrometry being the most accepted. Spectroscopic techniques are also essential for the identification of metabolites of drugs which may also be of concern in monitoring programs. Most antibiotics and their metabolites are difficult to analyze by GC-MS, since they are polar and thermally-labile. The lower molecular weight compounds can be converted to volatile derivatives, but such analyses are complicated and require extensive sample clean-up. All antibiotics can be analyzed by HPLC, however. Therefore, the combination of liquid chromatography and mass spectrometry (LC-MS) is clearly the most desirable method for confirmatory determinations.

We have evaluated various ionization and interfacing methods for the LC-MS analysis of antibiotics used in the aquaculture industry, and tested their application to the confirmation of residue levels in farmed salmon. The methods that have been compared include: ion-spray (ISP), thermospray (TSP), particle beam interface (PBI, both EI and CI), and moving belt interface (MBI, both EI and CI). The antibiotic and antimicrobial drugs that have been examined include: oxytetracycline (OTC), erythromycin (ETM), penicillin G (PCG), oxolinic acid (OLA), sulfamerazine (SMR), sulfamethazine (SMT), Romet-30® (sulfadimethoxine (SDM) and ormetoprim (OMP)), and Tribriessen® (sulfadiazine (SDZ) and trimethoprim (TMP)).

A comparison of the spectra generated for one compound, oxytetracycline (OTC), by the different techniques is provided in Figure 1. Ion-spray, an atmospheric pressure ionization technique, provided the greatest sensitivity and ease of interfacing with LC. Detection limits for standards ranged from 5 to 50 pg for selected ion monitoring; good spectra could be acquired on 1 to 10 ng of standard. Thermospray was the next most sensitive with detection limits of 1 to 10 ng with selected ion monitoring; good spectra required 50 to 500 ng. The particle beam and moving belt interfaces were able to provide good chemical ionization spectra for most of the compounds, but required levels ranging from 100 ng to 5 µg. Only the potentiators, OMP and TMP, gave good EI spectra with either of these interfaces. All other compound fragmented extensively or decomposed thermally.

Thermospray, particle beam and moving belt interfaces did not have the sensitivity required for the analysis of actual fish tissue samples with the conventional extraction methods used for HPLC screening. Only ion-spray LC-MS was able to provide detection limits at the ppb level (in salmon flesh) for all compounds tested. Excellent quantitation was also possible with ion-spray LC-MS. Tandem mass spectrometry on the triple quadrupole SCIEX API-III instrument was found to be useful for additional confirmation of structures and for selective detection of analytes with selected reaction monitoring. Figure 2 presents the ion-spray LC-MS analysis of salmon flesh contaminated with 160 ppb (ng/g) of OTC.

Steroids and prostaglandins play important roles as hormones in many biological systems. Water soluble metabolites of these compounds have recently been implicated as prime candidates for fish sexual pheromones [1]. Herring milt appears to contain such a spawning pheromone that would have practical significance in the "roe-on-kelp" industry [2].

Ionspray (ISP) is a recently developed atmospheric pressure ionization (API) technique, well suited for the mass spectral analysis of polar and thermally labile molecules of marine origin. The ISP technique is proving to be a practical interface for the routine coupling of liquid chromatography with mass spectrometry (LC-MS) [3]. We have developed LC-API-MS methods for the analysis of mixtures of underivatized steroids, their glucuronide and sulfate conjugates, and prostaglandins. Under positive ion ISP conditions the steroidal compounds produce abundant protonated molecules which are ideal for the detection of trace levels by LC-MS using selected ion monitoring and also as precursors in tandem mass spectrometric (MS-MS) experiments for structural confirmation. The ISP-MS and ISP-MS-MS spectra of testosterone glucuronide (100 ng) obtained by flow injection analysis are presented in Figure 1a and 1b, respectively. The MH+ ion of the conjugated steroid is clearly observed at m/z 465 in Figure 1a and this ion undergoes collision-induced dissociation to yield a characteristic product ion at m/z 289 (Figure 1b) corresponding to the parent testosterone. The prostaglandins were best analyzed in the negative ion mode, generally providing abundant deprotonated molecules, [M-H]-.

Figure 2a shows the analysis of a mixture of both free and conjugated steroids by LC-MS using selected ion monitoring. The separation was achieved on a 2.1 mm i.d. Vydac 201TP column using a mobile phase of aqueous acetonitrile containing 0.1% trifluoroacetic acid (TFA) at a flow rate of 200 μL/min. A linear gradient of 5% to 60% acetonitrile over 50 minutes was used. The reconstructed ion chromatogram is comprised of the MH+ ions of all the compounds. Similar results were obtained for mixtures of prostaglandins in the negative ion mode using acetic acid instead of TFA.

We have applied LC-MS and LC-MS-MS techniques to the screening of bioactive extracts from herring milt and testes for likely pheromone candidates. Figure 2b shows the ion chromatogram of m/z 465 extracted from the full-scan LC-MS analysis of a herring milt extract. The chromatographic peak at around 32 mins corresponds to the correct retention for the testosterone glucuronide standard (Figure 2a). LC-MS-MS experiments using selected reaction monitoring provided additional supporting evidence. Other steroidal compounds have been identified in this manner and have been subsequently isolated and their structures confirmed by high resolution mass spectrometry using fast atom bombardment and also nuclear magnetic resonance. We are currently assessing the bioactivity of these compounds.

b) m/z 465
Atmospheric pressure ionization mass spectrometry (API-MS) is rapidly becoming a universal detection system for the separation sciences. The ionspray interface (ISP) introduced by Henion and co-workers in 1982, has had a tremendous impact on the development of combined liquid chromatography mass spectrometry (LC-MS) [1]. Unfortunately, one of the problems associated with "soft" ionization techniques like ISP and the earlier developed thermospray (TSP), is that common MS reference compounds, such as PFK, cannot be used to calibrate the mass spectrometer. Polymers, such as polypropylene glycol (PPG), are generally used as calibrants in both TSP and ISP. Unfortunately, PPG mixtures are not the most suitable candidates for reference compounds, causing rapid contamination of the ion source in TSP [2,3]. In addition, it is often difficult to identify individual PPG oligomer peaks in the complex spectra obtained with the mixtures used to cover the entire mass range. There is a clear need for a more universal calibration method in ISP.

Cesium iodide cluster ions (Cs_{n}ln-i^{+}), and other alkali metal halide salts, are routinely used as mass calibration standards in fast atom bombardment (FAB) and liquid secondary ion mass spectrometry (LSIMS). However they have not thus far been amenable to any of the spray techniques. We report here on the formation of these and related cluster ions by ionspray ionization, under conditions typical of those used in LC-MS analyses of peptides and proteins. The spectrum shown in Figure 1 was obtained by flow injection analysis of 5 µL of a 0.1 mg/mL solution of CsI in water into a 10 µL/min flow of aqueous acetonitrile (50:50) containing 0.1% trifluoroacetic acid. Similar spectra were obtained, though at lower intensities, at flow rates of up to 50 µL/min. The well-known Cs_{n}ln-1^{+} ion series is observed (the Cs^{+} peak at m/z 133 was extremely intense, and has been omitted from the Figure). In addition, unexpected satellite peaks at lower mass are also observed for each of the Cs_{n}ln-1^{+} clusters. As shown more clearly in the insert in Figure 1, the spacings of these satellite peaks are all 14 Da, and the number of satellite peaks observed increases with the mass of the CsI cluster to a maximum value given by the number (n-1) of iodide ions in the particular cluster ion. These satellite peaks correspond to progressive replacement of iodide (127 Da) by the trifluoroacetate anion (TFAc; 113 Da) present in the mobile phase. Such a substitution for iodide is reminiscent of that observed for FAB ionization of CsI in glycerol-water mixtures, where the glyceride anion C_{3}H_{7}O_{5}^{−} substituted for one iodide per cluster ion [4]. In addition to the satellite peaks described above, other peaks due to cluster ions of the Cs_{n}ln-1^{+} series with mobile phase molecules are observed. For example the peak at m/z 534 in Figure 1 corresponds to the cluster [Cs_{2}I + (MeCN)_{3} + H2O]^{+}. Table 1 lists the molecular formulae and accurate masses of selected calibrant ions observed in this work.

An alternative approach to calibration for LC-MS is to use the mobile phase itself. It has been shown previously that acetic acid-ammonia cluster ions [(CH_{3}COOH)_{x} + (NH_{3})_{y} + NH_{4}]^{+} can be generated under certain conditions in TSP ionization to provide a convenient mass calibration over the range 100-1000 Da [2]. This range has also been extended to higher mass by the use of perfluorinated alkyl acids in place of acetic acid [3]. We have developed similar approaches for ISP using solutions of aqueous acetonitrile or methanol containing small percentages (0.1-5%) of acetic,
formic or trifluoroacetic acids which are commonly used as mobile phases for LC-MS in our laboratory. By optimization of the source parameters, intense mobile phase cluster ions can be selectively generated across the mass range (m/z 100-1500) which are suitable for calibration purposes.

Figure 1 Ionspray spectrum of CsI obtained by flow injection analysis
There is growing interest and awareness in the role played by sugars and other carbohydrates in biological systems. The analytical determination of these saccharides presents a significant challenge, however, since GC-MS cannot be used because of their thermal lability, and since LC is problematic because they have no chromophore. Several mass spectrometric techniques, have been successfully applied to study saccharides, so there is great interest in developing LC-MS methodology for this purpose. Thermospray LC-MS has been used to determine some mono- and di-saccharides, but it has not been successful for tri- and higher saccharides.

We have explored the use of an API (atmospheric-pressure ionization) LC-MS interface for this application, taking advantage of chemical ionization processes possible with this interface. Because of the high frequency of intermolecular collisions that occur in the APCI source, adduct ions and cluster ions are formed more effectively than is the case with ionization mechanisms that operate at low pressures or in a vacuum. Specifically, we used the attachment of chloride ions to hydroxyl groups in saccharides within the APCI source.

The work was carried out on an LC-MS instrument incorporating an atmospheric-pressure chemical ionization (APCI) interface similar to ones described in earlier work (1,2). The LC eluent is sprayed from a heated nebulizer, passes a vaporizer section where it is fully converted into an aerosol, and then it passes a corona discharge formed at the tip of a needle, all at atmospheric pressure. The ions enter an reduced pressure stage first and then into the high vacuum of the quadrupole analyzer. A voltage applied across the two apertures at the entrances to these two regions provides sufficient kinetic energy to strip away the solvent shell around analyte molecules as they pass through the reduced pressure region. Higher values of this “drift voltage” result in fragmentation of analytes (by collision-induced dissociation), and structural information about the analyte can be deduced from the fragmentation pattern.

The ionization process is initiated when a hydroxy hydrogen is stripped away from its oxygen atom in the corona discharge. The resulting alkoxyl or hydroxyl group then extracts a hydrogen from chloroform (added at a low level to the LC mobile phase), which in turn yields Cl⁻ ions as it falls apart. These chloride ions will interact with the hydroxy groups in a saccharide, but the resulting complex has too much internal energy to be stable. This excess energy is lost through the frequent molecular collisions occurring at atmospheric pressure, stabilizing the ion-molecule pair, that can then be detected in the mass spectrometer. Chloroform is a key factor; trials with CCl₄ and CH₂Cl₂ yielded sucrose peaks orders of magnitude smaller. The appearance of vacancy peaks in mass chromatograms, at mass values corresponding to Cl⁻ and to Cl⁻ complexed with one and with two methanol molecules (see Fig. 1) provide supporting evidence for the involvement of these as reagent ions in the APCI source.

Fig. 2 shows the quantitative analysis of several saccharides, where peak area is plotted as a function of the amount injected. In the top panel, no major difference resulted for mobile phase chloroform content ranging from 0.5% to 5%, but the signal intensity decreases when the chloroform content was dropped to 0.05%. Good linearity was demonstrated for between 1 and 100 ng injected (with a 4.0 x 250 mm LiChrosorb NH₂ column) for most saccharides, as shown in the lower panel of Fig.2. Fig. 3 shows the mass spectra obtained with chloride attachment LC-negative ion-APCI-MS for 1 μg each (by flow injection) of underivatized D-arabinose, D-glucose, and D-galactose.

We have injected several monosaccharides and disaccharides with good results. This chloride attachment chemical ionization method is easily implemented, requiring just the addition of a small amount of chloroform to the mobile phase in reversed-phase separations. Detection limits are attractive, below 1 ng (glucose) by SIM mode.

Atmospheric pressure chemical ionization (APCI) and Electrospray ionization (ESI) are complementary ionization techniques for liquid chromatography-mass spectrometry. Together these two ionization techniques can allow the analysis of most chemical classes. The range of molecules that can be efficiently ionized by each technique overlaps greatly, with APCI giving best sensitivity for molecules that have relatively low polarity to those with moderately high polarity. ESI yields the best sensitivity for ionic species, however, good ionization efficiency can be obtained for moderately polar molecules. ESI also gives the benefit of multiple charging, thus allowing the determination of high molecular weights on a compact quadrupole mass spectrometer.

In an atmospheric pressure ionization mass spectrometer, the ionization source is outside of the mass spectrometer. This allows very low maintenance on the high vacuum system since most of the solvent is removed at atmospheric pressure. Since the analyte is then expanded into a vacuum, adiabatic cooling occurs, causing analyte-solvent clusters to be formed. A collisionally induced dissociation (CID) technique is used to desolvate the analyte. Both ESI and APCI are soft ionization techniques, forming only molecular ions. By increasing the energy of the CID (Drift Voltage), one can cause easily controllable fragmentation of the analyte ions with APCI or ESI.

Two atmospheric pressure ionization sources - Electrospray ionization (ESI) and Atmospheric Pressure Chemical Ionization (APCI) have been developed for a Hitachi M-1000 single quadrupole mass spectrometer. These ion sources have been designed to be readily interchanged on the mass spectrometer, switching between the two ionization modes requires no tools and only a few minutes. The LC/MS system is comprised of a Hitachi L-6200 gradient HPLC pump, a Rheodyne injection valve, ionization source (either ESI or APCI), Differentially pumped CID region, single quadrupole mass analyzer, electron multiplier, and an LC/MS data station.

The APCI source uses a heated nebulizer, followed by a vaporizer and a corona discharge needle. Ionization occurs by gas phase ion-molecule reactions between the solvent (which acts as the chemical ionization reagent) and the analyte. Collisionally induced declustering occurs in an intermediate pressure (~1 torr) region. The bare analyte ions are then mass analyzed. This source allows flow rates from 0.2 ml/min to 2 ml/min. There is little sensitivity change due to nebulizer temperature variations, allowing multiple solvents to be used in gradient elution chromatography runs. The CID region consists of multiple apertures, each 0.3 to 0.5 mm id, to which a voltage differential is applied (Drift Voltage). The ESI source consists of a teflon inlet tube to a 0.1 mm id capillary tube to which 3-6 kV is applied. Nitrogen flows concentric to the capillary and both assists in the nebulization of the eluent, but also causes evaporation of the solvent from the charged, nebulized droplets. This design obtains efficient analyte charging and solvent removal without the use of a curtain gas. The analyte is ionized in the liquid-phase and ions are evaporated or ejected from the droplets. The capillary is off axis from the CID inlet to improve signal to noise by minimizing solvent that enters the mass spectrometer. Ions are directed into the CID region by the high voltage differential between the capillary and the inlet aperture. The ESI source uses the same electronics as the APCI source, including the HV supply. The CID region is also shared. The ESI source mounts to the front of the CID region by means of thumb screws.

In the data presented, examples are given for APCI, showing the use of ion selective detection of steroids, and the effect of the drift voltage for controlling the level of fragmentation from none to complete fragmentation. Examples are also given for ESI showing the determination of various proteins, and also an example of the use of ESI for smaller molecules, again demonstrating the use of controlled fragmentation. A calibration curve is presented showing linear response down to 100 pg (680 femtomoles of acetylcholine).

The applications of capillary electrophoresis (CE) are expanding rapidly, and a number of commercial instruments are now available. As applications have developed, the advantages of CE combined with mass spectrometry (MS) have been increasingly recognized. The first CE-MS was based upon an electrospray ionization (ESI) interface. Alternative CE-MS interface designs have also been reported based upon continuous flowing fast atom bombardment (CF-FAB) mass spectrometry. However, the ESI methods appear to offer clear advantages in most cases due to better sensitivity, reduced background, applicability to higher molecular weight compounds, and interface designs which do not require long transfer lines or incur a pressure drop across the capillary. To date, none of the CE-MS instrumentation has effectively utilized the full capabilities of the automated CE instruments now commercially available.

Our aim has been to exploit all the advantages of automated CE instrumentation, and particularly provisions for capillary temperature control by modifying a Beckman P/ACE 2000 capillary electrophoresis instrument to accept an ESI interface; to evaluate the performance of the combined instrument on separations of biological materials, and to demonstrate the capabilities of mass spectrometry combined with CE. The Beckman P/ACE 2000 system, as sold by the manufacturer, was too large to be mounted close to the inlet of our mass spectrometers. We opted to separate the P/ACE 2000 system into two subunits according to their practical and logical functions. The autosampler, interface block, optics module and detector were removed from the mainframe and mounted in a box as a separate "experimental module". The system power supplies (high and low voltage), controller, keyboard, temperature and pressure controls were left on the main frame as a "control module". The interface block of the instrument (which holds the capillary cartridge) was modified by the addition of an extension. The extension is sealed by septa at each end, has separate inlet and outlet lines for the cooling fluid and bolts onto the block immediately below the normal capillary exit. With the downstream septa removed the capillary can be threaded through the extension without removing it from the instrument. With this arrangement, a capillary of approximately 35 cm additional length is required. This length will be reduced in the future by direct incorporation of the electrospray interface at the end of the extension.

The performance of the combined CE-MS system was evaluated in these preliminary studies with a mixture of myoglobin proteins (M~17 kD). The separation was done in 10 mM TRIS buffer at pH 8.3 with an electric field strength of 120 V/cm. Approximately 100 femtoles per component was injected onto the capillary column. The results show that the ESI-MS interface has not degraded the quality of the separation by broadening of the peaks due to the electrospray source. In fact, these peak widths are sufficiently narrow to exceed current capabilities when signal intensities are low and slower scan speeds required. For targeted compound analysis (using single ion monitoring) peaks of 0.1 seconds in width could be detected.

An example of a separation of a more complex mixture is a tryptic digest of tuna cytochrome C. The digest was initially infused into the mass spectrometer and an ESI mass spectrum recorded. The most prominent ions in the spectra were identified and these were monitored in a multiple ion detection CE-MS experiment.

The results of a single ion monitoring experiment are shown in Figure 1. The detection of two different charge states for a fragment allows the assignment of charge and mass with greater certainty. This is particularly useful when the singly charged ion would be beyond the mass range of the instrument as in the TIQ fragment. Some results of a scanning experiment under the same conditions over the mass range from 710 to 1220 daltons at 1.3 sec/scan are shown in Figure 2. The spectra were taken as the TIQ fragment eluted. The doubly and triply charged ions are prominent. In addition, dissociation of the ions in the mass spectrometer interface produces ions characteristic of the sequence of the...
fragment. With good resolution in the separation, such fragmentation is equivalent to an MS/MS experiment and permits the unambiguous identification of the fragment in cases where the mass alone is insufficient.

This work was generously supported by Beckman Instruments Inc. and the U. S. Department of Energy, Office of Health and Environmental Research, under contract DE-AC06-76RLO 1830.

Pacific Northwest Laboratory is operated by Battelle Memorial Institute.

INTRODUCTION

Although examples of CZE-MS have been reported, the structure information obtained other than the molecular weight is lean, and an MS/MS coupled to CZE is much more desirable.

GOAL

To couple coaxial flow FAB, developed by Tomer, Jorgenson and coworkers[1] with a tandem mass spectrometer having extended mass range array detection.

CONSIDERATIONS FOR CZE IN CZE/MS

- Column Diameter. Fine capillary(<13 um i.d.) has to be used on account of the vacuum of the MS source chamber. Loss of resolution and weak UV signals are resulted (Fig. 1).
- Column Length. The continuous FAB probe is ca. half a meter long; therefore, the capillary for CZE cannot be shorter than 0.8 m. Rapid analysis is not likely.
- Viscosity of the Buffer. We suggest that efforts to increase viscosity are not productive.
- Voltage. The highest available voltage 30 kV of the CZE unit is reduced to an effective voltage of 22--24 kV due to an accelearing voltage of 6--8 kV at the probe tip, leading to considerably lower potential gradient.

CONSIDERATIONS FOR THE CZE/MS INTERFACE

Coaxial Flow FAB.
1. The probe is composed of a long coaxial flow path (see Fig. 2) and band broadening is kept minimal.
2. Such a probe is compatible with low flow rate analysis system such as micro HPLC or CZE, the latter being especially suitable.

CONSIDERATIONS FOR THE MASS SPECTROMETER

Operating Parameters.
1. Scan Speed. The high scan speed of ZAB-T matches the sharp peaks of CZE.
2. Sensitivity. The array detector provide a high sensitivity, on the order of low femtomoles and meets the demanding sensitivity requirement of CZE with a fine capillary.

EXPERIMENTAL

1. CZE Apparatus. ISCO (Lincoln, NE) Model 3850.
2. MS. VG ZAB-T, (Manchester, England) of B-E-B-E four sector design and a 15 x 15 cm array detector.

RESULTS

1. Sensitivity of the MS. At a mass flow of 12 fmol/s of brakdykinin, the observed S/N for detecting the molecular ions is approximately 50:1.
2. Mass spectrum of bradykinin introduced through the CZE capillary. See Fig. 3.
3. Further details are to be studied.

Figure 1. Electropherograms of capillaries of different sizes. UV detection at 215 nm. ELECTROCHROMATOGRAPHY/ESI/MS USING NANOSCALE CAPILLARY LC

Frantisek Pehal, Carol Parker, John R. Perkins and Kenneth B. Tomer

Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC 27709

Electrochromatography consists of liquid chromatography in which an electrical potential is applied across the column (1-4). This separation method, which utilizes mobility and sorptive interactions simultaneously, may be an alternative to CZE or conventional liquid chromatography for separation of components.

There are several potential advantages associated with electrochromatography. One advantage is the plug-glow obtained by electroosmotically driven chromatography which can result in higher efficiencies. The portioning of analytes between stationary and mobile phase is identical (3). Another advantage is the use of the high voltage as a modifier in conventional HPLC. In these experiments, a potential is used to retard or elute charged components (4). Verheij has also recently described the combination of electrochromatography with MS using CF-FAB interface.

The nanoscale electrochromatography column used in these experiments consists of a 135 cm long by 75 μ id fused silica column. The column is packed to a depth of 31 cm with Vydac AQC18. A short, 0.1 - 0.3 mm length of tubing that has been drawn out to a fine tip is used as the frit. The injection end of the column is placed in a buffer solution inside of a plexiglass pressure vessel. The high voltage source for the electrochromatography is wired into a lead that is inserted into the buffer solution inside the reservoir. Pressure for the LC component is provided by helium pressure introduced into the plexiglass vessel via a fused silica line. The entire apparatus is enclosed in a plexiglass box fitted with safety interlocks (the same as used for our CZE/MS interface). Samples are loaded onto the column using pressurized introduction. The column is inserted into the sheath flow column of a modified Vestec ESI probe. The end of the column is at the ESI needle, which acts as ground for the electrochromatographic column (3 kV). The mass spectrometer used is a VG 12-250 quadrupole mass spectrometer that has been fitted with a Vestec 611B Electro spray source.

As an example of electrochromatography the separation of the aminobenzoic acid ethyl ester (ABEE) derivatives of three oligosaccharides (2-acetamido-2-deoxy-6-O-(B-D-galactopyranosyl)-D-glucopyranose ABEE derivative, 2-acetamido-2-deoxy-3-O-(B-D-galactopyranosyl)-D-glucopyranose ABEE derivative, and 2-acetamido-6-O-(2-acetamido-2-deoxy-B-D-galactopyranosyl)–2-deoxy-D-glucopyranose ABEE derivative) is shown using nCLC, CZE and electrochromatography. Elution orders under EC are the same as with nCLC, but retention times are shorter.

These examples demonstrate the feasibility and the advantages of coupling electrochromatography with ESI/MS. Good separations and detection limits are observed. Separations are different from those obtainable by nCLC or CZE alone. This electrochromatography system is simple and can be used either as nCLC (without high voltage) or CZE (without pressure). The columns are quite easy to pack. Electrochromatography might be another way to solve separation problems in addition to CZE and LC.

The Determination of Veterinary Drugs using Nanoscale Separation Techniques In Combination with Electrospray Mass Spectrometry.

John R. Perkins, Carol E. Parker and Kenneth B. Tomer,
Laboratory of Molecular Biophysics, NIEHS, Research Triangle Park, NC 27709.

Introduction

In animal husbandry and fish farming veterinary antibiotics may be administered to livestock for therapeutic purposes or to promote growth. Absorption of the drugs in tissues may occur such that when the half life of the drug is sufficiently long then there is a risk of the presence of residues in tissues prepared for human consumption. The low levels at which these drugs may be present in tissues mean that sensitive analytical methods are required for their screening.

Our laboratory has been interested in the applications of nanoscale capillary liquid chromatography (nCLC) using 2m x 75 μ l.d. packed capillary columns packed to a depth of 25cm with 10 μ AQ C-18 and capillary zone electrophoresis (CZE) using 75 μ l.d. fused silica capillaries in conjunction with electrospray (ESI) mass spectrometry. These techniques utilize sub-microliter flow rates so sample consumption is limited. The make up flow (50:50 methanol : 3% acetic acid ) required for stable operation of the electrospray source is provided through the electrospray probe via a co-axial arrangement. Water containing 0.1% TFA was solvent A throughout the nCLC work. Solvent B was acetonitrile containing 0.1% TFA for the sulfonamide and acid separations and methanol containing 0.1% TFA for the tetracyclines. The buffer employed for CZE was ammonium acetate adjusted to pH 7 with ammonium hydroxide. The mass spectrometer used throughout the experimental work was a VG 12-250 quadrupole with a Vestec electrospray source and controller.

Results and Discussion

Electrospray spectra have been successfully acquired for a variety of veterinary drugs including sulfonamides, quinolone carboxylic acids, tetracyclines, β lactams, lincosamides, aminoglycosides and macrolide antibiotics. At low skimmer voltages the spectra are dominated by protonated molecular ions except for the aminoglycosides which mainly showed (M+2H)+ ions. Increasing the skimmer voltage can be used to produce CAD type spectra. For the sulfonamides this was of particular interest because four pairs of isomers were amongst those under study. The fragmentation of the sulfonamides all followed the same pathways and it was found that for three of the pairs that little differentiation could be made on the basis of relative abundances of daughter ions. Sulfamethazine and sulfisomidine, however, showed some difference at skimmer voltages > 25 V where the ion of m/z = 124, due to the (RNH)3+ dominated the spectrum of sulfisomidine while sulfamethazine showed several ions of comparable relative abundance. The isomeric pair of oxolinic acid and flumequine in the quinolone carboxylic acid mixture showed markedly different spectra due to major structural differences. At higher voltages the daughters mainly resulted from loss of side chains. Fragmentation of the aromatic skeleton was only seen at 75 V. The tetracyclines showed evidence of consecutive losses of H2O and/or OH from the protonated molecular ion at low voltages (Fig 1). Increasing the skimmer voltage had no discernible effect other than the increase in relative abundance of these fragments relative to the (M+H)+ ion.

To date we have investigated the on-line coupling of nCLC and CZE with ESI/MS for the determination of standard mixtures sulfonamides, quinolone carboxylic acids and tetracyclines. The sensitivity of the technique was found to be compound dependent where 5 to 10 times the sample loading was required for the tetracyclines relative to the sulfonamides and the quinolone carboxylic acids. Using nCLC/ESI/MS the sulfonamides were readily detected at the 50 to 70 pmole level but at the 30 pmole level detection limits were approached for some of the less sensitive species. For a simple mixture of nine sulfonamides a rapid gradient from 0% B to 50% B in 30
minutes was utilized but for a more complex mixture of 19 this was slowed to one hour. Three of the four isomeric pairs of the sulfonamides could be readily resolved using these gradients. CZE could be used to resolve sulfamethoxypyridazine and sulfameter. CZE/ESI/MS provided a comparable separation of the mixture of 9 sulfonamides in a third of the time with an order of magnitude increase in sensitivity. The disadvantage of CZE was that the upper limit of loading of the column was close to the detection limit of the mass spectrometer so the dynamic range was small. At this level noise spikes in the single ion electropherograms also seemed relatively intense.

The quinolone carboxylic acids could be seen readily at the 10 to 20 pmole level by nCLC/ESI/MS. All four acids were baseline resolved with a gradient from 0% B to 100% B in 15 minutes. CZE was of interest for the quinolone carboxylic acid because both oxolinic and piromidic acids can yield tailing peaks using LC. The quinolone carboxylic acids could be detected readily at the 1 - 3 pmole level where the elution order of the acids was altered relative to nCLC.

A mixture of tetracyclines, oxytetracycline and chlortetracycline was studied by nCLC where their structures only differ by one substituent group at either C6 or C7. They were readily resolved when a gradient from 0%B to 100 %B in 30 minutes was employed (Fig 2). This corresponds to an injection of 170 to 330 pmoles on column.

In our opinion nCLC/ESI/MS and CZE/ESI/MS are complementary techniques and can readily be applied to the determination of veterinary antibiotics.

Electrospray (ESI) and fast atom bombardment (FAB) are the "soft" ionization methods of choice for the mass spectral analysis of polar and thermally labile compounds. A major problem with these soft ionization techniques is that their ionization is dependent on the other components present in the matrix being analyzed. This discrimination may diminish the response or even prevent the compound from being observed. The use of liquid chromatography (LC) eliminates many of these problems in addition to providing a time domain to distinguish analyte and background. The use of packed capillary LC to interface to either continuous flow FAB (CF-FAB) or ESI is the preferred technique in both cases. The same system can be used for both techniques with minor modifications. The use of large sample injections combined with gradient LC allow chromatographic integrity to be maintained. Combined with the low flow rates (approx. 3 ul/min) of packed capillary LC columns, this allows the entire effluent to be directed to either MS technique with high sensitivity in the very low picomole range.

CF-FAB data were acquired on a VG ZAB 2-SE system while the ESI data were acquired on a Finnigan MAT TSQ-700 system. The capillary columns (320 um i.d., fused silica) were fabricated in-house.

The two mass spectrometric techniques often provide complimentary information dependent on the sample types. In the case of peptides, as others have reported for semi-micro LC, CF-FAB often provides sequence specific fragmentation while electrospray can cover a larger mass range due to multiple charging. This is illustrated for the tryptic digest of ubiquitin for which incomplete digestion occurs. For the T3 tryptic fragment, ESI gives only the singly and doubly charged protonated molecular ion species while the FAB mass spectrum contains significant fragmentation which allows a majority of the fragment's sequence to be determined as illustrated in Figure 1. The ESI spectrum of the partially digested ubiquitin shows two multiply charged ion series. Deconvolution gives the molecular weight for losses at the C-terminus of ubiquitin consisting of GG (small) and LRGG (large). This is shown in Figure 2.

For profiling of urinary metabolites (sulfates and glucuronides) of a smaller molecule, MDL 11,939, valuable information is obtained by both techniques. Again, the fragmentation observed in FAB can provide structural information lacking in ESI without the use of MS/MS. For larger molecules such as the glycopeptide teicoplanin, FAB and ESI both give only molecular weight information. However, some less hydrophilic trace components were observed by ESI and not by FAB. In conclusion, capillary LC interfaced to either technique is an excellent method for increasing sensitivity and reducing matrix effects for either FAB or ESI. For peptides below 2000 daltons, FAB offers sequence specific fragmentation while ESI can give spectra of large peptides and proteins with great sensitivity. Work on evaluation of both techniques with a variety of compound classes will help define the complimentary role of FAB and ESI as LC-MS techniques.

Introduction
Several genera of fresh and brackish water cyanobacteria, Microcystis, Oscillatoria, Anabaena, Aphanizomenon and Nodularia, produce some kinds of acute lethal toxins, and deaths of wildlife and domestic animals have been ascribed to taking toxin-containing water. Toxins from these genera are known to include cyclic hepatotoxic hepta- and pentapeptides and neurotoxic alkaloids. Cyclic hepatotoxic heptapeptides named microcystins consist of a common moiety composed of five amino acids, 3-amino-9-methoxy-10-phenyl-2,6,8-trimethyldeca-4,6-dienoic acid (Adda), N-methyldehydroalamine (Mdha), D-alanine, \( \beta \)-linked D-erythro-\( \beta \)-methylaspartic acid, and 7-linked D-glutamic acid, and two L-amino acid variants, and thirteen microcystins have been isolated so far (Fig. 1). Three new cyclic heptapeptides were recently isolated from Nostoc species, which have an acetyl group in Adda moiety instead of a methoxy group in usual microcystins. Lately it has been demonstrated that microcystins inhibit strongly protein phosphatases 1 and 2A. In this study we developed an analysis method using Frit-FAB LC/MS for rapid separation and identification of microcystins.

Experimental
A mass spectrometer (JMS-AX505W, JEOL) was used and connected to a data system JEOL JMA-DA5000. A JEOL Frit-FAB Probe with a stainless steel frit was connected to a pneumatic splitter. The FAB mass spectra were obtained in positive-ion mode by scanning from mass 50 to 1500 with a scan speed of 8 s/cycle. A FAB gun was operated at 3 kV with xenon gas. Injected samples were introduced into ion source at a split ratio of 8/500 after post-column splitting with the pneumatic splitter. A high performance liquid chromatograph equipped with a constant-flow pump (LC100 system, Yokogawa) was used. Separation was accomplished under reversed phase isocratic conditions on an ODS column (Nucleosil 5C18, 150 x 4.6 mm) with mobile phases of (a) MeOH:0.01% TFA (55:45) (containing 0.8% glycerol) and (b) MeOH:0.1M AcONH\(_4\) (adj. pH 5 with TFA) (53:47) (containing 0.8% glycerol). The flow rate was 0.5 ml/min and UV absorbance at 238 nm was used as the detection method.

Results and Discussion
FABMS and liquid SIMS have been only useful technique for determination of molecular weights of microcystins because it was very difficult to ionize these intact toxins by other ionization methods. Although several LC/MS interfaces, Frit-FAB, thermospray, atmospheric pressure ionization, continuous flow FAB, have been developed, Frit-FAB LC/MS was considered to be promising for our purpose. In our previous reports on HPLC for separation of microcystins, the following three solvent systems have been complementarily used: MeOH:0.05M phosphate buffer (pH 3)=6:4, MeOH:0.5M Na\(_2\)SO\(_4\)=1:1 and MeOH:0.05% TFA=6:4. TFA-containing solvent system was considered to be useful, because acidic matrix is suitable for ionization of microcystins. So the Frit-FAB LC/MS using the TFA-containing mobile phase could be successfully applied.

The HPLC conditions slightly modified, MeOH:0.01% TFA=55:45 (containing 0.8% glycerol) as a mobile phase and 0.5 ml/min as a flow rate, provided a base line separation of standard microcystins RR, YR and LR, and their geometrical isomers (RR-s, YR-s and LR-s) (Fig. 2). In this system a portion of 8/500 of the sample was introduced into ion source of mass spectrometer. The remaining part of the effluent was introduced into an usual UV (238 nm) detector for HPLC via a pneumatic splitter and the high performance liquid chromatogram was simultaneously measured. If larger amounts of samples are loaded, the preparative separation is also available using this system. Mass chromatography is a useful technique for identification of a desired compound, when its molecular weight is known. In fact, the technique enabled a rapid identification of the six components as shown in Fig. 2. Sixteen microcystins have been reported so far, whose molecular weights are different one another except for the case of 3- and 7-desmethylmicrocystins LR. The use of mass chromatography makes possible a rapid identification of at least fourteen microcystins. Additionally, both desmethylated microcystins LR were separated and identified by another Frit-FAB LC/MS using the mobile phase (b).

1382
The established method was subsequently applied to analysis of microcystins contained in both a culture strain and a field sample, and the procedure from toxin extraction to identification of microcystins was performed within one day. These results allowed the rapid identification of known microcystins without standard samples. In addition, other types of compound than microcystins were also detected in the course of screening of various samples by the method.

COMBINATION OF TEMPERATURE-PROGRAMMED CAPILLARY LIQUID CHROMATOGRAPHY WITH MASS SPECTROMETRY

J. S. YOO1, V. L. MCGUFFIN1 and J. T. WATSON1,2
Departments of Chemistry1 and Biochemistry2
Michigan State University, East Lansing, MI 48824

LC/MS with solvent gradient programming has become a powerful technique for the separation and identification of complex unknown samples of biochemical significance. However, the efficiency of most LC/MS interfaces based on vaporization, nebulization or desolvation processes varies during gradient programming because of the change in viscosity and surface tension of the mobile phase (1, 2). The use of temperature programming with isocratic mobile phase composition is an alternative solution to this problem. Temperature-programmed LC/MS may be achieved by using packed capillary columns, which have high separation efficiency and relatively modest demands for instrumentation (3). The narrow diameter (100-300 μm) and low flow rate (0.1-10 μL/min) ensure rapid heat transfer across the column during temperature programming and require only a simple LC/MS interface for the introduction of analyte under EI conditions. Application of temperature programming to capillary LC/MS provides a reduction in total analysis time with optimization of chromatographic resolution and an improvement in detection limits for highly retained solutes.

In this study, the temperature-programmed capillary LC/MS system shown schematically in Figure 1 has been developed. A single-piston reciprocating pump was used in the constant-flow mode to deliver the mobile phase. A conventional 1 μL injection valve was used for sample introduction, and the effluent was subsequently split to provide a flow rate less than 1 μL/min to the packed capillary column. A 200 μm I.D. x 40 cm column was prepared from 5 μm spherical silica particles with an octadecyl stationary phase. Both the column and splitter were kept in an oven to maintain a constant split ratio during temperature programming. A standard GC oven was modified for programming rates from 0.1 to 0.5 °C/min between 40 and 100 °C in order to be compatible with liquid chromatographic conditions. The effluent from the column flows sequentially through a UV absorbance detector, the LC/MS interface, and into the MS ion source. A direct coupling LC/MS interface with thermocouple and heater was designed to control the interface temperature independently. This interface can be inserted through a vacuum manifold for the direct insertion probe of a HP 5985 MS. The quadrupole MS was operated in the EI mode at 70 eV while scanning the mass range from m/z 50 to 400 in 4 to 5 seconds.

The performance of the capillary LC/MS interface was evaluated with a test mixture containing phenol, nitrobenzene, toluene, anthracene, and pyrene. The mixture was separated on the reversed-phase column using acetonitrile as mobile phase and the individual components (500 ng each) were identified by their EI mass spectra (Figure 2). To study the effect of interface temperature on the evaporation of nonvolatile solutes, a square wave pulse of the solute was introduced directly into the ion source. At 180 °C, sporadic evaporation of the solute was observed due to insufficient heat. As the temperature was increased, both peak shape and signal to noise ratio were improved. The optimum interface temperature was between 250 °C and 270 °C. Repeated injections showed 11% relative standard deviation in peak height from reconstructed mass chromatograms using individual fragment ions or total ion current.

The temperature-programmed capillary LC/MS system was applied to the separation and identification of unknown fatty acid constituents in a dietary fish oil sample. Figure 3 permits a comparison of chromatograms based on UV detection (top) and reconstructed mass chromatograms (bottom). Under optimized conditions, the separation of twelve methyl esters of fatty acids was achieved with baseline resolution of the reversed-phase column with 75% aqueous acetonitrile at a temperature programming rate of 0.34 °C/min from 40 to 80 °C. The saturated and unsaturated esters with fewer than two double bonds provided poor sensitivity with UV absorbance detection due to their low molar absorptivity. However, the reconstructed mass chromatograms showed a response for saturated and unsaturated esters with higher sensitivity. The C\(_{5}\)H\(_{11}\) ion at m/z 55 was used for universal detection of both saturated and unsaturated esters. The ions at m/z 74 (from the McLafferty rearrangement), 75, 87, and 143 were characteristic fragment ions from both saturated and mono-unsaturated esters, while the C\(_{5}\)H\(_{11}\) ion at m/z 96 was selective for mono-unsaturated esters. The C\(_{5}\)H\(_{13}\) ion at m/z 77, C\(_{5}\)H\(_{17}\) ion at m/z 79, and C\(_{5}\)H\(_{19}\) ion at m/z 91 were characteristic fragment ions from the highly unsaturated esters with more than three double bonds. The C\(_{5}\)H\(_{11}\) ion at m/z 91 from docosahexaenoate (22:6) was verified by collision induced dissociation with dimethyl ether using a Finnigan TSQ-70B triple quadrupole MS. The daughter ion mass spectrum of the parent ion at m/z 91 is identical to that of the tropylium ion from toluene as shown in Figure 4. The ion/molecule reaction of the tropylium ion with dimethyl ether produces collisional complexes consisting of the C\(_{5}\)H\(_{11}\)-CH\(_{3}\) ion at m/z 105 and the C\(_{5}\)H\(_{17}\)-CH\(_{3}\)OCH\(_{3}\) ion at m/z 137. These results strongly suggest that the peak at m/z 91 in the mass spectrum represents the tropylium ion as the isomeric tolyl ion also forms the C\(_{5}\)H\(_{14}\)(CH\(_{3}\))OCH\(_{3}\) ion at m/z 122 upon reaction with dimethyl ether (4), and no peak at m/z 122 was observed in the present work.

Ultrasound Based Direct Liquid Introduction CI Mass Spectrometry

Murray Hackett* and Glenn C. Miller
Department of Biochemistry, University of Nevada, Reno, Nevada 89557-0014

A simple, easily fabricated interface for flow injection and micro scale LC/MS has been developed which is based on a high frequency low capacity ultrasonic nebulizer. Additional nebulization and solvent declustering is provided by 2 to 5 mL/min of helium gas which flows coaxially around a 50 μm i.d. fused silica capillary which is used to admit sample directly into the source of a Finnigan 4023 quadrupole mass spectrometer. This design avoids the plugging and fabrication problems associated with the 5 μm or smaller constrictions which have been used with purely pressure driven systems. "Tight" source conditions were maintained with the aid of a polyimide foam gasket placed between the nozzle barrel and the source block. Conventional positive and negative CI spectra have been generated for common test solutes, e.g. caffeine and C17 fatty acid, as well as more difficult compounds. A high abundance molecular ion was generated under NCI conditions for an unknown macrolide which failed to yield unambiguous molecular weight information with direct probe methods or static FAB.

We are currently attempting to miniaturize the prototype interface such that it can be used with existing 1/2 inch direct probe inlets. Presently the interface requires a separate bolt on flange due to the size of the nozzle. With the recent advent of commercially produced 3/8 inch dia. ultrasonic nebulizers, which resist detuning at the temperatures encountered in MS work, such miniaturization is a realistic goal.

Our device differs from that reported by Ligon and Dorn (1) in that it was optimized for the low liquid flow rates, < 10 uL/min, required of DLI interfaces and CFLOW (Continuous Flow) FAB MS. It has generated steady sprays at flow rates down to 100 nL/min. Ligon and Dorn used a similar commercially available ultrasonic nozzle as part of their design for a particle beam type interface, a momentum separator designed to operate at flow rates on the order of 2 or 3 mL/min. Although Games reported the existence of German and Japanese patents for ultrasonically based LC-MS interfaces in a 1983 review (2), reports in the open literature of successful application have, to our knowledge, been limited to the work described here and that referenced above (1).

The combination of high frequency (120 kHz) ultrasound and gas nebulization has been observed to have desirable properties, applicable to many different types of LC-MS interfaces in addition to the specific device described here. These include overall mechanical robustness, ease of construction, and the absence of critical adjustments and orifices.

USE OF THE MOVING BELT INTERFACE FOR ON-LINE CHARACTERIZATION OF HIGH MOLECULAR WEIGHT POLYCYCLIC AROMATIC COMPOUNDS IN ENVIRONMENTAL SAMPLES by LC/MS and SFC/MS

H. Perreault, L. Ramaley, F.M. Benoit and P.G. Sim

a Dept. of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada
b Institute for Marine Biosciences, National Research Council, Halifax, Canada

One of the most powerful techniques for characterization of Polycyclic Aromatic Compounds (PAC) in environmental matrices is the combination of HPLC with mass spectrometry. The use of HPLC/MS interfaces based on mechanical transfer devices, such as a moving wire or moving belt, has fallen into disfavour in recent years, due mainly to the popularity of thermospray, particle beam, electrospray and ion spray interfaces. These newer techniques have largely supplanted the mechanical transport devices.

However, in our hands the moving belt has proven to be a reliable and efficient HPLC/MS interface for thermally stable analytes of moderate volatility, especially PAC. The ease of compatibility of this interface with EI and CI ionization sources makes it very suitable for the analysis of these compounds. The moving belt has also been shown to be a suitable interface for packed column SFC/MS.

Most applications of this interface to the HPLC analysis of PAC have been limited to compounds of molecular weights not much higher than the range accessible by normal GC/MS. Developments of HPLC methods based on UV and/or fluorescence detection on the other hand have involved the separation of PAC's of molecular mass up to 600 Da. We report here on the application of the moving belt interface to the on-line monitoring of the PAC in a complex coal tar sample, for compounds of molecular mass up to 580 Da. Also reported here are some preliminary results from a normal phase SFC/MS method, developed using the moving belt as the interface. It is hoped to adapt this SFC method to a preparative fractionation technique.

The sample studied here was obtained by extracting and fractionating excavated bulk material from the Sydney Tar Pond, Sydney, Nova Scotia. This site is the result of 60 years of uncontrolled discharge of effluent from a metallurgical coking operation. The sample was first analysed by reverse phase HPLC/MS. The solvent gradient system was a modification of that employed earlier for analysis of a carbon black extract. Later work involved SFC/MS analysis. Carbon dioxide, often used as a mobile phase in SFC, would not elute high molecular weight PAH within reasonable analysis times. We found pentane to be a suitable solvent for this purpose; with the addition of methanol as a modifier, it provides reasonable normal phase separation of PAC on a packed silica column. The moving belt interface was very suitable for this SFC/MS work.

Typical HPLC reconstructed ion chromatograms, for m/z 350 and 578, are shown in Figure 1. The belt transmits eluted compounds to the mass spectrometer (EI mode) with good preservation of chromatographic peak integrity. The column performance, in terms of isomer separation, appears to be better for the cata-condensed than for peri-condensed systems, as a general trend. This feature is almost certainly a manifestation of the well known molecular shape selectivity of polymeric phase columns.

In the mass spectra shown in Figure 2, the compounds depicted are examples of the possible PAH of the indicated masses. Work is proceeding on identification of the actual compounds present but is hampered by the lack of suitable standards. The ability of the belt interface to permit acquisition of good quality mass spectra, even for larger compounds, is evident from Figure 2. These spectra are like those of smaller PAH, in that they are dominated by molecular ions. The background from the belt is relatively unimportant at these higher masses.

Figure 3 shows the total ion chromatogram obtained from an SFC/MS normal phase analysis of the Tar Pond sample. Each fraction of a given molecular weight range may be collected and analysed off-line by HPLC/MS techniques.
The HPLC/MS and SFC/MS techniques described here offer a combination of retention and molecular weight data which can be invaluable in characterizing complex samples.

* NRCC No. 32976

Federal and State mandates for groundwater and soil dissipation studies usually require monitoring of pesticides used at low rates down to the part per billion level in soil and the sub-part per billion level in water. In addition to the soil and water monitoring studies, if the pesticide is to be applied in the field through aerial application, pesticide drift studies may be required in order to monitor off-target movement.

Migration of the pesticide during and after the aerial application is monitored by a combination of passive and active collection devices placed throughout the field and the downwind area which collect the sprayed material. Analysis of the filter pads then leads to a mapping of the spray drift which can be used in conjunction with application and weather data to characterize the off-target area.

Sulfonylureas, including primsulfuron-methyl, are a major group of commercially important herbicides which are very active at very low use rates, corresponding to subsequent low residue concentrations. In addition, many of these compounds readily decompose under normal environmental conditions. Because of the low use rates of sulfonylureas and their thermally labile nature, sensitive and reliable analytical methods are needed for their analysis. High performance liquid chromatography coupled with mass spectrometry (HPLC/MS) provides the needed selectivity and sensitivity.

Furthermore, by using the high resolution capabilities of a double focusing mass spectrometer, not only can many of the background interferences be easily eliminated but the level of confidence is increased by the enhanced specificity of the ion selection process. Because of the reduced background, extraneous clean-up steps during the extraction are not necessarily needed, thus contributing to a relatively minimal sample preparation procedure. The simple preparation procedure also helps avoid additional sample losses which lower sample recovery during extraction.

We have developed a simple extraction procedure requiring sonication of the filter pads (collected from spray drift studies on primsulfuron-methyl) in methanol followed by concentration using Kuderna-Danish techniques. The final concentrated extracts are then injected onto a normal phase HPLC column, eluted with 30% 1:1 methanol/isopropanol in cyclohexane and analyzed by single ion monitoring mass spectrometry using the moving belt interface. The mass spectrometer was operated using electron impact ionization and medium resolution (5000-6000). Mass 187, which is the most intense ion in the electron impact spectrum of primsulfuron-methyl, was used as the quantification ion and mass 199 was used as the confirmation ion.

Figure 1 shows the single ion chromatograms, at different instrument resolutions, of a sample extract obtained from a filter paper which was placed on the field during the aerial application of primsulfuron-methyl. Figure 2 represents the chromatograms of 10 ul of the lowest (0.1 ppm) calibration standard used for the study obtained under similar resolution conditions as the sample extract. Although the sample extract is sufficiently concentrated to be observed reliably at a resolution of 500 (Fig. 1a), the lowest standard (Fig. 2a) cannot be detected with any degree of confidence at the same resolution. At a resolution of 6000, however, the background interferences for the same sample extract (Fig. 1c) are completely eliminated and the lowest calibration standard (Fig. 2c) is easily recognizable. Moreover, the peak which is
obtained and quantified at 6000 resolution can be attributed to primsulfuron-methyl with a greater
degree of confidence than the corresponding peak at 500 resolution.

Using this analytical procedure the limit of quantification of primsulfuron-methyl extracted
from filter pads is 1.0 ng on column, representing twice the limit of detection. Moreover, this
approach can be used to quantify primsulfuron-methyl or other related compounds at similar
detection levels from matrices such as well-water and soil which have many more interferences
and require additional and sometimes complicated clean-up procedures.

standard obtained at a resolution of a) 500 b) 2000 and c) 6000.
Development and Refinement of an Element and Isotope Selective Detector for HPLC Based on Mass Spectrometry.

M.A. McLean, M.L. Vestal and F.P. Abramson¹, Vestec Corp., Houston, TX 77054; (1) George Washington Univ., Dept. of Pharmacology, Washington, DC 20037.

Introduction:

The CRIMS (Chemical Reaction Interface for Mass Spectrometry) technique was first developed by Markey and Abramson in 1982 as a creative way of utilizing the mass spectrometer as an element and isotope selective detector for gas chromatography. ¹ The basic principle is to feed the chromatographic effluent into a microwave powered reaction cell where the molecular species are broken down to their elemental form. The addition of a reactant gas to the microwave plasma results in formation of small gaseous reaction products that are characteristic of the elements contained in the original molecule. Conventional EI mass spectrometry is then used to detect specific elements or isotopes in the form of these reaction products. For example, ¹⁴N labeled species are detected at m/z 31 as ¹⁴NNO and, analogously, ¹³C containing compounds are detected at m/z 43 as the combustion product ¹³CO₂. Structural information on the molecular species may be obtained by simply turning off the microwave power supply and allowing the intact molecule to enter the mass spectrometer's ion source.

The success of this method as a specific detector for gas chromatography, has led us to couple the CRIMS device to HPLC. Initial results presented previously² were very promising but in some cases suffered from poor signal-to-noise. The work reported here is an extension of this earlier work and concentrates on efforts to increase the signal-to-noise ratio for ¹⁴N, ¹⁵N, ¹²C and ¹³C detection by: 1) using high purity solvents which exhibit a low residual after evaporation, 2) eliminating mechanical pump backstreaming by adding in-line filters to the momentum separator pump-out lines, 3) improving sample transmission through our particle beam/CRIMS interface by utilizing a more compact interface design and, 4) using a specially designed EI/CI particle beam ion source for improved sensitivity.

Results:

The objective of this paper is to report the refinements made to the LC-CRIMS system, as stated above, and to demonstrate the utility of combining CRIMS with liquid chromatography to selectively detect and identify urinary metabolites of ¹⁵N₂, ¹³C labelled caffeine. The analysis of caffeine metabolites serves as an example of how the isotopic and element specific detection capability of CRIMS can aid in identifying drug metabolites contained in a complex matrix. A general procedure for identifying and confirming the structure of a drug metabolite using CRIMS and particle beam LC/MS is outlined in the following steps;

1) administer stable isotope labeled drug to the desired subject,
2) collect appropriate biological fluid,
3) perform routine sample work-up procedure,
4) obtain selective isotope chromatogram on the sample using the HPLC-CRIMS technique by monitoring m/z 31 (¹⁵NNO) for a ¹⁵N enriched drug or m/z 45 (¹⁵CO₂) for a ¹³C labeled drug, and lastly,
5) in a subsequent HPLC run, obtain an EI mass spectrum of the intact molecule at the retention time predetermined by the isotope selective chromatogram.

This procedure was followed in our laboratory to identify ¹⁵N₂, ¹³C-caffeine metabolites in dog urine with minimal sample clean-up (ie. filtration through a 0.22 micron filter with no further purification). An isotope selective chromatogram obtained from this urine sample is shown in figure 1. The equation at the top left-hand corner of this trace is the equation used for subtracting out the signal at m/z 31 (¹⁵NNO) due to naturally occurring ¹⁵N in the sample. Distinct peaks corresponding to ¹⁵N isotopically enriched caffeine metabolites are observed well above the baseline noise. In figure 2, the ¹⁵N NO response (panel B) is compared to the m/z 44 response which is representative of the total ion chromatogram obtained for this sample and also for other nonspecific detection methods. With nonspecific detection the caffeine metabolites are hidden by interfering components, but by monitoring the isotope specific product produced by the CRIMS technique, it is possible to extract the metabolite peaks and assign appropriate retention times for subsequent full scan particle beam EI LC/MS experiments.
Conclusion:

The CRIMS technique coupled to HPLC allows element and isotope selective detection of isotopically labeled, or intrinsically labeled, nonvolatile compounds to be realized. This appears to be particularly important in drug metabolism studies where retention times of metabolites can be determined even in extremely complex matrices. Once the precise retention time is known, full scan particle beam EI LC/MS experiments can be used to identify the metabolite through molecular weight information or structurally significant fragmentation. This methodology was successfully used in this study to identify caffeine metabolites in dog urine.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The Interpretation of Daughter Ions from Multiply Charged Parent Ions
Ron Bonner, Tom Covey and Bori Shushan
SCIEX, 55 Glen Cameron Road, Thornhill, Ontario, CANADA, L3T 1P2

The increasingly widespread use of liquid phase ionization techniques based on ion evaporation (ionSpray and Electrospray) has shown that the mass range for detectable molecules can be dramatically extended because of the ready formation of multiply charged ions. We have shown, for example, spectra obtained on a quadrupole mass spectrometer with a mass range of 2400 amu that allowed the molecular weight of immunoglobulin at mass 148,000 dalton to be determined.

There have been several reports indicating that multiply charged ions can be fragmented in a triple quadrupole and that this process generally requires less energy than does fragmentation of the corresponding singly charged species. Our efforts have mainly concentrated on fragmenting doubly charged tryptic peptide ions; these spectra are straightforward to interpret since the charges tend to be localized on opposite ends of the peptide backbone (the N-terminus and basic C-terminal lysine or arginine) and hence breaking any backbone bond leads to the formation of two singly charged daughter ions. Smith and co-workers [1,2] have reported on the fragmentation of intact proteins with much higher charge states and, based on prior knowledge of the sequence, have been able to assign structures to many of the observed ions. Clearly it would be advantageous to be able to interpret the daughter spectra obtained from multiply charged ions and, hopefully, to be able to extend the mass range for daughters in the same way as for intact molecules.

Experiments with model compounds, the small proteins renin substrate (MW 1758.9) and mellitin (MW 2845.8), show that there are data processing methods for obtaining useful data from the daughter spectra of multiply charged ions. Two phenomena are fundamental to these approaches:

1) Smith et al have observed on several occasions that the daughter spectra of multiply charged protein ions tend to show similar mass fragments in different charge states. This situation is analogous to a 'conventional' multiply charged spectra where mathematical relationships can be used to determine the molecular weight. In the case of daughter ions, the mass determined is that of the parent and the difference is that a series of multiply charged daughters may not differ by the addition of protons; the actual relationship depends on the fragmentation mechanism. The phenomenon is believed to arise from the heterogeneity of the multiply charged parent, i.e. that the an ion with with, say, 5 charges exists in several forms with the charges located at different sites in the molecule. Simple cleavage of backbone bonds will therefore tend to produce fragments with the same mass but a distribution of charges.

2) In any fragmentation the charge and mass must be conserved. If a parent produces two ions, rather than ion(s) and neutral(s), the sum of the masses and charges of the fragments must equal those of the parent. If the charge state of an observed ion is presumed then the corresponding mass and charge of the matching fragment can be calculated: the presence of an ion at the calculated mass/charge corroborates the initial presumption. This allows the charge state of some ions to be verified. In the case of proteins, such matching pairs are also sequence ions since they correspond to backbone fragmentation.
Processing daughter ion data using algorithms designed for obtaining the molecular weight from the spectra of multiply charged ions often reveals data that were not previously apparent. The spectra below illustrate the process of reconstructing a daughter spectrum and applying a 'hit' filter of 2. The hit filter eliminates ions having fewer contributions than the specified value. The processed data reveals the majority of the sequence ions and eliminates ions, for example the doubly and triply charged sequence ions, that add complexity to the original spectrum.

The major disadvantage of this approach arises from a low level noise continuum that causes artificial hits. The 'noise' is made up from unresolved peaks caused by the poor resolution obtained for multiply charged daughters due to a large kinetic energy release, and the presence of ions that come closer together in m/z as the charge number increases. More sophisticated methods of thresholding and peak location could avoid some of these difficulties.

Recent developments in mass spectrometry are dramatically expanding its capability for the analysis of biopolymers including proteins and peptides. However, the extraction of the large amounts of information embedded in the mass spectrometric data is complicated. Therefore, there has developed a need for specific computer software for the convenient manipulation, interpretation, and display of the unique types of data generated in the analysis of these molecules. We have developed a suite of computer software to assist protein and/or peptide structure analysis by mass spectrometry.

**Molecular Weight Determination for Biopolymers -- BIOMASS Deconvolution Program:**
To facilitate the interpretation of ESI/MS spectra with multiple-charged ion distribution, we developed a deconvolution algorithm (1) which overcame the interference of "side peaks" from the algorithm described previously (2). This algorithm transforms the coherent series of multiply charged ions into a mass scale spectrum free of artifactual peaks, from which the parent mass can be readily determined. This allows the direct analysis of components of mixtures which would otherwise be difficult.

**Rapid Peptide Mapping of Proteins -- PEPMAP LC/MS Interpretation Program:**
Enzymatic peptide mapping (or finger-printing) with HPLC is one of the techniques most commonly used by protein chemists. Electrospray LC/MS is a very powerful tool for this purpose since it provides not only retention time but also structural information, namely the molecular masses, for every peptide in a digest. Nevertheless, the identification and matching of chromatographic peaks to every digested fragment from a known protein is still a tedious and formidable task. To speed up such efforts, we have developed an automatic program which allows rapid assignment of peaks corresponding to all types of predicted fragments, including complete, partial or incomplete, and disulfide-linked peptide fragments. The following shows the matching result of tryptic fragments of hemoglobin α-chain with LC/ESI/MS chromatogram for mixtures of tryptic digest of α and β chains:
All the matched fragments are automatically labeled with their scan numbers in the chromatogram. Similarly, tryptic fragments from β-chain can also be used to match with the same chromatogram and more peaks are identified by the program in this manner:

Additionally, some of the small peaks (•) in the chromatogram are identified to be the result of autolysis of the enzyme (trypsin) itself. Of those chromatographic peaks which cannot be accounted for in this first pass, other program tools are provided to assist further investigation for possible unanticipated cleavage or post-translational modifications.

Unknown Peptide Sequence Elucidation - PEPSEQ Sequencing Program:

Although the triple quadrupole mass spectrometer has been proven to be a powerful tool for peptide primary structure determination (3), interpretation of the resulting mass spectra can be a severe bottleneck to rapid analysis. A computer program has been developed to aid in the interpretation of low energy MS/MS mass spectra of unknown peptides using FAB MS/MS data in automatic, semi-automatic or manual mode (4). This program was successfully used to obtain the sequence information for the Protein Society workshop test peptide last year. A similar program is being developed to interpret ESI MS/MS data. A typical computer output of the interpretation of the CID spectrum for a doubly-charged parent of peptide FSWGAEGQR is showing here:

The interpreted result can be interactively matched by another program PEPMATCH which automatically labeled the spectrum with calculated sequence ions of any candidate peptide for rapid visual conformation. The preliminary results of the ESI/MS/MS sequencing program look promising, especially for tryptic peptides of up to 10-15 amino acid residues.

Manual or automated Edman degradation is the most widely employed method for N-terminal sequencing of peptides and proteins. Normally the sequentially liberated PTH-amino acids are identified by comparison with standard amino acid derivatives using HPLC separation.

Manual Edman degradation may alternatively be combined with mass spectrometric detection of the sequentially truncated rest-peptides/proteins. Both Field Desorption MS (1) and Fast Atom Bombardment MS (2) have been used for analysis of smaller peptides, and recently Plasma Desorption MS (3) have been employed. Advantages of this combination are primarily (i) the possibility of simultaneous sequence analysis of multi-component mixtures and (ii) the direct identification of posttranslational modifications.

The use of Plasma Desorption MS (PDMS) has been shown to be applicable to larger polypeptides (up to 15,000 Da (3)) and brings the additional advantage of the nitrocellulose interface, which makes it possible to employ a time-saving version of manual Edman degradation. The extraction- and washing-steps normally carried out in manual Edman degradation can be replaced by an "in-situ" rinsing step following sample application to the nitrocellulose surface. This step will remove most of the low-mass contaminants including excess coupling-reagent and liberated amino-acid derivatives, which otherwise may seriously hamper the molecular ion signal.

We have previously reported model-studies and several analytical applications of the combination of manual Edman degradation and PDMS (3). The technique has been further refined especially regarding optimization of PITC-coupling and sample application steps. Table 1 lists the obtained results from N-terminal sequencing of intact bovine insulin using the improved conditions. This analysis allows a direct identification of the intermolecular disulfide-bond between the two Cys\textsuperscript{7}-residues in the A- and B-chain, which is identified by the mass loss of 202.1 amu in the 7. cleavage-step. The Cys\textsuperscript{5}-residue, which forms an intramolecular disulfide-bond to Cys\textsuperscript{11} in the A-chain remains bonded to the rest-peptide following the 6. cleavage and would not be detected until the 11. cleavage step.
TABLE 1. N-terminal sequencing of intact bovine Insulin (MW 5733) using a combination of manual Edman degradation and PDMS.

The coupling reaction was carried out in a 1:1 mixture of 0.1 M ammonium carbonate and pyridine containing 5% PITC (pH 9.0). The reaction mixture was kept at 25°C for 40 minutes. Following cleavage in 100% TFA the reaction mixture was lyophilized, redissolved in isopropanol:0.1% TFA (1:1) and an aliquot finally applied to the nitrocellulose surface. The first seven degradation-steps was performed with an initial sample amount of app. 500 picomoles.

a) PITC-coupling to the free amino-group at Lys was only partial, but after three coupling-steps the coupled species is by far the most abundant.

Furthermore, the use of alternative isothiocyanate-derivatives in order to obtain higher coupling efficiency/selectivity and/or higher molecular ion yield of the coupling-product, has been evaluated. 4-(4-(dimethylamino)phenylazo) phenylisothiocyanate (DABITC), Benzophenonisothiocyanate (BITC), Malachitegreenisothiocyanate (MITC) and Erythrosinisothiocyanate (EITC) were tested and coupling was found to be quantitative for BITC and EITC, but only 50% for DABITC and MITC at standard coupling conditions. The molecular ion signal intensities generally decreased with the higher molecular weight coupling reagents. PITC thus appears most advantageous for sequencing application, since at the conditions outlined in Table 1 it reacts completely with free amino- and sulfhydryl groups. The coupling selectivity of higher molecular weight isothiocyanate reagents in proteins with intact tertiary structure is investigated at present.

4-Nitrophenylisothiocyanate In Peptide Sequencing By Negative Ion Chemical Ionization Mass Spectrometry
Suramya Waidyanatha and Robert J. Anderegg,
Department of Chemistry, University of Maine, Orono, ME 04469 and Glaxo Research Laboratories, Glaxo Inc., Five Moore Drive, Research Triangle Park, NC 27510

The suitability of 4-nitrophenyllisothiocyanate (NPITC) as a modified Edman reagent in peptide sequencing by Negative Ion Chemical Ionization Mass Spectrometry (NICI MS) has been proposed elsewhere (1).NICI mass spectra of most of the nitrophenylthiohydantoin (NPTH) derivatives gave only the molecular anions with no fragmentation. Hence, the amino acid residue can be detected by the diagnostic mass.

Initial rates of the coupling reaction between the two isothiocyanates (PITC and NPITC) with alanine were compared. NPITC coupled about 6X faster than PITC. It has been reported that NPTC-amino acids are about 3X slower to cleave than the PTC-analogues (2). Therefore, the advantage of having faster coupling rates with NPITC is partially offset by the slower cleavage rates.

Coupling yields of NPITC with amino acids reached between 92-98% (Fig.1) with NPITC to amino acid ratio of 2:1. Under similar conditions, PITC gave a yield between 78-80% (Fig.1). In a typical sequencing experiment 100-1000 molar excess of isothiocyanate is usually used. Therefore, with NPITC, a potential exists for faster sequencing cycles.

Detection limits of NPTH-amino acids were studied in both full scan (250 femtomoles) and single ion monitoring (50 femtomoles). S/N ratios observed were high enough to go to lower levels of detection. Detection limits calculated according to the method given in HP 5985 B GC-MS manual, less than 10 femtomoles can be detected with single ion monitoring.

Manual sequencing of 50 nanomoles of bradykinin with NPITC to peptide ratio of 8:1 gave a repetitive yield of 91% (Fig.2). Total cycle time was 60 min. Lower levels of peptides may be sequenced by using a higher ratio of NPITC to peptide and by optimizing the reaction conditions. This may also allow to reduce the total cycle time. Automated sequencing of 2 nanomoles of β-lactoglobulin gave a repetitive yield of 92% (Fig.3). Total cycle time and reaction conditions used were very much similar to that used with PITC, with a few minor changes. After each delivery of NPITC, the lines were washed out with ethylacetate. Post coupling solvent extraction was also done with ethylacetate. Reaction conditions remain to be optimized in order to achieve higher repetitive yields, which in turn will allow sequencing lower levels of peptides.

Our results, although preliminary, may indicate the potential for faster sequencing cycles with NPITC. In addition, given that the reaction conditions can be optimized to achieve higher repetitive yields, the low detection limits observed with NPTH-amino acids may allow sequencing of low levels of peptides.

A NOVEL APPROACH FOR SEQUENCING OF PEPTIDES:
PARTIAL HYDRAZINOLYSIS FOLLOWED BY MASS SPECTROMETRY

Jörg Herrmann and Hakon Leffler, Department of Psychiatry,
University of California, San Francisco, California 94143.
Ronald C. Beavis and Brian T. Chait, The Rockefeller University,
New York, N.Y. 10021.

Introduction
The most commonly used technique for peptide sequencing is automated Edman degradation. The long analysis time, difficulty to analyse mixtures and detect modified amino acids are major drawbacks of this method. Mass spectrometry has found an increasing use in mass mapping and sequencing of peptides over the last few years. The sequence analysis by tandem mass spectrometry may be very rapid, but success and sensitivity are variable and limited by the size of the peptide. Here we present preliminary studies of a different approach that could supplement the above methods.

Method
The peptide (here: glucagon or bradykinin) was first partially degraded by treatment with anhydrous hydrazine at 100 °C [1]. The reaction time was varied between 5 minutes and 8 hours. The C-terminal fragments of the generated mixture are free peptides whereas all other fragments contain hydrazides:

\[
\text{R-CO-NH-R'} \rightarrow \text{R-CO-NH-NH}_2 + \text{NH}_2-\text{R'}
\]

After removal of the hydrazides by binding them to an immobilized aldehyde (made by oxydizing Sepharose with periodate [2]), a "ladder" of C-terminal peptides was left which differ by the number of amino acids on their N-terminal side. Finally the mass of each component in the resulting peptide mixture was determined. This was done either directly or after partial HPLC separation. Matrix assisted laser desorption time-of-flight mass spectrometry with sinapinic acid as matrix [3] was used for analysis of the complex mixtures generated from glucagon. HPLC separated fractions were analysed by liquid secondary ion mass spectrometry on a Kratos MS50 instrument.

Results and Discussion
The time required for the ideal degree of fragmentation (cleavage at one peptide bond per molecule) was expected to be much shorter than required for complete hydrazinolysis. Accordingly, 15 minute treatment of glucagon generated an array of C-terminal fragments that covered about 40% of the sequence (Fig. 1). A side reaction converting arginine to ornithine occured rapidly but did not prevent the analysis. When glucagon was treated for 30 minutes with hydrazine an increased cleavage of the side chains of asparagine and glutamine was observed. Since this side reaction converted most molecules to hydrazides they were removed by the immobilized aldehyde. For bradykinin again arginine was rapidly converted to ornithine. The best conditions were found to be a 90 minutes hydrazinolysis which gave about 50% of the whole sequence.
The simplicity of the method and the small amount of sample used in the final mass mapping step suggest that this approach may be useful for partial sequencing of peptides. The method could also be used for larger peptides or intact proteins without prior enzymatic digestion. Here the limitation is the mass determination. At present matrix assisted laser desorption mass spectrometry is most useful due to its capability to analyse mixtures, but the mass accuracy is limited. We expect that the development of improved techniques for high mass analysis will increase the utility of this method.

Fig. 1. Glucagon (8 nmol) was treated with anhydrous hydrazine for 15 minutes at 100 °C. The hydrazides were removed using an immobilized aldehyde (oxydized Sepharose). The remaining mixture of C-terminal peptides was partially purified by HPLC and an aliquot of 0.1 pmol was analysed by matrix assisted laser desorption mass spectrometry. The inset shows the sequence of glucagon (G) and some hydrazinolysis products (G', G'-n). Note that arginine (in G) was rapidly converted to ornithine (in G').
Dimethylaminomethylene Derivatives of Peptides for Mass Spectrometric Analysis.

F. Aladar Bencsath, University of South Alabama, College of Medicine, Department of Biochemistry, Mobile, Alabama 36688

Derivatization is often employed in mass spectrometry (MS) in order to increase volatility, ionization yield, or specificity (1). Several derivatives have been demonstrated to be useful also in peptide analysis (2). We found that the dimethylaminomethyl derivatives of peptides have interesting characteristics that may analytically be exploited.

The derivatizing agent is dimethylformamide dimethylacetal, an often used reagent for carboxylic acids and amino acids in gas chromatographic analyses. It reacts smoothly with primary amino moieties turning them into dimethylaminomethylene groups. We derivatized several commercially available peptides with amino acid residues between 3 and 10 (such as trialanine, leu-enkephalin, angiotensin-ii, bradykinin), and found the following:

1. The derivatization can be carried out in micro-scale, e.g., on the fast atom bombardment (FAB) probe tip, with the peptide samples dissolved in glycerol. Water-free conditions are not required.
2. The derivative-formation is largely completed within one minute. Each primary amino-group (the terminal one and those in the basic amino acids' side chain) contributes 55 amu to the increase of the molecular weight.
3. The intensity of the derivatized spectra (TIC) is in general higher than those of the un-derivatized ones, and the molecular ion is the base ion.
4. The solubility of the analyte increases during derivatization, thus analysis can successfully be performed with peptides suspended in the glycerol matrix (e.g., p-nitrophenyl glutathione).
5. The low-energy daughter ion spectra are somewhat more complex than those obtained from the un-derivatized peptides, but still may be useful for sequence studies.

In conclusion, the dimethylaminomethylene peptide derivatives are interesting compounds that may serve well for molecular weight confirmation, for counting primary amino groups, and perhaps for sequencing, too. However, the conditions of reproducible derivative-formation should be explored.

The introduction of the continuous-flow probe has greatly facilitated the analysis of synthetic peptides and peptides derived from chemical or enzymatic fragmentation of proteins. Most applications of the flowprobe in protein analysis center around the determination of masses of peptides obtained with FAB or SIMS techniques. Peptide sequence analysis generally requires tandem MS techniques. CAD/Linked-scan procedures with two-sector instruments using 1FFR collision activation can also provide sequence ions. Such analyses are usually performed using peptides dissolved in a liquid matrix.

We have obtained sequence information from synthetic peptides by CAD/linked-scan analysis using a flowprobe with direct injection of the sample into the source. The peptides are analyzed in two steps. A first injection with conventional magnetic scanning establishes the masses of candidate parent ions. After a second injection, the peptides are analyzed by linked-scan analysis of daughters generated by 1FFR collision with helium. Peptides were analyzed with a Finnegan MAT 90, equipped with a continuous-flow interface which was modified to accept a stainless steel frit at the target. A syringe pump HPLC delivered solvent (0.1% TFA, 2% glycerol, 3% acetonitrile in Water) at 10 μl/min to the probe. Injections of 0.5 μl containing several micrograms of peptide dissolved in LC solvent were performed every 2 minutes. Scans of constant B/E were acquired at 15 sec/decade. The source temperature was 75°. A "chromatogram" plot of the injections of several peptides is shown in Fig. 1. Accumulated spectra of three peptides is shown in Figs. 2-4, along with their predicted ion series.

The utility of LC/CAD analysis was demonstrated using a peptide with a synthetic defect. The nonamer Cys-Gly-Ser-His-Leu-Val-Glu-Ala-Leu was prepared by solid-phase peptide synthesis using the NMP/HOBt method. This synthetic procedure is widely used and has been shown to produce peptides with higher average coupling efficiencies than other methods. A Bom-protected Boc-Histidine was used in the initial synthetic trials. FABMS analysis indicated the presence of the normal peptide at m/z 928, plus a significant ion at m/z 940, 12 amu higher than predicted. In the spectra obtained from some peptide preparations, the higher mass ion predominated. Sequence ions from m/z 928, obtained by linked scans using LC/CAD analysis showed the predicted b series expected for the normal peptide (not shown). Some spectra also showed a weak, overlapping y series which, together with the b series, provided complete sequence information for the peptide. A preparation of the modified peptide was then analyzed for daughters of m/z 940 using LC/CAD. The spectrum from accumulated scans of one of the injections is shown in Fig. 5. In this spectrum, the daughters of m/z 940 were consistent with a b series, starting with histidine, that is 12 amu higher than that predicted for the normal peptide. No other ion series was observed.

When the peptide was resynthesized using Dnp-protected Boc histidine, the mass spectra of the product showed no traces of the +12 amu ion. The Dnp protecting group must be removed prior to cleavage by HF. One possible interpretation of the results is that during the cleavage of the Bom-protected peptide form the PAM resin by HF, an imidazole nitrogen of histidine becomes methylated (Fig. 7). This might lead to the formation of an unprotonated molecular ion (M+) because of charge stabilization on the imidazole ring. It would also predict a peptide molecular ion and b4 - b5 series exactly 12 amu higher than expected for the normal peptide. An alternative explanation for this +12 amu modification is the conversion of the N-terminal cysteine to thioproline by formaldehyde. 4 Formaldehyde is liberated from Bom-Histidine during the cleavage step. While we cannot rule out this modification in the case of peptide 225, we have observed the +12 amu modification in other His-containing peptides which do not contain cysteine.

DETERMINATION OF RELATIVE RATES OF HYDROLYSIS OF BIOACTIVE PEPTIDES BY DIGESTIVE PROTEASES USING CONTINUOUS-FLOW FAST ATOM BOMBARDMENT MASS SPECTROMETRY.

Roderick G. Davis and Richard B. van Breemen
Department of Chemistry, North Carolina State University
Raleigh, NC 27695-8204

Many drugs under development contain peptide bonds or are peptide analogs. For oral administration(1), these drugs should resist hydrolysis by the digestive system. We have developed an in vitro assay using immobilized digestive enzymes and CF-FAB/MS with selected ion monitoring (SIM) to rapidly determine whether these compounds will be hydrolyzed and, if so, how rapidly they will be degraded. Previously(2), identification of hydrolysis products of immobilized enzyme incubations was demonstrated using frit-FAB LC/MS. CF-FAB/MS (with and without an internal standard) and HPLC with UV absorbance detection will be compared for the determination of hydrolysis rates of bioactive peptides by immobilized digestive proteases.

Porous glass beads were silanized, succinylated, and activated by 3-(3-dimethylaminopropyl)carbodiimide. Trypsin and chymotrypsin were separately immobilized(3). Enzyme activities were determined spectrophotometrically by monitoring the release of chromophore-containing products from peptide analogs(4). The in vitro assay using immobilized trypsin and chymotrypsin will be used to simulate digestion of three bioactive peptides in the 8 intestinal lumen. Angiotensin II, \([\text{Arg}^2]-\text{vasopressin}\), and \([\text{deamino-Cys}^8, \text{D-Arg}^9]-\text{vasopressin}\) will be individually incubated with each immobilized enzyme in 0.1 M ammonium acetate pH 7.5 at 37°C. Substrate-to-enzyme ratios of 50 to 1 and 200 to 1 were used for trypsin and chymotrypsin respectively. Ten microliter aliquots were withdrawn at regular intervals. Separate digestions were run for HPLC and CF-FAB/MS analysis.

Aliquots from each incubation were analyzed by reversed phase HPLC. A hybrid HPLC system consisting of Water's Model 501 pumps, Applied Biosystems (Foster City, CA) 757 UV detector, a Rheodyne (Cotati, CA) Model 7125 injector and a Vydac (Hesperia, CA) CIS column (4.1 mm x 25 cm). Various gradients were used to obtain complete resolution of the initial substrate from all hydrolysis products. Solvents were water and acetonitrile each containing 0.1% TFA.

The CF-FAB/MS system consisted of an Applied Biosystem Model 140A dual syringe delivery system equipped with a Rheodyne model 8125 injector and a JEOL HX110HF double focusing mass spectrometer equipped with a DA-5000 data system and frit-FAB interface. Fused silica capillary (0.75 mm id.) connected the injector with the frit-FAB interface. A carrier solution of water:acetonitrile:TFA:glycerol (80:20:0.1:0.5) was used to deliver incubation aliquots onto the ionization stage at 5uL/min. SIM was used for quantification.

The in vitro assay using immobilized enzymes, HPLC and/or CF-FAB/MS with SIM is amenable for hydrolysis rate determinations of bioactive peptides by digestive proteases. Rate determinations by HPLC and CF-FAB/MS with an internal standard yield statistically identical results.(table 1) The correlation coefficients, and error limits for both methods are similar. The separation requirement for HPLC limits its ability for rate determinations for some peptides (figure 1 and 2). For CF-FAB/MS, separation of hydrolys products from the initial substrate is not required and this method can be used to complement HPLC or as an alternative to it (table1 and figure 3). CF-FAB/MS also provides molecular weight information on hydrolysis products. It has been demonstrated that this assay can be used to identify enzymatic hydrolysis products of orally administered peptide drugs and to determine their hydrolysis rates. The assay can be used to assist pharmacologists in drug design.
Figure 1. HPLC analysis of AVP incubated with immobilized trypsin. The labeled peak contains AVP and a hydrolysis product as determined by positive FAB/MS (see figure 5). Gradient variations failed to obtain completely resolution with the Vydac C18 column. Hydrolysis rate determinations by HPLC are difficult in these cases where the substrate is not completely resolved.

Analysis of Hydrophobic Peptides by Liquid Secondary Ion Mass Spectrometry

Patrick R. Jones, Arnold M. Falick and Larry J. W. Miercke

Chemistry Department, University of the Pacific, Stockton, CA 95211, Department of Pharmaceutical Chemistry, Department of Biochemistry and Biophysics, University of California, San Francisco, CA 94143.

The application of mass spectrometry to the mapping and sequencing of proteins and peptides is well established. Liquid secondary ion mass spectrometry (LSIMS) methods generally work well for hydrophilic and moderately hydrophobic peptides, although hydrophilic peptides may require derivatization to make the compound more abundant on the surface of the liquid matrix material. Problems arise with more hydrophobic peptides which tend to aggregate at higher concentrations in aqueous solution or be insoluble. A digest of the protein of interest is carried out to provide tractable peptide fragments for LSIMS. The peptides are separated by HPLC and mass analyzed. In a typical water/acetonitrile gradient elution scheme on a reversed phase column with 0.1% trifluoroacetic acid (TFA) added, the peptides found in the initial portion (up to an HPLC Index of about 30 based on a calculation using the MacProMass program supplied by Dr. Terry Lee) may need derivatization. Those in the range 30 - 115 give LSIMS spectra readily, but those beyond 115 often give no appreciable signal.

We chose as a model, for work on extending the applicable range of LSIMS, bacteriorhodopsin, a membrane protein. A combination of CNBr and trypsin digestion schemes were used. The conventional HPLC analysis with C4 and/or C18 columns using a water-acetonitrile-0.1% TFA gradient proved unsatisfactory for the determination of all the peptide fragments. In part, this system is problematic since many of the peptide fragments are significantly hydrophobic. In addition, the peptides tend to precipitate in the HPLC and give troublesome residues that are difficult to elute.

An HPLC method using a water-acetonitrile-5% formic acid gradient proved to work well. The more hydrophobic peptides were collected and found to be amenable to LSIMS analysis on a Kratos MS50S mass spectrometer when the lyophilized samples were taken up in 96% formic acid just prior to analysis. Hydrophobic samples extracted with water-acetonitrile-0.1% TFA gave no peptide ion signals by LSIMS. The peptide sequences were confirmed by high energy collision induced dissociation in a Kratos Concept four sector tandem mass spectrometer.

Supported by NIH grant DRR 01614 and NSF grant DIR 8700766.

The recent development of the matrix-assisted UV laser desorption technique has enabled the formation and subsequent mass analysis of very large (>100 kDa) protein ions [1]. Most instrument designs have implemented costly Nd:YAG lasers typically equipped with frequency tripling and/or quadrupling devices to produce UV radiation. A linear TOF instrument that utilizes a multi-gas laser with a N2 lasing mixture as the UV photon source (337 nm) is shown in Figure 1. Using matrices such as sinapic acid, which exhibits strong solid-phase optical absorption at 337 nm, we have successfully desorbed and ionized proteins having high molecular weights with sensitivity in the low picomole range. Nitrogen lasers capable of producing the required irradiance levels (~1 MW/cm²) may be purchased for ~$10,000. A nitrogen laser system offers the advantages of a less complex optical system (the fundamental frequency is used), shorter pulse widths, higher repetition rates, and substantially lower cost when compared to a Nd:YAG laser.

**Charge State/Kinetic Energy Effects**

Figure 2 shows a portion of the mass spectrum of horse heart cytochrome c (MW 12,360) in sinapic acid analyzed with a nominal ion source bias of +30 kV. The apparent resolution (R= t/2At FWHM) of the M⁺¹ quasimolecular ion region is 140. However, the resolution of the M⁺² region is 280. This may be explained by considering the initial kinetic energy of the ions formed by the desorption/ionization process. The nominal kinetic energy (E) of the singly charged ions is 30 keV, while the nominal kinetic energy of the doubly charged species is 60 keV. If the greatest contribution to peak broadening is the initial kinetic energy spread (ΔE), the resolution may expressed as [2]

\[
R = \frac{t}{2\Delta t} = \frac{E}{\Delta E} \quad \text{(mass independent)}
\]

If the limiting factor in mass spectral resolution arises from initial kinetic energy, then these data suggest that the initial kinetic energy spread is in excess of 100 eV.

**Matrix/Analyte Molar Ratio Effects**

A series of solutions of varying matrix/analyte molar ratio were prepared using horse heart cytochrome c as the analyte protein and sinapic acid as the matrix. Samples were prepared by applying a 1µl drop of the matrix/analyte solution to the probe tip and drying under a N₂ stream. The protein loading and the laser irradiance were held constant for each analysis. The probe tip was rotated while a 500 shot averaged spectrum was acquired to provide uniform sampling of the surface. Matrix associated (low mass) and analyte M⁺¹ and M⁺² peaks were integrated. The absolute intensity of the matrix and analyte ion signals and the ratio of the analyte/matrix signals are plotted as a function of the matrix/analyte molar ratio in Figure 3. With the exception of the lowest (100:1) and the highest (10,000:1) relative concentrations, both the absolute and the relative abundances of the matrix and analyte ion signals remain relatively constant.

Utility of a cysteine-specific cleavage reaction in the structure determination of proteins by laser desorption time-of-flight and tandem mass spectrometry

J. Zaia, I.A. Papayannopoulos, and K. Biemann,
Department of Chemistry, M.I.T., Cambridge, MA 02139

Introduction. It has been known for some time that polypeptides can be cleaved at the N-terminus of cysteine after cyanation. The formation of an iminothiazolidine ring at the product N-terminus prevents sequencing by conventional Edman techniques. Further development of the cyanation and cleavage was thus delayed until introduction of tandem mass spectrometric sequencing. Peptides in the range of m/z 3000 or less can be sequenced with present technology, and it has been found that cysteine cleavage products in this range tend to yield complete sequence data, dominated by a and b ions.

Larger cleavage fragments can now be analyzed by employing the new matrix-assisted laser desorption (LD-TOF) technology. The reaction can be monitored for completeness with little or no cleanup required for a mass determination. The completed reaction can be desalted to yield sharper, adduct free peaks.

Method. The cyanation can be carried out in two different ways:

1. Electrophilic cyanate.
   Here the cysteine is reduced before reaction with the electrophilic cyanate reagent. The sulfhydryl acts as nucleophile to attack the cyanate moiety. 2-Nitro-S-thiocyanatobenzoic acid (NTCB) has been used in the past, but we have found 4-thiocyanatoaniline (TCNA) to be a useful alternative. The polypeptide is reduced, and cyanlated at pH 8, and then dialyzed or extracted to remove the excess of the peptide bond N-terminal to the original cysteine occurs at pH 9 at 37 °C.

2. Nucleophilic cyanide
   Cyanide ion is used to reduce the disulfide bond directly. One cysteine is cyanylated, and the other is left as a free thiol. The cleanup of the reaction is minimal, requiring only a desalting HPLC step prior to tandem mass spectrometry, and nothing at all for LD-TOF. The easy cleanup is a distinct advantage for very small peptides for which dialysis is impossible and extraction risky. For larger polypeptides with disulfide bonds, it may be possible to use this method of cyanylation and cleavage to determine location of the disulfide bonds.

Tandem Mass Spectrometry was performed on a JEL HX110/110 double focusing tandem mass spectrometer, which is of E^E,!^ configuration. Collision induced dissociation of the protonated peptide molecule selected with MS-1 took place in the field-free region after Bp. The collision cell potential was 3.0 kV and the ion collision energies were at 7.0 keV. Helium, the collision gas, was introduced into the collision chamber so as to reduce the precursor ion signal by 65-70%. 100 Hz filtering was used with a scan rate of m/z 0 to 6000 in 15 min. Only the C12 species of the protonated peptide molecule was transmitted through MS-1. MS-2 was operated at 1000 resolution and was calibrated with a mixture of CsI, NaI, KI, RbI, and LiCl.

Matrix-Assisted Laser Desorption Time of Flight Mass Spectrometry was performed on a Vestec VT2000 instrument. The 355nm, frequency tripled output of a Nd^YAG laser was used to ionize the sample. The laser output pulse length was approximately 15 ns, the irradiance used was approximately 10MW/cm^2, and the laser was operated at 5 Hz. The matrix used was sinapinic acid, and 1-2 pmol of analyte were placed on the probe tip. The instrument was operated at 30KV accelerating voltage. Spectra were obtained by adding together 40 laser shots using a transient recorder, which was controlled by a PC. The data were stored temporarily on the PC and then transferred to a VAX work station for analysis. Software for calibration, analysis, and presentation of the data were developed in our laboratory (see MP 111).

Results. Figure 1 shows the LD-TOF mass spectrum of human hemoglobin α chain which has been cleaved with the TCNA reagent. The average protonated molecular weights for the theoretical products and those found by the use of external calibration are,

and are easily identified from the spectrum.

The N-terminal Figure 2 shows the C-terminal peptide resulting from the cyanation and cleavage of ribonuclease A. The spectrum exhibits an a ion at m/z=101 which is indicative of the presence of iminothiazolidine at the N-terminus and is dominated by a and b ions which reveal the complete sequence.

Isotocin (CYSNCPIC) was used to demonstrate the cyanide ion induced reduction and cyanylation on a small peptide. Isotocin is typical of neuropeptides, having an N-terminal cysteine with a disulfide bridge. Cyanide ion alkylating at the cys-1 half of the disulfide bond
yields an iminothiazolidine ring at the N-terminus but does not involve a peptide bond cleavage. The CID spectrum (not shown) is dominated by a and b ions and contains complete sequence information. The use of cyanide salts for these small peptides is convenient due to the minimal cleanup required.

The treatment of larger polypeptides with cyanide salts may allow the assignment of the disulfide bonds. For a protein with two disulfides, there exist three possible disulfide bonding distributions. If a peptide is detected that is not possible for a given distribution, that distribution is eliminated from consideration.

Conclusion. Polypeptides can be cleaved at cysteine with the NTCB or TCNA reagents. For large products mass assignments can be made with the LD-TOF instrument, allowing for monitoring of the reaction as it progresses. Smaller peptide products can be sequenced with the tandem mass spectrometer.

Cyanide ion is preferable for smaller cysteine containing peptides where removal of the excess cyanate reagents proves difficult. The presence of N-terminal iminothiazolidine appears to direct fragmentation towards the production of a and b ions.

The reaction with cyanide ion may allow the assignment of the distribution of disulfide bonds in proteins.

Analysis of Highly Glycosylated or Hydrophobic Membrane Proteins by Laser Desorption Time-Of-Flight Mass Spectrometry

Stanley A. Hefta, Douglas C. Stahl, Alan M. Mahrenholz, Paul A. Martino, Shane M. Rutherfurd, and Terry D. Lee., Division of Immunology, Beckman Research Institute of the City of Hope, Duarte CA 91010.

Introduction.

Purification and structural analysis of highly glycosylated proteins or of hydrophobic membrane proteins present unique challenges to the protein chemist. Presence of carbohydrate complicates chromatography, proteolytic digestions, and structural analysis of the resulting glycopeptides. Glycoproteins often give broad, poorly defined bands by SDS-gel electrophoresis or gel permeation chromatography producing unreliable estimations of molecular weights. For the hydrophobic proteins, solubility is the problem and the use of detergents for purification and further analysis is generally required. As a consequence of these features, the utility of one of the most important contemporary analytical tools to the protein chemist, namely mass spectrometry, is compromised. As part of a continuing effort in the protein structural field, we have recently begun to use laser desorption time-of-flight mass spectrometry to analyze these types of proteins. We report here on some of the uses and limitations of this approach.

Materials and Methods.

Ribonuclease-B, ovalbumin, fetuin, and lactoferrin were purchased from Sigma. The NCA-50, NCA-75, and carcinoembryonic antigen (CEA) samples were isolated from a liver metastasis of a colonic tumor. For analysis by LD-TOF MS, these proteins were dissolved in 0.1% TFA and mixed with an equal volume of a saturated solution of 3,5-dimethoxy-4-hydroxy-cinnamic acid (sinapinic acid) dissolved in 30% aq. CH3CN, 0.1% TFA. An aliquot (generally ~1 ul) of the sample/matrix was spotted on a copper stage and allowed to air dry. Mass analysis was performed using a Shimadzu LAM-50KS LD-TOF mass spectrometer equipped with a Nd:YAG and operated at 355 nm.

Nine different cytochrome P450 samples were isolated from natural sources. Successful analysis in most instances required the removal of interfering components. Sample solutions were dried on the bare copper sample stage in vacuum and then washed with a solution of aqueous 30% acetonitrile, 0.1% TFA. Sinapinic acid matrix was added to the sample and mass spectra were collected as described above.

Results

LD-TOF MS of glycoproteins. The general trend observed was that as the complexity and amount of carbohydrate present increased, the molecular ion signal broadened reflecting a multiplicity of ions arising from microheterogeneity of glycosylation and matrix adduct formation. For example, for Ribonuclease-B (m/z 13572, one glycosylation site) the base of the molecular ion signal was 3000 amu wide, but for CEA (m/z 127,222, 28 glycosylation sites) the base width was >20,000 amu. Deglycosylation of the samples significantly increased the signal intensity and sharpness of the molecular ion peak.

Of particular interest in these analyses were the results for the LD-TOF MS of NCA-50 (m/z 46052) and NCA-75 (m/z 65594). These glycoproteins are expressed in granulocytes, the immune phagocytic cells, and function as bacterial binding receptors. They are identical.
with respect to protein sequence and numbers of glycosylation sites (12 N-linked sites) but differ in the types of carbohydrates present. These differences in carbohydrates are functionally important and directly affect binding specificities. In the case of NCA-50, the high mannose-types of carbohydrates are functionally relevant. To examine the amount of such structures, we treated NCA-50 with Endoglycosidase-H to remove high mannose-type structures and with trifluoromethanesulfonic acid to totally deglycosylate the sample. Endo-H treatment shifted the mass by 4444 amu while total deglycosylation caused a 11570 amu mass shift. These results indicate that NCA-50 contains approximately 40% high mannose-type of oligosaccharides.

**LD-TOF MS of Cytochrome P450 Enzymes.** Beavis and Chait have described a simple washing technique in conjunction with the use of sinipinic acid as a matrix to prepare samples for LDMS analysis. This technique proved ineffective for a large majority of the cytochrome P450 samples we have attempted to analyze. The alternative sample washing method described above was more effective for this class of compounds. Cytochrome P450D failed to yield spectra by any of the methods of washing the sample on the metal probe tip. In an effort to further immobilize the sample in order to wash with less polar solvents, the sample solution was spotted on a thin piece of polyvinylidenedifluoride (PVDF) membrane. After vacuum drying, the membrane was washed with 30% aqueous acetonitrile containing 0.1% trifluoroacetic acid. The sinipinic acid matrix solution was added to the membrane and allowed to air dry. Using this procedure, a reasonably good spectrum was obtained. No spectrum was obtained from PVDF without washing, and a very weak spectrum was obtained if the membrane was washed with cold water after applying the matrix. The use of the PVDF membrane introduces an additional complication. Because the membrane forms an insulating layer on the sample stage, the acceleration experienced by the desorbed ions is less resulting in longer flight times and artificially high mass values. If this technique proves generally useful, it will be necessary to have a separate calibration for samples on PVDF or include an internal standard.

**Conclusions**

Heavily glycosylated proteins invariably exist as a multiplicity of species that differ in the number of sugar units attached. Thus far, we have had no success analyzing members of the CEA gene family by electrospray mass spectrometry. We have had some success using laser desorption. The resolution of our instrument is not sufficient to separate the glycoforms. However, even the broad signals observed yield more accurate mass values than can be obtained by SDS page gel electrophoresis and the amount of sample required is generally less. The action of various carbohydrate cleaving enzymes can be followed by observing the mass shifts. As carbohydrate is removed, molecular ion signals narrow significantly and mass accuracy increases.

Hydrophobic membrane proteins pose an entirely different set of problems. Samples are generally heavily contaminated with interfering substances that must be removed for a successful mass measurement. In a few instances, electrospray data can be obtained using on-line LCMS analysis. For these measurements, the mass accuracy is very good. Using novel washing techniques involving binding of the protein to metal and fluorocarbon surfaces, it is possible to obtain laser desorption spectra of Cytochrome P450 enzymes accurate to within 1% or less. Laser desorption mass spectrometry is a nearly universal technique for the analysis of proteins. However, proper sample preparation is of great importance and in many ways mysterious.
INTRODUCTION

Peptide mapping by reversed-phase microbore liquid chromatography combined with ion spray mass spectrometry was used to determine carbohydrate composition and glycosylation sites of glycoproteins. Glycopeptides in proteolytic digest mixtures were identified by LC/MS/MS precursor ion scans. Utilization of collision-induced dissociation (CID) in the free-jet expansion declustering region of the atmospheric pressure ionization source enabled screening for glycopeptides in digest mixtures from full-scan LC/CID/MS experiments which contained the diagnostic ions (m/z 204, 366) and intact precursor ion information in the same data run.

The combination of CID before mass filtering and MS/MS was utilized for the identification of N-glycosylated peptides by: 1) exoglycosidase treatment of glycopeptides to reduce the carbohydrates to a common chitobiose core containing mannose residues, 2) CID in the declustering region to produce a singly charged peptide with one pendent GlcNAc, and 3) MS/MS to remove the GlcNAc as a neutral (-203) loss.

EXPERIMENTAL

A Sciex API III (retrofitted from TAGA 6000E) triple quadrupole mass spectrometer and an Applied Biosystems 140A micropump equipped with a YMC MAQ-110 1 x 100 mm C18 column was used with gradients from 0-50% CH3CN/H2O containing 0.05% TFA at flows of 40 µL/min. Typically, 0.5–10 nmol of glycopeptide digest mixture was injected in 5–20 µL of mobile phase and the gradient increased at 1% CH3CN/min.

Glycoproteins, proteases, and exoglycosidases were purchased from Sigma, and Staph. aureus protease V8 was purchased from Boehringer Mannheim. Ribonuclease (RNase) B was persulfonated by the method of Thannhauser; asialofetuin (ASF) and ovomucoid were reduced and carboxymethylated (RCM). Each was digested with trypsin; RCM ovomucoid and RCM ASF were also digested with chymotrypsin, and the latter was digested with Staph. aureus protease V8 (enzyme:substrate 1:50). Proteolytic digest mixtures were subsequently treated with α-mannosidase and β-N-acetylglucosaminidase in NH4HCO3, Na2HPO4, or NaOAc buffers (50-200 mM).

Data were acquired (6 sec/scan) at m/z 200–2000 for LC/CID/MS (with unit resolution at 50% valley), m/z 400–2400 for LC/MS/MS precursor ion scans and m/z 600–1600 for neutral loss scans (2–3 amu FWHM). Declustering energy in the orifice-to-RF-only quadrupole region (Q0) was 120–140 eV and collision energy in the RF-only quadrupole (Q2) between the tandem mass-resolving quadrupoles was 80–100 eV referenced to the laboratory frame for a doubly charged ion. Argon was used as a collision gas in Q2 at 200-230 x 1012 atoms/cm2, and ultra-high purity nitrogen was used as a declustering gas in Q0. MS/MS product ion spectra were obtained by continuous infusion in MCA mode (64 scans) of peptides which had been fractionated by solid-phase extraction or by LC/MS/MS of the digest mixture.

RESULTS AND DISCUSSION

LC/MS/MS identified glycopeptides containing HexNAc or HexHexNAc units in digest mixtures by precursor ion scans of the characteristic oxonium ions at m/z 204 and 366, respectively. The selectivity of MS/MS enabled the detection of a minor glycoform of ovomucoid containing a terminal galactose on a N-acetylglucosamine2 by a m/z 366 precursor scan. However, resolution was sacrificed in order to achieve adequate sensitivity.

Utilization of collision-induced dissociation (CID) in the declustering region (Q0) of the atmospheric pressure ionization mass spectrometer provided both oxonium ions and intact glycopeptide ions before mass resolution in Q1. LC/CID/MS with declustering energies of 120–140 eV caused both fragmentation of glycopeptides to oxonium ions and improved transmission of intact doubly charged glycopeptides (m/z 750–1500). A single LC/MS run yielded both diagnostic ions (m/z 204, 366) to screen for glycopeptides in mixtures and the distributions of the glycoforms with high sensitivity and unit resolution.
MS/MS of doubly charged tryptic-like glycopeptides containing N-linked carbohydrate yielded oxonium ions along with singly charged reducing-end fragment ions resulting from cleavage at glycosidic bonds. Intact peptide with N-linked GlcNAc was typically a major ion; little or no peptide bond cleavage was seen due to the relative strengths of amide vs. O-glycosidic bonds. Continuous infusion with signal averaging of peptides fractionated with solid-phase extraction produced better quality mass spectra; however, LC/MS/MS could be utilized if sample was not limited.

LC/CID/MS/MS was utilized to selectively determine N-linked glycosylated tryptic-like peptides which had carbohydrate reduced by exoglycosidases to a chitobiose core with mannose residues. The remaining O-glycosidic sugars were removed by CID in Q0 to produce singly charged peptides with pendent N-linked GlcNAc; MS/MS in Q2 efficiently cleaved the GlcNAc as a neutral loss (-203). LC/CID/MS/MS was used to determine the MW of the N-linked glycosylated peptides of persulfonated RNase B digested with trypsin and α-mannosidase (Figure 1) and RCM ovomucoid digested with trypsin and β-N-acetylglucosaminidase.

INTRODUCTION

In plasma desorption mass spectrometry (PDMS) [1], the sample solution is generally applied onto a nitrocellulose-coated, foil target and dried prior to analysis. During mass analysis, only a small fraction of the sample is consumed due to the low flux of primary ions and the high sensitivity of ion detection characteristic of this technique. The very low sample consumption makes it feasible to reuse the sample after mass determination. For example, mass analyses can be performed on the same sample target before and after in-situ enzymatic digestion or chemical reaction. Another approach is to recover the remaining sample from the nitrocellulose matrix for further study. Roepstorff has demonstrated that a peptide sample can be eluted from the nitrocellulose to a PVDF membrane for subsequent microsequencing [2]. We have devised a simple protocol for recovering sample in solution from the nitrocellulose matrix for further structural analyses. The effects of various eluting solutions on sample recovery yield and background contamination are discussed. Results from amino acid analysis, microsequencing and enzymatic digestion of samples recovered from targets after PDMS analysis demonstrate a practical approach to obtaining maximum structural information from a limited amount of peptide or protein sample.

EXPERIMENTAL

Instrumentation Mass analyses were performed using a Biolon™ 20 Biopolymer Mass Analyzer. Automated Edman degradation were performed using a Model 477A Pulsed Liquid Phase Sequencer with on-line model 120A PTH Amino Acid Analyzer. Amino acid compositions were determined using a Model 420H Amino acid Analyzer. (Applied Biosystems, Inc.)

Deglycosylation of peptide. Glycopeptide samples (approximately 200 pmol) were dissolved in 19 μL buffer containing 0.2M Na2PO4 (pH 8.5). One micro-liter (0.25 unit) of N-glycanase (from Genzyme) was added to the solution. The reaction mixture was incubated at 37°C overnight.

EVALUATION OF RECOVERY PROTOCOL

Choice of Method

A simple protocol is shown in Fig. 1 for recovering of samples from a nitrocellulose-coated target into proper solvent. The solution can then be directly applied onto a sequencing membrane, or collected in an Eppendorf tube for enzymatic treatment, HPLC, or amino acid analysis.

Choice of Extraction Solvent

The IPA and TFA were chosen because of the low solubility of nitrocellulose in these solvents resulting in less contamination during extraction [3, 2]. The effects of organic solvent concentration and pH of the extraction solution on the recovery yield and contamination were evaluated. For peptides, the results indicate typical recovery of 50 to 95% (not shown). Higher concentrations of isopropyl alcohol improve the recovery of peptides with longer retention time on the reverse-phase HPLC system. For protein samples, the recovery yield is more sample dependent. The solvent effects were evaluated using calmodulin (from porcine brain) as a model compound (Table 1). Other proteins, such as beta-lactoglobulin, lysozyme, insulin, extracted with standard conditions (70%IPA, 5%TFA) resulted in 30 to 90% recovery yield.

INTEGRATION OF PDMS WITH PROTEIN CHEMISTRY
Example: Analysis of Glycopeptide from Tryptic Digest of Carboxypeptidase P
Structural analysis of glycopeptides continues to be a challenge for most protein chemists. Little information can be obtained by conventional sequence analysis except for speculation that the sample may be glycosylated. In this example (Fig. 2), we performed mass analysis of the intact glycopeptide (Fig. 2, top right). The sample was recovered from the target, deglycosylated with N-glycanase, purified (middle left) and analyzed by PDMS (middle right). The mass difference suggested the possible carbohydrate structure. Furthermore, the complete sequence of the peptide was determined by microsequencing (Fig. 2, bottom) the peptide recovered after the second round of mass analysis.

CONCLUSION
- Protein and peptide samples can be recovered from nitrocellulose-coated targets after PDMS. The simple protocol presented here recovers proteins and peptides into IPA/TFA solution for further structural analysis.
- The recovered sample solution can be applied directly onto a pre-conditioned sequencing matrix, or subjected to amino acid analysis without further purification.
- The integration of PDMS with in-situ protease or chemical digestion protocols, microsequencing, amino acid analysis and HPLC provides a powerful tool for solving some of the more complicated protein structure problems.

Applications of the Parent Scan Mode for the Sequence Analysis of Amino-Terminal Derivatized Peptides

Mike S. Lee, Steven E. Klohr, Alan F. Wahl, Edward S. Kozlowski, and Ira E. Rosenberg
Bristol-Myers Squibb Company, 5 Research Parkway, Wallingford, CT 06492.

The determination of a peptide sequence directly from daughter MS/MS spectra involves a systematic process of logical deductions via fragmentation patterns and a knowledge of fragmentation pathways. The process of spectral interpretation is facilitated by the fact that peptides generally undergo characteristic fragmentations. The resulting fragment ions are typically indicative of a particular amino acid. However, this process can often be time-consuming, especially when dealing with an unknown peptide. A limitation of the daughter MS/MS mode for the direct sequence analysis of unknown peptides is the presence of both N-terminal and C-terminal sequence ions in the daughter spectrum. A complementary mass spectrometric method which could provide spectra containing only N-terminal or C-terminal fragment ions would result in rapid sequence determination of unknown amino acid sequences, and perhaps, a simpler and systematic method for amino acid sequence confirmation.

Here, the application of the parent scan mode for the unidirectional sequence analysis of peptides is demonstrated with methionine enkephalin (Figure 1). This method is based on the fact that peptides undergo similar fragmentations corresponding to cleavages through the amide linkages. Specifically, N-terminal and C-terminal substructures undergo characteristic MS/MS fragmentations indicative of the N-terminal amino acid and C-terminal acid, respectively. The parent scan mode is ideally suited for the analysis of typical fragmentation schemes and can generate spectra which contain characteristic precursors or substructures of a selected daughter ion. Microscale reactions of methionine enkephalin with phenyl isothiocyanate were performed to selectively "tag" the N-terminus for subsequent elucidation of the N-terminal amino acid.

The daughter MS/MS spectrum of the protonated molecular ion of methionine enkephalin (m/z 574) contain primarily A, B, C, and Y substructure ions (Figure 2). Fragment ions corresponding to the B, C, X, Z, and Y substructures are not present in the spectrum. The fragment ion at m/z 120 corresponds to the phenylalanine substructure and fragment ions at m/z 177 and 205 correspond to substructures of glycine-phenylalanine. The m/z 234 fragment corresponds to the glycine-glycine-phenylalanine substructure.

The daughter MS/MS spectra of the N-terminal and C-terminal sequence ions of methionine enkephalin exhibit a more selective fragmentation behavior than the spectra obtained from the molecular ion species. These spectra yield either N-terminal or C-terminal sequence ions exclusively. The fragmentation behavior of the N-terminal sequence ions of methionine enkephalin suggest that the parent MS/MS mode may be utilized to obtain exclusive N-terminal sequence information (A, B, and C substructures). Specifically, the parent MS/MS spectrum selecting all precursors of the A, substructure should provide unidirectional N-terminal sequence information. The fragmentation behavior of the C-terminal sequence ions suggest that the parent MS/MS mode may be utilized to obtain exclusive C-terminal sequence information (Y, substructures).

The parent MS/MS spectrum selecting for the precursors of the A tyrosine substructure of methionine enkephalin (m/z 136) is shown in Figure 3. All N-terminal sequence ions (A, B, and C) are present along with the protonated molecular ion. No ions corresponding to C-terminal sequence ions are present in the spectrum. These results indicate that all N-terminal sequence ions are formed in the ion source and undergo MS/MS fragmentations to yield the A, substructure ion. The B, C, and C substructures which are not present in the parent MS/MS spectrum of methionine enkephalin are readily apparent in this spectrum. The presence of the B, A, and C substructure ions indicate that these ions are indeed formed in the ion source.

The parent MS/MS spectrum selecting for all precursors of the Y, methionine substructure ion of methionine enkephalin (m/z 150) contain all the Y, substructures along with the protonated molecular ion (Figure 4). This result is due to the fact that each of Y, substructures form in the ion source and undergo MS/MS fragmentations to yield the Y, substructure ion. The complementary X, and Z, substructures are not present in this spectrum.

The parent MS/MS mode selecting precursors of the A, substructure is the most selective for generating exclusive N-terminal sequence ions. Utilization of this MS/MS sequencing methodology with amino-terminal derivatized peptides is useful for the identification of the A, substructure. The presence of all A, B, and C, fragments in the parent MS/MS spectrum indicate that each of these N-terminal sequence ions are formed in the ion source.

FORMATION OF INTERNAL FRAGMENTS DURING TANDEM MASS SPECTROMETRY OF PEPTIDE [M + H]⁺ IONS

Kevin D. Ballard and Simon J. Gaskell, Ctr. Exp. Ther., Baylor College of Medicine, Houston, TX 77030

"Internal" fragment ions of protonated peptides arise by charge retention on a portion of the structure excised from the peptide chain. The question which prompted the present studies was whether, during the formation of (BY)⁺ (or (AY)⁺) type internal fragments from peptides, the B-type (or A-type) cleavage preceded the Y'-type cleavage or vice versa. The genesis of internal fragment ions requires a minimum of two bond cleavages but the sequence of fragmentation is not revealed by a conventional product ion spectrum. Preliminary experiments1, based upon sequential product ion scanning, suggested that the Y⁺ ion from protonated leucine-enkephalin had a greater propensity to form the (B₂Y)⁺ species than did the B₂ ion. However, when two or more first generation intermediates can fragment to form the same second generation product, the relative contributions of the alternative pathways are difficult to judge based upon sequential product ion scanning alone. Reaction intermediate scanning2 can provide information regarding the relative quantitative significance of competing pathways which give rise to a common second generation product. For mechanistic studies, the population of intermediates available for subsequent decomposition during the reaction intermediate scan must be considered during the interpretation of the data. We have undertaken a broader study of the genesis of internal fragments from peptides using the reaction intermediate scanning capability of a BEqQ hybrid mass spectrometer.

Under low energy CAD conditions, leucine-enkephalin generates four internal cleavage fragments, designated as (A₂Y₂)⁺, (B₂Y₂)⁺, (A₄Y)⁺, and (B₄Y)⁺. Sequential product ion scans for four of the simple cleavage intermediate ions (B₂, A₄, Y₂, and Y₄) demonstrated that all four of the internal cleavage ions can be formed via either the B₂ ion or the Y₂ ion. However, the other simple cleavage ions also give rise to two of the internal cleavage ions, and the relative importance of these competing pathways was not apparent from second generation product ion scanning alone. In the reaction intermediate scan for the (B₂Y₂)⁺ ion from leucine-enkephalin, the major signals detected corresponded to the Y₂⁺ and B₂ ions, with the Y₂⁺ predominating. In assessing these data, reference was made to the MIKES spectrum of this peptide, which accurately represented the population of all potential intermediate ions available for subsequent decomposition during the reaction intermediate scan. The relative intensities of these two ions were reversed in the reaction intermediate spectrum as compared to the MIKES spectrum, indicating that the [M + H]⁺ → Y₂⁻ > (B Y Y)⁻ reaction sequence is much more highly favored than is the [M + H]⁺ → B₂⁻ > (B Y Y)⁻ sequence, although both reactions occur. The B₂ ion, which dominated the MIKES spectrum, also dominated the reaction intermediate spectra for the other internal cleavage ions. The relative abundances of the intermediates detected in these spectra more closely resembled those in the MIKES spectrum, indicating less dramatic differences in the relative contributions from the various competing pathways. Note that the formation of an AY ion via a B ion requires the cleavage of three covalent bonds, yet this pathway predominated for the (A₂Y₂)⁺ and (A₄Y)⁺ species.

Under low energy CAD conditions, des-Arg¹-substance P gives rise to at least eight internal cleavage ions of the A₄Y₂ and B₄Y₂ types. The metastable MIKES spectrum of this peptide (Figure 1) demonstrated that internal cleavage ions can be formed under spontaneous decomposition conditions on a microsecond time scale. In the second generation product ion spectrum representing the [M + H]⁺ → Y₂⁻ > (products) sequence for this peptide (Figure 2), all eight of the internal fragments from this peptide were detected. The reaction intermediate scan for the (B₂Y₂)⁺ ion obtained under metastable conditions (Figure 3) demonstrated that both the B₂ and the Y₂⁻ species were intermediates in the formation of this ion. Comparison with the MIKES spectrum indicated a greater inherent tendency for the Y₂⁻ species (as compared to the B₂) to give rise to the (B₂Y₂)⁺ ion. The complexity of the origins of internal cleavage fragments was further exemplified in the reaction intermediate spectrum for the [M + H]⁺ → intermediates > (B Y Y)⁻ reaction sequence for des-Arg¹-substance P. The Y₁⁺ ion was again prominent as an intermediate in this spectrum. However, all possible members of the B⁺ series were also detected, as well as several larger internal cleavage ions, and the sum total of these contributions exceeded that derived through the Y₁⁺ ion.

CONCLUSIONS: Certain Y₁⁺ ions (equivalent to truncated protonated peptides) have a high inherent tendency to fragment to (AY)⁺ (and (BY)⁺) ions. Internal fragment ions can also arise through alternative, multistep pathways which may dominate when the requisite intermediates are formed in high abundance. Reaction intermediate scanning (MS/MS/MS) reveals the relative significance of competing pathways provided the relative abundances of alternative intermediates are considered.

Figure 1.

Figure 2.

Figure 3.
Measurements of the kinetic energy (KE) released during the decomposition of metastable ions are conventionally performed by mass analyzed ion kinetic energy scanning (MIKES) using a BE geometry mass spectrometer [1]. However, the effective mass resolution of product ions with the MIKES technique (100-300) is insufficient to permit estimation of the kinetic energy released during the formation of two product ions which are very similar in mass and which consequently overlap in the MIKES spectrum. Furthermore, problems associated with the Derrick shift [2] can lead to erroneous interpretation even when the MIKES peaks appear to be well separated. With an EQ or a BEqQ hybrid instrument [3,4], it is possible to mass select (at unit resolution) the ions detected during the kinetic energy scan; this eliminates any uncertainty regarding the mass of the detected ions and permits deconvolution of overlapping MIKES peaks. Such a scan can thus be called a mass deconvoluted MIKES analysis (MAD MIKES). The characteristic MIKES peak shape is retained, permitting estimation of the kinetic energy released during product ion formation. Such calculations assume a single stage of bond cleavage. Caution is indicated, however, since profiles of ions generated through pathways involving sequential steps of bond cleavage can be broadened due to the kinetic energy released during the initial fragmentation, leading to potentially erroneous conclusions regarding kinetic energy release if the sequential reactions are not recognized.

We have employed the MAD MIKES technique in order to assess the kinetic energy released during the metastable fragmentation of peptide bonds. The reproducibility of the experiments has been examined, and a systematic study has been undertaken using relatively simple pentapeptides as model compounds. These experiments employed a hybrid instrument of BEqQ configuration.

RESULTS. The deconvolution of overlapping MIKES peaks through the use of the MAD MIKES experiment is exemplified in Figure 1. Peaks attributable to m/z 393 (Y4) and 397 (A4) from leucine enkephalin clearly overlap in the MIKES spectrum (upper trace), but are resolved into their individual components in the MAD MIKES spectra (lower two traces). Despite the sacrifice in signal intensity accompanying the use of MAD MIKES, careful attention to experimental parameters permits reproducible determinations of ion kinetic energy profiles, with intra-day coefficients of variation as low as 2% for calculated kinetic energy release values.

Table I summarizes the kinetic energy release calculated for metastable peptide fragmentations from MAD MIKES experiments with several simple pentapeptides. Higher values of kinetic energy release were consistently obtained from penta-Phe than were obtained for the corresponding fragmentations for penta-Gly or penta-Ala. Also noteworthy is the similarity of kinetic energy release values for B- and Y'-type ions involving cleavage of the same peptide bond (B3 and Y2 in these examples). Of particular note is the high value obtained for the A4 ion from leucine-enkephalin. A reaction intermediate scan [5] representing the [M + H]+→intermediates→A4 reaction sequence demonstrated that the A4 ion can be formed via initial formation of the B4 ion under metastable conditions. The high value observed for the kinetic energy release accompanying formation of the A4 ion is consistent with the occurrence of this pathway during the microsecond time scale of the MIKES experiment.

CONCLUSIONS. Mass deconvoluted MIKES analysis has been confirmed as an effective and reproducible technique for kinetic energy release measurements. Interpretation of kinetic energy release requires consideration of the possibility of multistage fragmentation. Several observations from these preliminary data are striking and encourage further study: (i) the kinetic energy release accompanying peptide bond cleavage appears to be influenced by the side chain structure of the amino acid constituents; (ii) an A-type ion may be formed via a B-type ion under metastable conditions on a microsecond time scale; (iii) the kinetic energy released during the formation of Y'-type ions and their B-type congeners are remarkably similar for all examples studied.

EVIDENCE FOR TWO POSSIBLE MECHANISMS IN THE FORMATION OF PEPTIDE [B'_{n-1} + OH]^+ IONS

S. Boel, W. Baeten, L. Dillen and M. Claeyss
University of Antwerp (U.I.A.), Department of Pharmaceutical Sciences, B-2610 Antwerp, Belgium

A novel fragmentation of peptide [M + H]^+ ions has recently been described on the loss of the C-terminal amino acid residue, yielding [B'_{n-1} + OH]^+ ions [1,2]. This rearrangement was shown to occur if the C-terminus consists of a free carboxyl group and is of diagnostic importance as it allows to determine the C-terminal amino acid. Thome et al. [2] proposed a mechanism for this rearrangement based on previous research carried out by Grese et al. [3] on peptide lithium adducts.

In the course of a study on the fragmentation of [M + H]^+ ions of the heptapeptide (met^2, arg^6, phe^7) enkephalin (YGGFMRF), the [B'_{n-1} + OH]^+ ion at m/z 730 was found to be the most abundant daughter ion (Fig. 1). However, the FAB/MS/CID/MS data obtained for the corresponding \textsuperscript{18}O\textsubscript{2}-analog revealed two corresponding ions at m/z 732 and 734 (ratio 3/1), for which only the former can be explained with the mechanism proposed by Thome et al. [2]. These data indicate that a single mechanism does not apply to this rearrangement. In an effort to rationalize the ions at m/z 734 in the \textsuperscript{18}O\textsubscript{2}-analog, a second mechanism is proposed (Scheme 1). This mechanism results in [C'_{n-1} + COOH]^+ ions, which in the case of the unlabelled product fall at the same mass as the [B'_{n-1} + OH]^+ ions.

An interesting feature is that this C-terminal rearrangement occurs in a peptide containing an arginine residue at the n-1 position, for which the formation of these rearrangement ions was shown to be inhibited [2,3]. Lowering the basicity of the arginine residue by conversion to its dimethylpyrimidylornithyl derivative resulted in a decrease of the abundance of the rearrangement ion.

SCHEME 1
Mechanism proposed for the formation of [C'_{n-1} + COOH]^+ ions.
Fast atom bombardment (FAB) with collisionally activated dissociation (CAD) of peptides yields a number of sequence ions that provide information about the primary structure. Specific mechanisms have been suggested and are widely accepted for the most commonly detected sequence ions: \( a_n \), \( b_n \), \( c_n \), and \( y_n \). However, few stable isotope labelling studies have been performed to substantiate these proposed mechanisms.

We previously described a new method for localizing a positive charge on either the N- or C-terminus of a peptide by derivatizing the peptide with an ethyl-triphenylphosphonium moiety. The FAB-CAD-B/E (linked scan) mass spectra of both the N- and C-terminal ethyl-TPP derivatives indicate ions are formed that differ in mass from the corresponding fragment ions in the spectra of the derivatized peptides by one to three mass units (not including the difference in mass due to the derivatizing moiety); we interpret these differences to be reflective of the formation of these fragments via charge-remote fragmentation mechanisms, rather than via charge-directed processes.

Using two different stable-isotope-labeled analogues of the peptide VGVAPG, we have investigated the mechanism of formation of some of these fragment ions. One of the analogues contained a deuterium on the \( \alpha \)-carbon of the alanine; the second deuterated analogue contained deuteriums at all exchangeable sites \((-\text{COOH}, -\text{CONH}_2, -\text{NH}_2)\) of the peptide (figure 1). The peptide VGVAPG, the deuterated labeled peptides, and the N- and C-terminal ethyl-TPP derivatives of the unlabeled and deuterium labelled peptides were analyzed by FAB-CAD.

The formation of \( y_n \) and \( c_n \) fragment ions is thought to involve protonation during ionization and the transfer of a second hydrogen atom to the amide nitrogen during bond cleavage. The hydrogen to be transferred to the amide involved in the bond cleavage can originate from several sites: (1) the \( \alpha \)-carbon, (2) an \(-\text{NH}_2\), or (3) one of the side chains.

The data indicate that both ions are formed by transfer of a hydrogen from an amide group. If the hydrogen transfer is from the adjacent amide, this would explain the absence of \( y_n \) ions that are adjacent on the C-terminal side to a proline residue, which does not contain a H on the imide group. Interestingly the spectrum of N-acetylated VGVAPG is noticeably different; the intensities of the \( y_n \) ion peaks are reduced dramatically from those of the peptide. This suggests that the N-terminal free amine may be the primary source for the hydrogen transferred during the formation of the \( y_n \) fragment ions.

Because CAD fragment ions from the ethyl-TPP derivatives of peptides are not protonated at the site of cleavage, but have a fixed positive charge, the structures and mechanisms for their formation were expected to differ from those of the derivatized peptides. We have found that the C-terminally derivatized peptide produces \( y_n-3 \), \( x_n-3 \), \( z_n \), \( v_n \), and \( w_n \) ions, while N-terminally derivatized peptides yield \( a_n-1 \), \( d_n \) and, to a lesser extent, \( b_n-1 \) and \( c_n-1 \) fragment ions. We speculate that the mechanism for forming the ions that are either 1 or 3 mass units lower than expected (compared to those from the derivatized peptides) does not involve protonation or a hydrogen transfer, but involves a 1,2 elimination reaction or the expulsion of a molecule of hydrogen. The expelled H atom can originate from three possible sites: (1) the \( \alpha \)-carbon, (2) an amide nitrogen or another exchangeable site, and (3) the \( \beta \)-carbon or the sidechain of the amino acid involved in the cleavage. Using the N- and C-terminal derivatives of the deuterated analogues of VGVAPG, the locations of the expelled H atoms from the molecular ion to form \( y_n-3 \), \( x_n-3 \), and \( a_n-1 \) fragment ions were determined.

From the mass spectra of the C-terminal ethyl-TPP derivatives of the deuterated analogues, it was deduced that formation of the \( y_n-3 \) ion proceeds through the loss of a H atom located on the \( \alpha \)-carbon. Scheme 1 represents a possible mechanism for formation of the \( y_n-3 \) ions. Similarly, it was found that \( x_n-3 \) ions form through expulsion of a H atom located on an amide N, represented in scheme 2 as a 1,2 elimination reaction. The mass spectra of N-
terminal ethyl-TPP derivatives of the deuterated analogues indicate that the $a_{1\text{n}}$ ion is formed by the loss of neither the H atom on an amide nor that on the $\alpha$-carbon. This suggests that the $a_{1\text{n}}$ ion is formed by loss of a H atom from the $\beta$-carbon located on the side chain of the amino acid involved in the cleavage. This mechanism, represented in scheme 3, suggests a 1,2 elimination reaction. We do not expect the fragmentation to involve expulsion of a hydrogen molecule from the molecular ion, since the $a_{1\text{n}}$ could not occur at residues that are $N$-terminally adjacent to a proline by this mechanism, and the spectra do indicate these ions. In addition the 1,2 elimination mechanism explains the absence of $a_{1\text{n}}$ ions for cleavages involving a glycine residue, as it does not contain a hydrogen-bearing carbon side-chain.

Protein Conformational Correlations in The Solution State and The Gas Phase: An Ionspray and Collision Activation Study

*Rong Feng and Yasuo Konishi, National Research Council of Canada, Biotechnology Research Institute, 6100 Royalmount Avenue, Montreal, Quebec H4P 2R2, Canada

It has been shown\(^1\) that the charge distribution profiles of protein ions generated from electrospray ionization are sensitive to the protein conformational changes in solution. Thus, it can be used to characterize protein folding properties. However, it remains unclear whether these conformational states still maintain their structural differences in the gas phase, where no or little solvation assistance is available. Addressing this question is of fundamental importance to our understanding of the nature of protein folding.

Two conformational states of papain (23,422 Da) in aqueous solution were detected using an ionspray (pneumatically assisted electrospray) mass spectrometer (Sciex API III MS). The first state (N state), whose charge distribution profile centered around 11+, probably corresponded to the native conformation, as it was the only charge profile detected in the neutral solution (Fig. 1a). The second state (D state) (Fig. 1c), which co-existed with N state in 10% acetic acid solution (Fig. 1b), had a profile centered around 19+, indicating a more extended structure, as the denatured protein had exposed more basic amino acids for charging. Upon further increasing the acidity (to 20% acetic acid), N state disappeared and only D state profile remained (Fig. 1c).

The ions from the two co-existing conformational states in solution were subjected to collisions in the gas phase to probe for their structural differences. The collision experiments were carried out in either the ionspray interface region with N\(_2\) collision gas or the MS/MS collision chamber with Ar gas in Q\(_2\) region of the triple quadrupole MS. Although the N state profile showed much less change upon collisions, the D state profile disappeared quickly with the increase of either the collision energy in the interface region (Fig. 2) or gas density in Q\(_2\) (Fig. 3), presumably due to the fragmentation or scattering loss of the D state ions. A clear discontinuity in the intensity pattern existed in the cross-over region of the two profiles, where the ions from the two conformational states have similar number of charges. Thus, the velocity difference between the low- and high-charged ions was not the major cause for their behavioral difference during collisions.

The observed collisional phenomenon demonstrates that the protein conformational difference still exists in the gas phase, which in turn implies that solvation is not a necessity for a protein to maintain a certain conformation. The following factors may account for the gas phase behavioral difference of the two conformational states. First, the compact ball-type conformation of N state has smaller physical cross-section than, and therefore has less scattering loss than, the extended conformation of D state. Second, the tight structure of N state may have wrapped the majority of the protein backbone tightly within, and the scission of the bonds on the ball surface may not lead to the release of the resulting fragments. Consequently, N state appears less sensitive to collisions, as the limited fragmentation has not changed its effective overall mass. On the contrary, the loose structure of D state enables the fragmented backbone pieces to fly away, thus resulting in the quick decrease in its profile intensity. Since the extended D state has a larger cross-section than the tightly folded N state, it may also on average encounter more collisions than N state, which in turn leads to more energy intake and more fragmentation for D state.

Similarly, two conformational states, i.e., the low-charged N state and the high-charged D state, of myoglobin (16,950 Da) were detected in neutral solution (Fig. 4a) (in acidic solution only D state is stable). In contrast to the two papain states that have the same mass, the mass of myoglobin N state is 616 Da higher than that of D state, due to the trapping of the non-covalently bound heme in N state. As in case of papain, ion-neutral collisions in Q\(_2\) region resulted in the disappearance of myoglobin D state, while N state was relatively less affected (Fig. 4b). However, further increase in collision gas density resulted in the gas phase denaturation of N state, as there appeared a new charge profile (Fig. 4c) in which heme had been collisionally removed (the protein mass is now 616 Da less than before).
Myoglobin, which has a linear structure with no disulfide cross linkages, has to have a native conformation to wrap heme inside. The fact that its N state can hold heme in the gas phase, and is relatively more resistive to collisions than its D state, indicates that N state is very likely to have retained the native conformation during the flight in vacuum. This N state also appears to be flexible in the gas phase, as indicated by the collision denaturation experiment (As a comparison, the conversion of myoglobin N state to D state in solution is also very fast). On the contrary, papain N state appears to be rather rigid in the gas phase, paralleling its high stability in solution.

The structural and stability correlations of the compact and the extended protein conformations in the solution state and the gas phase indicates that the isolated gaseous protein molecules, without the assistance of the solvation effects, are capable of retaining the conformational identities they have in solution.

CHARACTERIZATION OF VARIOUS DERIVATIVES OF CYSTEINE-CONTAINING PEPTIDES USING HYBRID TANDEM MASS SPECTROMETRY

Odile Builet\textsuperscript{1,2}, Chao-Yuh Yang\textsuperscript{3}, and Simon J. Gaskell\textsuperscript{1}

\textsuperscript{1}Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030, \textsuperscript{2}University of Houston, Department of Chemistry, Houston, TX 77204-5641 \textsuperscript{3}Department of Medicine, Baylor College of Medicine, Houston, TX 77030

Modifications of cysteine residues are implicated in the modulation of the biological properties of proteins. In the case of low density lipoprotein, which is the major carrier of cholesterol in the blood, modification of its protein component (apoprotein B-100) under oxidative conditions is known to influence cholesterol accumulation in the cells. Cysteine residues might be modified under these conditions. As an initial stage in the development of an analytical strategy to assess such changes, the synthetic nonapeptides, GTYGLSCQR and EELCTMFIR, corresponding to the tryptic fragments of apoprotein B-100 from the residues 1472 to 1480 and 4187 to 4195 respectively, were analyzed by tandem mass spectrometry.

Low energy ($E_{\text{lab}} = 8-13 \text{ eV}$) collisionally activated decomposition (CAD) of the protonated peptides resulted in a low fragmentation yield and gave poor product ion spectra displaying only a few $Y^\nu$ ions.

Derivatization of the cysteine residues of these nonapeptides was attempted to increase the sensitivity of detection and optimize the MS/MS fragmentations. Carboxymethylation of the thiol moiety was performed by initial treatment of the peptide with a 10-fold molar excess of dithiothreitol (DTT) and then adding a 50-fold molar excess of iodoacetic acid, sodium salt over DTT. Carboxymethylation of the cysteine residue gave only a minor improvement of the MS/MS fragmentation yield of the native peptide.

Modification of the nonapeptides under oxidative conditions was then performed by reacting the peptides with a 100-fold molar excess of freshly prepared performic acid. Conversion of the cysteine residues to cysteic acids and of the methionine residue to methionine sulfone resulted. The MS/MS analyses of these oxidized forms of the peptides under low energy CAD conditions gave product ion spectra displaying the complete series of $Y^\nu$ ions. The marked simplification of the product ion spectra allowed an easy determination of the localization of the oxidation on the tryptic peptide sequence. Moreover, the fragmentation yield was dramatically improved compared to the native peptides, implying intra-ionic interactions involving the cysteic acid residue.

To observe further the effect of converting cysteine residues to their cysteic acid forms, another synthetic tryptic peptide was studied: GFLCGHYR. The oxidized form of the peptide again gave an improved MS/MS fragmentation yield under low energy CAD compared to the native peptide and produced the complete series of $Y^\nu$ ions (Figure). High energy CAD (MIKES) analyses of the native peptide and its oxidized form gave fragmentations similar to those observed using low energy CAD (several $w$ ions were additionally observed in the MIKES spectra). A higher fragmentation yield of the oxidized form of the peptide was also observed under high energy CAD.

DETERMINATION OF AMIDE HYDROGEN EXCHANGE RATES IN PEPTIDES BY CONTINUOUS-FLOW FABMS

Géraldine Thévenon-Emeric, John Kozlowski, and David L. Smith
Department of Medicinal Chemistry and Pharmacognosy
Purdue University, W. Lafayette IN, 47907

Hydrogen exchange has been used in conjunction with FABMS for a variety of structure elucidation problems. Sethi et al. (BBRC 112, 126-131 (1983)) demonstrated that the number of rapidly exchanging hydrogen atoms can be determined if glycerol d$_3$ is used as the matrix. The amide hydrogens in peptides exchange more slowly and are not included in the group of rapidly exchanging hydrogens. Since the rate at which amide hydrogen atoms undergo exchange may be a useful probe of the structures of peptides and proteins, we have developed a method based on continuous-flow FABMS for determining their rates of exchange.

Although NMR has been the principal method for determining amide hydrogen exchange rates, it has disadvantages associated with peptide size, and solubility, and with the quantity of peptide required for measurements. CF FABMS offers advantages in all of these areas. Results obtained by CF FABMS and NMR for two model peptides are presented here.

Exchangeable hydrogens can be classified as either slow or fast, depending on their location in a peptide. These two classes of hydrogens are illustrated for bradykinin in Fig. 1. Amide hydrogen exchange is base catalyzed, and occurs approximately 1000 times faster at pH 8 than at pH 3. Slow and fast exchanging hydrogens in peptides were fully exchanged with deuterium by dissolving the peptides in deuterated solvents at pH 7 and 20°C. After approximately 1 hour, this solution was diluted 20 times with H$_2$O/acid (pH 2-3). The temperature was reduced to 0°C to reduce the rate of back exchange. Under these conditions, rapidly exchanging hydrogens revert back to protium within seconds, while slowly exchanging (amide) hydrogens may require a few hours to undergo exchange. The back-exchange of amide deuterium to hydrogen was followed by CF FABMS using a continuous-flow probe that has been described previously (1,2). To reduce the likelihood of back-exchange during the analysis, the injector and most of the fused silica was submersed in an ice bath. The first injection was made within 1 minute after addition of H$_2$O, with additional injections made at regular intervals for at least one hour. Mass spectra were acquired with a Kratos MS-50/DS-90 system and transferred to a Macintosh computer where the number of deuterium atoms per peptide was calculated. Part of this calculation required adjusting intensities for contributions from naturally occurring isotopes.

The average rate constant for hydrogen exchange, 2.2 x 10$^{-4}$ was determined by plotting the logarithm of the deuterium content vs time (Fig. 2). Data from replicate experiments indicate that the rate for back exchange can be determined with a coefficient of variation of 14%. The rate of hydrogen exchange in this peptide was also determined for the same conditions by monitoring the amide hydrogen signals by 500 MHz NMR. Data from this experiment, plotted in Fig. 3, show that essentially the same value for back-exchange was obtained by this alternate method.

Results presented here demonstrate that the rate at which amide hydrogens undergo isotopic exchange can be determined accurately by direct-injection FABMS. For slow exchanging conditions, pH 2-3 and 0°C, the half-life for exchange is 53 minutes. Since proteolytic digests of proteins can be analyzed in less than 20 minutes by directly-coupled HPLC FABMS, it follows that the number of amide hydrogens that have undergone exchange with deuterium can be determined by this approach.

The use of enzymes in mass spectrometry has found both on-line and batch sampling applications. In conjunction with various mass spectrometric sampling techniques, either approach can greatly facilitate sequencing of biomaterials, especially peptides. The most common application in this context is predigestion of protein analytes with specific endopeptidases, generating a mixture of smaller peptides amenable to sequencing analysis, usually by fast atom bombardment (FAB). This has proven to be a remarkably powerful sequencing approach, requiring relatively little material to provide, in favorable cases, full primary sequence information.

On-line applications offer the distinct possibilities of real-time monitoring of enzymatic reactions proceeding in situ within the spectrometer source or sampling system. This can in principle provide kinetics information (rates and mechanisms) in addition to relatively more limited sequencing. Limitations arise from the requirements of the various mass spectrometric sampling approaches which have been successfully employed, including thermospray, flow-FAB, and electrohydrodynamic (EH) MS. Successful applications must balance the chemical requirements of the reacting system with those necessary for stable and sensitive MS sampling, while achieving reaction on a time scale compatible with MS scanning. Under the best of cases, the MS data can provide an indication of reaction rates and intermediates. The latter information can provide useful mechanistic insight even if solvent modifications necessary for MS compatibility enforce significant deviations from the purely aqueous solvent conditions generally of greatest interest for studies of enzyme kinetics.

In one such application, we have used EH MS to monitor the progress of peptide hydrolysis proceeding in situ within the ion source, under the influence of the exopeptidase Carboxypeptidase-Y (CPY). For the pentapeptide leucine enkephalin (YGGFL), the procedure allowed observation of the disappearance of the intact substrate, plus the appearance and disappearance of each of the two reaction intermediates (YGGF, then YOG), and the generation of the final products (YG, G, F, and L). The kinetics curves had generally the correct qualitative appearance, but the organic co-solvent thiodiethanol (TDE), required for reasonably stable and sensitive EH sampling, slowed the rate of the reaction so that almost 20 hours were required for the reaction to “go to completion.” Because MS sampling was only active intermittently, sample consumption was limited to about 300 μL of 18mM solution (6 μmol, total sample consumption). In comparison with other peptide MS experiments, this is rather high; the specialized role of this approach for cases where kinetics or C-terminal information is of interest is thereby evident.

In order to assess the effect of the co-solvent on enzyme kinetics and MS sensitivity, we have undertaken parallel optical and EH mass spectrometric kinetics experiments, evaluating the rates of hydrolysis of selected dipeptides in matrices comprised of various TDE/water mixtures, plus phosphate buffer (pH 6.5, total phosphate 12.5 mM) and 0.5 M NaCl supporting electrolyte. For the simple dipeptide, two approaches to interpretation of the kinetics data are possible. At a given enzyme and substrate concentration (with substrate in excess), the rate of amino acid appearance or dipeptide disappearance can be modeled as a (pseudo-) first order reaction. An exponential fit of concentration vs time data can therefore provide an estimate of enzyme activity as represented by the first order rate constant, k. Repetition of the experiment at a variety of substrate concentrations (fixed [CPY]) can provide two additional measures of activity: the Michaelis constant (K_m, related to the substrate concentration at which the enzyme becomes saturated) and the maximum rate (V_max) at which hydrolysis proceeds in the presence of excess substrate. Values for these parameters derived from optical data are summarized in Table I, which shows that as little as 10% TDE attenuates enzyme activity by as much as 32%. For the concentrations employed, the hydrolysis took roughly 45 min.
Unfortunately, the MS limit of detection was significantly lower than that for the optical experiment, so that much higher enzyme and substrate concentrations were necessary for MS monitoring. However, it should be feasible to measure a pseudo-first order rate constant in reasonable agreement with that determined from standard optical experiments. This would be a promising indication that the kinetics in the presence of co-solvent are accurately represented by the MS.

This result gains significance when considering hydrolysis of a more complex, polypeptide substrate. For hydrolysis of the pentapeptide leu-Enk, the optical method is incapable of distinguishing contributions from the two intermediates and the final reaction products. Instead, the absorbance data (Figure 1) represent a convolution of the three sequential reactions. By contrast, in the MS data, contributions can be easily resolved, so that determination of the kinetics parameters for each separate step should be readily feasible. Figure 2 summarizes the time dependence of the EH mass spectrum of Leu-enkephalin, showing the variations in abundance of each residue (Figure 2a) and each amino acid final product (Figure 2b).

Alkaline earth metal ions form anionic complexes with di- and tripeptides upon FAB ionization. Two such complexes of the elemental composition, \([\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) and \([2\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\), were studied by tandem mass spectrometry.

The CAD spectra of \([\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) are very simple with respect to the spectra of protonated peptides and metal ion cationized peptides. The structure of this anion was shown to be one in which the metal ion binds to the deprotonated C-terminal carboxylate group and to two amide nitrogen atoms. Supporting evidence is that peptides without free C-terminal or amide hydrogens on the middle amino acid do not form this anionic ion. Fragmentation of labelled peptides shows that both remaining active hydrogen atoms are located at the N-terminal. This tightly bound complex has a free or loosely bound N-terminal amino acid. Upon CAD fragmentation it can be expected to be at N-terminal because it would not be productive to break bonds at other sites. The two abundant fragments, \(F_1\) and \(F_2\) are the products of decomposition of the N-terminal acid residue(spectra A and B and Scheme 1). The approach can be used to determine N-terminal amino acid.

The metal ion in \([2\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\), on the basis of experiments with C-terminal blocked peptides(for example, peptides with an ester or amide at C-terminus do not form this complex), binds to the C-terminal carboxylate groups of both peptides. The third binding site is the amide nitrogen atom of the C-terminal amino acid, which is supported by the experiments with proline containing peptide, that is, Ala-Pro does not form this anion whereas Ala-Pro produces this complex extensively and the complex fragment regularly.

The CAD spectra of \([2\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) show redundant sequence information(spectra C and D and attached schemes). The peptide sequence can be read from the y-type fragments; w-type ions are abundant if the amino acid that has the potential to form a w-type ion is not an N-terminal amino acid(spectrum c, the ion of \(m/z\) 325). Leucine and isoleucine can, therefore, be differentiated by the abundant w-type ions in the spectra. The CAD spectra of metal-bound dimers of peptides may be useful in peptide sequencing and isomer differentiation.

Another abundant fragment ion in the spectra of \([2\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) complexes is the \([\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) ions(the ion of \(m/z\) 239 in spectrum C and \(m/z\) 316 in spectrum D). The fragmentation process is illustrated in Scheme 4. The major evidence includes that \([\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) complexes formed from tripeptides with proline at the middle do not produce \([\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) ions, indicating the amide hydrogen of the center amino acid is necessary in the fragmentation. The favourable formation of \([\text{pept} + \text{Met}^2+ - 3\text{H}^+]^{-}\) reflects the stability of this complex.

The interaction of negatively charged peptides and alkaline earth metal ions appears to involve the carboxylate at the C-terminus and secondly deprotonated amide nitrogens. This conclusion applies to both metal ion bound anionic peptide complexes and metal ion bound anionic peptide dimers. We intend to pursue the mechanisms of fragmentation of these complexes and their applicability in sequencing and structure proofs.
Mass Spectrometric Analysis of Modifications to α-Crystallins

Wen Qin, Yiping Sun, Jean B. Smith, David L. Smith, and Beryl Ortwerth*, Department of Medicinal Chemistry and Pharmacognosy, Purdue University, West Lafayette, IN 47907, and * Mason Institute of Ophthalmology, University of Missouri, Columbia, MO 65212

The transparency of the lens depends on the proper close packing of the structural proteins of the lens. Posttranslational modifications to these proteins, called crystallins, can lead to formation of cross-links and aggregates that disrupt their native three-dimensional structure. We have used FABMS to examine two types of modifications to lens α-crystallins that are associated with cataractogenesis. The first, carbamylation, is a posttranslational modification that may occur in patients with chronic diarrhea or kidney failure due to a reaction of lysyl residues with isocyanate. The cataractogenesis of this modification is supported by Harding and Rixon's study showing that homocitrulline, the product formed by acid hydrolysis of carbamylated lysines, is present in cataractous Pakistani lenses. The other modification is the reaction of ascorbic acid with α-crystallin, a reaction that may be responsible for the development of senile cataract. A proposed mechanism for cataract due to ascorbic acid suggests that an oxidized form of ascorbic acid reacts with lysines of the crystallin causing further reaction and the formation of cross-links. The specific sites at which isocyanate and ascorbic acid react have not been determined. We have incubated isolated α-crystallins in vitro to cause these modifications and have identified the reactive residues and the extent of modification.

Bovine lenses were homogenized in 20 ml buffer (0.5 M NaCl, 0.001 M EDTA, 0.05 M Tris, pH 7.4), centrifuged to remove particulates, and fractionated into α-, β- and γ-crystallins by gel filtration chromatography (Sephadex G-200, 60x5 cm column, 10 ml/hr).

For the carbamylation study, the α-crystallins from the gel filtration were separated into αA- and αB-crystallins by reversed phase HPLC. αA, which was identified by electrospray ionization mass spectrometry, was used in the carbamylation experiments. A portion of the αA-crystallins was incubated in 0.1 M KCNO, 0.2 M NH₄OAc, pH 7.2, 0.02% NaN₃ at 37 °C for time intervals of 1-70 hours. A control of αA-crystallin incubated in 0.1 M KCl was prepared.

For the ascorbic acid study, α-crystallins from the gel filtration were incubated in 20 mM ascorbic acid with 40 mM NaCNBH₃ for one week at 37 °C and then separated by reversed phase HPLC. In both studies, the modified and unmodified proteins were digested with trypsin or chymotrypsin (1:50 enzyme:substrate in 0.1 M Tris, pH 8.2, at 37 °C for 1 hr) or with pepsin (1:50 enzyme:substrate in 0.03 N HCl, at 37 °C for 1 hr). The enzymatic digests were fractionated by reversed phase HPLC.

The peptides present in each fraction of the HPLC separated digests were identified by fast atom bombardment mass spectrometry (FABMS) using a Kratos MS-50 RF mass spectrometer. Portion corresponding to all of the sequence of unmodified α-crystallin was used in the carbamylation experiments. A portion of the αA-crystallins was incubated in 0.1 M KCNO, 0.2 M NH₄OAc, pH 7.2, 0.02% NaN₃ at 37 °C for time intervals of 1-70 hours. A control of αA-crystallin incubated in 0.1 M KCl was prepared.

For quantitation of the extent of modification, the pair of modified and unmodified peptides was collected in the same fraction and analyzed by FABMS. Investigations with model peptides comparing UV absorbances and FABMS intensities indicated that the FABMS responses for carbamylated and uncarbamylated peptides were similar. The relative intensities of modified and unmodified peptides, averaged over several scans, were used to calculate the percent modification at each lysine for incubations of 1, 2, 4, 8, 18 and 70 hours (Fig. 1). The extent of modification of each lysine after incubation of α-crystallin in ascorbic acid for 1 week is shown in Table 1.

The present study demonstrates that FABMS gives more specific and accurate information about the identification and quantitation of posttranslational modifications to lens crystallins than other methods. This precise information should prove valuable in assessing the factors, such as nearby sequence and conformation, which affect the reactivity of the specific lysyl residues. For bovine lens α-crystallins, the similarity in the reactivity of some lysine residues to carbamylation by isocyanate and glycation by ascorbic acid suggests that the three dimensional configuration is a major determinant of reactivity. Because human and bovine lens crystallins have similar sequences, the techniques developed in this study can be easily extended to study of human cataractous lenses. Such information about the modifications to lens proteins will be useful in designing drugs for the prevention and treatment of cataract.

Measurement of the Velocity Distribution of Polypeptide Ions Produced by Matrix-Assisted Laser Desorption

Ronald C. Beavis and Brian T. Chait
The Rockefeller University
1230 York Avenue, New York, NY 10021

This poster reported the measurement of the velocity and translational kinetic energy distributions of polypeptide ions produced by matrix-assisted laser desorption. These distributions were determined for ions that were produced in a field-free region of the ion source, removing all effects on the velocity distribution caused by ion extraction fields. The measurement was also mass resolved: the velocity distributions of different ions produced by the laser desorption event were simultaneously obtained.

In order to measure the velocity distribution of the ions, two experiments were performed. The first experiment measured the transit time of a particular ion species through the time-of-flight mass spectrometer with a high extraction field in the ion source. The second experiment measured the transit time of the same ion species, without any initial extraction field, that is with a field-free drift region prior to the high voltage acceleration field. These two measurements allowed the calculation the ion velocity distribution intrinsic to the ion production/sublimation process by calculating the velocity of ions crossing the field-free region used in the second experiment.

Three different polypeptides were examined: angiotensin (MM = 1030 u); insulin (MM = 5730 u); and superoxide dismutase (MM = 15,590 u). Each sample was prepared by mixing one microliter of a 100 micromolar solution of the polypeptide with five microliters of a 50 millimolar solution of sinapic acid (3,5-dimethoxy-4-hydroxy-(trans)cinnamic acid, obtained from Aldrich). One microliter of this mixture was placed onto the mass spectrometer's probe tip and dried. The sample was then inserted into the mass spectrometer and used to perform the two experiments described above.

The laser desorption ion source consisted of a series of parallel acceleration electrodes and an einzel lens. The laser used was a Lumonics HY400 Nd:YAG, operated in the Q-switched mode. The laser pulse duration was approximately 10 ns. The fundamental frequency was tripled, resulting in a wavelength of 354 nm. The laser fluence used to produce the matrix-assisted laser desorption event was 10 - 15 mJ/cm² (irradiance = 1 - 1.5 MW/cm²). The result of these experiments was the discovery that all three polypeptide molecules had very similar initial velocity distributions, independent of the molecule's mass. All three molecules had distributions centered at approximately 750 m/s. Therefore, the translational kinetic energy distributions for these molecules scaled directly proportional to the molecular mass according to the following expression:

\[
KE_{av} \text{ (eV)} = 0.003 \times \text{mass (u)}.
\]

This result has consequences for theoretical models proposed to explain the matrix-assisted desorption effect and for the design of ion sources and mass analyzers. Ion sources with low ion trapping potentials, such as ion cyclotron resonance mass spectrometers, will show strong mass discrimination effects caused by the high ion velocities intrinsic to the desorption event.
Covalent attachment of long chain saturated fatty acids has been recognized as an important post-translational modification of a wide range of proteins, and is considered essential for the proper functioning of these proteins in vivo. Fatty acids most commonly observed attached to proteins are myristate, bound to N-terminal glycine via an amide bond, and palmitate, linked to cysteine residues through a thioester bond. Characterization of the nature of the fatty acid moiety using mass spectrometry has proved useful in elucidating the presence and site of binding of such modifications. The objectives of this research are to gain an understanding of the fragmentation behavior of fatty acylated peptides to develop a general methodology for sequencing and determining the specific fatty acyl group and its binding site. In this investigation, model peptides and amino acids were reacted with myristoyl and palmitoyl acid chlorides to yield both mono-, di-, and per-acylated derivatives, and their fragmentation behavior investigated using FAB ionization and MS/MS techniques.

Monoacylated samples were prepared by first dissolving the amino acid or peptide in a pH 6.0 MES buffer and adding the acid chloride as a 300 mM solution in THF. The sample was incubated with agitation at 37°C for two hours. The reaction products were then isolated on a C18 solid phase extraction cartridge (Bond Elut), rinsed with 0.01 M sodium bicarbonate followed by DI water and then eluted with methanol. Multiply acylated amino acids and peptides were prepared and isolated in a similar manner, except a pH 9.5 borate buffer was used.

Positive ion mass spectra were obtained on a VG ZAB-HS-2F mass spectrometer using FAB ionization. The protonated molecular ions were further analyzed by CAD/MIKES, using helium as the collision gas. Both dimyristoylated and dipalmitoylated lysines showed loss of the fatty acid moiety as a ketene (R-CH=C=O) to yield the major fragment ion (Fig. 1). In addition, a minor fragmentation pathway for both dimyristoylated and dipalmitoylated lysines appears to involve loss of RCONH₂, whereas the monomyristoylated lysine showed only loss of the fatty acid as a ketene. The positive ion CAD spectrum of N-acetyl-S-palmitoylcysteine ([M+H]+ = 402) similarly shows loss of the palmitoyl residue as a ketene by cleavage of the thioester bond, producing a characteristic ion at m/z 164. Additionally, the [M+Na]+ = 424 also produced a series of less intense ions 14 mass units apart, indicative of the palmitoyl moiety, resulting from charge remote fragmentation.

In contrast to the amino acids studied, fragmentation of the monomyristoylated peptide Lys-Tyr-Lys ([M+H]+ = 648) did not result in preferential loss of the fatty acid moiety as a ketene, rather a prominent A₁ fragment was observed at m/z 311, in addition to loss of the fatty amide ([CH₃(CH₂)₁₄CONH₂] at m/z 421 (Fig. 2). The sodiated adduct of monomyristoylated Lys-Tyr-Lys ([M+Na]+ = 670) was also observed. The CAD/MIKE spectrum of 670 showed the most prominent ion as 542, corresponding to loss of the C-terminal amino
acid, typical for sodiated peptides, but provided little useful information characterizing the bound fatty acid. In summary, fragmentation of [M+H]+ ions of fatty acylated peptides and amino acids often yields an intense daughter by neutral loss of fatty ketenes or fatty amides. Further experiments will test how the proximity of the site of protonation influences this behavior.

Protein Complex of Rabbit Lung Flavin-containing Monooxygenase and Calreticulin Discovered by Mass Spectrometry

Shenheng Guan¹, Arnold M. Falick¹, David E. Williams², and John R. Cashman¹
¹Dept. of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143
²Dept. of Food Science and Technology, Oregon State University, Corvallis, OR 97331

Flavin-containing monooxygenase (FMO) is an important mammalian monooxygenase that catalyzes the NADPH-dependent oxygenation of nitrogen-, sulfur-, and phosphorous-containing drugs and pesticides in many tissues. The FMO isolated from rabbit lungs displays remarkable differences from the hepatic enzyme in catalytic behavior and sensitivity to thermal inactivation. The primary sequence of FMO from rabbit lung deduced from cDNA data shows more than 50% homology to the liver FMO. The difference in the primary sequence does not seem to be adequate to account for the enzymatic differences between lung and liver enzymes. There is also no information available concerning post-translational modification of these proteins. In this study, the lung FMO was subjected to denaturation, S-S bond reduction, carboxymethylation, digestion with endoproteinase Glu-C and trypsin, and mass spectrometric analysis. A peptide molecular-weight map which covered more than 90% of rabbit lung FMO's sequence was generated. The N-terminus and several peptides which contain FAD and NADP⁺ binding sites were sequenced by tandem mass spectrometry. The N-terminus was blocked with an acetyl group, similar to hog liver FMO*. In the process of mapping rabbit lung FMO, we found more than 50 peptides whose molecular weights did not correspond to the FMO sequence. This suggested the presence of another protein tightly associated with FMO. Since the proteinase digests generated very complicated peptide mixtures, each of HPLC fractions usually contained several peptides (see Fig. 1). It was difficult to sequence these peptides by conventional Edman sequencing. Several of the unidentified peptides were subjected to tandem mass spectrometric sequencing. Analysis by tandem MS generated sequences for 70% of those peptides (see an example in Fig. 2). Those sequences were searched for the protein data base which showed a 100% match with a calcium binding protein, calreticulin. This protein is not a simple contaminant of the lung FMO preparation because of the large difference in properties between the two. Calreticulin apparently complexes and solubilizes the FMO. The exact physiological role of both the FMO and the calcium binding protein are currently under investigation.

INTRODUCTION

Trichosporin-Bs (TS-Bs) are the series of antibiotic peptides produced by *Trichoderma polysporum*. Up to now, 11 compounds have been identified by MS (FAB) and NMR, and some by FAB-MS-MS. They are blocked N-terminal peptides containing unusual amino acids such as α-aminoisobutyric acid (Aib) and isovaline (Iva), and their C-terminal is linked with phenylalanine (Pheo). However, there remain many unknown minor compounds which are extremely difficult to separate by HPLC. Their identification by FAB MS and NMR is almost impossible because of their microheterogeneity. In order to clarify their structures, linked scan and CF-FAB were performed. In this study an HPLC-separated fraction (named TS-B-I-2-1), which contained trichosporin-B-Ia (shown in Table 1 as peak f) as the main component, was examined and a new type of peptides was found.

EXPERIMENTAL

FAB MS spectra (including linked scans and CF-FAB) were obtained with CONCEPT IH (Kratos Analytical). The matrix used was glycerol : thioglycerol containing ca.1% TFA, and the assignment of quasimolecular ions was confirmed using a second matrix containing NaCl in place of TFA. Helium was used as collision gas for linked scans. For CF-FAB analysis, the mobile phase, consisting of acetonitrile : water : glycerol (50 : 45 : 5), was delivered with an LC-9A pump (Shimadzu Co.) The flow rate was 60μl/min and the analytical column used was Shim-pack SBC-ODS (2.5mmx150mm).

RESULTS AND DISCUSSION

FAB mass spectra of TS-Bs have some characteristic points:

1. The peptide bond Aib-Pro is unstable and preferentially cleaved, resulting in two acylium ions (They are called as N- and C-terminal oligopeptide ions in this paper).
2. N-terminal oligopeptides give some sequence-specific ions. The peptide bond Aib-Gin is not as stable as others and the sequence from block 7-13 can't be determined clearly.
3. Unambiguous sequence-specific ions of C-terminal oligopeptide can't be obtained.

In order to elucidate structures of minor components in TS-B-I-2-1, three steps were performed. (1) Acquiring spectra of TS-B-I-2-1 fraction. (2) Analysing the quasimolecular, N-, and C-terminal oligopeptide ions of TS-B-I-2-1 fraction by linked scan. (3) Analysing TS-B-I-2-1 fraction by CF-FAB to confirm the existence of peptides indicated by step (2).

From the results of step (1), the masses considered to be derived from peptides were examined and chosen as parent ions for linked scan analysis. The results of linked scans of quasimolecular ions gave prominent N- and C-terminal oligopeptide ions. Possible primary structures of N- and C-terminal oligopeptides were indicated from the results of linked scans of N- and C-terminal oligopeptide ions. Although a great deal of information can be obtained from linked scans of TS-B-I-2-1, the assignments are not always unambiguous. Thus, in order to gather further information, this fraction was subjected to LC separation followed by CF-FAB analysis.

Fig. 1 shows on-line detected UV chromatogram of TS-B-I-2-1. The eluate was split (30:1) for CF-FAB. The injected amount of TS-B-I-2-1 was 50 μg so totally ca. 1.6 μg peptides were introduced to the mass spectrometer. Fig. 2 shows the mass spectrum of peak e as an example. The quasimolecular ion (m/z 1937) and the fragment ions derived from N-terminal oligopeptide (m/z 1163) and C-terminal oligopeptide (m/z 744) are clearly observed. Some sequence-specific ions from m/z 1163 appear. In Table 1, peptides tentatively identified from this study are summarized. Compounds a, b, c, e, g and H have Gly at position 3. This is the first time this type of peptides has been found in *Trichoderma polysporum*.

1449
The combination of linked scans and CF-FAB is a very powerful tool in the structural determination of such a complex peptide mixture.

CHARACTERIZATION OF BIOTIN-LABELLED PEPTIDES USING A HYBRID MASS SPECTROMETER

Ralph S. Orkiszewski¹, O. T. Jones², K. J. Angelides², and Simon J. Gaskell¹
¹Center for Experimental Therapeutics and Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX, 77030

Introduction

Compounds labelled with biotin exploit the strong interaction between biotin and streptavidin to provide a means of probing biochemical processes. Biotin labelling of peptides may be achieved by acylation of amine groups at the N-terminus or on amino acid side chains; there may accordingly be some uncertainty concerning the site of biotinylation in singly labelled species. We describe here a strategy for the characterization of biotin labelled peptides using a combination of trypsin hydrolysis and both conventional and tandem mass spectrometry.

We exemplify this approach using conantokin-G, a seventeen residue peptide which was the first peptide toxin reported to block the N-methyl D-aspartate (NMDA) preferring receptors with a high affinity and selectivity (1). The NMDA receptors have a unique role in brain function and their activation has been implicated in nerve death seen in stroke, epilepsy and other neuropathologies as well as in the learning and memory processes (2). The sequence is noteworthy for the presence of several carboxyglutamate (Gla) residues.

Methods

Peptides were allowed to react under lysine modifying conditions (100mM NaHCO₃, pH 9.5) with the N-hydroxysuccinyl ester of biotin. Reaction mixtures were purified by reverse phase HPLC using a 0-100% water-acetonitrile gradient with 0.1% trifluoroacetic acid. Fractions were collected and dried under vacuum. Peptides were dissolved in 200 ul ammonium bicarbonate buffer (100mM, pH 8.0) with 10% v/v n-propanol. 2 ug of TPCK treated trypsin was added and the incubations were performed at 37 C for 4 hours at which time a further 2 ug of trypsin was added and the digestion allowed to continue overnight. Products of the digestion were purified by reverse phase HPLC. Samples were analysed on a VG ZAB-SEQ Instrument of BEqQ configuration, ionization was by fast atom bombardment with a liquid matrix of either 3-nitrobenzyl alcohol or a 1:1 mixture of thioglycerol:2,2’ dithiodiethanol saturated with oxalic acid. Low energy CAD product ion scans used the qQ portion of the instrument with argon as the collision gas.

Results

Conantokin-G has two possible sites for labelling with biotin, the N-terminus and the lysine at the 15 position. The peptide was biotinylated, digested with trypsin and fractionated prior to mass spectrometric analyses. An equivalent amount of unlabelled material was treated in the same manner. Four HPLC fractions were generated and were analysed by conventional FAB mass spectrometry. MH⁺ ions were observed at m/z 1763 and 2064 for the native peptide and m/z 1763 and 746 (figure 1) for the biotin labelled peptide. The loss of the ion of m/z 2064 and the appearance of the ion of m/z 746 indicated the site of modification to be at the lysine. Low energy product ion scanning of the m/z 746 ion (figure 2) produced fragmentations consistent with the label located on the lysine. Low energy CAD of Gla-containing fragments display a propensity for losses of CO₂. In the case of the tryptic fragment 1-17 the number of residues present may be enumerated from losses of 44 from the MH⁺ ion.

DETERMINATION OF THE CARBOXY TERMINUS OF THE B-CHAIN OF PORPOISE RELAXIN

*A.S. Woods, K. Monti, and R.J. Cotter
Johns Hopkins University School of Medicine, Baltimore, MD 21205
E. Bullesbach, C. Schwabe, Medical University of South Carolina, Charleston, SC 29425

Relaxin a polypeptide hormone which is synthesized and stored in the corpus luteum during pregnancy, is responsible for the dilation of the symphysis pubis before parturition. The sequence of the A- and part of the B-chain of porpoise relaxin were obtained by Edman degradation. We used plasma desorption mass spectrometry (PDMS) to establish the MW of the A- and B-chains, to map the tryptic peptides, and (in combination with on-foil enzymatic digestion) to establish the sequence of the remaining C-terminal amino acids on the B-chain.

Molecular weights of the A- and B-chains. The relaxin treated with DTT gave MH⁺ of mass 2528.2 and 3532.6 for the A and B chains respectively (Figure 1), for a MW of the reduced A-chain of 2527.2 Da, (the MW calculated from the known aa sequence is 2527.4 Da). The MW of the B chain was determined as 3531.6 Da. When compared with the calculated mass for the known portion of the B-chain (2675.2 Da) this results in a mass deficit of 656.4 Da, corresponding to the unknown portion of the C-terminus. The MW of the relaxin can be calculated: 2527.2 + 3531.6 - 6(H) = 6052.8

Mapping of the tryptic digest. A spectrum of the tryptic digest was obtained by PDMS. The tryptic fragments are identified in structure [1]

```
[1] R|MILSEK|CCQVCCIR|K|DIAR|LC
[2] Pca-R|NDIK|ACGR|ELVR|MVVEICGSV...
```

The digest was injected on a HPLC C18 RP column. Fractions were collected, spectra obtained. In addition to the peaks corresponding to fragments of known sequence, we observed two peaks at m/z 1493.1 and 1726.1 which correspond to a fragment [11] in the C-terminus of the B-chain and that same fragment linked by a disulfide bond to the A-chain [6-11], respectively. By comparing these results with mass calculated for fragment [6] and the known portion of fragment [11], this suggest that the unknown portion of peptide [11] has a mass of:

1492.3 - 1005.3 = 487.0
1725.1 - 1237.6 = 487.5

When these results are compared with the measured mass of the B-Chain (3361.6 Da), there is an additional mass deficit of 172 Da, suggesting that there is an additional peptide [12] of mass 172 + 18 = 190 Da, that a lysine or an arginine is present at the C-terminal end of peptide [11], and the
B-chain sequence is:

\[ \text{Pca-RlTNDFIKlACGRlELVRlLWVEICGSV.. (K/R) lTA} \]  

Mass spectral analysis of purified B-chain. Reduced relaxin was injected on a RP HPLC column and fractions collected. A mass spectrum of fraction 72 gave a MH⁺ at m/z 3534.4 (corresponding to the protonated B-chain) and an additional peak at m/z 3462.8. The mass difference between these two peaks (71.6 Da) corresponds to an alanine residue. If we then subtract the mass of alanine residue (71 Da) from the mass deficit (172 Da) represented by peptide [12], this would suggest that the next residue is threonine (101 Da). Thus peptide [12] has the following sequence Thr-Ala, and the B-chain has the sequence

\[ \text{Pca-RlTNDFIKlACGRlELVRlLWVEICGSV.. (K/R) lTA} \]  

Fraction 76 shows 2 peaks, a molecular ions at m/z 3205.6 and 2877.8. The difference in mass (157.9 Da) between the peak at 3205.6 and the combined masses of the peptide [7-8-9-10-11] corresponds to an arginine residue (156.1 amu) plus a proton, suggesting arginine as the terminal residue of peptide [11]. The peak at m/z 2877.8 corresponds to the protonated molecular ion of peptide [7-8-9-10] + the known portion of [11] (1005.3 amu). If we subtract the arginine residue we get the MW of the remaining unknown residues, which is 330 amu. Therefore the sequence thus far is:

\[ \text{Pca-RlTNDFIKlACGRlELVRlLWVEICGSV (330) RlTA} \]  

"On-foll" digestion with carboxypeptidase Y. Carboxypeptidase Y was used to digest fractions 72 and 76 deposited on the sample foil. 10 minute incubations gave the best spectrum. The peaks at m/z 3533.2, 3462.6, 3361.0 3206.6 3149.2 and 2963.2 result in mass differences of 70.6, 101.6, 154.4, 57.4, and 186.0 Da, corresponding to the masses of alanine, threonine, arginine, glycine and tryptophan, respectively (figure 2). The remaining difference in mass between the mass of [7-8-9-10] + the known portion of [11] (2877.8) and the peak observed at m/z 2963.2 is 85.4 Da, which suggests that we have a serine, leading to the completed sequence of the B-chain:

\[ \text{Pca-RlTNDFIKlACGRlELVRlLWVEICGSVSWGRlTA} \]
MASS SPECTROMETRIC IDENTIFICATION OF BOVINE CHROMAFFIN GRANULE PEPTIDES

L. Dillen¹, S. Boel¹, W.P. De Potter² and M. Claeys¹
University of Antwerp (U.I.A.), Departments of Pharmaceutical Sciences¹ and Medicine²,
Universiteitsplein 1, B-2610 Antwerp, Belgium.

The chromaffin cells of the adrenal medulla, more in particular the subcellular chromaffin granules, are of biological and neuropharmacological interest since they provide a model for studying the storage and secretion of neurotransmitters and hormones. The aim of our study was to confirm the presence of the known neuroregulators methionine- and leucine-enkephalin mass spectrometrically and to isolate and characterize possible unknown neuropeptides.

Peptides were extracted from the lysate of isolated bovine chromaffin granules using 0.5g C₁₈ Bond-Elut extraction columns, which were eluted with methanol:water (25, 50 and 100% methanol). Subsequently, these extracts were fractionated by reversed-phase HPLC using gradient elution with acetonitrile (Fig. 1). Methionine- and leucine-enkephalin were identified by their chromatographic retention time and by the m/z value of their protonated molecules. With regard to the unknown peptides, a number of peptides with a Mᵋ of 1745, 1445, 1332, 976 and 900 were found in the different HPLC fractions. Upon trypsinolysis, all these peptides resulted in the loss of a component with mass 545, pointing to a structural relationship and a possible common precursor. Aminopeptidase M digestion was inhibited for all the peptides examined indicating a blocked NH₂-terminus. Carboxypeptidase Y treatment of the peptide with a Mᵋ of 1745 resulted in the formation of peptides with (M + H)⁺ values at m/z 1583, 1333 and 1220, which is in agreement with the hypothesis of a common precursor. Carboxypeptidase Y digestion was also performed on the smaller peptides and revealed the amino acid sequence of 9 amino acids at the carboxyl terminus (AELDQLLHY).

The peptide with a Mᵋ of 1745 could be identified based on the daughter ions observed in the FAB/MS spectrum (Fig. 2) as the BAM (Bovine Adrenal Medulla)-1745 peptide (<EYDRVAELDQLLHY), recently described by Flanagan et al., 1990. The other peptides with a Mᵋ of 1445, 1332, 976 and 900 were characterized as smaller fragments of the BAM-1745 peptide.

In conclusion, this extraction and isolation method resulted in the mass spectral detection of methionine and leucine enkephalin and in the characterization of a series of peptides derived from the BAM-1745 peptide in bovine chromaffin granules. The BAM-1745 peptide is a processing product of chromogranin B, a quantitatively important protein in the chromaffin granules.

Figure 1
Reversed-phase HPLC chromatogram of the 100% methanol eluate of the bovine chromaffin granule lysate extracted on C18 columns. A linear gradient of 30 to 70% acetonitrile in 0.1% aqueous trifluoroacetic acid over 45 min was run at a flow rate of 0.8 ml min⁻¹. UV-detection was carried out at 214 nm. The peak numbering corresponds to the fractions collected for FAB/MS analysis. The m/z values of the most intense (M + H)⁺ signals detected in the FAB/MS spectra are indicated.

Figure 2
FAB/MS spectrum obtained for HPLC peak 6 of the 100% methanol eluate showing a protonated molecule at m/z 1746. Daughter ions observed are A₁₅ = 617; A₆ = 688; A₁₇ = 817; A₇ = 930; A₈ = 1045; A₁₀ = 1175; A₁₃ = 1537; A₁₄ = 1699; C⁶ = 733; C⁷ = 1090; D₆ = 1001. The doubly charged (M + 2H)²⁺ ion is detected at m/z 873.
**Structural Characterization of Modifications to α-Conotoxin GVIA by Mass Spectrometry**

Joseph L. Herman and Russell C. Sprensen, ICI Pharmaceuticals Group, A Business Unit of ICI Americas Inc., Wilmington, DE 19897

**Introduction:**

Conotoxins are a variety of neurotoxins found in fish-eating marine snails. These peptide compounds are relatively small in size (13-29 amino acids), and typically contain one or more intramolecular disulfide bonds. Naturally occurring α-conotoxins are of particular interest for use in the characterization of presynaptic neuronal Ca\(^{2+}\) channels. These compounds generally prevent the voltage-activated entry of calcium into the nerve terminal and irreversibly block the release of acetylcholine. α-Conotoxin GVIA is commercially available and has been the focus of recent pharmaceutical studies.

α-Conotoxin GVIA is known to consist of 27 amino acids with 3 intramolecular disulfide bridges and an amidated carboxy terminus. The structure is shown in Figure 1. Analysis of disulfide linkages is complicated by the presence of adjacent cysteines at residues 15 and 16. The secondary structure of α-conotoxin GVIA has not been previously reported. Attempts to independently verify the locations of the disulfide bonds in α-conotoxin GVIA by mass spectrometry were only partially successful.

Specific modifications are of interest in investigating the structure activity relationship (SAR) of peptides. α-Conotoxin GVIA was modified chemically by reacting native α-conotoxin GVIA with acetic anhydride. The N-terminus and lysine residues are acetylated upon exposure to acetic anhydride. For orconotoxin GVIA, which has two lysine residues, there are three possible sites for acetylation. The three possible mono-acetylated compounds, the three possible di-acetylated compounds, and the tri-acetylated compound were produced by reacting α-conotoxin GVIA with a 1:1 molar equivalent of acetic anhydride. Each of the acetylated compounds was isolated by HPLC and identified by a combination of enzymatic digests and mass spectrometry.

**Experimental:**

α-Conotoxin GVIA was purchased from Bachem. Sequencing grade tryptic and α-chymotryptic were purchased from Promega. The buffers and calcium chloride (CaCl\(_2\)) were obtained from Aldrich. HPLC grade acetonitrile and acetic anhydride were from Baker. HPLC grade trifluoroacetic acid (TFA) was purchased from Pierce. Eighteen NDI Milli-Q water was made using a Waters millipore system.

The digests were performed by dissolving 50 μg of substrate into 100 μl of a 100 mM tris, 25 mM CaCl\(_2\) solution, pH adjusted to 7.8. Enzyme was added to the solution to produce a 50:1 molar ratio of substrate to enzyme. The solution was incubated at 37°C for 16-20 hours.

Reverse phase HPLC was performed on a Zorbax RX C8 15cm x 4.6mm column. Injections of 100 μls were used. The flow rate was 1 ml/min with the following gradient: 0-2.5 min = 100% A, 0 B; 2.5-7.5 min to 50 A, 50% B; where A = 0.1% TFA in H\(_2\)O, B = 0.1% TFA in acetonitrile. The chromatographic peaks were collected, vacuum centrifuged to dryness, and redissolved in 10-μl 0.1% TFA in H\(_2\)O. HPLC conditions for separating the acetylated conotoxins were the same as for the digests except that the gradient was 0-2.5 min = 50% A, 50% B; 2.5-22.5 min to 70% A, 30% B. The mass spectral analysis was performed on a V7-70-MS mass spectrometer at 1000 resolution. Ions were produced by fast atom bombardment (FAB) using 8 kV Xenon atoms. Two μls of sample were dissolved into a matrix of 3:1 dithiothreitol:dithioerythritol (magic bullet) directly on the FAB probe prior to mass spectral analysis.

The MS/MS experiments were performed on a VG 70-SEQ tandem hybrid mass spectrometer. For these experiments, ions were produced by liquid secondary ion mass spectrometry (L-SIMS) using a 35 kV Ca\(^{+}\) ion gun. All other conditions were the same.

**Results and Discussion:**

Figure 1 shows the expected cleavages for trypsin and chymotrypsin on α-conotoxin GVIA. Two major peaks are present in the chromatograph of the tryptic/acetehyryptic digest of α-conotoxin GVIA. The mass of the (MH\(^{+}\))\(^{-}\) ion for each digest fragment found in the chromatogram was measured and is shown in Figure 1 along with their proposed structures. It is evident from the observed masses that the cysteine at position 8 is bridged to the cysteine at position 19 and that the cysteines at positions 1 and 26 are bridged to the cysteines at positions 15 and 16. (Note: Under the conditions of the digest, an unexpected cleavage at threonine 11 occurred.)

MS/MS and linked scan experiments were performed on peak 1 in order to assign the disulfide linkages to cysteines 15 and 16. However, all the ions produced by these experiments could be accounted for by fragmentation between cysteines 15 and 16. Both of these ions can also be accounted for by fragmentation of both disulfide bonds.

Eight peaks were isolated in the chromatogram of acetylated α-conotoxin GVIA. The average masses of the (MH\(^{+}\))\(^{-}\) ion were measured for each peak in the chromatogram. Peak 1 is native conotoxin, Peaks 2, 3 and 4 are mono-acetylated conotoxins, Peaks 5, 6 and 7 are di-acetylated conotoxins, and Peak 8 is the tri-acetylated conotoxin (m/z = 3036, 3080, 3122) and 3165 respectively.

The positions of the acetylations were determined by digesting the modified conotoxins with trypsin. The structure of α-Conotoxin GVIA after tryptic digestion is shown in Figure 4. All the pieces of the tryptic digest are connected by disulfide bonds except for the arginine at position 25, which is lost.

The mass of the (MH\(^{+}\))\(^{-}\) ion for the major component from the tryptic digests of Peaks 2 thru 7 are shown in Figure 4 along with their proposed structures. When the N-terminus is acetylated, a shift of 42 daltons higher than native conotoxin is observed. When the lysine at position 2 is the acetylation site, the trypptic cleavage at position 2 is blocked and the mass will be 18 daltons lower than the mass of the N-terminus acetylated compound. When the acetylation is at the lysine at position 24, the trypptic cleavage at position 24 is blocked causing the arginine at position 25 to be retained and the mass to be 156 daltons higher than the mass of the N-terminus acetylation. Therefore, each of the possible tryptic digests of α-conotoxin GVIA has a unique molecular weight relative to the tryptic digest. Peak 2 is acetylated at lysine 2, Peak 3 is acetylated at the N-terminus, Peak 4 is acetylated at lysine 24, Peak 5 is acetylated at the N-terminus and lysine 24, Peak 6 is acetylated at lysines 2 and 24, and Peak 7 is acetylated at the N-terminus and lysine 24.

**Figure 4: Structure of α-Conotoxin GVIA After Tryptic Digest**

The recent observation of multiple charging of polymeric materials has revolutionized mass spectrometry. This technique has seen application in the determination of molecular weights of many different biopolymers. However, since each individual component present in a mixture will produce a unique set of parent ions, minor impurities present in a peptide mixture can also be characterized as to molecular weight and approximate abundance. This paper describes the characterization of peptide impurities in synthetic lots of insulinotropin, a naturally occurring insulin secretagogue.

Peptide lots were dissolved in a 50/50 mixture of acetonitrile/1% formic acid such that a peptide concentration of approximately 1 ng/μL was obtained. These samples were introduced directly into the mass spectrometer without chromatographic separation.

All analyses were performed on a SCIEX API III mass spectrometer fitted with an ionspray probe. Samples were infused at 10 μL/min into the API ion source using a syringe pump. The mass spectrometer was operated in the positive ion mode and spectra were acquired from m/z 600 to 1600 daltons. Molecular weights of detected peptides were calculated from manually selected ions using a software routine supplied with the instrument.

Ionspray of peptides produces multiply charged ions in a pattern that is dependent in part on the number of basic amino acids in the molecule. Insulinotropin produces three ions in its ionspray spectrum as indicated in Figure 1. A simple calculation using the masses of these three ions produces a molecular weight of 3355 daltons. This calculated value is in excellent agreement with the theoretical value of 3355.7 daltons.

If more than one peptide is present in the sample, multiply charged ions for each component of the mixture are observed and their molecular weights can also be calculated. Figure 2 shows the ionspray spectrum of an insulinotropin bulk containing several minor components. Nine different peptides were identified in eight different bulk samples (Table 1). Seven impurities appear to represent the loss or gain of a single amino acid residue from insulinotropin.

Data on the impurities was obtained by manual manipulation of the mixture spectra. Software based on the deconvolution algorithm described by Mann et al. could be used to automate this process.

Theoretical M.W. = 3355.7 daltons
THE IDENTIFICATION OF SYNTHETIC PEPTIDE PROCESS IMPURITIES BY ON-LINE CONTINUOUS-FLOW FAB ANALYSIS OF CARBOXYPEPTIDASE DIGESTIONS.

Stephen H. Grode, Diane S. Quattlander, Paul J. Dobrowolski, and Tom A. Runge
The Upjohn Company, Chemical Division, Kalamazoo, MI 49001

The investigation of peptides as therapeutic agents has spurred the use of mass spectrometry as a sequence determination tool. This is especially true in the case of N-terminally blocked or structurally modified peptides in which traditional techniques such as automated Edman degradation fail.

Tandem mass spectral techniques have had limited success when attempted to sequence peptides of unknown composition, as is the case with process impurities. A more selective mass spectral method is provided by following the course of an exopeptidase digestion with an on-line device such as continuous-flow FAB (CF-FAB).

A solid-state peptide synthesis of U-86364E, intended to give the N-terminal FMOC protected peptide, was characterized by low recovery from the resin and the concomitant appearance of two major and two minor impurities.

LYS-ARG-ALA-LYS-ALA-LYS-THR-THR-LYS-LYS-ARG
U-86364E

Initially it was suspected that the four impurities were the result of incomplete deprotection during recovery from the resin. The four protecting groups used were as follows:

- FMOC
- Tosyl
- ChloroZ
- Bz

The M+1 ions obtained by FAB for the four impurities were:

<table>

</tbody>
</table>

Compounds A and B corresponded to U-86364E+FMOC+Bz and U-86364E+FMOC+Tos, respectively. The molecular weights of the remaining two impurities were justified by invoking a decomposition of the ChloroZ protecting group to a Bz-Cl:

\[
\text{ChloroZ} \rightarrow \text{Bz-Cl}
\]

Compound C therefore corresponded to U-86364E+FMOC+Bz-Cl and compound D to U-86364E+FMOC+Tos+Bz-Cl.

The supposition at this point was that the impurities were incomplete deprotection species, however, repeated HF treatment did not remove the protecting groups. Determination of the location of the protecting groups was attempted using tandem mass spectrometry but was not successful; daughter ion spectra were dominated by an ion corresponding to the base peptide U-86364E.

An enzymatic digestion using Carboxypeptidase P was allowed to proceed over the course of a number of hours and monitored by CF-FAB. The results for compound A are presented in the following figure:
In each case it was possible to observe cleavage of the peptide down to an ion corresponding to FMOC, lysine, and the corresponding protecting group. These data reveal that the impurities were not the result of incomplete deprotection but the result of migration of the protecting groups to the N-terminal end of the peptide.

What remained to be confirmed was whether these protecting groups had migrated to the N-terminal FMOC. 13C-NMR DEPT experiments indicated the impurities consisted of the appropriate aromatic substitutions. Two-dimensional NMR experiments are in progress to determine the exact site of substitution.

Experimental Procedures:
Mass spectral data were collected and processed on a Finnigan TSQ-70 triple stage quadrupole mass spectrometer. FAB was acquired using Xenon atoms generated by an Ion Tech saddle field gun operating at 8KV in static mode and 5 KV in continuous-flow (CF-FAB) mode. CF-FAB was performed in 5% glycerol/water and flowed to the source at 10μl/minute. Excess matrix was absorbed onto a circular piece of filter paper which had been fitted around the probe tip. The probe, manifold, and source were kept at a temperature of 30°C, 50°C, and 55°C, respectively.

The peptides were constituted in 150μl of pH Milli-Q filtered water, at a concentration of 2 nmole/μl. Carboxypeptidase P was added such that the substrate:enzyme ratio was 100:1. After the designated time interval 23μl of digest were removed and quenched with 2μl of 20% TFA. Ten microliters of this aliquot were immediately loaded into the CF-FAB injection port and mass spectral data collected scanning from 500 amu to molecular weight plus 50 amu. A second 10 μl aliquot was injected immediately after and used to scan the low mass range from 50 amu to 500 amu.

Structural characterization of cysteine proteinases isolated from lobster gastric juice using LC-MS enzymatic mapping and on-line LC-MS-MS

1P. Thibault, 1M.V. Laycock, 1,2S. Pleasance, 1R. MacKay and 1R.K. Boyd; 1Institute for Marine Biosciences, NRC, 1411 Oxford St., Halifax, Nova Scotia, 2SCIEX, 50 Glen Cameron, Thornhill, Ontario, Canada

Cysteine proteinases such as papain are quite distinct from other endopeptidases as their enzymatic activity depends on the presence of a free thiol group of a cysteine residue, located within the catalytic site [1]. Recently a new cysteine proteinase, which accounts for 80% of the proteolytic activity in the lumen of the lobster hepatopancreas, was purified in this laboratory [2]. Further work was conducted to clone DNA sequences that encode this enzyme using oligonucleotide probes synthesized using information from the N-terminal amino acid sequence previously reported [2]. This latter work yielded three distinct cysteine proteinase clones having approximately 210 amino acids and average molecular weights of 23066, 23270 and 23377 Da.

Mass spectral analyses using Ionspray were conducted to characterize the proteinases found in the gastric juice of the lobster, and to relate these to the amino acid sequences encoded in the cDNA clones. These analyses were also undertaken to determine sites of post-translational modification, in particular disulfide bridge location. Purified lobster cysteine proteinase extract was first denatured to minimize the effect of protein folding. A portion of this preparation was then alkylated using iodoacetamide both with and without prior disulfide bond reduction. Figure 1 shows the Ionspray mass spectra of the denatured proteins, and indicates two coherent series of multiply-charged ions corresponding to molecular weights of 23378 and 23085 Da respectively. These masses were in close agreement with those predicted from two of the proteinase clones. Alkylation of free thiol groups resulted in a mass shift of approximately 57 Da for both proteinases, indicating the presence of only one free cysteine in each case. Upon reduction/alkylation the multiply-charged ion envelope is shifted toward lower m/z ratios, consistent with the protein unfolding and a higher number of available protonation sites. Also, the masses of the two proteinases were shifted by 590 and 567 Da respectively, implying a total of 10 cysteine residues in each case. The higher number of alkylation sites could be explained by reaction of other amino acids such as histidine.

Primary structure characterization of these two proteinases was investigated by analyzing tryptic digests of denatured and alkylated proteins using Ionspray LC-MS. An example of such analyses is presented in Figure 2a, which illustrates the reconstructed ion chromatogram (m/z 600-1400 Da) of the tryptic digest of reduced/alkylated proteinases. Alkylated cysteine peptides were rapidly identified by both their shift toward lower retention times and their incremental shift in mass with respect to their underivatized counterparts. Finally, amino acid sequence assignment was confirmed using LC-MS-MS analyses of selected tryptic peptides. Figure 2b shows the fragment ion mass spectrum of the doubly-charged peptide T79_94 of the major proteinase (peak 1 on Figure 1). This on-line LC-MS-MS shows almost complete peptide sequencing using less than 100 pmols of total protein digest.

INTRODUCTION

High resolution of high-energy, high-mass ions in a Fourier Transform Ion Cyclotron Resonance (FT-ICR) Mass Spectrometer has proven to be difficult or impossible to obtain. This may be due to varying or unknown parameters or to unforeseen nonlinearly varying inputs. Practical limits may be made on design variables as well as generic computerized models. Simulation studies show the possibilities of effectively resolving high-energy, high-mass ions in the mass range beyond that which is obtainable in the present day FT-ICR mass spectrometer. Recent development in FT-ICR mass spectrometry may pave the way to more promising design and operation parameters necessary for high-energy, high-mass resolution. Such analytical instruments would promise high performance superiority over present day methods. The possibility of defining such parameters is considered. The study will focus on FT-ICR ion mass resolution design equations whose variables will be tested for optimum performance.

EXPERIMENTAL

All simulations were done using IBM computer. The computer simulations assume totally homogeneous electric and magnetic fields gradient, ideal cell dimensions and design, and non-reactive hard-sphere ions. The computer program is based on analytical solution of the equation of motion for the ions accelerated by an applied rf electric field. Only ions in a X-Y plane are addressed by the program to allow specific studies of radial motion to be performed. Variables of the design equations were tested and the search for optimum ranges of variable parameters was conducted.

RESULTS AND DISCUSSION

The final radius distribution was plotted versus the frequency sweep rate figure 1. The plot shows that at varying sweep rates ions will obtain different degrees of coherence. The level of coherence seems to vary in an oscillating manner. That is the same level of coherence is obtained at different sweep rates. Thus different degrees of resolution will be obtained depending on the sweep rate used for excitation and from the data it is possible to obtain the same results at different sweep rates.

The effect of voltage on ions coherence was tested for consideration as one of the essential forces required to coerce randomly distributed ions into coherence. Four different sweep rates were tested varying the excitation voltages. The number of cycles to obtain the same level of coherence were normalized and plotted versus the excitation voltage change. The behavior of the irradiltated ions under electromagnetic effect is described in plots of their trajectories as shown in figures 2. Attempts to ensemble ions at low voltage was not very successful. At such insufficient voltage, ions lacked sufficient energy to overcome the diffusive and repulsive forces that dominate similar-charge ions. Thus it would take a larger number of cycles to obtain any degree of
coherence no matter what the sweep rate was. At high voltage, the ions acquired sufficient energy to achieve phase advancement, ensemble, and radially accelerate. It was observed that ions with ideal sweep rates would obtain coherence at fewer cycles of oscillation at higher excitation voltages.

CONCLUSION

The accompanying plots and illustrations show what should happen theoretically and what happens in the computer simulation. The plots show two ions which have different phase angles due to the difference in the times of their formation. In order to achieve a good signal, the ions must be in phase with each other and the applied electrical field before they reach maximum excitation. The plots of voltage vs. frequency show that with a high voltage the ions can be driven into phase quickly, but if the voltage is too high, the ions' radii exceed the limitations of the instrument's cell. The steps in which the frequency is swept also determine whether or not the ions go into phase. Smaller increments seem to drive the ions into phase while larger increments drive them further out of phase than is caused by their times of formation.
INTRODUCTION

The 69-kDa outer membrane protein (OMP) of *B. pertussis* is considered to be a potentially useful vaccine component in acellular vaccines and therefore has been subjected to further characterization. Automated Edman degradation through 20 cycles showed that the N-terminal sequence corresponds to that predicted from the DNA sequence. C-terminal analysis by carboxypeptidase Y digestion gave ambiguous results due to co-elution of Ser and Asn. These data were not sufficient to assign a specific C-terminus but did indicate that the putative termination site at residue 677 which corresponds to a molecular mass of 69 kDa was incorrect. Instead, the data were compatible with sequences found between residues 597-599 and 597-600. In addition to the 69-kDa species, certain protein preparations showed a doublet on SDS-PAGE with a second band at ca. 67 kDa. With time, it appeared that the 69-kDa species could be completely converted to 67 kDa, and therefore it was assumed that the conversion was due to adventitious proteolysis. Alternatively, sequence analysis was identical to that from the 69-kDa species, implying C-terminal cleavage to yield the 67-kDa product.

HIV reverse transcriptase (RT) p51, a part of the heterodimer p51/p66, is produced by cleavage of p66 by HIV protease. In order to rapidly determine the exact cleavage site, the protein was subjected to various forms of mass analysis coupled with chemical and enzymatic degradation.

PROBLEMS

a) Determine/verify N- and C-termini of natural and recombinant 69 kDa pertussis outer membrane protein relative to the DNA-derived sequence by measuring molecular masses. Also, determine/verify the N- and C-termini of the natural 67 kDa form that appears to result from adventitious proteolysis. b) Establish location of cleavage site in HIV reverse transcriptase p56 that yields p51 of the heterodimer.

DISCUSSION

Pertussis Outer Membrane Protein. Analysis of each protein by electrospray MS yielded spectra for both the 69-kDa OMP and the 67-kDa protein. Close examination of each spectrum revealed that the peaks were wider than is typical for ESMS spectra suggesting the presence of components contributing to peak broadening. Other experiments (e.g., FABMS of limited tryptic digests) suggested the cause to be cations (Na+, K+) and, for the 67-kDa protein, a ragged C-terminus (see below). Careful evaluation of the peaks resulted in reasonably accurate mass measurement. In separate experiments on different protein preparations, molecular weights of 60,297±16 and 60,291±8 were measured for the 69-kDa protein. A molecular weight of 58,132±8 was measured for the 67-kDa protein. These data are consistent with sequences of Asp-Asn and Asp-Ala for the 69-kDa and 67-kDa species, respectively.

To confirm these conclusions, the two proteins were subjected to limited trypsin hydrolysis (15 min; E:S 1:1000) and size exclusion HPLC. The peptide fraction from the hydrolysis of the 69-kDa OMP gave a readable sequence of 27 amino acids by automated Edman analysis corresponding to the expected trypsin fragment Glu-Ala-Ser-Ala-Ala-Ala-Asn. ESMS analysis of the tryptic peptides was in agreement with the Edman analysis. The peptide fraction from the hydrolysis of the 67-kDa degradation product was also analyzed by automated Edman analysis yielding a readable sequence of seven residues: Glu-Leu-Ser-Ala-Ala-Ala-Asn. However, ESMS analysis showed a mixture of peptides of molecular masses of 489, 560, and 674 Da corresponding to Glu-Ala, Glu-Ala, Glu-Ala-Asn, respectively, indicating a ragged C-terminus for the 67-kDa species.

Molecular mass measurements of the intact 69-kDa OMP and the peptides released by limited trypsin digestion are consistent with Asp-Asn from the DNA-derived sequence of Charles et al. (PNAS, USA, 1989, 86, 3554) corrected for sequencing errors. These errors (Leu→Pro and Pro→Ser), which were detected by amino acid analysis of internal tryptic peptides (data not shown) and correspond to single base pair replacements, produce mass shifts of -16 and -10 Da, respectively. Note that our data are equally consistent with the uncorrected DNA-derived sequence (M_calc = 60,308). Molecular mass measurements of the recombinant 69-kDa OMP and the peptides released by limited trypsin digestion are consistent with the sequence Met-Ser-Glu-Ala-Ser-Glu-Ala-Asn. Molecular mass measurements of the intact 67-kDa OMP are consistent with the sequence Asp-Ala, and the peptides released by limited trypsin digestion are consistent with the presence of sequences Asp-Ala, Asp-Ala, Asp-Ala, Asp-Ala-Asn, respectively. The peaks corresponding to protein molecular ions for the ragged C-terminus could not be resolved due to the presence of cations (Na+, K+) or other adducts.

HIV Reverse Transcriptase p51. In a similar fashion, the p51/p66 heterodimer of HIV reverse transcriptase (RT) was analyzed by ESMS. The data though weak showed two major series corresponding to masses of 51,298±5 (M_calc = 51,302) and 64,494±10 (M_calc = 64,432). Analysis by LDMS showed M_calc = 51,451 and 64,451. The LDMS data were acquired in nominal mass mode, without internal calibration references, and therefore the masses are only approximate.) In order to corroborate the cleavage site which distinguishes p51 from p66 (believed to be near residue 432), p51 was isolated and subjected to oxidative cleavage at tryptophan followed by FABMS. A peak was observed at m/z 1624.6 which reasonably corresponds only to Tyr-Phe. To verify the assignment of the m/z 1624.6 peak, a Lys-C digest was performed on the putative C-terminal peptide. FABMS analysis of this digest gave an expected peak at m/z 963 which corresponds to Glu-Phe which was further confirmed by one cycle of manual Edman degradation.
CONCLUSION: These examples illustrate some of the limitations of both MS and automated Edman analysis. In the ESMS data of the "67 kDa" OMP, the presence of a ragged C-terminus was not observable in the presence of intractable cationic contamination. Even under ideal conditions on a pure sample, the presence of a ragged C-terminus with differences of +1 and +2 amino acids would have been barely perceptible for a protein of this mass; the difference in mass for an additional Ala (71 Da) divided by the charge state (e.g., 50+) gives a difference in m/z of only 1.4, which is approaching the theoretical peak width for these proteins. In automated Edman analysis, quantitation may not be sufficiently reliable to establish the presence (or absence) of mixtures. Such analyses should be coupled with analysis of the peptide fraction by RP-HPLC with UV detection for better quantitation (temporal separation) and MS for greater selectivity (mass separation). HPLC/MS with simultaneous UV detection provides a powerful solution to both problems.

Figure 1. ESMS analysis of ca. 300 pmol of B. pertussis 67-kDa OMP. The sample (ca. 20 pmol/μL in 3:7 MeOH/H₂O containing 2% acetic acid) was introduced into the mass spectrometer at 2-3 μL/min and data collected for ca. 6 min.

Figure 2. ESMS analysis of ca. 150 pmol of the limited trypsin digest (15 min, E:S = 1:1000) of B. pertussis 67-kDa OMP. The sample (ca. 20 pmol/μL in 3:7 MeOH/H₂O containing 2% acetic acid) was introduced into the mass spectrometer at 2-3 μL/min and data collected for ca. 3 min.
HIV-gp120 is the surface receptor of the AIDS virus. This glycoprotein is believed to mediate viral attachment to host cells through the CD4 receptor. Due to the critical role that gp120 plays in the life cycle of HIV, it is of possible interest as a therapeutic target and as a vaccine candidate. The glycoprotein expressed in Drosophila contains 454 amino acids and 24 possible N-linked glycosylation sites, and is known to be heavily glycosylated. The carbohydrate moieties of gp120 may have important roles in the activity of the glycoprotein since deglycosylation results in diminished binding activity of gp120 to CD4\(^1\). The 44 amino acid of gp120 that is believed to be responsible for binding to CD4\(^1\) contains one possible glycosylation site that was found to be filled. Additionally, the V\(_\alpha\) loop, which is thought to be the portion of gp120 that generates neutralizing antibodies, contains one, and is bounded by two possible glycosylation sites, all of which have been found to contain carbohydrate. The objective of the current study was to develop mass spectrometric and liquid chromatographic methods to confirm the expected sequence of recombinant gp120, determine which of the 24 possible glycosylation sites are utilized, and ascertain the structural class, branching, and molecular heterogeneity of the carbohydrate units at each attachment site.

Peptide and carbohydrate mapping of recombinant gp120 was accomplished by LC-ESMS. Reduced and carboxymethylated gp120 was subjected to enzymatic digestion prior to and after release of the carbohydrate moieties with PNGase F (Figure 1). Three different enzymatic cleavage schemes were employed so that glycopeptides that contain only one glycosylation site could be produced for a majority of the 24 possible attachment sites. These include a tryptic digestion, a tryptic digest followed by endoproteinase Glu-C, and tryptic digestion followed by asparaginylendopeptidase cleavage. The molecular weights of the resulting peptides from each enzymatic digestion were observed by LC-ESMS and fitted to the deduced sequence of the glycoprotein. Some glycopeptides were also observed by LC-ESMS and yield information concerning structural class and microheterogeneity of the carbohydrate units. PNGase F release of the oligosaccharide moiety converts Asn to Asp, which aids in the determination of attachment sites since Asp weighs one more dalton than Asn. Possible glycopeptide containing fractions are identified by comparing UV and ESMS of digested RCM-gp120 and PNGase treated RCM-gp120.

Putative glycopeptide containing fractions were then subjected to direct mass spectral analysis followed by PNGase treatment. The former glycosylation site peptide was then identified by MS analysis. Portions of the PNGase reaction mixtures were retained for high performance anion exchange chromatography to obtain a high resolution carbohydrate fingerprint at each site, and the remaining material was permethylated with DMSO/NaOH/Mel. The permethylated oligosaccharides can be analyzed by FAB or ESMS and methylation analysis. This strategy enables a great deal of information regarding structural class, microheterogeneity, and branching to be gathered very quickly.
Using this strategy, more than 95% of the polypeptide portion of gp120 has been mapped. Of the 24 possible glycosylation sites, 18 have found to be filled and 3 partially occupied. We have found that recombinant gp120 from Drosophila contains primarily oligomannose type carbohydrate structures (Man$_n$-Man$_8$). Different attachment sites tend to exhibit varying amounts of carbohydrate processing. The extent of glycosylation observed in the mapping studies is consistent with the mass of 83,000 Da obtained by laser desorption time-of-flight mass spectrometry (B. Chait personal communication). The average mass of the polypeptide core of gp120 is 50,777 Da indicating that 36% of the glycoprotein is carbohydrate.

RecA (recombinase A) is a 38 kilodalton enzyme which is essential for genetic recombination and repair in E. coli. The sequence of recA has been deduced from a gene sequence and partially verified by amino acid analysis. The protein binds to DNA, ATP and ADP. A three-dimensional structure of recA was recently proposed based on x-ray crystallography data obtained for recA bound to ADP. Traditionally chemical modification of proteins has been used as a tool to study their three-dimensional structure and locate binding sites. Chemical modification studies of recA have indicated that in the presence of ATP two of the three cysteines present in the recA sequence are protected from reaction with a sulphydryl modifying agent. In the absence of ATP all three cysteines react with the modifier, but as ionic strength increases one cysteine becomes protected. The position of this protected residue could not be identified using amino acid analysis. We are using mass spectrometric techniques to determine the extent and location of chemical modification of recA protein under various reaction conditions in an effort to study the three-dimensional structure of recA protein in solution and locate DNA, ATP and ADP binding sites.

When analyzed by direct injection using a Finnigan TSQ 70 quadrupole fitted with a Finnigan MAT electrospray ion source, a 500 ng injection in 60% methanol/5% acetic acid in water of recA yielded a series of multiply-charged ions. The deconvolution of this series of peaks resulted in an average molecular weight of 37,852. This represents an error of 0.03% from the predicted value of 37,842. In addition, analyses of the recA tryptic digest by standard FAB MS, continuous-flow FAB MS and LC/electrospray MS confirmed 92% of the predicted sequence for recA protein.

RecA protein was treated with N-ethylmaleimide (NEM) in a 15-fold molar excess and incubated for ninety minutes. NEM reacts with sulphydryl groups and increases the mass of cysteine residues by 125 u. RecA contains three cysteines at positions 90, 116 and 129. The modified recA protein was analyzed by electrospray MS. The resulting envelope of multiply-charged ions was deconvolved to yield an average molecular weight distribution which indicated two to three residues had been modified. An expansion of the deconvoluted spectrum is shown in Figure 1. The peak at 37,843 daltons corresponds to unmodified recA with a predicted molecular weight of 37,842. The peak at 37,970 daltons corresponds to recA modified by one NEM group with a predicted molecular weight of 37,967; that at 38,097 daltons to recA modified by two NEM groups with a predicted molecular weight of 38,092; and that at 38,201 daltons to a small amount of recA modified by three NEM groups with a predicted molecular weight of 38,217 daltons. An expansion of the deconvoluted spectrum for recA which was not treated with NEM is shown in Figure 2 for comparison.

To locate the sites of NEM-modification within the recA sequence, a tryptic digest of NEM-modified recA was analyzed by standard FAB MS. The three cysteines of recA are contained in two tryptic peptides: (89-105) at m/z 1907.1 and (107-134) at m/z 2974.3. These peptides are clearly seen in the spectra for the tryptic digest of unmodified recA. The tryptic digest of modified recA yields a peak at m/z 2032.2, which represents (89-105) modified by one NEM group, a peak at m/z 3100.7, which represents (107-134) modified by one NEM group and a peak at m/z 3224.3 which represents (107-134) modified by two NEM groups. The peak at m/z 2032.2 indicated cys 90 has been modified. The peak at m/z 3224.3 shows both cys 116 and cys 129 have been modified. However, the single site of modification for the peptide at m/z 3100.7 cannot be differentiated between cys 116 and cys 128. The m/z values for peptides which do not contain cysteine were unchanged by treatment with NEM.

Our findings show that electrospray can be used to monitor the extent to which recA reacts with NEM under specific reaction conditions. Tryptic FAB-mapping can be used to locate a modification of cys
90. However, this technique alone cannot differentiate between modification of cysteine 116 and 129. We will employ tandem mass spectrometric analysis of the peptide at m/z 3100.7 for this purpose. Further studies are underway which will utilize mass spectrometry to study the chemical modification of cysteine and other recA residues under a variety of reaction conditions and in the presence of coenzymes and substrates such as DNA, ATP and ADP.

Fragmentation of Proline Containing Peptides

M. Vestling, S. Hua, C. Murphy, R. Orlando, Z. Wu, and C. Fenselau
Department of Chemistry and Biochemistry, University of Maryland Baltimore County
Baltimore, MD 21228

Proline has been reported to influence the collisionally induced fragmentation of peptides in characteristic ways. Biemann has pointed out its inability to form d series ions (1), and Hunt reported that peptides containing proline produced decomposition products by double cleavage of the peptide chain (2). Williams has suggested that formation of pairs of y and y' ions is characteristic of proline residues (3). While sequencing S. aureus V8 protease, we have acquired more than a score of peptides with proline in every third position (4).

This set of peptides has allowed us to evaluate the effect of proline on fragmentation initiated by different kinds of ion activation. Three types of fragmentation have been studied: high energy collision induced decomposition (CID), reaction induced decomposition (RID), and collisional activation of multiply charged ions produced by an electrospray ionization source (ESD). For CID and RID, the peptide samples were dissolved in 0.1% trifluoroacetic acid and added to either thioglycerol or 3-nitrobenzyl alcohol before being introduced into the FAB source. CID spectra were obtained using all four sectors (EBEB) of a JEOL HX110/HX110 high performance mass spectrometer with resolution set at 1000. Helium was used as the collision gas between the two mass spectrometers at a pressure sufficient to attenuate the precursor ion beam by 80%. The accelerating voltage was 10 kV, and the collision cell was floated to 4 kV. For the RID experiments, ammonia was used as the reaction gas, and the collision cell was maintained at 10 kV - Vlab where Vlab = Elab/e and Elab = beam energy. Product ion spectra were obtained for beam energies ranging from 1 to 60 eV, by scanning the magnetic field in MS-2. The ESD was done with a Vestec electrospray ionization source coupled to a Hewlett Packard 5988A quadrupole mass spectrometer. Fragmentation was achieved by changing the repeller voltage.

All three kinds of fragmentation are illustrated in Figure 1 for a synthetic peptide, DNPNNPDPNNPNPD. The high-energy CID fragmentation is quite complex when compared to the low energy reaction induced fragmentation. Preferential reaction and subsequent fragmentation occurs at peptide bonds where proline contributes the amine group. The electrospray fragmentation shows most of the y series ions this peptide could generate, simplifying the interpretation relative to the CID spectrum also. In all cases studied, the RID spectrum shows proline amide bond cleavage almost exclusively. This work demonstrates progress in controlled fragmentation leading, we think, to improved mass spectrometric sequencing protocols for peptides and proteins.

FAB-MS ANALYSIS OF A MASTOPARAN B ISOLATED FROM THE HORNET (VESPA BASALIS) VENOM WITH B/E LINKED SCANNING

Yong-Chien Ling*, Bang-Ji Liu, Jirn-Mehng Lo, and Chewn-Lang Ho

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043, R.O.C., and Institute of Biological Chemistry, Academia Sinica, Taipei, Taiwan 10798, R.O.C.

INTRODUCTION

Vespa Basalis is one of the most dangerous hornets found in Taiwan. The incidence of sting death caused by this hornet is high and is probably due to its aggressiveness and highly toxic venom. Freshly collected venom was fractionalized into 13 fractions on a Fractogel TSK HW 50 gel filtration column. Fractions 3 and 6 were further purified from the venom after cation-exchange chromatography on CM-Trisacryl M. Fraction 3 showed the highest lethality and was estimated to have approx. 32,000 daltons molecular weight by gel electrophoresis and amino acid analysis (1). Fraction 6 was a tetradecapeptide, designated as mastoparan B, possessed the potent hemolytic activity and synergized with the lethal fraction 3. It was suggested that mastoparan B might possibly involve the lethal effect of Vespa Basalis venom. The sequence of mastoparan B from position 11 to 14 was difficult to ascertain by Edman degradation method. The aim of this study is to determine the amino acid sequence of the mastoparan B using FAB-MS with B/E linked scanning.

EXPERIMENTAL

A 1-μL aliquot of the peptide solution (approx. 5-μg peptide dissolved in 5-μg water) was mixed with 1-μL of thioglycerol matrix on the FAB probe tip. The mass spectrometric analysis were carried out with a two-sector magnetic deflection mass spectrometer (JEOL HX-110, EB geometry) operated either in the normal scan or in the linked scan mode. Ionization was achieved by bombardment with a 6-KeV Xe° beam and the accelerating voltage of the mass spectrometer was operated at 10-KeV. (CsI)nCs+ cluster ions are used for mass calibration. High resolution measurements for ions in the normal FAB spectrum were made at the resolving power of 10,000, otherwise the resolving power was set at 3,000. The normal FAB spectrum was collected in 10 sec. In the linked scan mode, the collision-induced decomposition (CID) spectrum was obtained by admitting the Helium into the collision cell (first field-free region) at the pressure (approx. 10^-4 ~ 10^-6 torr) that the precursor ion was attenuated to 50% of its original abundance. The linked scan at constant B/E ratio was generated by the JEOL JMA-DA5000 data system. The single scan raw data profile was recorded in 1 min.

RESULTS AND DISCUSSION

Peaks of (M+H)+ and (M-H)- with m/z = 1612 and 1610 are observed from the normal positive and negative FAB spectrum respectively. The protonated molecular ion of the peptide was further ascertained to be m/z = 1612.01 from the
high resolution measurement and the formation of \( (M+Na)^+ = m/z = 1634 \) and \( (M+K)^+ = m/z = 1650 \) by adding a small amount of 0.1 M NaNO₃ and KNO₃ solution to the sample. It is found out that the carboxylic acid in the C-terminus is converted to an amide group. The characteristics of the normal FAB mass spectrum that the lack of continuous series of ions of one type (the various ion types proposed by Roepstorff and Fohlman (2)) and the difficulty of interpreting the mass spectrum in the low-mass region due to the matrix interferences are evident. The attributes of the CID mass spectra of peptide exhibiting extensive series of the same ion type and reduced matrix interference effects via the appropriate selection of the precursor ion are exploited to overcome the aforementioned shortcomings. The illustrative example is shown in Figure 1, which represents the CID spectrum of \( (M+H)^+ = m/z = 1612 \) protonated molecular ion. The y-ions are of \( m/z = 1499, 1371, *, 1130, 1043, *, 831, 744 \), which corresponds to the partial sequence of Leu-Lys-Leu-Lys-Ser-Ile-Val-Ser. The position labelled with * indicates a missing y-ion and the corresponding amino acid is determined using the dipeptide residue masses. The dominant b-ions are of \( m/z = 1482, 1383, 1255, 1127, 1056, 869, 782, 683, 570, 352, 242 \), which corresponds to the complete sequence of NH₂-Leu-Lys-Leu-Lys-Ser-Ile-Val-Ser-Trp-Ala-Lys-Lys-Val-Leu-NH₂. It is noted that certain b-ions with the measured \( m/z \) from 869 down to 242 are all one mass unit smaller than the expected \( m/z \). Similar, but less, amount of information are also obtainable from the CID spectrum of \( m/z = 1028 \). In both cases, the differentiation of Gln/Lys and Leu/Ile are clarified with the partial information from the amino acid analysis and the Edman degradation method.

Sequence-Informative fragmentation in \(^{252}\text{Cf}\)-Plasma Desorption Mass Spectrometry

P.A. van Veelen, U.R. Tjaden and J. van der Greef
Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences,
P.O. Box 9502, 2300 RA Leiden, The Netherlands.

Plasma desorption mass spectrometry (PDMS) has been reported to yield sequence-informative fragmentation several times now.\(^1\) Fragmentation in oligopeptides beyond the scope of collisionally activated dissociation (CAD) using sector instruments was first observed for ions up to 4.6 kDa, but the upper limit has been extended to 8.9 kDa.

Fragmentation of ions of this size is far beyond the scope of CAD of macromolecular ions using sector instruments. On the one hand, it raises questions about the upper limits of sequencing by PDMS. On the other hand, it poses queries about the ionization process and the physics involved. The coupling among the many oscillators present in the molecule would seem to be low in the involved time-frame and the energy pumped into the molecule by the ionization/desorption process would seem to remain quite localized during the fragmentation processes which take place within nanoseconds at most.

Another aspect of the fragmentation is the pattern of it. What types of fragment ions are usually observed? In our experience we often observe \(a\)-ions, \(d\)-ions, \(x\)-ions, \(w\)-ions and \(z\)-ions. We seldomly observe \(b\)-ions, \(c\)-ions, \(y\)-ions and \(y\)-ions. The ion types we observe indicate a high internal energy content of the ions. The spectra of some peptides only show \(a\)-ions whilst that of other peptides show \(a\), \(d\), \(x\), \(w\) and \(z\)-ions. This is undoubtedly a consequence of the primary structure. It would be interesting to know the influence of the secondary and/or tertiary structure on the fragmentation pattern. When we look to the fragmentation pattern of the 8.9 kDa oligopeptide (see Figure 1) we only observe fragments from the first 20 amino acids of the N-terminus. This is remarkable since we seldomly observe fragments arising from cleavages very close to the termini in the larger oligopeptides.

A third aspect of the fragmentation is the amount of sample needed to get fragments. At this moment 200 pmol is the minimum amount. This is a relatively large amount. The phenomenon that more fragments are observed when using larger amounts is known from Fast Atom Bombardment (FAB) mass spectrometry. It would be very useful to lower this amount needed.

In conclusion it can be stated that promising progress has been made. However, a lot of questions have to be answered. What is the upper mass limit for finding fragments? How is the internal energy gained in the ionization process distributed among the many oscillators? Can we influence the intensity of the fragment ions or the pattern of fragmentation? Can we learn more about the ionization/desorption process? Can we find methods using less sample and still find fragments? The majority of these questions seems to be closely related to applying a correctly chosen matrix.

ION/MOLECULE REACTIONS AND ENERGY DEPOSITION IN PYRENE STUDIED BY MS° EXPERIMENTS USING AN ION TRAP MASS SPECTROMETER.

*B.D. Nourse, K.A. Cox and R.G. Cooks; Purdue University, Chemistry Department; West Lafayette, IN 47907

The well-known carcinogenic hazards posed by polycyclic aromatic compounds (PACs) has sparked a demand for new and reliable techniques for their characterization [1]. The quadrupole ion trap mass spectrometer (ITMS) includes unique capabilities for single ion selection and multiple activation steps (MS°) which provide methods for examining fragmentation pathways and energy deposition in PACs as well as elucidating their ion/molecule reactions [2].

Traditionally, the ITMS has been considered a device in which relatively low energy collisions occur. However, the structural stability of PACs necessitates that relatively large internal energies be supplied to observe fragmentation. Through the MS° capability of the ITMS, we have shown that large amounts of energy can be deposited in a sequential manner. As a result of these experiments, extensive fragmentation occurs to give dissociation reactions such as:

\[
\begin{align*}
\text{C}_{16}\text{H}_{10}^+ & \rightarrow \text{C}_\text{8} \text{H}_6^+ \rightarrow \text{C}_\text{8} \text{H}_4^+ \rightarrow \text{C}_\text{8} \text{H}_2^+ \rightarrow \text{C}_\text{6} \text{H}_2^+ \rightarrow \text{C}_\text{4} \text{H}_2^+ + \text{C}_\text{2} \text{H}_4^- \\
\end{align*}
\]

The activation energies for this process, approximated from \( \Delta H \) for each dissociation reaction, are \( 7.2 \pm 0.7, 0.6 \pm 1.3, 8.0 \pm 1.0, 3.9 \pm 0.9, 2.7 \pm 0.4 \) and \( 6.5 \pm 0.4 \) eV, respectively. Although each individual dissociation step has an activation energy < 8.0 eV, the total energy required to produce \( \text{C}_\text{8} \text{H}_4^+ \) by this route is \( 29 \pm 2 \) eV (the sum of the \( \Delta H \) values). An activation time of 50 msec at an ac amplitude of 1000 mV\( _{pp} \) \( (q = 0.26) \) was typically used. When unusually high activation conditions are applied \( (10 \ V_{pp} \ for \ 100 \ msec) \) to the molecular radical cation \( \text{M}^+ \), direct formation of the fragment ion \( \text{C}_{10} \text{H}_4^+ \) is seen (Fig. 1) although the dissociation efficiency for this process is only 7%. This process requires an energy between 17 and 22 eV, depending on the neutral losses observed. The base peak \( \text{C}_\text{16} \text{H}_4^+ \) is formed by loss of 6H from the molecular ion.

Fragmentation pathways of PAHs can also be assessed by utilizing the MS° capability of the ion trap. The fragments observed are similar to those seen with one-step high energy processes [3]. However, through the use of multiple activation and dissociation steps of the ITMS, the origin of these fragments can also be determined. Neutral losses common to all PAHs \( (e.g. \text{H}, \text{H}_2, \text{C}_\text{2} \text{H}_4, \text{C}_\text{3} \text{H}_6) \) were observed for the pyrene system and some fragment ions could be accessed by a number of different pathways. The longest sequence of dissociations performed on pyrene involved nine separate isolation and activation steps, producing \( \text{C}_\text{8} \text{H}_2^+ \) \( (m/z \ 84) \) from \( \text{C}_\text{16} \text{H}_4^+ \) \( (m/z \ 202) \).

Ion/molecule reactions of the pyrene molecular radical cation, \( \text{M}^+ \), the \( \text{(M-H)}^+ \) ion and the \( \text{(M-H}_2^2) \) ion, as well as the corresponding \( \text{C}_\text{16} \text{D}_{10}^+ \) ions, were investigated to further characterize ionized pyrene. The \( \text{C}_{16} \text{H}_{10}^+ \) species showed no reactivity toward the neutral reagents pyrene, methyl iodide, ethyl iodide, isoprene and 2-iodopropane. This is attributed to delocalization of the radical cation throughout the aromatic system. However, the \( \text{C}_{16} \text{H}_8^+ \) ion is an even electron species with a more localized charge site. It behaves much like the phenylium ion, showing high reactivities with the above reagents and giving predictable products. Consequently, the \( \text{(M-H}_2^2) \) ion shows intermediate reactivity in accordance with its odd electron character containing a localized charge and radical.

1479
Addition of isoprene to the (M-H)^+ and (M-H2)^+ ions of pyrene occurs via cycloaddition with a characteristic fragmentation by methyl radical loss from each adduct ion. Evidence obtained using d0-pyrene indicates that the adduct of (M-H)^+ fragments via methyl loss to give an ionized indene-type structure. Figure 2 suggests that the first CH3 loss does not come from the isoprene portion of the adduct ion, but from within the aromatic ring where H/D exchange can readily occur.

Addition of methyl iodide, ethyl iodide and 2-iodopropane to the (M-H)^+ ion of pyrene occurs through the iodine atom (C6H5-I^+). The methyl iodide adduct fragments by loss of I and CH3 to give methyl pyrene and iodopyrene product ions. CAD studies on the d10-iodopyrene ion (Fig. 3a) gave loss of I, indicative of this bridged-type structure. Reactions of ethyl iodide and 2-iodopropane with the (M-H2)^+ ion give primarily a HI addition product, together with small contributions from the intact adduct ion. In this case, the alkyl halide and the HI molecules add across the carbon-carbon bond rather than forming an iodine bridged adduct as indicated by the CAD products of the (C16D8 + HI)^+ ion (Fig. 3b). This data shows loss of I with no HI or H' loss.

An experiment in which the (2M-H)^+ adduct, C26H19^+, is converted to C22H5^+ in nine consecutive isolation and activation steps (MS10) without carbon-carbon cleavage, exemplifies the intriguing ion chemistry as well as the stability of the carbon skeleton of the adduct ions.

HIGH MASS-RESOLUTION USING A QUADRUPOLE ION TRAP MASS SPECTROMETER

J.D. Williams, K. Cox, K.L. Morand, R.G. Cooks, and R.K. Julian, Jr., Dept. of Chem. Purdue University, West Lafayette, IN 47907; R.E. Kaiser, Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, IN 46295

With recent developments in ionization techniques which transform molecules of high molecular masses into gas phase ions, mass spectrometry is gaining prominence as a method for biomolecule characterization. The quadrupole ITMS has been used to produce high sensitivity MS/MS spectra on peptides of molecular masses up to 3000 Da. To enhance the capabilities of this instrument, an offset DAC/attenuator network was constructed to slow down the scan rate when the ion trap is operated in the mass-instability mode of operation with resonance ejection \(^{1/2}\). Figure 1 shows that the unresolved isotopes of the \((M+H)^+\) region of Substance P (MW 1347) become more than unit resolved with an attenuation of 40x, and a final resolution of 350,000 (FWHM) is observed on the \(^{13}\text{C} (M+H)^+\) isotope (Figure 1d). As seen, the spacings are not equivalent between the isotopes. This is due to space charge effects which greatly influence the ejection process (Figure 2). This experiment was done using Substance P with an attenuation of 700x, and a change of only 1 ms in the ionization period. Space charge can be minimized by using a short ionization period and low He pressures. Similar high resolution results (Figure 3) have been obtained on another peptide Gramicidin S (MW 1140).

Due to instability of the peak position when the scan ramp is attenuated by 200 times or more, spectra can only be recorded under single scan conditions. To improve the quality of spectra and provide a means of off-line alignment of peaks for signal averaging and filtering, a data acquisition system has been implemented which samples the pre-amplified signal from the ITMS electronics. Due to differences in the sampling rate of the Keithley analog-to-digital converter and the scan rate of the drive frequency of the ion trap, it was necessary to preprocess the analog signal via a sample-and-hold filter prior to A/D conversion. Using this data system, the Ca\(^{11}\) cluster ion at \(m/z\) 3510 was studied (Figure 4). A marked increase in resolution occurs due to the lack of isotopic ions. A resolution in excess of \(10^6\) (Figure 4d) is achieved when the scan rate is slowed by a factor of 333 times (2000X attenuation divided by 6x mass range extension). The shape of the peak for this ion is not distorted with changes in the scan rate.

Figure 4
A sampling system using mass flow controllers has been developed for the introduction of gases at atmospheric pressure into the Finnigan ion trap mass spectrometer. This system is similar in concept to other atmospheric sampling systems that use capillary tubing or a single leak valve for pressure control. However, the mass flow control system described here has two distinct advantages over these methods. (1) Gas flow into the ion trap is regulated. This is especially important when the pressure of the sample gas is not constant, for example, when gases are produced by a chemical process in a closed or flowing system. (2) A second mass flow controller has been incorporated to introduce a gas which serves as an internal standard. We have observed substantial time-dependent decreases in ion trap response when monitoring gases in real-time (Fig. 1). In such cases, the internal standard can be used for abundance correction with dramatic increases in accuracy and precision.

Typical flow rates through the mass flow controllers are 30-40 cm$^3$/min. A constant pressure of about 10 torr in a differentially pumped interstage region results from these flow rates. Helium buffer gas is introduced directly to the ion trap vacuum manifold through an independent leak. In these experiments, the optimum helium partial pressure is 5 x 10$^{-4}$ torr and sample partial pressure is 1.3 x 10$^{-6}$ torr. A gas splitter is used to present sample and internal standard directly to the orifice of the sample introduction valve. Sample and internal standard are then directed into the electrode assembly of the ion trap through a modified sample entry port. Data were acquired using the automatic gain control function (AGC) of the ion trap mass spectrometer.

Argon and krypton have been assessed as internal standards in combination with CF$_3$Br and C$_2$HCl$_3$ as sample test gases. Argon ions at m/z 40 did not present mass interference to ions of interest in these experiments. However, under other conditions, ionized argon may present an interference with ions of analytical significance and has only a single major isotope to use as an internal standard, which leads to large changes in sample/standard ion intensity ratios (Fig. 2). Krypton was therefore evaluated as an internal standard. The krypton isotopes and their naturally occurring abundances are at m/z 78 (0.35%), m/z 80 (2.25%), m/z 82 (11.60%), and m/z 84 (57.00%). Using these isotopes for standardization, the krypton internal standard can cover a wide concentration range with a sample/standard ion intensity ratio near unity (Fig. 3).

No problems were observed as a result of charge exchange reactions. The limit of detection for trichloroethylene in air determined by exponential dilution is less than 10 ppm with the differentially pumped direct sample introduction system. The limit of detection for CF$_3$Br in N$_2$ is less than 40 ppm and is limited by background. The usable calibration range for CF$_3$Br spans from less than 10 ppm to 2% relative concentrations in air. Internal and external precisions for CF$_3$Br calibrations are 4.5% and 5%, respectively, for concentrations greater than 10 ppm. Experiments with various permanent gases and C$_1$ to C$_6$ aliphatic hydrocarbons are in progress to further evaluate this system.
Figure 1. Ion trap response to CF$_3^+$ has been observed to decrease with time.

Figure 2. Using an internal standard improves the linearity and slope of the calibration curve for CF$_3^+$.

Figure 3. Using several Kr isotopes for standardization further improves calibration linearity, especially over wide concentration ranges.
Relative Ion Trap Storage Efficiencies of Ions Up to m/z 1500 By Capillary GC/MS

J. R. Simms and R. J. Strife
Miami Valley Laboratories
The Procter and Gamble Co.
P. O. Box 398707
Cincinnati, OH 45239-8707

INTRODUCTION - There has been increased interest in recent years concerning interfacing external ion sources to the ion trap mass spectrometer (ITMS). This is primarily due to the potential for sensitive sequencing of biologically important compounds such as peptides, proteins and oligonucleotides using the MS" capabilities of the ITMS. Storage of ions injected from external sources has been reported out to m/z 50,000 on an ITMS (1). However, the storage efficiency of ions above the "normal" 650 Da mass range of the ITMS has not been addressed. Therefore, the storage characteristics of "high mass" ions were investigated independently of external ion sources by using volatile "high mass" compounds.

EXPERIMENTAL - Trisperfluoroheptyltriazine (MW 1185) and trisperfluorononyltriazine (MW 1485) were dissolved equimolar with propylbenzene (MW 120) and decylbenzene (MW 218) (Fig. 1) and introduced into the ITMS by capillary gas chromatography (GC) (15 m x 0.25 mm i.d., 0.25 micron film, DB-1, Injector port 250°C, 5 pmol on column). The scan editor software was used to vary the rf-voltage level at the electron ionization pulse in each separate experiment. The "high mass" work was done using z-axis ejection (6 V) at a $q_z$ value of 0.30067.

RESULTS - The alkylbenzenes were used to bracket the triazines by retention time and to serve as positive controls for "normal" ion trap operation since their $q_z$ values are high relative to those of the triazines. All test compounds were introduced via capillary GC and electron ionization was used to create the ions within the electric field. The trapped ions were then scanned out and the total ion current was used to accurately measure the area under the gaussian GC peaks that appear at unique retention times. The GC peak areas for a family of linear alkylbenzenes run under "normal" Ion trap conditions were consistent over an rf level range corresponding to a cut-off mass of 8 - 45 Da (Figure 2). Below 8 Da, the field collapses and above 45 Da apparently the electron energy and the trajectory of the electrons become unfavorable. In both cases the capillary GC peak areas decrease sharply. This range of rf levels was considered to be the most favorable region to make and store ions in the trap. This working range of optimal rf levels corresponds to $q_z$ values for the triazines ranging from 0.005 to 0.035 and $q_z$ values for the alkylbenzenes ranging from 0.033 to 0.341.

The mixture of alkylbenzenes and triazines run at an ionization rf level of 30 Da showed slightly greater GC peak areas for the triazines than the alkylbenzenes. At this rf level all compounds had $q_z$ values greater than 0.018. This indicates that the "higher mass" triazines are being stored efficiently and that they have slightly higher ionization cross-sections relative to alkylbenzenes. When the ionization rf level is dropped to 10 Da, the GC peak areas for the triazines are reduced by at least an order of magnitude relative to the alkylbenzenes which stay within 70% of their initial peak areas. Clearly, the $q_z$ values (less than 0.008) of the triazines are too low and they are not efficiently stored under these operating conditions (Fig. 3). Therefore, for optimal sensitivity we suggest $q_z$ values greater than 0.02 during injection of ions in the 1500 Da range.

Once "high mass" ions have been created and efficiently stored in the ion trap they can be mass analyzed using z-axis ejection at different $q_z$ values (0.30067 was used for all of these experiments). Operating beyond the "normal" mass range of the ion trap (650 Da) using z-axis ejection techniques requires calibration of the mass range. The mixture of triazines and alkylbenzenes were used to calibrate the ITMS out to m/z 1500. The intense well-known ions of the triazines and the alkylbenzenes were observed in the z-axis ejected mass spectrum at approximately one-third their normal m/z values. A correction factor (0.91/0.30067 = 3.03) was applied to these m/z values and the approximate m/z values were plotted against the known m/z values for each of the appropriate ions. The line has a slope of 1.011 and a y-intercept of -2.1698 with an excellent correlation coefficient of 1.000.

The calibration line was then used to measure the mass spectrum of perfluorotributylamine (PFTBA, FC-43), with its ions z-axis ejected at $q_z = 0.30067$. Figure 4 shows the "calibrated" mass spectrum of PFTBA under the operating conditions described above. The measured m/z values are as much as 3 Da off from the expected values. We hypothesize that this is due to a limitation in the ITMS software package. The mass range has been tripled over the same number of DAC steps, and masses are still assigned to 1 Da "buckets." These errors are compounded by back multiplication.
Large Scale Computer Simulation of the Quadrupole Ion Trap Mass Spectrometer

Randall K. Julian Jr, Hans-Peter Reiser, R. Graham Cooks
Department of Chemistry, Purdue University
West Lafayette, In 47907

Computer simulation of the quadrupole ion trap has long been a tool for analyzing the performance of this device [1]. Programs which have been developed in the past have been effective at determining the stability of a limited number of ions under static conditions of constant RF amplitude [2]. Some programs have included models of ion-neutral collisions as a means of simulating the effects of a buffer gas present in the trapping space [2]. Recently computer models of ion motion under the influence of auxiliary (AC) potentials applied to the end-cap electrodes have been used to study the nature of resonance excitation and resonance ejection [3]. To better understand how changes in device operation will affect performance, a new program has been written in our group to simulate the ion trap on a large scale which can produce simulated mass spectra, as well as other information. The program implements a set of "scanning" functions for the amplitude and frequency of each of the potentials making up the electric field: RF, DC, and the Auxiliary (AC) potential. Utilizing large virtual memory computers with vector processors a goal of \(10^6\)-\(10^7\) ions is possible.

In the results reported here, the simplest version of the program has been used. It uses a Taylor Series expansion of the Mathieu equation to compute the ion trajectories, and buffer gas collisions have been ignored. To study the effects of auxiliary fields, a dipole field term has been added to the Z component of the electric field equation. The program requires an ion population be "created" by the user prior to execution so changes in operation can be observed on the exact same ion population. A number of ions of any m/z value may be generated according to user specified distributions for initial position and velocity.

The program has been used to study the effects of scan speed on resolution and to observe mass shifts which occur during axial modulation mass range extension. Figure 1 shows the simulated (top) and experimental (bottom) mass spectra of the molecular ion region (M+H)+ of Substance P, a peptide with mass 1347, using the normal mass instability scan speed of \(\sim 62400\) V/sec and a 2.25X mass extension. A mass shift of approximately 2.5 amu was corrected in the experimental data, and the simulated data was corrected by the same amount. In Figure 2, the exact same ion population as was used in Figure 1 is now scanned at 1/10 the normal speed. As indicated a mass shift is observed when axial modulation is used to extend mass range. The nature of this mass shift and its causes are not well characterized, preventing accurate mass assignment at high mass (large mass range multiplications). Figure 3 shows a both the experimental and simulated mass shifts for the CsI cluster m/z 912.3, as a function of mass range multiplication. The simulation matches the experimental data for the lower multiplication factors despite not modeling field distortions, space charge effects or the buffer gas.

Figure 2. Simulated (top) and Experimental (bottom) mass spectra of Substance P, 1/10 the normal scan rate, 2.25X mass range extension.

Figure 3. Simulated vs. experimental mass shifts as a function of the mass range multiplication factor.
The isolation of ions is recognized as an important step in many of the experiments that can be performed with the quadrupole ion trap mass spectrometer. Selective mass storage (SMS) at the apex of the stability diagram has been employed to isolate a parent ion prior to additional stages of mass spectrometry, including collision induced dissociation and ion/molecule reactions (1). Also, notable examples of SMS to reduce space-charge conditions in the trap have shown improved results for a variety of analytical studies, including MS/MS of biological extracts (2) and isotopically labeled internal standards (3).

The tandem-in-time nature of the ion trap allows us to change the analyzer voltages and the associated trapping field while an ion is held in the trap. A new mass isolation technique, dubbed "Two-step isolation", takes advantage of the tandem-in-time nature of the ion trap by separating the mass isolation process into two steps that are performed sequentially in time. In general, an ion is isolated by first applying analyzer voltages to the trap that produce unstable conditions for ions that have an m/z greater than the ion that is to be isolated. Next, the analyzer voltages are changed so that all ions with an m/z less than that of the ion of interest follow unstable trajectories. The combination of these two steps results in the isolation of a single m/z in the ion trap.

We have performed a comparative study of SMS and Two-step Isolation which reveals that the Two-step method is 1.5 times more efficient than SMS. Although the Two-step isolation scan function is more complicated than the SMS isolation scan, it requires less time to set up and is much easier to tune due to the separable nature of the method. Evaluation of the $\beta_1=0$ and $\beta_2=0$ edges of the stability diagram show that the best stability edge for eliminating higher mass ions without loss of the ion of interest is $\beta_1=0$ at $q=0.7$. We also observe that axial modulation offers slight improvements in the "sharpness" of the $\beta_2=1$ edge. Two new figures of merit were introduced that (a) measure how efficiently the ion of interest is stored and (b) assess how effectively ions other than the ion of interest were ejected.

Introduction

The Ion Trap Mass Spectrometer is a very sensitive instrument, but trace detection can be severely limited by the presence of abundant matrix ions. Accumulation of unwanted ions can lead to limited ion accumulation time due to early onset of space charge. Previous studies [1] have shown that removal of unwanted ions during accumulation of ions injected from an external ion source enhances analyte signal by allowing longer accumulation times before onset of space charge. We have investigated two selective ion accumulation techniques that eject unwanted ions during electron ionization within the trap. It was our intention to identify methods which would yield the maximum usable analyte signal from a complex mixture.

Methyltestosterone was chosen as a model of a complex mixture because of its complex mass spectrum. A relatively low abundant ion was chosen as the "analyte" ion while all others were considered unwanted ions and served as the "matrix". The two mass-selective ion accumulation techniques investigated were DC ejection and DC/Resonant ejection.

Results

**DC Ejection**

While operating at a \( q < 0.85 \) for the ion of interest, we applied either a +DC or -DC voltage to the ring electrode so that ionization would be performed at either the \( \beta_x = 0 \) or \( \beta_y = 1 \) stability edge. It is possible to selectively store any range of ions in the spectrum by simply moving along either stability edge. Figure 1 compares the full mass spectrum of methyltestosterone to a spectrum acquired at \( q = 0.8 \) and \( a = 0.3 \) (\( \beta_z = 0 \) stability edge). Figure 2 shows results of accumulation of m/z 41 while a DC voltage was used to eject all ions above m/z 50. The full mass signal for 41+ shows a total loss of resolution above 1 ms ionization time while DC ejection allows 50 ms ionization time without loss of resolution and a 20 fold increase in ion signal with +DC ejection and 10 fold increase with -DC ejection. Accumulation of ions above m/z 100 is less efficient with this technique. Accumulation of m/z 199, for example, requires a 15 fold increase in ionization time in order to achieve a 2 fold increase in the full scan 199+ ion signal. This is believed to be due to the higher voltages required to reach a stability edge for higher m/z ions. High voltages applied during ionization are believed to disrupt the ionization process by altering electron energy and electron trajectory within the trap. Although some signal is lost, a linear increase in ion signal is obtained with increasing ionization time.

**DC/Resonant Ejection**

While ionizing at \( q = 0.2 \) for the ion of interest, a supplementary excitation signal \((6V_{pp})\) was applied across the endcap electrodes to eject lower mass ions while a +DC voltage was applied to the ring electrode to eject higher mass ions. We investigated two frequency-swept resonant ejection techniques: frequency scanning, which is a single linear scan of the frequency range and broadband ejection, which is a customized frequency sequence that repetitively sweeps the frequency range. Figure 3 compares efficiency of resonant ejection for both techniques by scanning the frequency range between 375 kHz and 75 kHz (m/z 33 to m/z 164). Since an ion's
resonant frequency is scanned repetitively during ionization with the broadband technique, the unwanted ions are only allowed to accumulate after the last scan. Figure 4 compares results of accumulation of 199+ ion with DC/Resonant broadband ejection and with DC ejection. DC ejection exhibits a linear response up to 50 ms while DC/Resonant ejection shows non-linearity at high ionization times. This is believed to be due to the limited amplitude offered by the internal frequency synthesizer (6V_p-p). Although DC ejection yields a higher signal for m/z 199, DC/Resonant ejection may be more useful for accumulating higher m/z ions since much lower voltages are used with this method.

EXTENDING THE DYNAMIC RANGE OF THE QUADRUPOLE ION TRAP FOR GC/MS ANALYSES EMPLOYING ISOTOPICALLY LABELLED INTERNAL STANDARDS

Brent L. Kleintop and Richard A. Yost
Dept. of Chemistry, Univ. of Florida, Gainesville, FL 32611
Craig R. Abolin
Sandoz Research Institute, East Hanover, NJ 07936

Introduction
The extreme sensitivity and versatility of the quadrupole ion trap mass spectrometer (ITMS) would appear to make GC/ITMS the method of choice for GC/MS trace analysis. However, there have been limited applications of this sensitive mass spectrometer to quantitative GC/MS analyses employing isotopically labelled internal standards (IS). An analyte and its isotopically labelled IS typically coelute, often producing space charge conditions which may cause loss of sensitivity, mass resolution, and degradation of spectral quality. This typically limits the linear dynamic range (LDR) of these analyses to two orders of magnitude.

Recently we have developed a new ion trap scan method which employs alternating mass selective storage (RF/DC isolation) for ions of an analyte and its coeluting isotopically labelled IS in successive scans. This work presents the results of this method and compares them to results obtained using a similar method which utilized a supplementary FORTH program to control alternating RF/DC isolations [1,2]. The effects of axial modulation on the LDR for these types of analyses are also presented.

Experimental
All experiments were performed on a Finnigan MAT quadrupole ion Trap Mass Spectrometer interfaced to a Varian 3300 Gas Chromatograph via a specially designed, resistively heated transfer line probe. Compounds were dissolved in o-xylene and serial dilutions performed. The GC effluent was ionized by El and m/z's 163 and 167 were monitored for the analyte and IS, respectively.

Results and Discussion
The results of linear regression analyses (peak area ratio 163+/167+ vs. amount ratio d4/d4) with and without axial modulation are shown in Table 1. Use of axial modulation provides excellent linear correlations (r^2 = 0.9994) and precision (RSD's of triplicate injections <6%) over three orders of magnitude. Because of these improvements, axial modulation was used in subsequent studies involving RF/DC isolation.

Table 2 shows a condensed version of the new RF/DC isolation scan function developed for these studies. It requires no supplementary FORTH program to control alternating between analyzing an analyte and IS in successive scans. The RF timing traces of Figure 1 show the acquisition rate of this method being 8 times faster than the previously used method [1,2]. Table 3 compares results of linear regression using this method with the previously used method. The new method provides excellent linear correlations (r^2 = 0.9991) and precision (RSD's of triplicate injections <10%) over four orders of magnitude. The improvements over the previous method are attributed to the ability to acquire more data points over a GC peak which results in more reproducible peak shapes and areas for quantitation.

EFFECTS OF EXPERIMENTAL PARAMETERS ON ION STORAGE IN A QUADRUPOLE ION TRAP MASS SPECTROMETER

K.J. Hart, Scott A. McLuckey and Gary L. Olish
Oak Ridge National Laboratory, P.O. Box 2008
Oak Ridge, TN 37919-6365

Several empirical and simulation studies have been undertaken to increase our understanding of the operation of the Ion Trap Mass Spectrometer (ITMS). In particular, the poor ion yields obtained when attempting to mass-selectively accumulate ions of a particular m/z using combined RF and DC voltages applied to the ring electrode during ionization was investigated. The experimental studies compared the ion abundances (Σ m/z 117 thru m/z 123) observed in the spectrum obtained for N,N-dimethylaniline (DMA) using electron ionization (EI) and photoionization (PI). The abundance of the DMA ions decreased by 85% to 90% as the RF voltage during the ionization pulse was changed from a low mass cutoff of 30 (q[121] = 0.225) to a low mass cutoff of 110 (q[121] = 0.825) as shown in Figure 1. The DC component of the voltage applied to the ring electrode was zero. The abundance of the DMA ions observed as the DC voltage was changed from -100 V to +280 V at an RF level of 105 also varied as shown in Figure 2. Note that the maximum signal for PI was 0 V while the maximum signal for EI was +190 V. Originally, it was thought that the differences observed between PI and EI might be due to an effect on the electrons by the quadrupole field that would not be observed on photons. One factor that complicated this comparison was the orientation of the ionizing beam in the EI (oriented axially - z) and PI (oriented radially - r) experiments. An electron gun assembly was devised that allowed radial injection of electrons into the ion trap. The results for axial and radial injection of electrons versus RF voltage and DC voltage are shown in Figures 3 and 4, respectively. Note that these results show the decrease in abundance with increasing RF level (ionization) as was shown in Figure 1. The data shown in Figure 4 indicate that the difference between the EI and PI data lies in the orientation of the ionizing beam and not with an effect on the electron.

Simulation of the ITMS using a modified version of the SIMION program and the included ion trap simulation was used to estimate "effective ionization path lengths" and "effective ionization volumes" within the trap where neutral molecules at thermal temperatures can be ionized and remain trapped. Ions which are formed outside of this area are lost from the trap even though the a,q parameters which determine the m/z values that are stored have been appropriately selected. These ions have been termed "quasi-unstable" [1]. Other ion loss mechanisms such as scattering, charge transfer, ion-molecule reactions, non-linear resonances and self-emptying were not considered. The sample pressure and ionization times for the experimental data were selected so that complications due to space-charge should be small. A plot of radial and axial effective path length estimated from the SIMION simulations is provided in Figure 5. The effective axial path length decreased substantially (approximately 72%) from an RF level of 30 to an RF level of 110 while the radial path length changes very little (approximately 4%). The ionization volume (calculated as a cylinder - πr²z) decreased 74% over the same RF range. The cause of the decreased abundance observed for the DMA ions observed using PI (quite similar to that observed for EI) may be due to scattering of the laser radiation in the trap and or emission of secondary electrons and subsequent ionization of DMA within the effective ionization volume. Both of these ionization mechanisms would account for a decreased abundance of ions due to the smaller ionization volume at the two RF voltages. An additional 12% ion loss was observed when an ionization RF voltage corresponding to a low mass cut-off of m/z 30 was used with a ramp up to m/z 110 and an analysis ramp from m/z 110 to m/z 140.

For the case where the trap was set to store only one specific m/z, the calculated effective path length and ionization volume decreases to virtually zero. This includes both the upper (-DC) and lower (+DC) apexes of the ion trap stability diagram. It is possible, of course, to decrease the DC voltage and accept less than perfect isolation of specific m/z.

Research sponsored by the U.S. Department of Energy, Office of Basic Energy Sciences, under contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc. and an appointment to the U.S. DOE Laboratory Cooperative Postgraduate Research Training Program administered by Oak Ridge Associated Universities.

"SPONTANEOUS" CLUSTER DECOMPOSITION IN A QUADRUPOLE ION TRAP

Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

John E. Bartmess
Department of Chemistry, University of Knoxville
Knoxville, TN 37996-1600

Cluster ions normally found in high pressure ion sources are not usually observed under chemical ionization conditions in the quadrupole ion trap. This is mainly due to the lower pressures in the ion trap which affect third body stabilization. But, even for cluster ions injected from an external source, decomposition is observed. By injecting cluster ions of known stability and measuring the decomposition rate as a function of pressure and time, we can determine what affects various parameters have on the internal ion temperatures in the quadrupole ion trap.

The desolvation experiments were carried out by injecting ions formed via electrospray into the quadrupole ion trap. The atmospheric sampling glow discharge ionization (ASGDI) source served as the interface between atmosphere and the vacuum chamber. Protonated water clusters were formed by spraying distilled water at a flow rate of 1 μL/min and protonated methanol clusters were formed by spraying HPLC grade methanol at 1μL/min. Since fragmentation of ions upon injection into an ion trap has been observed in our lab as well as others, we needed to determine if ions are "excited" during injection. Therefore, the cluster ion mass spectra from the ion trap was compared to the cluster ion mass spectra from a quadrupole mass filter using the same interface and electrospray conditions. The results showed that, under the ion injection conditions used in this study for both the water and methanol clusters, significant internal excitation did not occur during injection. The clusters, therefore, acquired the necessary energy for dissociation after they were trapped.

The major variables found to affect the appearance of the mass spectra for the cluster ions are time and pressure. The pressure studies, illustrated in Figure 1, show that at higher helium bath gas pressures (1 mtorr) rapid desolvation occurs due to higher collision frequencies. At relatively short delay times, the highest protonated methanol cluster observed is the tetramer. With no helium bath gas present which corresponds to a pressure of 2 x 10^-5 torr, lower collision frequencies favor the appearance of higher protonated species (hexamer) but overall shows more extensive desolvation, dissociating to \(\text{H}_3\text{O}^+\) compared to the protonated methanol dimer with 1 mtorr of He.

To calculate the desolvation rate constants, the cluster ion of interest was isolated and the rate of loss was monitored by varying the time delay. Figure 2 shows the plot of the negative logarithm of the relative water tetramer signal as a function of delay time indicating a linear decay expected from pseudo first-order kinetics. The overall decomposition (desolvation) rate is actually second order since the rate determining step is expected to be the rate of energy transfer via collision rather than the rate for unimolecular decay of the cluster. Hence, the bimolecular rate constant for these cluster ions is determined by dividing the slope of the line by the neutral number density. For each cluster ion studied, the desolvation rate constant decreased with increasing bath gas pressure. As shown in Figure 3, the desolvation rate constant for the water tetramer has an inverse relationship with the log of the bath gas pressure. This is attributed to the rate constant increasing with ion internal temperatures.

Based on the bimolecular (desolvation) rate constants calculated from the kinetics experiments, an internal temperature for these cluster ions was assigned using the thermochemical parameters for these desolvation reactions reported by Kebarle and co-workers(1) as well as others(2). Table 1 lists the dissociation threshold temperature and the calculated internal temperatures for the cluster ions at given pressures. The internal temperature was calculated by the equation:

\[ T = -\Delta H/R \ln(k_{\text{obs}}/k_{\text{inf}}) - \Delta S \]

where \(k_{\text{inf}}\) is the standard trajectory rate constant(3).

Ion-Locked Cyclotron Resonance: 
A Means for Instantaneously Changing Ion Cyclotron Orbital Radius 

Ruldan Chen†, Alan G. Marshall‡,# and Mingda Wang‡

Departments of Chemistry† (and Biochemistry‡), The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210
‡Walnut Creek Instrument Division, Varian Associates, 2700 Mitchell Drive, P.O. Box 9016, Walnut Creek, CA 94598-0916

The central Lorentz magnetic force, \( q v \times B_0 \), acting on an ion of velocity, \( v \), and charge, \( q \), moving in a static magnetic field, \( B_0 \), may be increased (or decreased) by adding a rotating electric field, \( E_{\text{eff}} \), directed radially inward or outward [i.e., along (or opposed to) \( v \times B_0 \)] (Fig. 1). The effective magnetic field is \( B_{\text{eff}} = B_0 \pm (E_{\text{eff}}/v) \), in which \( v \) lies in a plane perpendicular to \( B_0 \). Because the ICR orbital radius, \( r \), varies inversely with \( B_{\text{eff}} \), such a rotating rf electric field can be used to pulse the radius (and ICR orbital frequency, \( \omega_c = qB_0/m \)) effectively instantaneously to larger or smaller value, in an experiment we call "ion-locked" cyclotron resonance by analogy to "spin-locking" in NMR [2]. The "ion-lock" event sequence for Figure 1c is shown in Fig. 3.

Following a conventional coherent resonant excitation of ions of a given \( m/q \) ratio to a given radius by an rotating electric field, \( E = E_0 \exp(-i\omega_c t) \), the phase of the electric orbit field can be shifted by \( \pm 90^\circ \) with a concomitant increase in rf amplitude and frequency to "lock" ions into a smaller (Fig. 1c, 2a) or larger (Fig. 2c) radius orbit whose ICR orbit center is spatially displaced. In order to produce a \(-90^\circ\) phase shift, \( E_{\text{eff}} = E_0 \exp[-i(\omega_{\text{eff}} t + \pi/2)] \) for the ion-lock event, where \( E_{\text{eff}} >> E_0 \). Note that if \( E_{\text{eff}} \) is to be kept aligned along \( q v \times B_{\text{eff}} \), then the frequency of the rf electric field and the instantaneous ICR orbital radius must change from \( \omega_c \) and \( r_0 \) to \( \omega_{\text{eff}} \) and \( r_{\text{eff}} \) at the same instant that the rf phase is shifted by \(-90^\circ\):

\[
\omega_{\text{eff}} = \frac{qB_{\text{eff}}}{m} = \omega_c \left(1 + \frac{E_{\text{eff}}}{vB_0}\right) \quad \text{and} \quad r_{\text{eff}} = \frac{r_0}{1 + \frac{E_{\text{eff}}}{vB_0}}
\]  

The feasibility of the ion-lock experiment has been treated analytically as a function of \( m/q \), and supported by ion trajectory modeling, as will be reported more fully elsewhere [3]. Possible applications include: (a) rapid mass-selective ion ejection by \(+90^\circ\) shift in the phase of \( E_{\text{eff}} \) (Fig. 2c); (b) mass-selective shift in ICR orbital radius and ICR orbit center (Fig. 1c, 2a, 2c); and (c) increased ion energy for collision-induced dissociation by a combination (Fig. 2b) of a traditional excitation event followed by an ion-lock excitation event: e.g., \( E(t) = vB_0 \exp[-i(2\omega_c t + \pi/2)] + E_2 \exp(-i2\omega_c t) \), with \( E_2 << vB_0 \). This work was supported by N.S.F (CHE-9021058) and The Ohio State University [3].

ULTRAHIGH RESOLUTION FT/ICR MASS SPECTROMETER

Nicholas C. Hill†, George M. Albert†, LutzSchwinkelhardt*,
Tom L. Ricca†, and Alan G. Marshall†,§

Departments of Chemistry* and Biochemistry,§ The Ohio State University
120 West 18th Avenue, Columbus, Ohio 43210
* On leave of absence from the Institute of Physics, University of Mainz, Germany.

In this abstract, we describe our recently constructed ultrahigh-resolution FT/ICR mass spectrometer, and show two of the first spectra recorded with this instrument.

The ultrahigh vacuum needed for high mass resolving power is provided by a Perkin-Elmer TNB-X pumping station, comprising a sorption pump, ten ion pumps (300 L/s pumping speed) and four titanium sublimation filaments which provide increased pumping speed for removal of common residual gases. The entire vacuum chamber can be baked at 200 °C.

The vacuum system is mounted on a rail carriage riding on Thompson linear bearings. During bakeout it is possible to roll the vacuum system out of the Oxford horizontal-bore 7-tesla superconducting magnet (magnetic field homogeneous to within 1 part in $10^5$ over a $1" \times 1" \times 4"$ volume). A non-magnetic 1" cubic ion trap built of oxygen-free hard copper is designed to accommodate screens. When these are grounded they shield the ions from the effect of the trapping field so that the ICR frequency becomes virtually independent of orbital radius and trapping potential [1]. An electron gun for electron beam ionization is mounted in the fringe field (about 0.02 T) of the magnet, at a distance of ~1 m from the center of the ion trap. Moving the ion gun largely eliminates the transmission of noise from the electron-gun filament power supply to the detect plates of the ion trap. It also assures that the electron beam and ion trap are centered in the magnetic field and that the spread in initial radial position of the ions is minimized, because the electron beam is focused by the magnetic field.

The excitation and detection electronics are built around an Extrel 2000 data station. Performance of the data station was extended to the high ICR frequencies of low-mass isobars (e.g., ~27 MHz for $m/z = 4 \ u/e$ at 7 tesla), by addition of a PTS-40 frequency synthesizer (40 MHz), AR-25A100 high frequency power amplifier, homebuilt detection preamplifier, and associated TTL switches, filters, mixers, and buffers. For precision monitoring of doublets, dual-frequency excitation is generated by heterodyning sinusoids from the PTS frequency synthesizer and the Extrel data station. This excitation method can be followed by one of two detection schemes. The ion decay signal can be simultaneously heterodyned with the dual reference signals generated for excitation. Alternatively, cascaded heterodyning of the free ion decay signal can be performed by mixing it with the carrier signal from the PTS-40 and then mixing the produced difference signal with the Extrel 2000 reference signal. The data are then Fourier transformed and displayed by the Extrel 1280 computer. Details of these procedures will be described elsewhere [2].

In this way, the frequencies of the signals of ions of two different $m/z$ values can be made arbitrarily low and close together [2], thereby vastly decreasing the number of sampled data points without loss of precision in the determination of the resonant frequencies. For example, ICR signals (not shown) from $N^+$ and $N_2^+$ (frequency difference of 3.86 MHz) have been shifted to only 100 Hz apart, without the added noise produced by multiple-foldover techniques [3]. The performance of the system is illustrated in Figures 1 and 2. This work was supported by N.S.F (CHE-9021058) and The Ohio State University.
Figure 1. FT/ICR magnitude-mode mass spectrum of electron-ionized $^4\text{He}^+$ and $\text{D}_2^+$, based on a single time-domain free ion decay transient signal. The detected signal frequencies, 1007.6 Hz and 969.0 Hz (i.e., a frequency difference of 38.6 Hz), correspond to actual ICR frequencies of 27,031 and 26,859 kHz (i.e., a frequency difference of 172 kHz).

$\Delta m > 50,000,000$

$\Delta m = 19.5 \text{ nAMU} = 18.2 \text{ eV}$

$\frac{m}{\Delta m} > 200,000,000$

$\Delta v = 0.132 \text{ Hz (FWHM)}$

Resolving power is limited by the base pressure, measured as $3.6 \times 10^{-11}$ torr (gas constant of the Bayard-Alpert ion gauge set for m/z = 28 u/e).

HARTLEY/HILBERT TRANSFORM SPECTROSCOPY: ABSORPTION-MODE RESOLUTION WITH MAGNITUDE-MODE PRECISION

Christopher P. Williams and Alan G. Marshall†

Department of Biochemistry (and Department of Chemistry†), 776 Bioscience Bldg., The Ohio State University, 484 West 12th Avenue, Columbus, OH 43210

Fourier transformation (FT) of an N-point time-domain discrete signal produces, after phase correction, two independent data sets: an N/2-point absorption spectrum, A(ω), and an N/2-point dispersion spectrum, D(ω), each with the same information content. Usually only A(ω) is kept. The dispersion-mode information has conventionally been recovered in either of two ways. [1] First, the N/2-point magnitude-mode spectrum, M(ω) = [(|A(ω)|^2 + |D(ω)|^2)^(1/2), offers a √2 improvement in precision compared with the original N/2-point absorption spectrum, but with poorer resolving power (factor of √3 to 2). Alternatively, zero-filling the initial time-domain data to 2N data points prior to Fourier transformation results in an N-point absorption-mode spectrum with the same peak width and peak-height-to-noise ratio as the original N/2-point absorption spectrum, but with a √2 improvement in precision. Thus, magnitude-mode display improves FT spectral precision [2] at the expense of a loss in resolving power, whereas zero-filling improves precision at the expense of having to store twice as many data points.

In this abstract, we describe a third method of recovering the dispersion information. Specifically, discrete Hilbert transform of D(ω) (obtained by discrete Hartley transformation [3] of N time-domain data) yields an N/2-point "pseudo-absorption" spectrum which may be added to the original A(ω) to yield an N/2-point "enhanced" absorption spectrum with the same peak width and same number of data points, but with peak-height-to-noise ratio improved by a factor of √2 over the original N/2-point absorption spectrum. In other words, the new procedure yields an FT spectrum with enhanced precision, without any attendant loss in resolving power (as for magnitude-mode display) and without any increase in the number of stored data points (as for zero-filling).

Figure 1 shows absorption-mode, magnitude-mode, and enhanced absorption-mode spectra for a simulated time-domain signal consisting of three damped sinusoids of relative amplitude, 10, 1, and 3. The peak corresponding to the weakest signal is much more easily distinguished from the baseline noise in the enhanced absorption-mode signal. (Magnitude-mode offers the same ratio of peak height to baseline noise standard deviation as does enhanced absorption-mode, but the root-mean-square magnitude-mode noise is √2 higher, making the signal peak harder to recognize visually.)

Figure 2 shows the method applied to actual FT/ICR experimental data for N₂⁺ produced by electron ionization (Extral FTMS-2000, single-frequency on-resonance excitation, heterodyne-mode detection at 129 kHz bandwidth to yield 8K time-domain data). The narrower peak width for the enhanced absorption-mode compared to magnitude-mode is clearly evident.

This work will be reported more fully elsewhere, [4] and was supported by N.I.H. (GM-31683) and Ohio State University.
Figure 1. Absorption-mode, magnitude-mode, and enhanced absorption-mode FT spectra of a time-domain signal consisting of three exponentially damped sinusoids of relative amplitude, 10:1:3. The frequency of the weakest signal is shown by an arrow. Note the improved (peak height)/(rms baseline noise) ratio for the enhanced absorption-mode display (see text).

Figure 2. Absorption-mode, magnitude-mode, and enhanced absorption-mode FT/ICR mass spectra of an experimental time-domain N$_2^+$ signal. The higher resolution of the enhanced absorption-mode compared to magnitude-mode is especially obvious.

ICR ORBITAL RADIUS DETERMINATION

Peter B. Grosshans, Patrick A. Limbach, and Alan G. Marshall

Depts. of Chemistry (P.B.G., P.A.L., and A.G.M.) and Biochemistry (A.G.M.),
The Ohio State University, 120 W. 18th Avenue, Columbus, OH 43210.

Measurement of the ion cyclotron orbital radius of an ion packet is of fundamental importance for several reasons. First, it provides for better quantification of ion abundances (from which ion-molecule reaction equilibrium constants are determined) from FT/ICR mass spectral peak areas. Second, the energy threshold for collision-induced (or collision-activated) dissociation, CID (or CAD), can be measured more accurately if the ICR radius (and therefore the ion translational energy) is known [1,2]. Third, the detection limit of an FT/ICR instrument may be determined directly by combining the measured ion packet cyclotron orbital radius with the measured ICR signal (for known receiver amplifier gain and equivalent capacitance of the entire detection circuit) to yield the number of ions which contribute to the signal [3].

Elsewhere, we showed that a standard cubic FT/ICR ion trap is capable of, but not ideally suited for, measuring ICR orbital radius [4-5] by measurement of the ratio of the magnitude of the third harmonic to that of the fundamental ICR signal. In this work, we present experimental results from a new six-detection electrode ion trap specifically designed for ICR radius determination (see Figure 1D). Because the new trap has four sets of detection electrodes, four different wiring configurations are possible (see Figure 1). This novel trap causes the signal to have a higher third harmonic content, thereby providing better sensitivity in the radius determination measurement. Theoretical values of the ratio of the third-to-first harmonic magnitudes are plotted in Figure 2a vs. ICR orbital radius, normalized to the maximum allowed radius. Note the increase in the sensitivity of this ratio, especially in configuration D. From these calculated values, the radius of the ion may be determined by measuring the relative magnitudes of the third and first harmonics. In Figure 2b, radii (normalized) determined in this way, for benzene molecular ion (on-resonance, single frequency excitation), are plotted versus the normalized post-excitation cyclotron radius predicted under the infinite electrode approximation for each of the four wiring configurations. Under the same ionization and excitation conditions, radii measured with the four different wiring configurations demonstrate good agreement with one another. Furthermore, in all four cases, the last measured radius before complete radial ejection is near the maximum allowed radius.

This method for determination of the ICR cyclotron radius should prove extremely useful for determining either the number of ions for a given signal or the energy of the ion packet before collisional dissociation. Fuller details will be presented later [6]. This work was supported by NSF (CHE-9021058) and The Ohio State University.

INTERFACING HPLC to FTMS USING THERMOSPRAY DEPOSITION ON A MOVING BELT

Mehdi Moini
Department of Chemistry and Biochemistry,
University of Texas at Austin, Austin, Texas 78712.

INTRODUCTION

Liquid chromatography/mass spectrometry (LC/MS) is an increasingly popular technique for the analysis of complex mixture not suitable for GC/MS with particular emphasis on polar, nonvolatile or high molecular weight compounds. Many biomedical analyses are performed by HPLC, which obviates inherent thermal lability and derivatization problems and thus may demand less complex sample preparation than GC. Among the several approaches to LC/MS coupling the moving belt is particularly suitable for HPLC/FTMS. This approach results in complete removal of the mobile phase between the LC column exit and the FTMS. This complete removal is important in terms of high pressure limit, space charge effect and chemical interferences contributed by mobile phase solvents in the analyzer cell of the FTMS.

APPARATUS

A device is described for coupling HPLC to FTMS using a variable speed, stepping motor driven moving belt constructed on a 3/4” diameter 38” long solid probe (standard probe diameter for the Nicolet FTMS-2000). This shaft has been grooved on the top and the bottom to accommodate a 0.0625 inch wide, 0.003 inch thick belt when the shaft is inserted in the seals, as shown in Figure 1. A thermospray nebulizer deposits materials eluting from the HPLC column on to the continuously moving endless belt. The effluent from the HPLC enters the vaporizer through the 0.0625 inch o.d., 0.004-0.005 inch i.d. stainless steel capillary tube which is embedded at one end into an aluminum block. The block is heated by two commercial 100 W cartridge heaters. A thermocouple is embedded in the cooper block to monitor the temperature of the vaporizer. The temperature of the vaporizer is controlled by a variable autotransformer. The moving belt is 0.0625 inch wide, 0.003 thick Nichrome ribbon and may be used as an endless loop or open strand. An endless belt is made by spot-welding the terminal 2-3 mm of the 2.5 m long ribbon. The overlapping sections of the belt are ground to keep the belt thickness approximately constant (0.003 inch).
The belt is driven by a controlled stepping motor that drives the main pulley. The belt carries these compounds through three tunnel seals in a two stage vacuum lock arrangement into the FTMS where they may be vaporized by a laser or a variety of other techniques. A return pulley is mounted at the tip of the probe. Two wires are also terminated at the tip of the probe and are available for heating or mounting a grid to control the velocity of the laser desorbed ions. A Busch vacuum pump with 1 1/2 HP motor and 20 CFM was used for the first stage of pumping and an Alcatel mechanical pump with 3/4 HP motor was used for the second stage of pumping.

**Deposition Efficiency.** Deposition efficiency from the HPLC to the belt via the thermospray is approximately 70% of the response to the same size sample placed directly on the belt. The main reasons for this percentage are, the belt width with respect to the thermospray spot size, the reflection of some of the particles at the belt surface as a result of their momentum, and evaporation at the nozzle tip.

**Pressure Study In the FTMS.** When one stage of pumping was used, the source and analyzer pressures were ca $10^{-6}$ and $10^{-7}$ torrs respectively. When two stages of pumping was used, after 1/2 hour, pressure in the analyzer side was the base pressure, i.e., $8 \times 10^{-9}$ torr while the source pressure was $9 \times 10^{-8}$ torr.

**Why the Moving Belt**

1) The moving belt is compatible with the FTMS. The main characteristics of the moving belt are that it allows the complete removal of the mobile phase and the achievement of the base pressure in the analyzer cell of the FTMS.

2) The moving belt is versatile. The whole HPLC to MS interface is built on a solid probe that can be inserted when needed.

3) The moving belt is suitable for use with several desorption and ionization modes, including laser desorption, FAB, SIMS, El, CI and MPI. It is also completely compatible with all nonvolatile analytes, regardless of their polarity, size, or molecular weight.

4) The moving belt is inexpensive. The cost of this interface with respect to the other alternative, i.e., an external ion source, is minimal.

**Future work**

1) Experimentation with this device using laser and SIMS.

2) Since stainless steel belt cost only a few cents per foot, the continuous endless belt can be easily converted to an open loop design which uses a disposable belt. The disposable belt will eliminate belt cleaning and associated memory effect.

Ion Spectra from Two-Laser Infrared Multiple Photon Dissociation Experiments

Mitchell A. Cheeseman and John R. Eyler, Department of Chemistry, University of Florida, Gainesville, FL 32611-2046.

We have developed a two-laser approach for studying infrared multiple photon dissociation of gaseous ions which uncouples the (initial) resonant absorption of the first 1 or 2 IR photons from subsequent up-pumping through the quasicontinuum to the dissociation limit. Thus, a low-power tunable laser can be used for probing the resonant absorption spectrum, and a more powerful CO₂ laser (which does not have to be tunable) can then be used to drive the photodissociation, resulting in a "probe-pump" experiment. This two laser photodissociation process is shown schematically in Figure 1.

Experiments were performed on a home-built FTICR mass spectrometer, which utilized an Extrel FTMS 1000 data station and superconducting magnet of nominal 2T field strength. Our standard ICR cell was replaced with a White type cell which incorporated three spherical mirrors (one on one side and two on the other) as receive plates. Outputs from a cw CO₂ and a pulsed CO₂ laser were reflected into the vacuum chamber through two ZnSe windows on a three window flange. The probe laser beam was focussed using a gold-coated spherical mirror (125 cm focal length), reflected from the turning mirror attached to the cell, and made up to 24 passes through the White cell. Ions were produced by electron ionization, unwanted ions were then ejected with normal swept frequency ejections, and a delay period of 500 ms was inserted to allow collisional cooling and ion relaxation toward the center of the cell. Ions were then irradiated by multiple passes of the resonant "probe" laser beam and the pump laser in 2-laser experiments. Following this, product and reactant ions were detected by standard FTICR methods.

Photodissociation spectra, which can be related directly to ion vibrational spectra, have been obtained for a number of simple organic molecular ions which have absorption bands within the tuning range of the CO₂ laser. Figure 2 shows an example obtained without use of the White-type cell, but a double pass of two CO₂ lasers in the probe-pump arrangement. For comparison, in recent work infrared spectra of a number of organic ions have been obtained utilizing a single moderate power resonant laser and the White-type ICR cell. The resonant 'probe' laser was tuned to various wavelengths at constant power and mass spectra showing the extent of photodissociation were taken, thus providing an infrared spectrum of the ion under study. An example of such spectra is shown in Figure 3. Comparison of this technique with the standard double pass technique used to produce Fig. 2 shows a dramatic enhancement in photodissociation for all of the ions studied when using the multipass cell.

A difference frequency accessory for our Nd:YAG-pumped dye laser has been installed which will provide tunable output in the 3000 - 3600 cm⁻¹ wavenumber region. This laser will be used as the probe laser in the "probe-pump" scheme (with a CO₂ laser still used as the pump laser) to provide infrared spectra of ions in wavelength regions corresponding to N-H, O-H, and C-H stretches.

Using 4-nitroaniline as a matrix, we have successfully obtained the spectrum of melittin (Figure 1). The key to our success was in choosing a suitable matrix, such as 4-nitroaniline. Figure 2 contains the spectrum of renin substrate using the same matrix (4-nitroaniline). Based on our experience with different matrices such as 2-nitroaniline, 3-nitroaniline and 2,4-dinitroaniline we feel that a good matrix should have: 1) an electronic transition corresponding to the wavelength of the laser used (energy of photon), 2) higher acidity in its electronically excited state (of course, compounds with higher basicity in the excited state can be used for negative ion production), and 3) a resonant stabilized structure in its excited state after transferring the proton (a stable deprotonated matrix anion). These findings are in agreement with our proposed mechanism for matrix assisted laser desorption. In laser desorption experiments high mass ions are formed with appreciable kinetic energies (> thermal) and require higher trapping voltages for efficient trapping because conventional radio frequency excitation methods do not uniformly excite the ion ensemble.

A New Laser Microprobe/FTMS System
Based on an Electromagnet

W. R. Creasy and J. A. Zimmerman
IBM Corp., Dept. T67
Endicott, NY 13760

The IBM-Endicott Laser Microprobe/FTMS system\textsuperscript{1} has been used in many fundamental and applied studies in order to obtain qualitative elemental and molecular information on small spots and thin films of interest in electronics packaging applications. The system was designed around an Extrel FTMS/2000 Fourier Transform Mass Spectrometer with a 3.0 T superconducting solenoid and a 2 in. cubic cell. The performance of this system has been described previously.\textsuperscript{2}

This system has limitations for routine analysis of some types of samples. Due to the configuration of the sample lock and probe rod, the sample size is limited to 7/8 in. in diameter or about 1 cm. square. This is a serious size constraint, since it means that larger samples have to be cut up for analysis, effectively destroying them. The 2 in. cell, along with the restrictions of the bore of the vacuum chamber, limit the focal length of the objective lens to 60 mm or more. A sample motion system\textsuperscript{3} was designed for the probe rod, but it is difficult to make it compatible with the high magnetic field and the high vacuum. Some sample motion can be accomplished by moving the probe rod, but the motion is limited and the sample must be very accurately positioned. Finally, the visualization and illumination system was not very flexible. The illumination was limited to the direction perpendicular to the visualization optics, so shiny samples gave a reflection into the eyepiece but some other samples were completely dark or had no contrast. This problem makes it difficult to identify or locate small spots for analysis.

Therefore, a new laser microprobe/FTMS system was designed and built to overcome these limitations. Due to the geometry of the electromagnet pole caps, much more space is available perpendicular to the magnetic field than in the solenoid system. The Electromagnet Laser Microprobe (ELM) allows a sample size of 15X15 in. The system uses a 1 in. cubic cell, which allows room for a 25 mm focal length lens. An XYZ stage provides greater sample motion, and the system is designed for flexibility in positioning the optics.

The ELM system is suitable for a number of particular applications. It can be used to analyse contaminants on large substrates, boards, or panels without destroying them by cutting them up. It can be adapted to use with difficult samples, rather than requiring the samples to be adapted to the instrument. Since the samples remain in their original size, they can be processed subsequent to analysis, allowing the determination of changes caused by the later processing. Finally, the ELM should allow faster analysis of routine samples.

A detailed diagram of the vacuum system and optical system of the ELM is shown in Figure 1. The sample size of 15X15 in. is limited by the vacuum chamber in height and width. The maximum thickness is 1/2 in., which is sufficient for most electronic circuit boards. A sample lock provides rapid introduction of 1X4 in. samples. For larger samples, the end flange of the chamber can be removed for mounting and positioning the sample in the correct location. Since the cell and all the optics are mounted to the end flange, the sample can be positioned in air exactly as it will be located inside the chamber in vacuum. The cell is designed to be moved fairly readily to the portion of the sample which is of interest.

The sample is moved on a probe rod mounted on an XYZ translation stage bolted to the gate valve. The range of the translation stage is 1X1X2 in.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The Z axis motion of the stage brings the sample into focus. Motion is accurate to .001 in. In the Y and Z directions, motion of the probe rod is limited by the gate valve, but in the X direction the motion is limited only by the chamber.

The sample visualization and laser focussing are both accomplished with the same fused silica, 25 mm focal length lens and Al mirror. The lens is mounted next to a hole in one excite plate. The viewing angle is about 60° from the sample normal, although the sample can be rotated to some extent to make a smaller angle. This optical design is fairly simple and is similar to the previous solenoid system.

The electromagnet for the ELM was purchased from GMW Assoc. The power supply was selected for its exceptional stability, and it was tested to give a drift of <6 ppm after warmup. Due to the stability, a Hall probe feedback sensor is not required. The pole caps are 10 in. in diameter, and the pole gap is variable from 0 to 6 in. For a 3 in. pole gap, the maximum field is 1.3 T.

The laser and interface systems have been described previously, and have only been slightly modified. A Continuum YG660 Nd:YAG laser operated on the fourth harmonic provides 266 nm laser radiation. The laser is triggered from an IBM PC-AT interface. The AT communicates with the Nicolet 1280 computer via an Rs232 port to begin experimental sequences. The communications also allows downloading of spectra or data to the AT for plotting or processing.

At present, the ELM system has not been tested due to problems with the vacuum system. Therefore, the ultimate spot size and mass resolution have not been determined. Further work on the system is necessary to determine the general utility of the system for routine sample analysis.

Figure 1: Diagram of the Electromagnet Laser Microprobe/FTMS vacuum and optical systems. The diagram is to scale.
The ion chemistry of XeF₂ after electron impact ionisation is studied. The product ions XeF⁺, XeF₂⁺, XeF₂⁺, XeF₂⁺ and XeF₂⁺ are formed. Of special interest is XeF₂⁺, also known in the condensed phase. For this ion the following formation reactions are possible:

A: by addition: \( \text{XeF}^+ + \text{XeF}_2 \rightarrow \text{XeF}_2^+ \)

B: by fluoride transfer: \( \text{XeF}^+ + \text{XeF}_2 \rightarrow \text{XeF}_2^+ + \text{XeF}_2 \)

In the negative mode XeF₂⁻ ions are observed.

For the investigations we use a modified Spectrospin CMS 47 ICR Spectrometer. We operate at a magnetic field strength of 7.02 Tesla. The ICR cell is of 43 mm length and 34 mm diameter. The direct inlet system is made of stainless steel. The sample is stored in a small autoclave directly connected to the UHV system by a leakvalve. The small tube connecting autoclave and leakvalve can be pumped separately. The autoclave is filled with 100 mg XeF₂. The surface of the inlet system and the ultrahigh vacuum region are conditioned with SF₆ / F₂ to suppress surface reactions.

Reactions of XeF₂ at a pressure of 1.6 x 10⁻³ mbar are shown in the following diagram.

The curves show the ions of \(^{132}\text{Xe}^+\), \(^{131}\text{Xe}^+\) (m/z=161), \(^{130}\text{Xe}^+\) (m/z=320) and ten times amplified \(^{132}\text{Xe}^+\) (m/z=228) and \(^{130}\text{Xe}^+\) (m/z=301).

By ejection of a single or several isotops during the reaction delay it is possible to modify the pattern of an educt ion. The modified pattern of the selected educt shows an influence on the product peaks, only if the modified xenon isotope is transfered to the product ion. The following figure shows the calculated pattern of \(^{132}\text{XeF}_2^+\) after modification of \(^{132}\text{Xe}^+\) and \(^{129}\text{Xe}^+\) isotops.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The next diagram shows the experimental data. The ions of XeF\(^+\) (m/z=161 and m/z=149) are ejected during the reaction time.

Changes in the isotopic pattern of Xe\(^+\) and XeF\(^+\) do not yield any alterations in the isotopic pattern of the ionic reaction products. This can only be explained by a reaction with a dimeric XeF\(_2\) (Xe\(_2\)F\(_4\)) (or higher oligomers). The observed reactions are dissociative fluoride-transfer:

1. \(\text{XeF}^+ + \text{Xe}_2\text{F}_4 \rightarrow \text{Xe}_2\text{F}_3^+ + [\text{Xe}^+, 2\text{F}]
2. \(\text{Xe}^+ + \text{Xe}_2\text{F}_4 \rightarrow \text{Xe}_2\text{F}_2^+ + [\text{Xe}^+, 2\text{F}]
3. \(\text{Xe}^+ + \text{Xe}_2\text{F}_4 \rightarrow \text{Xe}_2\text{F}_3^+ + [\text{Xe}^+, 3\text{F}]

In future we plan to investigate the reactions of XeF\(_2\) with the dioxygenyl cation, rare gases and halogens. We also want to analyse xenonoxo and halogen compounds. A pulsed inlet system has already been developed. First experiments with mixtures of xenon, xenon difluoride and carbon dioxide show formation of XeFCO\(_2\)\(^+\).

Work is granted by Deutsche Forschungsgemeinschaft. We thank EMG Bremen, especially Mr. K. H. Kaiser from EMG Bremen for support.
A high precision solid sample probe has been developed to analyse the ICR spectra of some polyperfluoroethanes like polytetrafluoroethylene, polyperfluoroethylenepropylene and polyperfluoroalkoxyteflon. We have also been able to obtain the ICR spectrum of the perfluorinated polyether KRYTOX 143 AZ (Dupont). A prototype Spectrospin FT-ICR spectrometer with a cylindrical ICR cell has been employed. The probe is introduced into the ultrahigh vacuum system via a differentially pumped vacuum lock. The pushrod used has a length of 900 mm and a diameter of 22.6 mm. The top of the pushrod is equipped with three electrical feedthroughs, one suited for a high voltage of 12 kV. The solid trapping plate of the ICR cell in front of the pushrod is replaced by a copper grid to increase the ion yield. The formation of negative ions from the solid sample is assisted by the Penning discharge induced by the magnetic field of 7 Tesla and the high voltage in the range from -3 to -8 kV which depends on the sample. A mass range up to 1200 is covered for the teflon derivatives and up to 1800 for the polyether. For each of the samples characteristic fragmentation patterns are obtained. However, it has not been possible to determine the molecular weight distribution of the polymers. Most of the mass spectra of teflon described in the literature are restricted to the lower mass range (m/e < 360)\(^1\). Recently some TOF mass spectra\(^2\) and Laser Desorption FT MS spectra\(^3\) have been described.

\[
\Delta (\text{CF}_2)_n^+ \quad n = 4 - 21
\]
Figure 1 shows the ICR spectrum of polytetrafluoroethylene at a pressure of \(2 \times 10^{-7}\) mbar. The spectrum is obtained at a high voltage of \(-8\) kV. A characteristic fragmentation pattern appears with a mass difference of 50 amu. This corresponds to ions of the formulas \((\text{CF}_2)_n^\text{-}\). The strong signals in the lower mass range belong to the ions \(\text{C}(\text{CF}_2)_n^\text{-}\).

The second example (Fig. 2) shows the ICR spectrum of polyperfluoroalkoxyteflon at a pressure of \(1 \times 10^{-7}\) mbar. The high voltage used is \(-5\) kV. The characteristic fragmentation pattern is \(\text{O}(\text{CF}_2)_n^\text{-}\) ions with formulas \((\text{CF}_2)_n^\text{-}\) and \(\text{CF}(\text{CF}_2)_n^\text{-}\) are also formed. Fragmentation products of low intensity that occur in both spectra are \(\text{C}_2^\text{F}(\text{CF}_2)_n^\text{-}\), \(\text{C}_2(\text{CF}_2)_n^\text{-}\) and \(\text{C}_2\text{F}(\text{CF}_2)_n^\text{-}\).

Finally a possible ionization mechanism will be discussed. At the surface of the counter electrode electrons are emitted due to the high voltage. These electrons are spread in all directions. If they hit the surface of the solid sample ions and neutrals will be sputtered from this surface. Neutrals that reach the space between pushrod and ICR cell will be ionized by electron attachment and detected inside the ICR cell. We call this discharge-assisted ionization.

Work granted by the Deutsche Forschungsgemeinschaft

3. EXTREL FTMS Application Report No. 6.
Simultaneous Trapping and Mass Spectrometry of Positive and Negative Ions in the ICR Cell

Y. Wang and K. P. Wanczek,
Inorganic Chemistry, NW 2, University, D-28 Bremen 33,
West Germany

The reactions of positive and negative ions in the gas phase are of great interest in astrophysics, atmospheric physics, heavy ion plasmas and in chemistry. The study of the reactions of positive and negative ions is very difficult and despite their great importance only a few investigations have been published.

In the ICR cell until now only positive or negative ions or electrons could be trapped, due to the trapping potential applied. To trap ions of both polarities two methods are proposed: (i) confinement by an additional RF electric quadrupole potential, or (ii) confinement by an additional static electrical potential. In this paper the second method and its experimental realization will be described.

The investigations are performed with a prototype Spectrospin FT ICR spectrometer CMS 47. It is equipped with a superconducting magnet of 7 T field strength, and controlled by an Aspect 3000 computer. The base pressure is in the $10^{-10}$ mbar range.

In Fig. 1 the cylindrical ICR cell employed for the study is shown. It is equipped with two additional grids in front of the trapping plates. The trapping plates and the grids are at opposite potentials, e.g. the grids at positive and the trapping at negative potentials of a few volts. With this arrangement positive and negative ions are trapped simultaneously. Excitation and detection of the ions of both polarities can be performed either simultaneously or after ejection of one kind of ions with the standard detection scheme, which employs the two cylinder segments $E$ for excitation and the two segments $D$ for detection (cf. Fig. 1).

The new method is applied to the ion chemistry of sulfur hexafluoride. Electron impact ionization of this compound yields as the major positive ions $\text{SF}_5^+$, $\text{SF}_4^+$, and $\text{SF}_3^+$. No positive molecular ion is formed. With the near-thermal electrons, which are formed in large amounts in the ICR cell the negative molecular ion, $\text{SF}_6^-$, is generated, and
electrons of higher energy, also $\text{SF}_5^-$ is formed. In the mass spectrum all the ions are detected. Their relative intensities depend on the grid and trapping plate voltages. At constant trapping plate voltage a range of grid voltages exist where both positive negative ions are trapped. The grid voltage can also be adjusted to operate the ICR cell in the "normal" mode to trap only one polarity of ions. Figure 2 shows a spectrum where the ions $\text{SF}_5^+$ and $\text{SF}_6^-$ dominate. The trapping potential was $-15$ V and the grid potential was $+0.6$ V.

With SIMION program (1) the trajectories of the trapped ions are calculated and the mechanism of the simultaneous trapping can be shown.

With the new method, the reactions of positive and negative ions can be studied with ICR, a new application of the method.

Comparison of Detection Modes of ICR-MS for Intensity Accuracy
Deborah T. Grimm and John E. Bareness,
Dept. of Chemistry, Univ. of Tennessee, Knoxville TN 37996-1600

Using an ICR-MS equipped with all three modes of detection - slow passage (SP), rapid scan (RS) and Fourier Transform (FT) - a comparison of ion abundance measurements has been made. SP detects only the absorption of energy, RS detects both absorption and emission and FT detects only emission. All three modes have been studied while varying experimental parameters, and compared for gas-phase basicity experiments.

The RS and SP hardware utilize a capacitance bridge detector, run by an IBM PC. The FT hardware involves a partial IonSpec detection system. For all three, interface boards on the PC generate the pulses and their timing. A 1.3 T electromagnet and 2.5 cm cubic cell were used.

Non-reacting Ions (CHC12⁺ Isotope Ratio):

The number of ions in the cell affects the apparent isotope ratio. The number of ions was assumed to be proportional to the product of the emission current and grid pulse duration. Better results are obtained with lower numbers of ions in the cell for all methods.

The magnitude of the detected signal should be linearly proportional to the excitation RF amplitude, up to ejection. For each method, the 85/83 ratio from the CHC12⁺ fragment from CHCl3. All 3 modes give slightly lower than theoretical values. The RS data are much less affected by changes in excitation RF amplitude than FT. (FT spectra were corrected by division by the excitation spectrum.)

Reacting Ions:
To determine if the 3 modes of detection yield similar results for a common thermochemical measurement made by ICR-MS, two basicity equilibria were studied:

\[ \text{CHC}_2\text{H}_4\text{OSO}_{2}^- + \text{H}_2\text{O} \rightarrow \text{CHC}_2\text{H}_4\text{OSO}_{2}^+ + \text{H}_2\text{O} \]  [12 dalton (12%) difference in masses]

\[ \text{C}_6\text{H}_5\text{BRH}^+ + \text{MeOH} \rightarrow \text{C}_6\text{H}_5\text{Br} + \text{MeOH}_2^+ \]  [124 dalton (37%) difference in masses]

For the first system, the measured ΔG for all 3 methods was within the ±0.1 kcal/mol error generally associated with the method.

The unusual results obtained by RS are probably a function of the detection method. In this experiment, C6H5BRH⁺ was detected first (increasing frequency sweep). Before detection of MeOH2⁺ (ca. 100 msec), the excited C6H5BRH⁺ could react further with methanol and increase the MeOH2⁺ population. In an FT experiment all ions are excited and detected simultaneously and do not have time to react further.

We conclude that:
1. RS is less affected by experimental parameters (excitation RF amplitude, # of ions in the cell) than either FT or SP.
2. FT, RS and SP all give similar results for reacting ions over a narrow mass range.
3. Errors may be introduced in RS equilibrium experiments over wide mass range, while FT experiments are not affected. Sweep direction may alleviate the problem in RS experiments.

A MECHANISM FOR POOR HIGH MASS PERFORMANCE IN FTMS.
Christopher L. Holliman, D.L. Rempel, and M. L. Gross
Midwest Center for Mass Spectrometry, Department of Chemistry
University of Nebraska, Lincoln, NE 68588-0304

INTRODUCTION

The need for high mass capabilities has increased due to ionization techniques such as electrospray[1] and matrix assisted laser desorption.[2] Fourier transform mass spectrometry (FTMS) is a high mass, high resolution, multichannel analyzer which is being coupled to these techniques[3]. The potential of FTMS is seldom achieved with small ion populations such as those generated with large biomolecules. The reasons are likely to be electrical in nature. Scaling experiments show that elimination of peak splitting and optimization of resolution are achieved by an increase in ion number, or simple compensation of the trapping plates.[4] Russell et. al suggest that ion cloud expansion would result in loss of ion phase coherence and signal.[5] Expansion by long delays between ionization and detection, electrical effects, and ion partitioning or injection are proposed as possible mechanisms. Here we describe new experimental evidence that ion cloud expansion is a cause of signal loss. We propose and present evidence of a new mechanism for mass dependent cloud expansion.

THEORY

In anharmonic wells, coupling can occur between the radial and z modes, which leads to parametric resonance and radial expansion of the cloud. The masses that are affected are those whose radial frequency is an integer multiple of the z mode frequency in the trap center approximation. Thus these masses are given by \( m = m_e \left( \frac{1}{2k^2 + 1} \right) \).

EXPERIMENTAL

The FTMS system in this study consisted of a 2.54 cm cubic trap with split (ring and disc) trap plates[4]. Both plates are at 1 V in the uncompensated mode, and the ring is increased to 1.7 V in the compensated mode. A Varian V-3400 iron magnet with a V-FR250 Fieldial current regulator and a maximum field of 1.2 Tesla was employed. Except where noted, ion populations were from benzene at 2x10^-6 torr, ionized at 15 eV and 300 nAmps. Excitation was by a 0.35 Vb-n constant frequency r.f. pulse to each excitation plate. Detection was in the heterodyne mode using 4k data points. The behavior of various high mass ions at 7 Tesla were investigated by benzene ions by scaling the magnetic field, and time parameters appropriately.[4]

DISCUSSION

Signal loss due to cloud expansion is established by overt expansion of a methane ion cloud at 1.2 Tesla. This is achieved by application of a 1.6125 MHz r.f. burst on the D.C. bias of the trap plates. Methane is observed to mimic high mass behavior with respect to signal and ion number. The role of electric effects at high mass is established by 20,000 amu ion behavior modeled with benzene. Signal degrades as a delay time as long as ten seconds between ionization and detection expands the cloud. Compensation moderates the electric effects, and there is no loss in signal within the delay period.

Trap resonance is a mass dependent, radial expansion mechanism and apparently similar to those observed in magnetic bottles.[6] The figure shows the mass range of a 2.54 cm cubic trap in a 7 Tesla field as modeled with benzene. Regions of signal loss are centered at approximately 14,500, 34,500, and 91,000. Not shown here are calculation and experimental results which demonstrates that compensation shifts the resonance centered at 91,500 to a lower mass. Effects of compensation on the less intense resonances are under investigation.

Anharmonic traps should produce more extensive coupling between modes and produce wider and stronger resonances. We propose that harmonic wells are the appropriate direction for trap designs.

INTRODUCTION

For the analysis of volatile compounds, high resolution gas chromatography (HRGC) is far superior in separation characteristics to any other method. In terms of chemical analysis, Fourier transform mass spectrometry (FTMS) has been shown to be superior to sector instruments in the areas of ultra-high resolution, multi-channel detection, and fast scan capabilities\(^1\). With this understanding, the coupling of HRGC and FTMS should yield an analytical system capable of trace analysis for most volatile chemical species.

HRGC/FTMS in a single cell instrument is performed most efficiently via the use of a high speed pulsed valve\(^2\). Due to the narrow pulse width of the sample, with respect to the eluting time of the GC peak, we calculate that roughly 1% of the peak is actually detected while 99% is pumped away. If the entire GC peak were trapped, concentrated, and directed into the cell in a single pulse, the limits of detection should improve by approximately 100 times.

OBJECTIVE

To actually detect 100% of an eluting analyte, some basic requirements for a perfect cold trap interface must first be satisfied:

- The temperature gradients of the cold trap must be narrow and very well defined
- The width of the sample plug eluting from the cold trap must be very narrow in time (<20 ms)
- The cold trap interface must be capable of introduction into the vacuum system in close proximity to the FTMS cell to alleviate any diffusion broadening of the analyte plug

COLD TRAP DESIGN

The cold trap region is established and defined by thermal contact between a section of 0.635 mm o.d. x 0.305 mm i.d. stainless steel tubing brazed between two pieces of 6.35 mm brass plates. To one end of this tubing is attached the GC column while the other end is connected to the sample inlet of the pulsed valve. Channels have been milled in the brass stock to allow for the flow of liquid nitrogen. In this manner, the trap reaches near liquid nitrogen temperatures, while the thickness of the brass defines the width of the trap.

To control the temperature gradients of the cold trap, a set of moveable heater blocks have been positioned on either side of the trap at a separation of 0.305 mm. This forms a gradient of approximately 300°C over a distance of 0.305 mm.

To pulse the analyte from the trap we must invert the temperature of the cold trap. This is accomplished by passing a closely controlled current across the cold brass plates to heat resistively the steel tubing across its width. The variable amperage is supplied by a custom built power supply under computer control (SEE FIGURE 1).

As the analyte is vaporized and re-entrained into the helium flow of the carrier gas, a computer controlled pulsed valve opens for sample admission. By varying individual parameters, values for each interface sequence step can be optimized.

COLD TRAP EVALUATION

By passing a current of varying amperage across the width of the cold trap we detect gross temperature changes of 430°C for 850 and 700 amps at current pulse widths of 10 and 15 ms respectively. Under liquid nitrogen cooling and a current of 850 amps for 10 ms, we are able to invert the trap temperature from -140°C to +20°C at the center of the trap, and from -90°C to +180°C at the edge of the trap (SEE FIGURE 2).

Experiments show that the efficiency of the trap at producing narrow pulse widths is dependent on the amount of analyte sampled (SEE FIGURE 3). This phenomena is possibly due
to saturation of the trap. This reinforces the claim that this technique is for trace analysis.

The capability of our trap in creating very narrow pressure profile widths becomes evident in FIGURE 4. From this graph it is apparent that there is a problem due to dead volumes. By introducing an auxiliary helium flow at various pressures we can sweep out this volume to arrive at a profile width which is indicative of the cold trap.

Our future work will attempt to produce a better pulsed valve resulting in a substantially lower dead volume, and hopefully result in the ability to locate the trap in close proximity to the FTMS cell.

REFERENCES
Ions in an FT/MS® cell can be trapped, excited for detection, excited for collisional activation, or excited for ejection. Stored waveform inverse Fourier transform (SWIFT™) excitation is a technique for selectively coupling these characteristics over a range of ions, or in other words, "tailoring" the ion excitation energy profile in the mass domain. The advent of memory-based waveform generation for ion excitation allows complex pre-experiment excite waveform tailoring, which leads to analysis time savings and more effective experiments. Traditionally FT/MS has been calculation intensive after the experiment. By budgeting more time before an experiment, that time may be made up later by less stringent post-processing, and the high-resolution, user-friendly features of FT/MS can be applied to a wider range of problems.

The excitation and detection parameters in FT/MS are equivalent. The length of time spent in excitation affects the ultimate ion selectivity in the same way that the length of time in detection affects mass resolving power. In the ultimate sense, selectivity and resolution are constrained by pressure-limited collisions of cyclotroning ions. Historically, only the detection parameters have extended into the pressure-limited collision constraint. Recent developments in SWIFT hardware allow broadband, ultrahigh-resolution mass-selected excitation. This feature has been implemented in a versatile, user-friendly FT/MS system.

Ultrahigh-resolution detection is improved by using ejection sequences to remove interfering ions from the cell. We proposed that the same technique would improve excite resolution. Accomplishing ion ejections with a sine wave or swept sine wave (chirp) has its limitations. The swept sine wave typically induces an offset and side-lobe energy to ion species remaining in the cell. Successive swept sine wave ion ejections have been limited to low-resolution because of the accumulation of these effects. Combinations of low- and high-resolution chirp ejections improve the situation somewhat; however, SWIFT techniques combine multiple-band excitation in to a single, apodized, and offset-corrected event. We show how SWIFT can be used to 1) improved resolution, 2) provide parent ion selectivity for MS/MS experiments, and 3) provide ultrahigh selective excitation.

All results were run on a standard EXTREL FTMS instrument with a SWIFT/Cell Controller module. The system has a dual ion source/analyzer with a 3-Tesla magnet. For collision-induced dissociation (CID), argon was introduced through a static valve on the analyzer side. Some of the features of the SWIFT module used in these experiments include:

- 65.5 kHz to 8 MHz (Nyquist) memory-based waveform generator with 1 megaword of 12-bit data.
- 8 MHz (Nyquist) swept frequency generator with ultrahigh-resolution (heterodyne) capabilities.
- Data system programmable filters and attenuators, and high-speed switching analog electronics.
- Unified, user-friendly software package.

1) Figure 1A is ultrahigh-resolution detection and isolation of Bromochlorobenzene isotopic ions at m/z 192 by using a single SWIFT excitation for isolation.

2) A mixture of anisaldehyde and d-limonene is a system that requires more than a resolving power of 2,000 for isolation. Once isolated, low-resolution detection can be used with their CID spectrum to identify each component. In order to selectively eject each of the molecular ions, a SWIFT waveform was produced. It is very easy to switch between the two samples by changing only the SWIFT reference by the difference in their masses. Figure 2A and 2C show the ion isolations, and Figure 2B and 2D show their respective CID spectrum.

3) An ultrahigh-resolution SWIFT excitation was used as the excite-for-detection with a notch having resolving power of 215,000, which leaves a non-excited millimass unit wide ion species in the mass domain.
the center of the cell (Figure 3A). By successively scanning, and incrementing the SWIFT reference mass over the m/z 192 region, the following isolations were achieved (Figures 3B, 4 - 7). The increment between each Figure in the series is 0.4 Hz which is equal to 0.3 millimass unit at m/z 191.

In conclusion, SWIFT techniques add to the spectrometrist's capabilities by affording high-resolution excitation capabilities, predictable ion radii and energies, apodized balanced waveforms, and reduced off-resonant effects. Tailoring excitation through preprocessing provides a versatile experimental platform, which is easy to use, simple to verify, and provides rapid isolation and analysis on ion species of very close mass-to-charge ratios.

Future enhancements to SWIFT preprocessing algorithms will undoubtedly speed calculation times, and provide more flexibility in the definition of “don't care” regions of the mass spectrum. This indicates an opportunity to develop algorithms for more efficient excitation and higher resolution selection.
Effects of Tailored Excitation Waveform Sampling Rate on the Signal Experienced by Ions In FTMS

Zhenmin Liang and Richard Hein. EXTREL FTMS Inc., 6416 Schroeder Road, Madison, WI 53711.

Stored waveform inverse Fourier transform (SWIFT) excitation is becoming a widely used technique in Fourier transform mass spectrometry (FTMS). SWIFT excitation involves the transmission of a signal (excite waveform) through the digital-to-analog conversion (DAC) of a stored waveform. The effects of the sampling rate of a digital waveform on the analog waveform experienced by ions in the ion trap is discussed.

It has been shown that oversampling of time domain signals in analog-to-digital conversion provides little improvement to FTMS spectra. For tailored waveform excitation, the sampling rate of the waveform customarily used is equal or slightly greater than the Nyquist limit of an excite band. However, this rate results in two artifacts in the power spectrum that ions experience during excitation, namely a roll-off of power in the excite waveform from low frequency to high frequency and large amplitude harmonics of the excite band. Depending on the sampling rate and the bandwidth of the excite waveform, the roll-off can be greater than 25% of the magnitude of the low-frequency edge of the band. The magnitude of the harmonics can be as high as 50% of the low-frequency edge of the requested excite band, as shown in Figures 1.

The roll-off and the harmonics are artifacts of DAC conversion. During the excitation, a zero order recovering filter is normally used; that is, the electronics step through a digital waveform point-by-point and the value of each data point is held for the length of a dwell time period of the excite waveform. Discrete mathematics predicts that there are artifacts in the frequency domain response of the waveform.

The DAC of a waveform by a zero order recovering filter is a process of convoluting a filter box function on the SWIFT waveform. According to the Fourier convolution theorem, the frequency spectrum of the convoluted waveform is the product of a sinc function and the normal SWIFT waveform spectrum, as illustrated in Figure 2. Note that the normal spectrum of a discrete waveform is a periodic function with a period of $2f_n$, where $f_n$ is the Nyquist frequency of the waveform. The above phenomenon can also be explained qualitatively. The resulting analog waveform from DAC is a square-cornered step function. It is well known that square corners in the time domain is the sum of a series of harmonic frequency components. In addition, the step function analog waveform can be viewed as a sum of a series of waveforms with a fixed time delay between each other. From the Fourier transform shift theorem, this can also be translated as a series of waveforms with phase differences between each other that are applied simultaneously to excite the ions. The phase difference between the series of waveforms is proportional to the frequency and is within pi/2 radian; the lower the frequency, the smaller the phase difference between the series of waveforms. Therefore the low-frequency section of the spectrum has higher amplitude, resulting in a roll-off of power in the excite band from low frequency to high frequency.

When a first order recovering filter is used (by using the first derivative to interpolate the points in between the existing data points), improvement is seen in reducing the amplitude of harmonics, but the roll-off is more severe, as shown in Figure 1c. The same effect can be achieved with a low pass filter, as shown in Figure 1d. A second order filter was also tested; the reduction of harmonics is about the same as with first order recovering filter, but the roll-off is more severe than that with first order filter. Broadening the sinc function envelop will result in less roll-off. This can be achieved by reducing the width of the recovering window. One way to reduce its width is to shorten the holding period of data points during DAC. But this requires a higher voltage excite amplifier to achieve the same excite level. In addition, the harmonics have a higher amplitude. An electronic device may also be used to compensate the roll-off, but the closely spaced first harmonics may not be completely filtered out and the cutoff filter may also introduce roll-off. A purposefully predistorted waveform may also be constructed to produce a waveform with the roll-off compensated by dividing the original requested excite spectrum by the sinc function of the recovering filter. The simplest method is to construct the waveform at the sampling rate higher than the Nyquist limit, at the expense of requiring more computer memory and computational time. Computer simulation shows that when four times the Nyquist rate is used, the distortion of the spectrum of the waveform is within a few percent. Figure 3 shows the spectrum of a waveform generated at four times of the normal sampling rate.

In conclusion, a waveform free of roll-off and harmonic artifacts can be obtained when four times of the Nyquist sampling rate is used. Other methods also correct the DAC artifacts to some extent, but they have limitations. Balancing the trade-off of memory requirement and computational time, a better solution is to use twice of the Nyquist sampling rate, predistort the requested excite spectrum by the recovering filter sinc function and use an effective harmonic cut-off filter.

SECONDARY NONLINEAR RESONANCES
DUE TO EXCITATION ELECTRIC FIELD INHOMOGENEITIES
IN A CUBIC FT/ICR CELL

Department of Geological Sciences
State University of New York at Albany
Albany, NY 12222

In this study, we investigate the effects of excitation at frequencies away from \( w_+ \) and \( w_- \) due to electric field inhomogeneities from a sinusoidal excitation across the x-plates of a cubic FT/ICR cell [1].

To obtain analytically manageable expressions we first expand the exact electric potentials about the cell center in a Taylor series keeping terms up to the leading excitation inhomogeneities and quadrupolar trapping. Next we transform the cartesian equations of motion to a coordinate system co-moving with the linear quadrupolar system by the method of variation of parameters [2]. These coordinates correspond to the cyclotron, magnetron and z-mode amplitudes and their respective phases. In this amplitude/phase representation, the first-order resonance structure due to the excitation field inhomogeneities appears as terms with slowly-varying phases. The complete set of equations in amplitude-phase coordinates is still too complicated to be solved analytically. However, since the inhomogeneities are small perturbations and the resonances are usually widely separated, we obtain greatly simplified but still accurate expressions by averaging.

Two different classes of resonances are found: resonances dependent only on nonlinear terms and resonances which depend also on the linear excitation term. The second class of resonances is generally much weaker than the first. For the first class, secondary resonances occur at excitation frequencies near \( 2w_\pm w_+ \), \( w_+ \pm 2w_\pm \), \( 2w_\pm w_- \), \( w_\pm 2w_\pm \), \( 3w_\pm \) and \( 3w_\mp \). For the second class, resonances occur at \( (w_\pm w_-)/2 \), \( w_\pm /3 \), \( w_- /3 \) and \( w_\pm \). The first class includes the well-known z-mode coupling with the radial modes as well as coupling between the cyclotron and magnetron modes and sub-harmonic resonances of order 1/3.

Inspection of the coupling coefficients in the amplitude-phase equations of motion show that the resonances at \( 2w_\pm w_- \) and \( w_\pm \pm 2w_\pm \) have generally the strongest effect on ion motion.

A simple analysis of the resulting equations of motion, assuming each resonance is widely separated in frequency from all other resonances, shows that for each mode-coupling case there is one resonance which gives bounded trajectories while the other can give unstable motion due to the presence of invariants coupling the mode-amplitudes in the averaged equations. For example, the equations of motion for the resonance at \( w_+ + 2w_\pm \) possesses the constant of motion

\[ c = 2(w_\pm - w_-)a_\mp^z - w_\pm a_\mp \]

while for the \( w_+ - 2w_\pm \) resonance the constant of motion is

\[ c = 2(w_\pm - w_\pm) a_\pm^\mp + w_\pm a_\pm \]

where \( a_1 \) and \( a_3 \) are the cyclotron radius and z-mode amplitude, respectively. These two resonances have previously been predicted [3] and the above constants of motion can account for their observed behavior. The first of these equations is
a hyperbola while the second is an ellipse describing, respectively, unstable and stable motion. Additionally, for the averaged equations another invariant exists identifiable as the energy integral in a rotating coordinate system which along with the above constant of motion \( c \) can be used to reduce the original set of four first-order time-dependent equations of motion to a single time-independent equation integrable by quadrature. The averaged equations in the amplitude-phase representation contain just two modes at most. The mode-amplitude and phase of the third mode not in the averaged equations are constants of motion.

For the strongest secondary resonances we can take the ratio of the largest coupling coefficients in the averaged equations to the linear on-resonance cyclotron excitation expression

\[
\frac{\frac{d}{dt}}{d/B} = E/B
\]

To obtain the maximum order of magnitude of these terms. We find that the maximum value

\[
\frac{\gamma^2(E/B)}{d w_c} = 1.6 a_1 a_2 w_c
\]

where \( d \) is the cell length. If we take the case \( a_1 = a_2 = d/10 \) and \( w_c/w_c = 100 \), this ratio is on the order of 1, indicating that for large initial mode amplitudes, ejection is very rapid for the unstable \( z \)-dependent resonances. By minimizing either \( a_1 \) or \( a_2 \), the relative effect of this secondary nonlinear behavior can be reduced greatly. These secondary effects are probably minimal for most experiments as the initial mode amplitudes are usually much less than \( d/10 \).

However, in studies requiring extreme accuracy in ion abundance measurements, care must be taken when exciting ions at these secondary resonance frequencies because ion ejection and/or mode interchange could lead to anomalous results. If possible, a narrow pulse at the cyclotron frequency should be used rather than a sweep across many decades of frequency. This will minimize the excitation at the secondary resonances. For studies involving more than one mass (the vast majority of all studies), minimizing the frequency range of the excitation pulse is suggested to help prevent inadvertent secondary nonlinear effects.

A Fourier Transform Ion Cyclotron Resonance (FT-ICR) laser microprobe system, designed for the analysis of specific mineral grains in geological samples, was developed. Design criteria included the accommodation of standard geological thin sections (27 x 46 mm), a laser spot size of ca. 30 μm, sample placement to ca. 10 μm, movement of the sample of at least ±1/2" in the xy plane, sample viewing capability, and the ability to interface with a modified Nicolet/Extrel FTMS-2000.

The commercial solids probe that came with the system was limited in size to sample disks 5/8" in diameter and limited in sample placement to rotation about the z-axis. For the analysis of geological samples, an xyz manipulator was used to allow both larger samples and much more flexibility in sample positioning. A load-lock system was designed to allow the transfer of the sample onto the xyz manipulator under high vacuum, thus allowing manipulation of the sample under ultra high vacuum. The sample holder, load lock system, and xyz manipulator accommodates either standard 1" diameter or 27 x 46 mm geological thin section slides. With a resolution and repeatability of 5 μm along the x and y axes, excellent placement of the sample is accomplished. With the laser beam and other optics fixed, movement of the manipulator in the xy plane selects the target area for the laser while movement of the sample manipulator along the z axis provides for focussing of the laser on the sample surface. Movement in the xy plane allows not only positioning of a mineral of interest into the path of the laser for analysis but also allows a series of spectra to be taken across a particular area of interest (the resolution in this case is limited by the spot size of the laser). The ±1" movement of the xyz manipulator allows the full area of either size thin section to be analyzed.

The optical system includes a straight optical path inside the vacuum system along the z-axis to the sample through holes in the two trap plates of the FT/ICR analyzer cell. A 75 mm focal length planoconvex lens just outside the trap plate opposite the xyz manipulator serves both to focus the laser light onto the sample and to provide viewing of the sample before the analysis. A HeNe laser beam, collinear with the Nd:YAG laser shows the point where the laser beam is focussed, so choosing a particular mineral grain (or crystal zone within a mineral) on the sample for
analysis is simple. All of the alignment optics are outside the vacuum chamber, mounted on an optical table for ease in adjustment. For laser desorption, the Nd:YAG, operating at the fundamental wavelength of 1064 nm, is focused through the analyzer cell onto the sample just outside the opposite trap plate, producing ions directly from the solid sample, followed by subsequent ion excitation and detection with the FT/ICR electronics. Because a complete mass spectrum can be obtained from a single laser shot, subsequent laser shots can either probe deeper into the sample if the sample is not moved or spatial information about species present in the sample can be obtained if the sample is moved after each laser pulse.

A laser spot size of approximately 100 μm was attained by the optical setup before the addition of a 3x beam expander. The beam expander should reduce the spot size by a factor of 3, allowing more spatial information to be obtained from a geological sample.

Limitations and difficulties of the system include difficulty in performing electron impact experiments, a longer pumpdown time, viewing optics that are not so flexible, and fairly slow and tedious sample introduction. Electron impact experiments currently require the complete removal of the xyz manipulator and the focusing lens because they are both along the z axis. Future plans include the design of a filament that will mount on the end of the xyz manipulator and a shutter that will block the path to the focusing lens, preventing damage by electrons. The flexibility in sample movement and the ease in alignment of the optics more than makes up for the longer pumpdown time required for analysis. The 3" focal length lens for focusing the laser pulse and magnification of the sample image limit the resolution of the viewing system. A system with different paths for sample viewing and the laser beam is currently under consideration. Motorization of the xyz manipulator would provide greater resolution and repeatability and faster operation. As the xyz manipulator has the ability for field fitting of stepper motors, this would be a simple upgrade.

In summary, the system allows the laser microprobe analysis of individual mineral grains directly from standard geological samples. Information on the spatial distributions of chemical species can thereby be obtained that is not available by more traditional techniques.

As this system has flexibility in sample introduction, sample movement, and the optical system, a similar system could be readily used in other applications where mass spectral spatial information of solid samples is desired.
Spontaneous Coherent Magnetron Motion. Ion motion within the trapped ion cell may be described as the superposition of the trapping, cyclotron, and magnetron motions. Magnetron motion results from a combination of radial electrostatic forces and the magnetic forces and amounts to a drift of the center of cyclotron gyration along the closed isopotential contours of the radial electric field. Unlike the trapping and cyclotron motions, the amplitude of the magnetron motion will increase as the energy associated with this mode decreases. For FTICR experiments in which a well-behaved ion population is created along the cell axis, magnetron motion and the associated effects are minimized. However, for experiments in which ionization conditions are more extreme or not as well controlled, the magnetron effects may be significant. Moreover, under certain conditions, coherent magnetron motion may spontaneously occur, as evidenced by the direct observation of magnetron transients in the absence of an excitation event. Such motion has important implications for FTMS detection.

Examples of the coherent motion resulting in magnetron transients display an initial growth and subsequent decay in signal amplitude. The behavior shown corresponds to an increase in magnetron radius until ions begin to collide with the cell perimeter and are lost. Figure 1 is an expanded segment of a typical magnetron transient acquired following an LDI event in the cubic cell. The sinusoidal nature of the detected magnetron signal is evident as well as the high signal to noise ratio which implies a large magnetron radius and a high degree of coherence to the ion cloud.

Another feature of the magnetron transient is an evolution of the magnetron frequency with time. The initial frequency is higher than predicted based on the radial component of the trapping field alone, but quickly decays to the expected value. The initial frequency enhancement is attributed to space-charge effects which decrease as the ion cloud evolves. Evidence that space charge is responsible for the frequency enhancement is presented in Fig. 2, where a suspended-trapping event is applied to reduce the ion population and thus the space charge contribution to the radial electric field in the trapped-ion cell. The initial magnetron frequency is 950 Hz, 50% higher than the predicted value of 634 Hz. Following a brief suspended trapping event to eject some ions, the observed magnetron frequency is 670 Hz, within 6% of the expected value. This additional radial electric field component depends linearly upon the total number of ions (represented by ionization time). A linear shift in magnetron frequency is displayed until it levels off at longer beam times as the space charge capacity of the trapped-ion cell is achieved. The space charge in combination with the resulting image charge on the cell electrodes creates a net electric dipole.

The magnetron frequency varies with trapping potential because the radial electric fields responsible for magnetron motion are a component of the applied trapping potentials. For the cubic cell, this frequency shift can be predicted based on a quadrupolar approximation of the cell electric fields. Attempts to predict behavior for elongated cells may be unsuccessful if ion motion is not constrained to a region very near the center of the cell. Fig. 3 demonstrates the failure of the quadrupole approximation to predict the relationship between trapping potential and magnetron frequency for the elongated cell. From SIMION work, the cubic cell radial electric field is found to vary by less than 20% over a z-axis range covering 70% of the z-dimension of the cell, so the quadrupole approximation closely approaches the observed result for the cubic cell. In contrast, a variation in excess of 600% for the radial electric field exists over a 70% fraction of the elongated cell length. A prediction of 52.5 Hz/V is made for the slope of Fig. 3 using the average radial electric field over the full z-axis dimension of the cell. The behavior of ions confined to a smaller range of the z-axis motion approaches the predicted value because the quadrupolar approximation is valid at the center of the cell.

Resistive-wall Destabilization. Resistive-wall destabilization is a collision-independent ion transport mechanism which results from the destabilization of coherent ion magnetron motion in the trapped ion cell. This results in radial ion transport and potential ion loss for ion populations that exhibit a significant degree of coherent magnetron motion. This transport mechanism is an important factor to be considered in the experiment design process. Comparison of magnetron transients acquired with differing values of external circuit resistance provides a direct demonstration of the resistive-wall effect on magnetron motion. Fig. 4a and 4b demonstrate
growth proportional to the external resistance in the detection circuit of magnetron transients with time. In Fig. 4b, the eventual decay of the magnetron transient corresponds to the loss of ions at the cell perimeter and is direct evidence that resistive-wall destabilization is an important ion loss mechanism.

Coupling ion motion to a resistive external circuit is an effective means of removing energy from ions confined in an electromagnetic trap because the ion energy is dissipated by Ohmic power loss in the external resistance. Eq. 1 was derived to show that the growth of the magnetron radius due to resistive heating of the external circuit increases linearly with number of ions (approximated by ionization time), trapping potential, and resistance.

$$r = r_0 \exp \left( \frac{t}{\kappa} \right)$$

The behavior of magnetron motion is consistent with a radial displacement of the ion cloud. This displacement can occur as a result of the acquisition of an off-center ion cloud, or as a result of the resistive-wall destabilization of an initially centered cloud. If the external resistances associated with each electrode are not balanced, the asymmetrically distributed image charges induce a net force on the cloud which causes radial displacement.

![Figure 4](image4.png)
Different from commercial FTMS data systems and data systems constructed by other laboratories, this simple modular data system for selective waveform excitation and programmable trapping experiments employ readily available, inexpensive "off-the-shelf" components. No hardware construction and minimal programming skills are required. System complexity is dramatically reduced with an arbitrary function generator (AFG) that drives, with appropriate amplification, all forms of radial ion excitation and z-axis trapping and excitation. Examples to be presented include SWIFT and multiple frequency excitation as well as the use of adiabatic compression of trapping potentials to drive ions to the center of the cell.

The spectrometer of the FTMS includes a 2.0T superconducting magnet and is pumped to pressures of $10^{-9}$ torr. The system is configured as an external ion source tandem time-of-flight FTMS. However, for this work an axial probe-mounted electron gun was installed to permit conventional electron ionization in a 5x5x10 cm trapped ion cell.

A block diagram of the data system is presented in Figure 1. The primary components of the system are a personal computer (PC), a dual channel arbitrary function generator, and a digital storage oscilloscope (DSO).

A typical pulse sequence for an FTMS experiment includes ion-quench, ion formation, ion excitation and signal acquisition events. The modular data system analog to this sequence is executed in the form of waveforms and triggers, as shown in figure 2. These waveforms are first created on the PC using W.A.V.E. and then downloaded and stored in the AFG memory for output when the experiment is initiated.

A useful feature of the DSO is the ability to perform independent signal averaging and Fourier transforms. The signal averaging feature reduces the demand for data transfers to the PC and frees the PC for other work during lengthy periods of data acquisition.

The simplest excitation waveform is the single frequency sine wave. This waveform is useful when it is desirable to observe or eject selected ions of a single mass-to-charge ratio. Multiple frequency waveforms are constructed by adding together any desired number of single frequency waveforms. As will be shown, multiple frequency excites are advantageous for quantitative observation or ejection of small numbers of selected ions. This type of excitation can be an attractive alternative to SWIFT for high resolution selective excitation measurements. If the excitation of a large number of ion masses or a range of masses is desired a swept frequency excitation waveform may be employed. In this case the waveform is still sinusoidal but the frequency is varied linearly with time. Such waveforms are useful for observing or ejecting a broad mass range of ions with a single waveform. However, it is not generally possible to effect both observation and ejection of different ions with a single sweep frequency excitation.

The technique of multiple frequency excitation was employed for simultaneous excitation of multiple selected ions, it offers selectivity equal to or better than the corresponding SWIFT excitation but is computationally much simpler to generate. Of interest here are significant advantages for detecting daughter ions resulting from a CID experiment. For example, because daughter ions are formed in regions of the trapped-ion cell where electric fields are less homogeneous, they should exhibit greater coupling between the cyclotron, magnetron, and trapping motions. Selective excitation is much less likely to excite magnetron and trapping motion than broadband excitation and thus should provide a more homogeneous cyclotron excitation. The stored waveform inverse Fourier transform (SWIFT) method can be used to effect simultaneous observation and ejections over any desired mass range with very high resolution. Thus, the technique combines the advantages of both discrete and swept frequency excitation. The desired waveform is initially described in the frequency domain and then an inverse Fourier transform is applied to create a time domain waveform. Quadratic phase encoding is employed to keep the dynamic range of the resulting waveform within the limits of the excitation amplifier.

The second output channel of AFG can generate versatile trapping and excitation waveform for application to the trap plates. This opportunity to manipulate trap plate potentials
of the ions. Adiabatic potential ramps have also been suggested as a means to accomplish axial ion compression and thus minimize temporal variation in image current signal strength due to relaxation effects. Programmed potential changes have been further employed in dynamic trapping experiments where they are used to control the mass range of ions collected from an external ion source. A more complex manipulation of trap potentials may be employed to deliberately excite the trapping motion of ions by superimposing a waveform of the appropriate frequency on the trap potential. Shown in Figure 3 are spectra to illustrate excitation of adiabatic potential ramps with the data system. Figure 3a is the output second channel, Figure 3b is FTMS detection at 0.5 V with severe axial ejection of low mass PFTBA ions, and Figure 3c is the result from execution of the trapping profile in Figure 3a to compress ions to the middle of the cell with a ramp to 3 V before detection at 0.5 V.

HIGH MAGNETIC FIELD ELECTROSPRAY SOURCE FOR FTMS

Steven A. Hofstadler, David A. Laude, Jr., Department of Chemistry and Biochemistry
The University of Texas at Austin, Austin, TX 78712-1167

Among the variety of techniques available for sample ionization, electrospray ionization (ESI) is unique in that it is an extremely soft technique which produces little or no ion fragmentation and it produces multiple charges on single ions. This lowers the mass-to-charge ratio of large ions such that they can be detected by mass analyzers with a modest mass range. With high mass multiply charged ions, several peaks can occur within a single amu window and high resolution is required to adequately resolve individual charge states. FTMS may prove to be a suitable complement to ESI for a variety of reasons including routine ultra-high mass resolution, the ability to do ion molecule reactions in the trapped ion cell, and important for protein sequencing, the ability to do MS/MS. To be presented here is a novel ESI source for FTMS in which ion formation and desolvation occur in the high magnetic field of a superconducting magnet. This is made possible by a pumping configuration which utilizes multiple concentric vacuum chambers. Also to be presented is the use of a skimmer capillary as an alternative to conventional skimmer assemblies. The advantage of this approach is improved differential pumping which can be particularly important with the ultra-low pressure conditions required for FTMS detection. Preliminary results to be presented compare kinetic energy spreads for ions exiting skimmer and skimmer-capillary interfaces. This data is will be useful in efforts to efficiently trap ions for detection in the FTMS trapped ion cell.

Presented in Figure 1 is the instrumentation being developed for ESI/FTMS. As will be discussed, the ionization occurs within a 3/4" probe which is inserted into the strong magnetic field within 13 cm of the analyzer cell. Multiple stages of pumping permit 10^{-8} torr pressures to be obtained in the analyzer trapped ion cell. The vacuum chamber is positioned in a 3.0T superconducting magnet. The FTMS experiment will be conducted with components from the Extrel FTMS-2000 including dual cell, analog electronics, cell controller, and data station.

One unique feature of this interface is the formation of electrospray ions within the strong magnetic field in order to simplify the necessary ion optics. This requires that some means be found to reduce pressures from atmosphere to 10^{-8} torr within a few cm length of the magnet solenoid. As shown in Figure 2, this is accomplished by using a probe to insert the ESI assembly into the center of the magnet. Three stages of differential pumping through multiple stages of concentric vacuum tubes of increasing diameter reach mtorr, 10^{-4} torr, and 10^{-6} torr pressures, and finally the Extrel dual cell conductance limit is used to achieve a final two orders of magnitude reduction in pressure to 10^{-6} torr. The use of multiple concentric vacuum tubes is an ideal approach to pressure reduction in confined spaces such as the FTMS magnet solenoid. Their use for other high pressure source interfaces to FTMS To date, the vast majority of high pressure ionization sources which have been coupled to FTMS have been done through the fringing field. Ions are consequently injected into the trapped ion cell with electrostatic focusing optics or quadrupoles operating in the rf only mode. These injection techniques are often prone to significant ion loss due to the magnetic mirror effect. In order to overcome the adverse effects of fringing field injection we have designed a high magnetic field ESI source. The ESI probe in Figure 3 is modeled after the ESI source designed by Chait, Katta, and Chowdhury. The heated capillary serves to desolvate the electrospray aerosol without the additional gas load associated with countercurrent gas flow. The ESI probe is translatable such that the end of the desolvating capillary can be positioned within 13 cm of the analyzer cell.

Once an ion has been formed, in order for it to be trapped and retained in the FTMS cell it must have a kinetic energy along the z-axis which is less than the depth of the potential well in the trapped ion cell. In order to evaluate the kinetic energy of ESI generated ions, retarding grid studies were undertaken to assure that the kinetic energy of the ions was appropriate for FTMS detection. Figure 4 shows kinetic energy profiles utilizing two different source configurations. Figure 4a demonstrates that when a skimmer cone is placed beyond the desolvating capillary the kinetic energy of the ions is directly controlled by the potential applied to the skimmer, thus...
trapping potentials and kinetic energies can be selected for maximum trapping efficiency. If a 6 cm x 700 μm I.D. stainless steel capillary is used in place of the skimmer cone, the pressure beyond the skimmer capillary drops an order of magnitude but a much broader distribution of ion energies results.

ISOLATED DUAL TRAPPED ION CELL ASSEMBLY FOR FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

Steven A. Hofstadler and David A. Laude Jr.
University of Texas at Austin, Austin, TX 78712

The single cell FTMS experiment offers simplified and inexpensive operational advantages. However, reduced performance for many applications has prompted the evolution to more complex FTICR instruments, with the simplest of these designs consisting of adjacent cubic trapped ion cells which share a common trap plate. This dual cell offers several advantages but still does not correct an inefficient electron ionization duty cycle. This reduced ionization efficiency is important to FTICR because in dynamic sampling environments, its multiplex advantage for S/N is diminished if ionization occurs only during a small fraction of the total experiment time with the majority of the transient sample instead being discarded during execution of other events in the pulse sequence.

In our alternative FTICR dual cell design, two electrically isolated trapped ion cells are positioned in the strong magnetic field to facilitate concurrent ion formation, trapping, and detection. This new configuration exploits the magnetic field to deliver full FTICR detection capabilities in the source region and much higher transfer efficiencies. The primary advantage is a unit ionization duty cycle which maximizes the number of externally generated ions which are detected. Demonstrated S/N improvements for high resolution are greater than 30:1.

Isolated dual cell experiments were performed with the system shown in Figure 1. The vacuum chamber is housed in the bore of a 3.0 T superconducting magnet and is pumped with two 700 l/s diffusion pumps to low 10^-9 torr base pressures. The isolated source cell features an elongated rectangular trap with 5x5x10 cm dimensions which is probe mounted to permit z-axis translation from within 5 cm of the analyzer cell to the fringing field, 30 cm from the analyzer cell. Separating the source and analyzer regions is a 4 mm conductance limit mounted on a 4" diameter cylinder which, when differentially pumped, allows a pressure differential in excess of 10^2. A repeller electrode is positioned between the isolated cell and the grounded conductance limit to divert the electron beam from the analyzer cell during continuous beam experiments.

In conventional mass spectrometers, ionization and detection regions are separated to permit concurrent ionization and detection. Similarly, any FTICR spectrometer which isolates source and analyzer volumes should also accommodate continuous ionization and provide a near unit detection duty cycle. Wanczek placed such a source in the fringing magnetic field. In contrast, we placed the isolated source in the high magnetic field to substantially improve confinement time in the source cell, minimize the negative effects of the radial magnetic field, and minimize the spatial dispersion of the source ions.

One aspect of equilibration transfer which is of increasing importance as path length increases is that equilibration between the two cells does not occur instantaneously. This effect is more important for the external cell and is an additional reason the two cells should be closely spaced.

A gated transfer pulse sequence is often used with the isolated cell. Advantages include dual cell transfer efficiencies in excess of 95% and a crude mass filtering capability. The sole advantage of increasing the distance between cells is this improved time-of-flight-based mass selection. This can be exploited to select against low mass matrix or carrier gas ions associated with desorption or chromatographic detection. The cell can be altered to select different mass ions by changing the distance between the cells. Mass selection can be further improved by reducing the source cell length to provide better spatial focussing of the initial ion population.

A continuous beam pulse sequence was used to obtain EI spectra in the Nicolet dual cell and high field isolated cell. Peak shape distortion and line broadening are evident for the dual cell. In
contrast, for the isolated cell the spectra are unperturbed because the repeller grid ensures that ions are created and trapped exclusively in the isolated cell. The 100% ionization duty cycle which results translates into a signal enhancement which is proportional to the ratio of ionization duty cycles. Figure 2 shows analyzer cell spectra of PFTBA ions gated from the isolated high field cell following 5 ms and continuous beam events. The S/N improvement of 5.5 is in good agreement with the predicted improvement of 6.3 based on a ratio of duty cycles. Included in Figure 3 is the sensitivity profile for the continuous beam experiment acquired under high mass resolution conditions. The 30-fold change in slope is indicative of the sensitivity increases that are possible.

The duration of the transfer event, which distinguishes between mass selection and equilibration studies, is important to transfer efficiency. Figure 3 shows that equal numbers of ions are formed in gated and equilibrium transfers, yet relative sensitivity doubles for the gated transfer event because of a spatially focussed transfer and minimal losses due to collisions. A second factor in transfer efficiency is distance between source and analyzer regions. The five-fold increase in transfer efficiency for the high field source compared to the fringing field source is due in part to minimizing ion reflection in the radial magnetic field. Another problem with increasing the path length is greater dispersion of ions formed at different positions in the source cell. Signal intensity drops off rapidly with increasing source distance from the cell.

Figure 2. PFTBA

Figure 3. Comparison of S/N for Various Dual Cells and Pulse Sequences
Collision induced dissociation is the most popular of ion dissociation techniques in Fourier transform mass spectrometry. Still, any quantitative evaluation of the data is suspect because the dissociation event causes the spatial and kinetic energy distributions of ions to be significantly altered prior to detection. For example, it is not readily apparent how dissociation products are efficiently detected or transferred in a dual cell, if substantial radial displacement of the precursor ion has occurred.

In this work an observed pressure dependent mass discrimination effect in CID product spectra will be evaluated. The source of this mass discrimination, whether part of the CID process, excitation and detection, or collisional relaxation, will be discerned with variable excitation profiles.

CID was performed on parent ions formed by electron ionization in a 5 cm cubic cell in a 3.0 T magnetic field. Various combinations of swept, single frequency, and simultaneous single frequency excites were applied to manipulate radial ion motion. The argon target gas was maintained at various constant pressure below 10⁻⁵ torr. A 100 to 500 μs tickle pulse ensured essentially all parent ions achieved the maximum collision energy.

CID was performed on the parent ion of phenylether (m/z 170) to examine daughter ions at m/z 142 and 77. Figure 1 shows these pathways and their associated internal energies. In all experiments, the pressure of phenylether was maintained at 3 x 10⁻⁸ torr above background so that reactions with product ions, even at delays of 200 ms, were negligible. Shown in Figure 1 are breakdown curves for phenylether at increasing Ar pressure, with a 10 ms delay between tickle and detection. Under these conditions, on the order of ten or fewer collisions with the target gas are calculated. A pronounced trend to favor the lower energy (or higher mass) product is observed. One argument for this is that at higher pressures, ions do not achieve maximum translational energy before collision, thus favoring the lower energy dissociation pathways. This is unlikely, however, because the tickle pulse was chosen to be much shorter than the average time between collisions. We are examining instead mass discrimination effects in the FTICR detection process. These might result from mass dependant differences in relaxation, diffusion, or other manifestations of the collision process.

One tool developed to examine the source of the mass discrimination is the variable excitation profile which should yield information about the radial distribution of ions at different points in the FTMS experiment. Presented in Figure 2 are product ion excitation profiles for the m/z 77 and m/z 142 ions at different pressures following formation by CID at their breakdown curve maxima. What is observed is a dramatic shift in excitation energy maxima and reduction in signal intensity as pressure increases. Evidently, at higher pressures there is a significant loss of ions if excited to high energies (or increased cell radius) for detection. This effect is mass dependent with the lower mass ion, m/z 77, is lost in greater proportion at higher energies than the m/z 142 ion.

In order to target the actual location of the mass discrimination effect in the FTMS CID experiment, the molecular ion of naphthalene was examined with excitation profiles as various experiment parameters were altered. For example, Figure 3 presents control profiles for the ion at different pressures; the FTMS control experiment included a 3 ms delay between ion formation and detection, a 100us single frequency excite pulse, and broadband detection. Data, presented in the form of kinetic energy and excite radius, demonstrates a low pressure maximum at about 1200 eV kinetic energy. As pressure increases, the relative abundance decreases through a loss of ions at higher energy. This is the same effect observed in the CID product excite profiles in Figure 2, and therefore suggests that the CID portion of the experiment is not the source of the mass discrimination.
A delay was inserted between excitation and detection to produce the profiles in Figure 4. These results exhibit similarity to the control profiles in Figure 3. Evidently, the collision-related discrimination effect that occurs at high pressures is related to the portion of the FTMS experiment that follows excitation to higher kinetic energies (or larger radii). Suggestions for the mass discrimination in the CID profiles of Figure 2 are now more clearly defined. One possibility is that at increased radius, radial electric fields are more severe and ions diffuse more rapidly from the cell at higher pressures. However, this effect should not exhibit a mass dependence. Another possibility is that increased scattering of ions occurs at higher energies and higher pressures. If a sufficient increase in z-axis kinetic energy results, ions will be ejected axially. Because low mass ions are more severely scattered, the effect would be mass dependent. Excitation profiles at higher trap potentials do show a reduction in this form of ion loss. The shift in the profile to higher energy at higher trap potentials indicates some fraction of the more energetic ions are retained.

Figure 3

Figure 4
Infrared laser desorption/ionization (LDI)/mass spectrometry of organic molecules is characterized by formation of an abundant \((M+N)^+\) species from gas phase attachment of a proton or metal cation, \(N^+\), to the intact molecule, \(M\). This work is directed toward a better understanding of the mechanisms of ion formation and trapping for detection in the infrared LDI as applied to Fourier transform mass spectrometry (FTMS). The major finding to be presented is that the precursor ion in the cation attachment reaction is not the bare cation, but rather an adduct of the salt. For example, when KBr is mixed with organic samples, \(K_Br^+\) rather than \(K^+\) is found to react with \(M\) to produce \((M+K)^+\). The origin, properties, and reactivities of potassium halide adducts are evaluated. Assuming that adduct formation is a prerequisite for production of abundant \((M+K)^+\), LDI and FTMS conditions are then determined which maximize formation and trapping of these reactive adducts from the pure salts.

All experiments were performed with a FTMS assembled with components that constitute the Nicolet FTMS-2000. These include a 3T superconducting magnet, differentially diffusion-pumped ultrahigh vacuum chamber operating at base pressures in the mid 10^{-9} torr range and adjacent 5 cm cubic dual cells. A Spectra Physics DCR-11 Nd:YAG laser capable of 300 mJ pulses at 1064 nm was interfaced through a probe mounted fiber optic interface to the FTMS. The maximum power density achieved with this fiber optic interface was 3 \times 10^8 W/cm^2 at the sample surface. This value is based on 28 mJ, 9 ns laser pulse focused through the fiber to a spot size of about 900 \mu m on the sample surface. A demountable stainless steel probe tip with cylindrical geometry (20 mm length x 5 mm diameter) was used for all experiments. Two types of samples were prepared. In initial studies with the pure salt, KF, KCl, KBr, and KI salts were dissolved in water and sprayed onto the probe tip. For organic LDI experiments, a sample consisting of a 1:1 mixture of dilaurylthiodipropionate (DLTP) and a potassium dissolved in methanol was aspirated onto the spinning probe tip.

KBr adduct ions have been observed in LDI/TOF studies, but have not been proposed as possible precursors to the \((M+K)^+\) product. However, evidence that \(K_Br^+\) is involved in the FTMS experiment comes from a variable trapping profile in Figure 1 which shows the \(K_Br^+\) is less energetic than \(K^+\), and instead approximates the energy distribution for \((M+K)^+\). Additional work shown in Figure 2 and 3 with the pure potassium salts was conducted to better characterize kinetic energies of the ions formed by LDI. Presented in Figure 2 are the trapping potential profiles for \(K^+\) alone, formed from pure KF, KCl, KBr, or KI. In each case, beyond a threshold which differs for each salt, \(K^+\) is observed in increasing amounts as trapping potential increases. With the exception of KF, this threshold is above that used for most LDI/FTMS work. In Figure 3 both adduct and \(K^+\) are shown for KI at two laser energies. FTMS detection of adducts is observed to increase with laser power densities and explains why \((M+K)^+\) intensity in LDI/FTMS increases with laser power density. The individual salts can be distinguished by the overlap of kinetic energy distributions between \(K_Br^+\) and \(K^+\)--for example, \(K^+\) and \(K_Br^+\) profiles are almost completely resolved while \(K_Br^+\) overlaps with \(K^+\). This suggests that KI would be superior for LDI/FTMS work.

In comparing the four potassium halides, it was desirable to determine which of them generated \(K_Br^+\) in highest yield. As the mixture spectra of adducts in Figure 4 show, relative ranking in terms of peak areas for combined isotopes of each adduct is \(K_Br^+ > K_BrCl^+ > K_Br^2+\), but there is little difference in relative abundance. In considering the origin of the adduct, it is possible that intact \(K_Br^+\) from the desorption site subsequently penetrates the trapping fields and is retained for detection; alternatively, the adduct could be generated in the cell by gas phase attachment of \(K^+\) to the neutral salt or by decomposition from larger adducts. Double resonance experiments were performed to distinguish this. In the absence of an ejection event, both \(K^+\) and \(K_Br^+\) are immediately detected and at longer delays remain in a fixed proportion which is indicative that neither undergoes gas phase reactions. But, when the \(K^+\) is ejected continuously between desorption and detection, the \(K_Br^+\) remains in large abundance. This indicates \(K_Br^+\) is not formed in the cell from \(K^+\). Sample preparation is an important consideration in preferential formation of adduct in the LDI/FTMS experiment. KBr is seen to dominate at 25°C. In contrast, results are for a vacuum chamber heated...
to 170°C and maintained for several hours. In this case, K⁺ dominates under otherwise identical conditions.

Evidence that the adduct, KₓX⁺, rather than K⁺ reacts with M comes from double resonance experiments as shown in Figure 5. In Figure 5a, when K⁺ is continuously ejected to reduce space charge, abundant (M+K)⁺ is seen. In contrast, when Kₓ⁺ is ejected in Figure 5b, no (M+K)⁺ is detected which indicates it is a precursor to the cation attachment process. In order to evaluate whether the higher adducts are also involved in reactions with M, a series of double and triple resonance experiments involving K⁺, KₓF⁺, and KₓF₂⁺ reactions with DLTDP were performed. Here KₓF₂⁺ is observed to be highly reactive.

Ion/molecule Reactions of Externally Produced Metal Ions
In a Quadrupole Fourier Transform Mass Spectrometer

Eric Gard, Sesi McCullough, Carlito B. Lebrilla
Department of Chemistry, University of California, Davis, CA 95616

The External source quadrupole Fourier Transform Mass Spectrometry (QFTMS) instrument, although well suited for ion/molecule reactions, has not been used for this purpose. We are currently investigating the use of the instrument built at U.C. Davis for the formation and reaction of ligated transition metal ions (Figure 1). The instrument has been developed to be versatile for use in both ion/molecule chemistry and analysis. It has both EI/CI and FAB sources. An electrospray source is currently being developed. A split foreline allows introduction of reagent gasses into the source and the analyzer region via either pulsed valves or precision leak valves. High mass range is obtained despite the relatively low (3 tesla) superconducting magnet. Cesium iodide clusters as large as m/z 16241 (CsI)62Cs+ are observed. Resolution of 41,000 for m/z 1692 (CsI)6Cs+ is obtained.1

There were two major concerns on doing metal ion chemistry in the external source instrument with ions produced from a SIMS source. The first was whether low mass ions could be effectively transported from the source to the analyzer cell by the RF only quadrupole broad band mass filter and second was whether the large presence of Cs+ from the cesium gun would simply swamp out any metal ions injected into the analyzer cell. As seen in figure 2 metal ions can be produced and transported into the analyzer cell in large abundance and in the absence of Cs+. We now routinely produce bare transition metal ions using a secondary ion mass spectrometry (SIMS) source from either the neat metal salt or a liquid (glycerol) matrix. Forming ions with this method offers an alternative to laser ablation and electron impact ionization which are currently the most commonly used technique.

The metal ions are trapped and isolated in the analyzer cell and the reagent gas pulsed into the chamber. Argon is used to translationally cool the ions before reaction. Known metal reactions such as the reaction of Fe+, Co+, and Ni+ with alkane (n-pentane) are examined and the branching ratios compared to literature results (Table 1).2 We find little difference between our results and those experiments performed in an FTMS with laser ablated ions. Cooling the ions with argon before the reaction does not significantly vary the branching ratio. There is however evidence that the metal ions are translationally excited when trapped in the analyzer cell. A comparison in the reaction of Fe+ to CH3S-SCH3 with (Figure 3b) and without Ar (Figure 3a) precooling shows dramatic differences in the products formed. By collisionally cooling the metal ions with Ar before the reaction only one ionic species is observed corresponding to Fe(CH2-S)+. Without argon at least four major products are obtained including highly endothermic reactions such as charge transfer (to form the methyl/disulfide cation) and formation of FeSCH3+. Our interest in this reaction is the use of metal ions as a Cl gas to locate the position of S-S bonds in bio-organic molecules.

The SIMS source is ideal for the formation of simple and complex ligated metal ions. These ions will be used to react with organic compounds to determine the effect of ligation on the reactivity of the metal ions. We plan to produce metal complexes with varying denticity as well as types of coordinating atoms. So far ligated metals from simple Co(H2NCH2CH2NH2)+ to metal octaethyl- and tetraphenylporphyrins (M= Fe, Co, Ni, Zn) are readily produced.

Reference

Electrospray ionization (ESI) has made remarkable strides recently as a very soft ionization method for proteins. However, the application of ESI to complex mixtures and the unambiguous determination of mass and charge of daughter ions in MS/MS requires high mass resolution. Fourier transform mass spectrometry (FTMS) can provide that resolution given that detection occurs at pressures below \(1 \times 10^{-1}\) torr. This requires two orders of magnitude further pressure reduction beyond what is typically required in a quadrupole instrument, and requires that the ions be injected from an external atmospheric pressure source through the fringe field of a 3 tesla superconducting magnet. Previous workers (K. Henry and F. W. McLafferty, and J. Shabanowitiz and D. F. Hunt, 38th ASMS, June, 1990, Tucson, AZ) have used a quadrupole operated in the RF-only mode to guide ions to the cell, and have detected multiply charged ions from peptides as large as bovine serum albumin, MW 66,000.

Our design is shown in the figure, and consists of two stages of differential pumping before the analyzer cell of a Nicolet (now Extrel) FTMS-2000. Ions are electrostatically focused through a conductance limit and then into the magnet at 500 eV, followed by deceleration just prior to the cell. The ion optics were designed with the aid of MacSimion (D. McGilvery and R. Morrison, Monash University, Centre for High Resolution Spectroscopy and Opto-Electronic Technology). At present, while electrospraying water-methanol-acetic acid, 50 picoamps reach the skimmer, up to 5 picoamps pass through, and of this, up to 3 picoamps reach the FTMS cell. Pressures are 0.4 torr before and 4x10^{-4} torr after the skimmer, respectively, and 1x10^{-5} torr in the analyzer cell region. This is with a 4 mm orifice into the cell region. Reducing this and the skimmer orifice while increasing the diameter of the capillary should lower the pressure by a decade and increase the current by at least a decade. This increased current, coupled with improvements in the kinetic energy distribution of the transmitted ions, should allow ions to be trapped and mass analyzed in the FTMS.

NOVEL REARRANGEMENT OF SiH(CH₃)(C₂H₅)⁺ TO Si(CH₃)₃⁺  

R. Bakhtlar, C. M. Holznagel, and D. B. Jacobson  
Department of Chemistry, North Dakota State University  
Fargo, ND 58105-5516

Organosilicenium ions (SiR₃⁺) are highly reactive in the gas phase with a number of interesting rearrangements observed[1]. The facile elimination of ethene for CAD of Si(CH₃)₃⁺, process 1, is particularly intriguing[2]. We have studied the mechanism of rearrangement of simple organosilicenium ions by using Fourier transform mass spectrometry (FTMS) in conjunction with isotopic exchange/labeling and CAD. Our results suggest that SiH(CH₃)(C₂H₅)⁺ can readily rearrange to the more stable Si(CH₃)₃⁺ ion, presumably by a concerted 1,2-methyl/1,2-hydrogen migration (dyotropic rearrangement), process 2[3].

Si(CH₃)₃⁺ + C₂H₄ → SiH⁺ + CH₃CH₂⁺  

(1)

Si(CH₃)₃⁺ is inert with ethene-D₄ however, SiH(CH₃)₂⁺ undergoes exclusively one facile H/D exchange, process 3. Both Si(CH₃)₃⁺ and SiH(CH₃)₂⁺ are inert with ethene-¹³C₂. The H/D exchange in process 3 presumably proceeds by reversible ethene insertion/β-hydrogen migration, process 4. The above results suggest that SiH₂(CH₃)⁺ should yield two exchangeable hydrogens with ethene-D₄. Surprisingly, all five H's in SiH₂(CH₃)⁺ are rapidly exchanged with C₂D₄. The H/D exchange for SiH₂(CH₃)⁺ must proceed via two distinct mechanisms, one where the Si-H's are exchanged (process 4) and one where the methyl-H's are exchanged. In addition, SiH₂(CH₃)⁺ undergoes facile carbon atom exchange with ethene-¹³C₂.

How can these dramatic differences between these seemingly similar silicenium ions be rationalized. We propose that this scrambling for SiH₂(CH₃)⁺ with labeled ethene involves initial insertion into an Si-H bond yielding an ethylmethylsilicenium ion. This activated ion subsequently undergoes concerted 1,2-methyl/1,2-hydrogen migration (dyotropic rearrangement), presumably via a four centered transition state, 1, that is a thermally
allowed \([O^+ + \text{Si-CH}_2]\) process. 1 requires that the methyl group migrates with inversion. \(\text{Si-CH}_3\) is not sterically hindered and does not require the involvement of d orbitals or the empty p orbital on silicon. The facility of the isotopic exchange demands a low barrier for the rearrangement, process 2. The driving force for process 2 is the increase thermal stability of \(\text{Si(}\text{CH}_3\}_3\)\(^+\) (~17 kcal/mol).

We now have to address the fact that reaction of \(\text{SiH(CH}_3)_2\)\(^+\) with labeled ethene does not result in isotopic exchange of the methyl groups. Here, initial ethene insertion would generate an ethyldimethylsiliconium ion. A thermally allowed \([O^+ + \text{Si-CH}_2]\) can proceed in analogy to \(\text{H}_2\) where the migrating hydrogen atom is replaced with a methyl group. Again, this concerted migration would not be sterically constrained. There must, however, be a prohibitive barrier for this rearrangement since it is not observed. We believe that there is a prohibitive barrier to this process, presumably do to the smaller size of the sp\(^3\) hybrid orbital on the methyl relative to the H 1s orbital.

\(\text{SiH(Cl)(CH}_3\}_3\)\(^+\) behaves analogously to the \(\text{SiH(CH}_3)_2\)\(^+\) ion yielding only one H/D exchange with ethene-D\(_4\).

TRIMETHYLSILYL GROUP MIGRATIONS IN ELECTRON IMPACT
MASS SPECTRA OF CHOLESTEROL OXIDES:
MECHANISTIC INTERPRETATIONS AND PRODUCT CHARACTERIZATION

Meg Annan, Phillip W. LeQuesne, Paul Vouros;
Department of Chemistry, Northeastern University, Boston, MA 02115

It is well known that the migratory aptitude of the trimethylsilyl (TMS) group is high and that it will migrate to a suitable electron rich site via a wide range of intermediate ring sizes. In fact, TMS migrations have been shown to be more competitive than hydrogen migrations. As expected, such migrations have been observed in the EI mass spectra of semi-rigid sterols where the TMS group and the electron rich site are arranged such that a 6-membered ring transition state is clearly available. Brooks and co-workers have, however, demonstrated the migration of the TMS group in the EI mass spectra of a number of \(\Delta^3\)-3-fraction-stereoids. The migration was proposed to occur over 5 atomic centers in a conformationally rigid system and precede A-ring cleavage. We report a variation of this decomposition in the EI mass spectra of cholesterol autoxidation products. The TMS group has been observed to migrate to electron rich functional groups in the 6 and 7 position of the B-ring. Tandem mass spectrometry was used to examine the nature of the ion produced from the intramolecular TMS group transfer. High and low energy collision induced dissociation (CID) and isotope labelling were employed to confirm and elucidate this process.

All high energy CID experiments were performed on a VG-70/250SE double focussing mass spectrometer using B/E linked scanning. The laboratory collision energy was 8KV and the collision gas was Helium. All low energy CID experiments were performed on a VG-QUATTRO triple quadrupole mass spectrometer. The laboratory collision energy was 70V and the collision gas was Argon.

TMS migration has been observed in the EI mass spectra of cholestan-5\(\beta\),6\(\alpha\)-epoxy-3\(\alpha\)-ol (\(\alpha\)-epoxide), cholestan-5\(\alpha\),6\(\alpha\)-epoxy-3\(\alpha\)-ol (\(\alpha\)-epoxide), 5\(\alpha\)-cholestan-3\(\alpha\)-ol-6-one (6-keto), 5\(\alpha\)-cholestan-3\(\alpha\)-ol-7-one (7-keto), and cholestan-3\(\alpha\),5\(\alpha\),6\(\alpha\)-triol (triol). The TMS migration is believed to precede A-ring fragmentation and result in the loss of 71 amu in the case of the triol, 6-keto, and epoxides. The same is believed to occur in the case of the 7-keto. The TMS migration, however, is instead associated with the loss of 69 amu. The mechanism for the 6-keto, epoxides, and triol are thought to be the same, while that for 7-keto is thought to be different. Two different structures for the resultant m/z 403 ion are, therefore, expected. They are shown in Figures 1a and 1b.

The migration of the TMS group as well as the proposed mechanisms are in agreement with mass shifts in the EI spectra of the 2,2,4-\(\Delta\)-, the d\(9\)-TMS, and the \(18\)O labelled analogues. The high energy CID spectra of the products of migration in the epoxide, 6-keto, and the triol also support the proposed mechanism. The CID spectrum of the product ion from the triol is shown in Figure 2 and is representative of the others. Based on the proposed mechanism the 6-keto, triol, and \(\alpha\)-epoxide are expected to yield the same fragment ion structure. The similarity of the CID spectra from these compounds supports this expectation. The fragmentation is primarily confined to loss of the side chain and cleavage through the rings C and D. Furthermore, the limited amount of cleavage involving the TMS group or the B-ring indicates charge stabilization in that region. In contrast, the product of TMS migration in the 7-keto is expected to have a structure in which the charge delocalization is not so extensive. That a structural difference exists is apparent in the comparison of the CID spectrum from 7-keto in Figure 3 with Figure 2. The striking suppression of all but one of the charge remote cleavages and the intensity of the ion at m/z 313 resulting from loss of trimethylsilanol is indicative of a structure such as that proposed in Figure 1b. The loss of TMSOH is expected to be intense since it would result in aromatization of the B-ring.

The difference between the low energy CID spectrum of 7-keto and those from the 6-keto, epoxide, and triol is still pronounced, with the 7-keto yielding an intense peak at m/z 313 from the loss of TMSOH. In general, however, the low energy fragmentation appears to yield primarily low mass ions below mass 200. This suggests that at low collision energy rearrangement as well as charge induced fragmentation is favored.

In conclusion, the migration of the TMS group to various electron rich sites on the B-ring has been confirmed by isotope labelling and B/E linked scanning. Furthermore, high and low energy CID of the product has provided useful information regarding the mechanism of the migration / fragmentation sequence.

A CID AND METASTABLE ION STUDY OF M/Z 84 IONS FORMED FROM 2-ETHYLPIPERIDINE, N-(2-
HYDROXYETHYL)PYRROLIDINE, N-METHYL-2-HYDROXYMETHYLPIRROLIDINE AND n-
BUTYL(BENZYLIDENE)AMINE

Yee-Chung Ma and Burnaby Munson, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716
Russell C. Spreen, ICI Americas Inc., Wilmington, DE 19897

Relatively few mass spectrometric studies have been made for organic Schiff bases as compared with other classes of organic compounds. Many interesting rearrangement decomposition ions exist in the El mass spectra of alkyl(benzylidene)amines, C6H5CH=N-R, for example, the m/z 84 ion (loss of C6H5) formed from n-butyl species (R = n-C4H9, compound I) and the m/z 160 ion (loss of CH3, when R is n-pentyl; loss of C2H5, when R is n-hexyl, etc.). Two independent mechanisms have been postulated for the formation of the m/z 84 and m/z 160 ions (1)

An alternative mechanism involving competing decompositions might be operative:

This study compared the daughter ion spectra (metastable and collisionally induced decompositions (CID)) of m/z 84 ions formed from compound I and those formed from electron ionization of (a) 2-ethylpiperidine, (b) N-(2-
hydroxyethyl)pyrrolidine and (c) N-methyl-2-hydroxymethylpyrrolidine to provide the insights of the ions structure.

Experiments were performed with a VG 70-VSEQ triple sector (E/B/q/Q) instrument. Samples were separated from a mixture with an HP 5890 gas chromatograph. Mass spectrometer conditions: source temp. = 205 °C; high energy CID in the first field free region with He as the collision gas at 60 % attenuation; low energy CID in the third field free region, 15 eV collision energy, -6 x 10^-4 mbar Xe. Samples: (a)-(c) commercially available, compound I was prepared from reaction of equal molar amounts of benzaldehyde and n-butylamine.

The formation of m/z 84 in the El mass spectrum of compound I involves a rearrangement process (1). Several structures are possible for this m/z 84 ion, i.e.

(a1)-(c1) give easily distinguishable daughter ion spectra from linked scan (metastable decompositions), high energy CID and low energy CID. Ionization energy does not have any significant effect on the spectra. The daughter ion spectra are not available for ion (d1). The m/z 84 ion formed from compound I gives daughter ion spectra similar to (a1). Low energy CID shows differences in the relative abundances of m/z 54, m/z 55 and m/z 69 etc. At 70 eV ionization energy, the differences are fairly small, ca. 10 % of m/z 56. The differences increased when ionization energy was decreased. This result suggests that at high ionization energy, the m/z 84 ion formed from compound I may have main structure of (a1), instead of our suggested structure (b1). At low ionization energy, another structural isomer may also formed. One possible structure is (d1), the previously suggested structure, since any linear combination of (a1) with (b1) or (c1) ion will not fit the CID data.

It was found that low energy CID spectrum of m/z 84 ion formed from n-butyl(acetylidene)amine, C6H5CH=N-C4H9, is indistinguishable from that of (a1). The formation of stable (a1) ions is a common process for both C6H5CH=N-C4H9 and C6H5CH=N-C4H9. Further studies are necessary to determine the structure of m/z 160 ions in higher alkyl species.
Suggested mechanism for the formation of (a1) from compound I:

Reactions of V⁺ With Small Heteroatom Containing Molecules
R. Marshall Pope, Steven L. VanOrden, Steven W. Buckner, Department of Chemistry, University of Arizona, Tucson, AZ, 85721

Introduction
We report here on the reactivity of atomic vanadium cation with water, small alcohols, and amines. V⁺ has been previously observed to activate C-H bonds in hydrocarbons. We have studied the product distributions, kinetic isotope effects, and subsequent reactions for these small molecules and observed some expected and some interesting behavior.

Experimental
All experiments were performed on a Fourier transform ion cyclotron resonance mass spectrometer. Atomic vanadium cations were generated by focusing the fundamental output of a Spectra-Physics pulsed Nd:YAG laser (pulse energies of ~135 mJ) on pure metal blocks. Reagent pressure in the vacuum chamber was ~5-8x10⁻⁶ torr (uncorrected). After initial ionization, the metal ions were trapped for 200-400 msec to allow for collisional and radiative cooling. After the cooling period the ions were isolated by swept double resonance ejection pulses. This cooling period should allow for nearly complete translational cooling (35-70 collisions).

Results
The reactions of V⁺ react with water via three primary reaction pathways, formation of VO⁺, VOH⁺, and VH₂O⁺, with formation of the oxide being the dominant pathway. The reaction to produce VH₂O⁺ exhibits an isotope effect, indicating the complex formed in the low pressure environment of the FT-ICR has a bond inserted structure. The overall reaction exhibits a normal kinetic isotope effect. The secondary reactions differ from the primary reactions in that VOH⁺, which is the most reactive primary ion, produces predominantly V(OH)₂⁺ with only a small amount of V(OH)O⁺. This is due to electronic saturation effects, as shown in scheme I. V(OH)₂⁺ subsequently attaches three molecules of water, reaction (1). The primary reaction to form VOH⁺ implies D(V⁺-OH)>118 kcal/mol.

The reactions with methanol produce the metal oxide, metal hydroxide, and metal alkoxide. A partial breakdown of the reactions with V⁺ is shown in Figure I. In contrast to methanol which does not undergo a 1,2 dehydrogenation pathway in the primary reactions, ethanol reacts via a 1,2-dehydrogenation mechanism to produce V(acetaldehyde)⁺. Methylamine reacts to (1) generate the amide (2) via a 1,2 hydrogen migration to produce the imine (VNH⁺). Similar behavior is observed for ethylamine. As for all molecules reported in this study, extensive subsequent reactions are observed with V⁺.
\[ \text{Scheme I} \]
A mass spectrum can be considered to be the result of a kinetics experiment. It is a convolution of a series of competitive and consecutive reactions that depend upon the internal energy deposited during ionization and the time-frame during which reactions can occur. The complexity of many mass spectra generated by electron ionization results from the fact that a range of internal energies are deposited by the ionization event and that reactions can occur over six or more orders of magnitude of time, i.e. from $10^{10}$ to $10^{6}$ seconds on traditional beam (sector and quadrupole) instruments. For ion trapping instruments this time range is increased by several more orders of magnitude since the mass analysis generally occurs some milliseconds or more after the ionization event in these instruments. In general, nevertheless, EI spectra on trapping instruments and beam instruments are quite similar if the experiments are done appropriately.

The same kinetic considerations apply to MS/MS experiments. However, the differences in time-scale between trapping and beam instruments may have more of an effect upon MS/MS spectra. There are two potential effects resulting from the different time scales. The first of these is the internal energy/structural distribution of the parent ions. In the trapping instruments parent ions must be stable for milliseconds as opposed to microseconds for beam instruments. Therefore parent ions that are "metastable" in beam instruments are unstable in trapping instruments. For ion trapping instruments this time range is increased by several more orders of magnitude since the mass analysis generally occurs some milliseconds or more after the ionization event in these instruments. In general, nevertheless, EI spectra on trapping instruments and beam instruments are quite similar if the experiments are done appropriately.

There are two possible effects of the difference in the dissociation "time-window". The first of these is that the much shorter time window in beam instruments may favor observation of faster reactions such as simple cleavages as opposed to rearrangement reactions. The other possible effect is that the several orders of magnitude longer dissociation time-window in trapping instruments may allow much higher MS/MS efficiencies due to the longer "integration" time for the dissociation.

Figure 3 shows an example in which the faster, simple cleavage reactions are substantially enhanced in the TSQ MS/MS spectrum. The parent ion in this example is (M-H)$^+$ from N,N-dimethylaniline. The simple cleavage ions are m/z 105 (loss of methyl radical) and m/z 77 (loss of CH$_3$N+). All the other ions are the result of rather complex rearrangements. These simple cleavage ions dominate the MS/MS spectrum if more internal energy is put into the parent ion by using Ar instead of He as the collision gas.

While it can be argued that the simple cleavage ions are enhanced in the beam instrument due to internal energy considerations, the relative intensity of the rearrangement ions is substantially different between the two instruments and these relative intensities are very insensitive to collision energy in each instrument. This is shown in Figure 4 which are plots of the relative intensity of three major rearrangement ions in the ion trap experiment and absolute intensity of these ions in the TSQ 700. Another pertinent difference in the MS/MS spectra of this species obtained on the two different instruments is the MS/MS efficiency. The MS/MS efficiency for the ion trap is an order of magnitude greater than that for the TSQ.
As parent ions get larger and larger the dissociation time-window may be even more important since there will be an ever increasing kinetic shift due to the increase in the number of degrees of freedom. A specific case in which this may be significant is in the dissociation of peptides. While the critical energy for a given type of dissociation (i.e. a,b,y, etc.) should not be dependent upon the size of the peptide, the amount of excess internal energy required for the dissociation to occur within the dissociation time-window will increase with increasing mass. Our observation with small protonated peptides is that very similar dissociations are observed in the ion trap as with quadrupole instruments but that the ion trap MS/MS efficiency usually approaches 100% whereas the quadrupole efficiencies are typically a few percent. The most striking difference we have thus far observed is for leucine enkephalin-Arg. While spectra of this compound obtained on beam instruments are consistent with the general observation that a terminal arginine can drastically affect the dissociation pathways, in the ion trap MS/MS spectrum the dissociation pathways differ little from those of leucine enkephalin, with all the typical sequence ions being observed. Additionally, the ion trap has ≈100% MS/MS efficiency while the beam instruments have efficiencies < 10%.

The interaction of \( p \)-benzoquinone (Q) with electrons has been studied extensively in the gas phase. A particularly interesting characteristic of Q is that it undergoes electron capture, reaction 1, extremely slowly, despite its high electron affinity (1.9 eV). We have investigated two gas phase photochemical reactions involving Q, methyl-\( p \)-benzoquinone (MQ), 2,6-dimethyl-\( p \)-benzoquinone (DMQ), and tetramethyl-\( p \)-benzoquinone (TMQ), and the molecular anions of these molecules at atmospheric pressure using a modified electron capture detector (ECD) and atmospheric pressure ionization mass spectrometry (APIMS). Electron photodetachment (PD), reaction 2, from the molecular anions is observed in the UV-visible spectral range. In addition, electron capture enhancement (ECE), reaction 3, by the neutral molecules is observed when light of specific wavelengths is passed through the ECD. Although these two processes occur simultaneously over a portion of the UV spectrum, we have developed a method that allows the study of either of these reactions without interference from the other. Therefore, the ECE spectra of the quinone molecules and the PD spectra of the quinone anions can be independently determined and are reported here. We also report APIMS measurements which show that within the ECD, a photochemical dimerization of Q takes place which is responsible for the ECE by these molecules.

The modified ECD is shown in Figure 1. The compounds are introduced to the ECD by means of a gas chromatograph. A 1000 W Xe arc lamp, an optical chopper operated at 5Hz and a high throughput monochromator are used to focus a chopped light beam with a 20 nm bandwidth into the ECD cavity. The current signal from the ECD is processed by the electrometer and is sent to pen 1 of the recorder and also to the lock-in amplifier (LA) as shown. In the LA, the electrometer signal is mixed with the square waveform coming from the chopper. The phase angle offset of these two waveforms may be adjusted manually or optimized internally by the LA. The resulting product is sent to pen 2 of the recorder. Thus, pen 1 provides a response, \( \delta_{\text{ECE}} \), that is closely related to a normal ECD response, while pen 2 provides a response, \( \delta_{\text{PD}} \), due to any photochemical processes occurring within the ECD.

At wavelengths near 300 nm, both PD and ECE occur within the ECD simultaneously. We were able to obtain the PD and ECE spectra independently and without interference from each other by careful manual control of the LA phase angle offset (\( \delta \)). Typical chromatograms are shown in Figure 2. Beneath the chromatograms are included simulations of the two waveforms sent to the LA and the manually chosen \( \delta \) for that measurement. In A, the ECE signal is maximized with a \( \delta \) of -90° and in B, it is zeroed with a \( \delta \) of 0°. Thus, when the PD signal is maximized, the ECE signal is zeroed, and vice versa. The reason for the difference in \( \delta \) for the two processes is that the PD rate constant of 300 s\(^{-1}\) is fast when compared with the chopping frequency of 5Hz, while the ECE signal changes very slowly. At 5Hz, the PD signal assumes the shape of a square wave and closely tracks the reference square wave. The optimal \( \delta \) for PD is therefore 0°. However, the triangular waveform of the ECE signal must be shifted by -90° to obtain optimal mixing with the reference square wave in the LA.

The PD spectra of the molecular anions are shown in Figure 3. In A, in addition to the PD spectrum for Q\(^{\prime} \), the known condensed phase absorption spectrum of Q is shown. The peaks in the PD spectrum resemble those in the absorption spectrum closely, because in the regions where Q\(^{\prime} \) absorbs strongly, resonance PD occurs. The ECE spectra of the molecules are shown in Figure 4. In Figure 5, the known condensed phase absorption spectra for the neutral molecules are shown for comparison with the ECE spectra. All of the molecules show the most pronounced ECE at \( \lambda_{\text{ECE}} \).

MQ and DMQ also show weak ECE at X, which show that within the ECD, a photochemical dimerization of Q takes place which is responsible for the ECE by these molecules. The mechanism responsible for ECE was elucidated using negative ion APIMS. The setup of the APIMS experiment is shown in Figure 6. The optical setup is identical to the previous experiment except that no optical chopper is used. The ion source is a modified ECD similar to the ECD in the previous experiment. For better signal intensities, a low resolution was used during acquisition of mass spectra. The mass spectrum of Q acquired with the arc lamp turned off is shown in Figure 7A and exhibits only one peak at m/z 108, which corresponds to the molecular ion, Q\(^{+} \). Figure 7B shows the mass spectrum taken with the arc lamp turned on and the monochromator set at 240 nm. The base peak at m/z 108 corresponds to Q. The large peak at m/z 216 is thought to be due to Q\(^{\prime} \), the negative ion of a dimer of Q. The mechanism for formation of Q\(^{\prime} \) is believed to be a simple photochemical 2+2 cycloaddition between two molecules of Q. Q\(^{\prime} \) is thought to have an electron capture rate coefficient that is several orders of magnitude greater than that for Q. The ECE response is therefore explained by reaction 4, in which Q is excited to Q\(^{\prime} \) by absorption of a UV photon. It then dimerizes with a ground state Q to form Q\(^{\prime} \), which rapidly captures an electron. It is believed that ECE by MQ, DMQ, and TMQ is also due to formation of dimers that have higher electron capture rate coefficients than the monomers.

Our research efforts have been directed at understanding the mechanism of one-electron reduction of polychlorodibenzo-p-dioxins (PCDDs) under electron capture negative ionization mass spectrometry (ECNI-MS) conditions. We have shown, for example, that there exist a linear correlation between the branching ratio $\log \left( \frac{[M-Cl]}{[Cl]} \right)$ and the LUMO energy for the PCDDs and polychlorinated dibenzofurans (PCDFs) under ECNI-MS conditions (1). A subsequent study has also shown that a linear correlation exists between the branching ratio $\log \left( \frac{[M-Cl]}{[Cl]} \right)$ and the energy of the products formed when PCDDs were subjected to ECNI-MS conditions (2). It was hypothesized that the one-electron reductive dehalogenation of PCDDs under ECNI-MS conditions could be regioselective (3). Testing this hypothesis required the synthesis of chlorine-37 labeled PCDDs (4).

Isotope enrichments were calculated using an in-house program. The algorithm seeks to minimize the Chi-square between a synthetically generated isotopic pattern based on a modified binomial expansion and the experimental data (4,5). The relative abundance of chloride ion ejected from each position was determined from the observed $^{35}Cl/^{37}Cl$ ratio by solving the following simultaneous equations (5).

$$ax + cy = I_{35}$$
$$bx + dy = I_{37}$$

$I_{35}$: Relative intensity of $^{35}Cl$ in the NCI mass spectrum.
$I_{37}$: Relative intensity of $^{37}Cl$ in the NCI mass spectrum.
$c$: Relative abundance of $^{35}Cl$ at the labeled position.
$d$: Relative abundance of $^{37}Cl$ at the labeled position.
$a$: Relative abundance of $^{35}Cl$ at the unenriched positions.
$b$: Relative abundance of $^{37}Cl$ at the unenriched positions.

$$a = 0.757n$$
$$b = 0.243n$$

$n$: Number of natural chlorines present in the molecule.
$x$: Relative chloride ion loss from unenriched position(s).
$y$: Relative chloride ion loss from the labeled position.

Our results clearly show that the one-electron reductive dehalogenation of PCDDs under ECNI-MS conditions is regioselective. The process does not exhibit any primary kinetic isotope effect. This is illustrated by the equal chloride ion loss from the unenriched and labeled position in the symmetrical dichlorodibenzo-p-dioxin (DCDD) isomer (see Figure 1).

The most interesting results are those found for the reductive dehalogenation of 1,2,3,7,8-PCDD and 1,2,3,4,7,8-HexCDD. Under ECNI-MS conditions, chloride ion loss from a position (ortho to the oxygen) is predominant in both cases. Thus, the reductive dehalogenation of 1,2,3,7,8-PCDD yields the extremely toxic 2,3,4,8-TCDD; while the 1,2,3,4,7,8-HexCDD would afford 1,2,3,7,8-PCDD upon loss of a chlorine atom. This tends to support the view that the reductive dehalogenation of toxic PCDDs does not necessarily lead to a less toxic product.

COMPEITION BETWEEN S_N2 AND PROTON TRANSFER; 
ANIONS REACTING WITH THE CHLOROMETHANES

Xueheng Cheng, Marc Mosbacher and Joseph J. Grabowski; 
Department of Chemistry, Harvard University, Cambridge, MA 02138.

Proton transfer (PT) and nucleophilic substitution (S_N2) are among the most important chemical transformations. We were interested in exploring the competition between PT and S_N2 reactions and the effects of anion structure and reaction exothermicity. The chloromethanes were chosen because the simplicity of this neutral system; there are generally no energetically accessible channels available other than PT and S_N2. By combining the data for reactions of monochloromethane which have been extensively studied [1,2], the complete picture of the chloromethane system can be assembled. The reactions were carried out in a flowing afterglow at room temperature.

For dichloromethane (CH_2Cl_2) reacting with anions of decreasing basicity, the fraction of S_N2 product remains low (~5%) until PT is close to thermoneutral and the S_N2 process becomes predominant (Figure 1). Delocalized anions react slower than localized anions with similar basicity but the PT/S_N2 ratio are essentially the same.

In the case of chloroform (CHCl_3), independent of the nature of the anions, proton transfer and the adduct formation when PT is endothermic, are essentially the only observed processes. Very slow formation of S_N2 product is observed only when PT is shut off completely by reaction endothermicity.

In the reaction of anions with carbon tetrachloride (CCl_4) where there is no proton transfer channel available, the formation of CI^- is also very slow except for NH_2^- and C_3H_5^-.

A new and interesting channel opens up which is the substitution at Cl. This new channel is very fast and constitutes the major products for NH_2^-, C_3H_5^-, O^- and EtO^- while in the case of OH^-, F^- and HS^-, substitution at Cl is quite slow and the major products are the formation of the adduct (Table 1).

Comparing the reaction of all chloromethanes revealed that S_N2 process competes with PT favorably in CH_3Cl, less favorably in CH_2CH_2 and poorly in CHCl_3 (Table 2 shows a typical set of data). Because exothermic PT are generally fast, the decrease of S_N2 yield on increasing Cl substitution must reflect the decrease in S_N2 efficiency which is supported by reactions of CCl_4 with anions other than NH_2^- and C_3H_5^-.

This decrease of S_N2 efficiency with increasing Cl substitution may have electronic origin or more likely, steric origin caused by the bulky electron crowd around Cl.

The results of the reaction of CH_2Cl_2 with anions reflect the interplay among the following factors: (1) PT has lower kinetic barriers than S_N2; this dictates the low fraction of S_N2 product. (2) PT is generally less exothermic than S_N2 for the same anion which causes the sharp increase in the S_N2/PT ratio when PT becomes thermoneutral. (3) Electron delocalization in the anions slows down both reaction channels.

The observation of the facile process of substitution at Cl in CCl_4 is very interesting because this is an uncommon type of reaction and the leaving group here is a carbon base. The fast formation of Cl^- in the reaction of CCl_4 with NH_2^- and C_3H_5^- may be due to the dissociative electron transfer rather than a S_N2 process (Figure 2). The abundant amount of adduct formed in reaction of OH^-, RO^-, F^- and HS^- with CCl_4 may serve as a convenient way of preparing those clusters for CAD experiments.

Tetranitromethane (TNM), a commercially available, stable liquid, has been shown to be very reactive towards electrons and reducing agents in the liquid phase. In addition, TNM is used in the condensed phase to label tyrosyl residues on proteins, to inactivate certain enzymes and has been examined as an oxidizer for liquid rocket propellants. We were led to examine the reactions of this intriguing compound for a number of reasons, including the wide-ranging utilization of the molecule and the paucity of mechanistic understanding of its reactions. We are always on the lookout for new chemical reagents that can be used to identify structural properties of gas-phase ions; the utilization of TNM to identify carbanionic intermediates in enzymatic chemistry suggested that TNM might be useful in the gas-phase as well. We have therefore examined the thermally-equilibrated (300 K), gas-phase ion-molecule reactions of TNM with a large number of anions by means of the flowing afterglow technique.

All the reactions of anions with TNM studied in this work are fast; representative rate coefficients are shown in Table 1. Three different product ions have been observed for the various reactant ions that have been examined; \( \text{C(NO}_2\text{)}_3 \) is generally the most abundant product ion and is the sole product ion for many reactions. The second most common product ion is NO\(_2^+\); this primary product ion also undergoes a facile secondary reaction with TNM to yield additional \( \text{C(NO}_2\text{)}_3 \). Four of the reactant ions (F\(^-\), PhC=C\(^-\), CN\(^-\), and Cl\(^-\)) also produce various amounts of an ion of form \( \text{NuC(NO}_2\text{)}_2^-\).

A typical reaction scheme, that for the reaction of Cl\(^-\) with TNM is shown in the Figure. Similar schemes can be written for each reactant ion examined. Two competitive processes are necessary to account for the observations; the first-formed ion neutral complex \( [\text{Cl}^- + \text{C(NO}_2\text{)}_3] \) can either undergo dissociative electron transfer followed by breakup to yield the major product ion, trinitromethide, or it can undergo an \( S_2^1 \) process to yield a product ion-neutral complex of chlorotrinitromethane and NO\(_2^-\). This latter product ion-neutral complex can simply dissociate to give the observed NO\(_2^-\) or it can undergo a second dissociative electron transfer followed by complex dissociation to give the chlorodinitromethane anion. Independent generation of NO\(_2^-\) and examination of its reactions with tetranitromethane confirm the secondary reaction indicated in the Figure. All reactions postulated in

the Figure are thermochemically allowed and are consistent with all relevant observations and literature data. Two processes that might have been included in the Figure have been omitted. While there are reports that tetranitromethane does have a bound molecular radical anion, under the conditions of our room-temperature swarm experiment, we never found a trace of that species; hence the molecular radical anion of TNM, as either a distinct product or even as a postulated reaction intermediate has been omitted from the scheme. The second mechanistic omission is a pathway to produce the trinitromethide anion by way of an addition-elimination process; addition of the nucleophile to the nitrogen to form a tetravalent nitrogen adduct followed by elimination of \( ^1\text{C}(\text{NO}_2)_3 \). This latter pathway, while not formally excluded from occurring has no precedent and is not necessary to account for the structure-reactivity trends observed.

\[
\begin{align*}
[\text{Cl}^- + \text{C(NO}_2)_4] & \xrightarrow{\text{det}} [\text{Cl}^- + ^1\text{C}(\text{NO}_2)_3 + \text{NO}_2^-] \\
& \xrightarrow{\text{S}^2} [\text{ClC}(\text{NO}_2)_3 + \text{NO}_2^-] \\
& \xrightarrow{\text{m}z 46} [\text{ClC}(\text{NO}_2)_3^- + \text{NO}_2^-] \\
& \xrightarrow{\text{m}z 139} \text{ClC}(\text{NO}_2)_3^- + \text{NO}_2^- + \text{NO}_2^- \\
\end{align*}
\]

The structure-reactivity trends observed can be summarized as follows. All weakly nucleophilic species (HgCsCH-CHa", I", etc.) give exclusively trinitromethide anion. The excellent nucleophiles but which have moderate electron affinities, (H2N", MeO", etc.) give trinitromethide as the major product but also yield some NO2". The good, sterically small, nucleophiles which also have strongly bound electrons give varying amounts of the third product, NuC(NO2)_2" as well (eg., 50% from F", 100% from CN", 9% from Cl"). The acidity of trinitromethane is below 327 kcal mol\(^{-1}\), making this molecule a very strong carbon acid. Tetranitromethane also appears to be an efficient "plasma modifier", since it is able to convert free electrons and many common anions into very unreactive inert anions, (i.e., either di- or trinitrosubstituted methide). Tetranitromethane does not appear to be a useful probe for gas-phase anion structure since all types of anions give essentially the same products. Other experiments have also shown that \(^1\text{C}(\text{NO}_2)_3\) clusters to typical organic molecules only slowly in the flowing afterglow (0.30 Torr helium environment), hence even though trinitromethide anion can be produced in copious amounts, it does not appear to be a great candidate for a NICIMS clustering-type reagent ion.

The synthesis of ammonia from $N_2$ and $H_2$ over an iron-oxide catalyst (Haber process) is an important industrial reaction. This process proceeds by

$$N_2 + 3H_2 \rightleftharpoons 2H_3 \quad (1)$$

initial dissociation of $N_2$ on the catalyst followed by a complex sequence of events leading to ammonia synthesis. Important species include surface bound $N$, $NH$, $NH_2$, $N_2H$, and $N_2H_2$. The chemistry of these intermediates is not well understood. We have applied Fourier transform mass spectrometry (FTMS) to generate intermediates of relevance to ammonia synthesis and subsequently characterized their properties (i.e., structure, rearrangements, etc.).

We have found a convenient route to the generation of $MM'\text{ONH}^+$ and $MM'\text{N}_2\text{H}_2^+$ ions ($M, M' = \text{Fe, Co, Ni}$) and have focused our attention on the $MM'\text{N}_2\text{H}_2^+$ species.

The $MM'\text{N}_2\text{H}_2^+$ are generated by sequential reaction of the corresponding dioxide with ammonia, process 2. There are several possible structures for $\text{MM'N}_2\text{H}_2^+$, structures 1-4. The structure of the $MM'\text{N}_2\text{H}_2^+$ ions was probed by monitoring isotopic exchange reactions with both N-ammonia and deuterated ammonia. In addition, collision activated dissociation (CAD) was also informative.

The specific ions studied include $\text{FeCoN}_2\text{H}_2^+$, $\text{FeNiN}_2\text{H}_2^+$, $\text{CoNiN}_2\text{H}_2^+$, and $\text{Co}_2\text{N}_2\text{H}_2^+$. All four ions undergo a single facile nitrogen atom exchange with $15N$-ammonia, process 3. This clearly indicates two distinct and non-interconverting types of nitrogen atoms. In addition, all four ions undergo exchange of both hydrogen atoms with $\text{ND}_3$ indicating that both hydrogens are chemically equivalent.

CAD of the $MM'\text{N}_2\text{H}_2^+$ yield three primary fragmentation, reactions 4-6, with elimination of $\text{N}_2\text{H}_2$ the dominant channel. $\text{FeCoN}_2\text{H}_2^+$ yields exclusively
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

\[ \text{process 6, FeN}_2\text{H}_2^+ \text{ and Co}_2\text{N}_2\text{H}_2^+ \text{ processes 4 and 6, and CoN}_2\text{H}_2^+ \text{ processes 4, 5, and 6.} \]

\[ \text{CAD of the product of reaction 3 yields exclusive loss of the} \]

\[ \text{N label for process 5.} \]

The isotopic exchange results combined with the CAD results are consistent with a nitrido-amido structure, for all four MM'N\text{H}_2^+ ions. The elimination of N\text{H}_2, presumably diazene, requires significant rearrangement prior to fragmentation.
A growing body of synthetic methodology has been developed in the last two to three decades which involves the use of stoichiometric or catalytic amounts of transition metals to mediate carbon-carbon bond forming reactions. Palladium-catalyzed cross-coupling reactions have become increasingly useful for the mediation of reactions of electrophiles which have sp or sp² carbons at or immediately adjacent to the electrophilic center. During a program directed toward the development of Group 10 metal complexes which would catalyze carbon-carbon bond formation using primary neopentyl electrophiles, we were attracted to a recent report claiming that dichloro-1,1'-bis(diphenylphosphino)ferrocenylpalladium(II) (dppf/PdCl₂) will effectively catalyze the cross-coupling of alkyl halides with Grignard reagents [2]. It was noted that the reaction required pre-reduction of dppf/PdCl₂ to dppf/Pd(0) using dialkylaluminum hydride (DIBAL) [2,5].

On attempting to apply this methodology to the cross-coupling of neopentyl halides, we discovered that treatment of any alkyl halide with Grignard reagents in the presence of either dppf/PdCl₂ or dppf/Pd(0) afforded only the products of reduction [3]. Since reduction would not have been expected whether or not cross-coupling occurred, we undertook a mechanistic study of the reduction [4]. It was determined that the palladium catalyst is not involved in the reduction when highly polar solvents, such as tetrahydrofuran are used [4]. In this case it was possible to elucidate two competing mechanisms both of which lead to reduction.

In less polar solvents, such as diethyl ether, reduction of the alkyl halide by the Grignard reagent does not occur in the absence of palladium catalysts. We have proposed that in these cases reduction occurs following a catalytic cycle common to many cross-coupling reactions. Thus, as shown in Scheme 1, we suggested that dppf/PdCl₂ is reduced by the Grignard reagent to dppf/Pd(0) [4,5], which then oxidatively adds the electrophile. Hydride transfer from the Grignard reagent to the resulting palladium(II) complex generates an olefin (from the Grignard reagent), magnesium halide, and an organopalladium(II) hydride. Reductive elimination from the palladium hydride should rapidly afford the observed alkanes with concomitant regeneration of the dppf/Pd(0) catalyst. The order of the oxidative addition and hydride transfer steps remains unclear.

Scheme 1. Proposed mechanism for the palladium-catalyzed reduction of alkyl halides to the corresponding alkanes.
Central to this proposal is the oxidative addition of the alkyl halide. However, oxidative addition of "unactivated" alkyl halides, those not containing sp or sp$^2$ carbons at or immediately adjacent to the electrophilic center, is unprecedented.

In recent years, we have shown that Group 10 metal complexes are readily analyzed using fast atom bombardment (FAB) mass spectrometry [6-8]. In this paper, we report on the analysis of the palladium-mediated Grignard reduction of alkyl halides of the type phenylpropyl iodide, phenylneopentyl iodide, neopentyl iodide, and methyl iodide to their corresponding alkanes. In general 2 to 2.5 equivalents of Grignard reagent were added to the palladium(II) pre-catalyst for reduction to palladium(0) after which a large excess of alkyl iodide was added to observe the product of oxidative addition as the first intermediate of the proposed reaction mechanism.

FAB mass spectra of the reaction mixtures were obtained by placing a 2 μl aliquot of reaction mixture on a standard FAB probe tip using sulfolane as the liquid matrix. When methyl iodide is used as the alkyl halide for this reaction, a molecular ion from the product of oxidative addition is observed at m/z 603 [9], which is assigned as the [M + H$^+$]$^+$ ion of the oxidative addition product shown in Scheme 1 (compound II; Figure 1). In addition, structurally significant fragment ions are observed. For example, ions observed at m/z 787 and 675 are assigned as [dppf/Pd] and [dppfPd(C$_2$H$_5$)]$^+$, respectively. In addition, ions at m/z 660 (with a 661 component in the isotope pattern) and 583 are assigned as (dppfPd(0))$^+$ and (dppfPd(0) - phenyl)$^+$, respectively. This is the first clear, unambiguous, observation of the intermediate, formed by oxidative addition, for unactivated alkyl halides.

Results from the phenylpropyl-, phenylneopentyl-, and neopentyl iodides was not as conclusive. In each case ions at m/z 787 ([dppfPd]$, 741 ([dppfPdI]$^+$), 689 ([dppfPd(Et)]$^+$), 660 ([dppfPd(0)]$^+$), and 583 ([dppfPd - phenyl]$^+$) were observed. Ions corresponding to an alkyl group containing palladium(0) catalyst (with or without iodide) were not observed. It can only be postulated that the organo-palladium bond is weak or that the palladium iodide species observed is formed by palladium(0) catalyst acting as a scavenger of iodide from solution.

BIRADICAL ISOMERS OF CYCLOPROPANOL AND OXETANE AND THEIR COUNTERPART IONS

M. J. Polce, F. A. Wiedmann and C. Wesdemiotis
Department of Chemistry, The University of Akron, Akron, OH 44325-3601, U.S.A.

Biradicals, species with two radical centers in the same molecule, are the postulated intermediates of important thermal and photochemical reactions, including stereoisomerization, polymerization, and synthesis of ketones and alcohols. Biradicals are the neutral counterparts of distonic radical ions, which can be formed easily in the mass spectrometer via ion-molecule reactions or unimolecular rearrangement-fragmentations. Such distonic radical ions can then be used as a source of gaseous elusive biradicals in neutralization-reionization mass spectrometry (NRMS) experiments. In this study we produced and studied in the gas phase CH$_2$CH$_2$CHOH and CH$_2$CH$_2$OCH$_2$-, the ring-opened forms of cyclopropanol and oxetane, respectively.

-CH$_2$CH$_2$OCH$_2$- This 1,4-biradical is formed by neutralization of the distonic ion CH$_2$CH$_2$OCH$_2$+ which has been characterized as a stable cation by Grützmacher et al. Its CAD spectrum (Figure 1) is distinctively different from that of ionized oxetane, displaying no appreciable m/z 36-39 (C$_3$H$_n$+) fragments.

In the neutralization-reionization (NR) spectrum of •CH$_2$CH$_2$OCH$_2$ a recovered parent ion is observed indicating that the 1,4-biradical CH$_2$CH$_2$OCH$_2$+ survives, at least partly, intact. The absence of m/z 36-39 peaks proves further that ring-closure to more stable oxetane has not taken place in the μs time window of our NR experiment. The smaller molecular ion in the biradical spectrum (Figure 1) is consistent with a more severe fragmentation of the biradical into CH$_2$CH$_2$OCH$_2$+ which after reionization contribute to the intense m/z 24-30 peaks.

CH$_2$CH$_2$CH•OH An ideal precursor for this 1,3-biradical is the distonic ion CH$_2$CH$_2$CH•OH which can be produced from ionized 4-oxobutanoic acid and is a distinct C$_3$H$_6$O+ isomer according to McAdoo et al. Although the CAD spectrum of this ion (Figure 2) looks similar to the CAD spectrum of cyclopropanol+, small but significant differences, e.g., in the abundances of the m/z 57 (H-loss), 44,

1572
(CH₂ loss), and 43 (CH₃ loss) indicate that these two ions do not interconvert freely and must therefore be separated by a considerable barrier. The CAD spectrum of the allyl alcohol ion (not shown), on the other hand, is virtually identical to that of cyclopropanol‡, showing that the former readily rearranges to the latter which is the thermodynamically more stable isomer, in agreement with the photoelectron-photon coincidence studies of Bombach et al. Finally, the CAD spectra of ionized propanal and its enol are clearly different from the spectra of the distonic CH₂CH₂CH⁺OH ion and the cyclopropanol ion. Thus four C₅H₁₀O⁺ ions, namely CH₃CH₂CH=O⁺, CH₂=CHCH(OH)⁺, cyclopropanol⁺, and CH₂=CHCH⁺OH, represent stable, distinguishable isomers from which the counterneutrals can be prepared by neutralization. The corresponding NR spectra were measured in order to determine the fate of the 1,3-biradical CH₂CH₂CH⁺OH: is it stable, does it cyclize to cyclopropanol, or rearrange via H migration to propanal, the most stable of these C₅H₁₀ neutrals?

The appearance of a sizable recovered parent cation (m/z 58) in the NR of CH₂CH₂CH⁺OH (Figure 2) provides evidence that CH₂CH₂CH⁺OH can survive undissociated. The NR spectrum for this biradical is substantially different from that for propanal indicating that the isomerization CH₂CH₂CH⁺OH → CH₂CH₂CH=O does not occur. Furthermore, the structurally diagnostic peaks at m/z 43 and 44 (vide infra) are more intense in the biradical spectrum than in the spectrum for cyclopropanol showing that there is a noticeable barrier for CH₂CH₂CH⁺OH ring-closure to cyclopropanol. Consequently, the "Norrish like" biradical CH₂CH₂CH⁺OH is a chemically bound species.

**Figure 2.** (a,b,c,d) Partial CAD, O₂ and (e,f,g,h) partial +NR⁺, Xe/O₂, spectra of (a,e) CH₃CH₂CH=O⁺, (b,f) CH₂=CHCH(OH)⁺, (c,g) cyclopropanol⁺, and (d,h) CH₂CH₂CH⁺OH.
The unimolecular dissociation of dimethyl sulfide was investigated using threshold photoelectron photoion coincidence (TPEPICO) and tandem (MS/MS) mass spectrometry. From the TPEPICO study the breakdown graph is obtained in the energy range of 10.35 eV to 14.0 eV. Fig. 1 presents the TPEPICO breakdown diagram constructed from ion abundances obtained from peak areas in coincidence TOF mass spectra. The peaks of $\text{CH}_3\text{S}^*$ (m/z 47), $\text{CH}_2\text{S}^*$ (m/z 46) and $\text{CHS}^*$ (m/z 45) in TOF spectra were treated as one peak of m/z 47 since it was not possible to deconvolute these overlapping peaks reliably. Table I. presents the appearance potentials observed in the present work.

* Metastable appearance energy measured using a Kratos MS 50 TA
b Obtained by taking the mid point of two energies: last absent and first observed
c Ref. 2
d Ref. 2

The breakdown diagram is dominated by ions of mass m/z 47 (46, 45) throughout the energy range covered. The relative abundance of m/z 61 increases from about 12.09 eV to 13.54 eV whereas the relative abundance of ion m/z 47 (46,45) decreases in the same energy range. In the He-I photoelectron spectrum$^1$ of $\text{CH}_3\text{SCH}_2^*$ this energy region corresponds to the $B^2B_2$ ionization transition state of the molecular ion. Ionization to this state leads to a complete dissociation of the molecular ion. Our breakdown diagram suggests that the ionization transition to the $B^2B_2$ state produces predominantly $\text{CH}_3\text{S}^*$ (m/z 47, 46, 45). The decrease in the relative abundance of m/z 61 ion around 13.54 eV is accompanied by a rise in $\text{SH}^*$ (m/z 35) (not shown in Fig 1) and $\text{CHS}^*$ (m/z 47,46,45) ions. In the He-I photoelectron spectrum this energy region is characterized by a broad band which includes the transition states of $\text{CH}_3\text{SCH}_2^*$ localized in the methyl group. Ionization to these transition states gives rise to the formation of $\text{SH}^*$ and $\text{CH}_3^*$ cations that appear at higher photon energies.

In earlier studies$^2$ it has been observed that the fall in the yield of $\text{CH}_3\text{SCH}_2^*$ is accompanied by the formation of $\text{CHS}^*$ and $\text{C}_2\text{H}_3^*$. This observation was
attributed to a successive decomposition of CH$_3$SCH$_2^*$ leading to the formation of CHS* or C$_2$H$_3^*$. Although successive dissociation cannot be ruled out, our CA MS/MS study has established that all major fragments originate directly from the parent ion (Fig. 2). In the present experiment the major ions observed are C$_2$SCH$_3^*$ (m/z 62), CH$_3$SCH$_2^*$ (m/z 61), CHS* (m/z 47), SH* (m/z 35) and C$_2$H$_3^*$ (m/z 27). Fig 3. presents the metastable ion spectrum of CH$_3$SCH$_3^*$ measured on a Kratos MS 50 TA.

From the breakdown curves, MS/MS study and energetics considerations the major fragmentation pathways are derived as shown below:

\[
\begin{align*}
\text{CH}_3\text{SCH}_3^* & \quad \rightarrow \text{CH}_3\text{SCH}_2^* + e \\
\text{CH}_3\text{SCH}_2^* & \quad \rightarrow \text{CH}_3\text{S}^* + \text{CH}_4 \\
\text{CH}_3\text{S}^* & \quad \rightarrow \text{CHS}^* + \text{CH}_4 + \text{H} \\
\text{CHS}^* & \quad \rightarrow \text{SH}^* + \text{C}_2\text{H}_3 + \text{H}_2 \\
\text{C}_2\text{H}_3^* & \quad \rightarrow \text{C}_2\text{H}_3 + \text{H}_2 \text{S} + \text{H}
\end{align*}
\]

Our MNDO calculation agree with earlier reports that the stable structures of fragments of mass 47 and 46 are CH$_3$SH* and CH$_3$S* respectively. The stable structure of the fragment ion CH$_3$S* has long been a subject of interest. Early collisional activation study of dimethyl sulfide has revealed that at low ionization electron energies the ion of mass 47 produced is the mercaptomethyl (CH$_3$SH*) cation and not the thiomethoxy cation (CH$_3$S*). In addition, ab initio calculations have shown that the singlet mercaptomethyl cation is the most stable isomer lying about 113 KJmol$^{-1}$ lower in energy than the triplet thiomethoxy cation.

Production mechanisms of quasi-molecular ions in atmospheric pressure spray (APS) ionization

A. Hirabayashi, Y. Takada, H. Kambara, Y. Umemura,* H. Ito* and K. Kuchitsu*

Central Research Laboratory, Hitachi, Ltd. Kokubunji, Tokyo 185, Japan
*Nagaoka University of Technology, Nagaoka, Niigata 940-21, Japan

In spray ionization methods, mechanisms by which quasi-molecular ions are produced have not yet been investigated in detail. For example, the ion evaporation model proposed by Iribarne and Thomson\(^1\) is often accepted as the mechanism producing quasi-molecular ions by electrospray and thermospray, but this model has not been proved experimentally. Ion-molecule reactions in the gas phase can also contribute to the final production of quasi-molecular ions. It is therefore important to investigate their roles in the spray ionization generation of quasi-molecular ions. Recently, we have developed another spray ionization method, called atmospheric pressure spray (APS) ionization.\(^2\) The present work uses APS to distinguish a gas-phase ion-molecule reaction from ion evaporation in producing quasi-molecular ions.

Positive ions produced in APS ionization from sucrose, ammonia, and alanine in aqueous solutions have been measured with a double focusing mass spectrometer, and the obtained mass spectra are analyzed as a function of the distance between the nozzle tip and the mass-spectrometer sampling aperture. The time for an ion-molecule reaction at atmospheric pressure increases with this distance.

Cationized sucrose molecules, i.e., \(\text{MNa}^+\), are produced from an aqueous solution containing \(7.5 \times 10^{-5}\) mol/l of sucrose and \(4.0 \times 10^{-7}\) mol/l of NaOH. As shown in Fig. 1, the relative intensity of \(\text{MNa}^+\) ion is independent of the distance. It is therefore concluded that cationized sucrose molecules are produced by the spray process rather than by a cation transfer reaction in the gas phase. This spray formation of \(\text{MNa}^+\) may thus be described in terms of the ion evaporation model\(^1\) in which final ion formation is completed during the spray.

Figure 2 shows the relative ion intensities for a \(5.0 \times 10^{-6}\) mol/l solution of ammonia in deionized water as a function of the distance. The relative intensity of \(\text{NH}_4^+\) ions increases with a decrease in that of \(\text{H}_3\text{O}^+\). Furthermore, the \(\text{NH}_4^+\) intensity tends to be zero at zero distance. This indicates that the neutral \(\text{NH}_3\) molecules are evaporated from the ammonia solution and that \(\text{NH}_4^+\) ions are produced in the gas phase by an ion-molecule reaction with \(\text{H}_3\text{O}^+\) produced by the spray.

Figure 3 shows the observation for \(5.0 \times 10^{-6}\) mol/l aqueous solution of alanine. The relative intensity of the protonated alanine molecule, \(\text{MH}^+\), increases with the distance, but tends to be about 50 % at zero distance. This indicates that neutral as well as protonated...
alanine molecules are produced by the spray, and that the former species are partly protonated after the spray by a similar ion-molecule reaction in the gas phase. (Since the atmosphere in the ion source was contaminated by ammonia in this particular experiment, a small amount of $\text{NH}_4^+$, not shown in the figure, was also observed as a result of an ion-molecule reaction with $\text{H}_3\text{O}^+$) Therefore, it is concluded that the production mechanism of quasi-molecular ions depends on the molecular species.

Ammonia Laser Desorption/Chemical Ionization with Ammonium Bromide: Fourier Transform Ion Cyclotron Resonance Mass Spectrometry of Aromatic Hydrocarbons

Troy D. Wood† and Alan G. Marshall†,§

Departments of Chemistry† and Biochemistry§, The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

Laser desorption/ionization combined with Fourier transform ion cyclotron resonance mass spectrometry (LD/FT/ICR/MS) is a proven technique for the analysis of nonvolatile materials. Unfortunately, LD tends to produce a large excess of neutrals relative to ions. Because of the inherent inefficiency of ion formation in LD, several methods have been applied in FT/ICR/MS to increase the number of ions formed after desorption. These include adding a small amount of an alkali halide salt (e.g. KBr) to the sample [1] and post-desorption methods such as electron ionization [2], resonance enhanced multiphoton ionization (REMPI) [3] and chemical ionization (CI) with an added reagent gas [4].

In this poster, we report that ammonia LD/CI can be performed simply by addition of a small amount of ammonium bromide (NH₄Br) to an involatile sample, i.e. the ammonium salt is used in place of ammonia reagent gas. Such an experiment does not require addition (e.g., by pulsed valve) of reagent gas from outside the vacuum chamber, and should thus prove useful for applications in which high mass resolution is needed. For various aromatic hydrocarbons, (M+H)⁺ ions are produced in enhanced abundance as a result of chemical ionization. The mechanism proposed for ammonia LD/CI with NH₄Br is given as follows:

\[
\begin{align*}
\text{M}^\text{sol} & \rightarrow \text{M}^\text{as} + \text{NH}_4^+ + \text{Br}^- \\
\text{M}^\text{as} + \text{NH}_4^+ & \rightarrow [\text{M}^\text{as} - \text{H} - \text{NH}_3]^+ + \text{NH}_3 \text{ gas} \\
[\text{M}^\text{as} - \text{H} - \text{NH}_3]^+ + \text{X} & \rightarrow \text{MNH}_4^+ + \text{X} \text{ gas}
\end{align*}
\]

In which M is the analyte and X denotes any neutral species which may be in the ion trap. Proton transfer (Eq. 4a) will occur only if the proton affinity of the sample exceeds that of ammonia. Thus, the LD/CI technique should prove to be chemically selective. Cation attachment (Eq. 4b) is unlikely because the FT/ICR/MS operating pressure is too low to collision-stabilize the intermediate.

Results:

We have observed some degree of protonation with this alternative LD/CI technique for the hydrocarbons: pyrene, 2-methylanthracene, hexamethylbenzene, and coronene. Only for hexamethylbenzene was [M + H⁺] more abundant than M⁺, as shown in Figure 1. For coronene, the most abundant species in the LD/FT/ICR mass spectrum is the unusual protonated fragment ion, C₁₂H⁺, which is formed when coronene is protonated, followed by loss of six C₆H₂ molecules located at the perimeter of the coronene ring system, as shown in the following mechanism:
The ratio, \((\text{MH}^+)/\text{(M}^+)\), is controlled by at least three factors: laser irradiance, concentration of \(\text{NH}_4^+\) in the plume of desorbed species, and fragmentation of \(\text{MH}^+\) to form \(\text{M}^+\). Thus, the \((\text{MH}^+)/\text{(M}^+)\) ratio should not be used to compare the relative efficiencies of LD/CI and photolization, since proton transfer at a collision-limited rate is expected to occur whenever the proton affinity of the analyte molecule significantly exceeds the proton affinity of the reagent [5]. A fuller account of this work will be published elsewhere [6].

AN INVESTIGATION OF THE MECHANISM OF GLYCOSIDIC BOND CLEAVAGE IN THE 
NH3-DCI MASS SPECTRA OF PERACETYLATED CARBOHYDRATES: *J. M. Pelletier, R. W. 
Smith, D. B. MacLean, Department of Chemistry, McMaster University, Hamilton, Ontario, L8S 4M1, 
Canada and W. A. Szarek, Department of Chemistry, Queen's University, Kingston, Ontario, K7L 
3N6, Canada.

The NH3-DCI mass spectra of peracetylated carbohydrates exhibit ions which correspond to 
species resulting from cleavage on either side of a glycosidic oxygen with attachment of (H + NH4\(^+\) or 
(CH\(_2\)CO + NH4\(^+\)) to the observed fragment. The first of these two ion types will be referred to as an 
H transfer ion and the second will be referred to as an acyl transfer ion. Both types of ion can be used 
to determine the sequence of carbohydrate residues in an oligosaccharide and thus are useful in the 
structure elucidation of carbohydrates. However, little has been reported regarding the structure and 
formation of these ions, although Dougherty et al. have proposed that the acyl transfer ions arise by 
"thermolysis of the parent molecule followed by NH4\(^+\) attachment to the neutral fragments".1

In an attempt to gain further insight into the structure of the ions formed and the processes 
occurring on glycosidic bond cleavage, the spectra of the gentiobioses shown below have been studied.

Mass spectra were obtained on a VG Analytical ZAB-E mass spectrometer. The electron beam energy 
was ~ 70 eV. The source temperature was maintained at 200°C; the DCI probe was not heated. The 
reagent gas (Matheson, anhydrous ammonia) was maintained at a pressure that resulted in a 20:1 ratio 
of NH4\(^+\) to (N\(_2\)H\(_7\))\(^+\). Mass-analysed ion kinetic energy (MIKE) spectra were acquired employing the 
CI conditions described above.

Octa-O-acetylgentiobiose (1) was obtained from Sigma Chemical Company. The synthesis of 
compounds 2 to 5 will be reported elsewhere. The purity and structure of the compounds studied was 
established by \(^1\)H-NMR, gas chromatography and mass spectrometry. Compound 3 was found to be a 
60:40 mixture of anomers as determined by \(^1\)H-NMR. The two anomers were separated in a GC-MS 
experiment, which showed that their spectra were essentially the same. A J&W Scientific DB 
1701-30W column was used at 280°C isothermal with a head pressure of 1.5 psi and with helium as 
the carrier gas.

The H transfer ions derived by cleavage at \(x\) or \(y\) in compound 1 both appear at m/z 366 and 
cannot be distinguished from each other. In the case of compounds 2 and 3 the H transfer ions derived 
from the two ends of the molecule can be distinguished and are represented as shown below. MIKE 
experiments indicate that the H transfer ions are not derived direct from the [M+NH4\(^+\)]\(^+\) ions of 1 - 3.

The MIKE spectra of ions 2b and 3a were compared with the MIKE spectra of the 
pseudomolecular ions, [M+NH4\(^+\)]\(^+\), of 4 and 5, respectively.

1580
The MIKE spectra of ions 2b and [4 + NH₄]⁺ were virtually identical, as were the MIKE spectra of ions 3a and [5 + NH₄]⁺, which suggests that the H transfer ions have the structures indicated.

The ratio of intensities of 2a:2b and 3a:3b are 4:1 and 3:1, respectively. The fact that ions of type a and b are observed confirms that cleavage occurs on either side of the glycosidic oxygen. However, the relative ratios of the ions indicate that cleavage at 'x' dominates in gentiobiose.

Similarly, acyl transfer ions can be formed by cleavage at 'x' or 'y'. The two ions generated from compound 1 will both appear at m/z 408 and thus, cannot be distinguished from each other. In the case of compounds 2 and 3 it is possible to determine the end of the disaccharide from which the ion is derived and to determine the type of the acyl group transferred.

In the spectrum of compound 2 only one acyl transfer ion at m/z 420 is observed, while in the spectrum of compound 3 acyl transfer ions at m/z 408, m/z 411, and m/z 420 are observed. The acyl transfer ions are assigned the structures shown below.

![Diagram](image)

The MIKE spectra of ion 3c and the [M + NH₄]⁺ ion of peracetylated glucose are the same, which suggests that the structure of the two ions is the same. Both of their MIKE spectra are characterized by a single intense ion resulting from the loss of NH₄⁺ and the group at C-1. This type of fragmentation has been observed previously. The MIKE spectrum of ion 2d also exhibits a single intense ion, which indicates that a nondeuterated acetate was lost from C-1. The position of the nondeuterated acetate group in ion 2d suggests that acyl transfer ions are formed with selective transfer of an acyl group to C-1 in the case of those ions derived from the non-reducing end of the disaccharide. Attempts to obtain MIKE spectra of ions 3d and 3e were unsuccessful due to the low intensity of those ions.

Ion 3e at m/z 408 and ion 3d at m/z 411 differ by three mass units. This difference can occur only if the acyl transfer ions in question are formed by transfer of an intact acyl group. If these ions were formed by the addition of ketene to the free hydroxyl of a H transfer ion then addition of dideuteroketene instead of ketene would cause a two mass-unit shift.

Finally, both the sugar moiety and the transferred acyl group in ion 3c are derived from the non-reducing end of the disaccharide. Since the reducing end of compound 3 contains only trideuteracetacetyl groups, the transferred acyl group in ion 3c must have come from a different molecule.

Our experiments did not provide any insight into the nature of the species from which the H transfer ions and the acyl transfer ions are derived. However evidence was found to support the previously proposed structures for these ions. Furthermore, in the case of the acyl transfer ions there is evidence to suggest that they are formed, at least in part, by intermolecular transfer of an acyl group and by transfer of that acyl group to C-1 for ions derived from the non-reducing end of the disaccharide. Finally the acyl transfer ions appear not to be formed by addition of ketene to a free hydroxyl.

Effect of Substituent Identity on Electron Capture Enhancement in Negative Chemical Ionization of Pentafluorobenzoyl Derivatives of Substituted Phenylpiperazines

*C. D'Arienzo, P. J. Gale, M. Jemal, E. Ivashkiv and A. I. Cohen
Bristol-Myers Squibb Pharmaceutical Research Institute, New Brunswick, New Jersey, 08903-0191

Introduction:

We have been interested in the analysis of phenylpiperazine compounds, since they are metabolites of a number of CNS drugs. GC/MS is the analytical method of choice because it can provide sufficient sensitivity to quantitate at the low levels of metabolites produced by the typical dosings of these drugs. Derivatization at the unsubstituted nitrogen of the piperazine ring by pentafluorobenzoyl chloride (PFB) was utilized to allow these compounds to elute from the GC column.

GC-EI/MS analysis yielded spectra containing relatively intense ions but with significant fragmentation at the derivatization site as shown in Fig. 1 for the 3-chloro analog. Similar spectra were obtained for all the compounds studied. Given their electron capture capability, it was not surprising that the derivatized phenylpiperazine analogs produced negative chemical ion (NCI) spectra containing only molecular ions at intensities far greater than the electron impact spectra. The degree of intensity enhancement was not the same for all analogs, however; it appears to depend on not only the identity of the substituent but also its position on the ring. The compounds shown in Table I were studied at three different source temperatures: 100°, 150°, and 200°C (ammonia gas pressure optimized at each temperature). Ion yields were compared by substituent, position and source temperature:

**Results:**

1. Source temperature had some effect on the relative resonant electron capture ability of these analogs but no consistent trend was observed.

2. Relative to the unsubstituted phenylpiperazine, electronegative substituents enhanced electron capture provided while alkyl substituents diminished it.

3. Position of the substituent on the phenyl ring was significant in the case of the chlorinated positional isomers, i.e., 3-chloro was slightly more intense than the 2-chloro analog at the two higher source temperatures and twice as intense as the 4-chloro compound.

**Discussion:**

The substituent effect on phenylpiperazine analogs relative to 1-phenylpiperazine is analogous to that of substituent groups on aniline. Electron donating groups such as -CH₃ and -OCH₃ stabilize a positive charge on the molecule through resonance. Electron withdrawing groups such as halogens and -CF₃ reduce the ability of the molecule to have a positive charge enhancing the likelihood of resonant electron capture. This results in greater intensity of the molecular ion largely independent of source temperature.

We find no obvious explanation for the magnitude of the differences in the electron capture efficiencies of positional isomers of the chlorinated phenylpiperazine analog. The meta position consistently showed the greatest response.
Use of Molecular Modelling in Interpretation of the Electron Capture Negative Chemical Ionization Mass Spectra of Polychlorinated Biphenyls.

J. Greaves, E. Harvey and W. G. Maclntyre.

Virginia Institute of Marine Science,
College of William and Mary,
Gloucester Point, VA 23062.

Electron capture negative chemical ionization (ECNCI) mass spectra of polychlorinated biphenyls (PCB) show fragmentation that is related to the molecular structure of the compounds. The fragmentation is influenced predominately by two structural characteristics. Fragmentation is reduced with increasing number of chlorine atoms on the PCB congener, but conversely becomes more pronounced as the number of chlorine atoms in the 2 & 6 (ortho) positions increases. Correlations between structure and ECNCI fragmentation have also been reported for polybrominated biphenyls (PBB) and polychlorodibenzo-p-dioxins (PCDD).

The importance of fragmentation differences in ECNCI spectra has been demonstrated by its use in the identification of a PCB congener in environmental samples that had not been previously detected because of its coelution with PCB congener IUPAC # 138.

Molecular model results for PCDD, using complete neglect of differential overlap (CNDO) approximations, have been evaluated with respect to ECNCI spectra. Fragmentation was related to the energies of the lowest unoccupied molecular orbital (LUMO) and LUMO+2 (where LUMO+n = molecular orbital n levels above the LUMO).

The objective of the present work was to evaluate ECNCI spectra of PCB congeners in terms of their molecular parameters derived from the MOPAC molecular model program which uses modified neglect of differential overlap (MNDO) approximations. Correlations between molecular structural properties and ECNCI spectra may result in better understanding of the ECNCI process and be useful for obtaining structural information on unknown compounds.

ECNCI mass spectra (moderator = methane) of 50 PCB congeners (tetras, pentas, hexas) were obtained on an Extrel ELQ 400-2 quadrupole mass spectrometer.

The molecular model program, MOPAC, was obtained from the Quantum Chemistry Program Exchange (QCPE, Indiana University, Bloomington, IN) and was run on a DEC Micro VAX II computer. MOPAC, using the AM1 Hamiltonian operator, was run for all 209 PCB congeners and biphenyl. Model generated molecular properties of particular interest were: heats of formation, twist angle between the phenyl rings, and the energies of the highest occupied molecular orbital (HOMO), LUMO, LUMO+1, and LUMO+2.

MOPAC results were related to various molecular structural properties. The calculated heats of formation decreased as the number of substituent chlorine atoms increased. The energies of the HOMO, LUMO, LUMO+1 and LUMO+2 were similarly reduced. The calculated twist angles increased as the number of 2 & 6 Cl atoms increased. Thus, for 0 - 4 Cl, the mean twist angles were 41°, 56°, 76°, 86° and 87°, respectively.

The number of 2 & 6 Cl atoms on a molecule particularly influenced the LUMO energy. The change in LUMO energy was observed as a decrease in the energy difference between the LUMO and LUMO+1. For 0 - 4 chlorine atoms, the mean differences were -0.49, -0.32, -0.16, -0.09, and -0.07 eV, respectively. The overall influence of the increasing number of
chlorine atoms on the congeners tended to disguise some of the relationships. However, within homologous groups of congeners, e.g. pentachlorobiphenyls, the effect of the number of 2 & 6 Cl atoms was clearly observable from plots of the number of chlorine atoms against twist angle, LUMO and LUMO - LUMO+1 energies.

ECNIC spectra of PCB included [M]', [M-H]', [M-Cl]' and [M-2Cl]' ions. Fragmentation ratios of [M]/[M-X]' (where X = H, Cl, 2Cl) were calculated and correlated with various MOPAC molecular parameters including HOMO, LUMO, LUMO+1, LUMO+2 energies, twist angle and the number of 2 & 6 Cl atoms. Correlations of these parameters with the [M]/[M-Cl]' fragmentation ratios were observed and when the fragmentation ratios were log, transformed the data yielded linear results. Because LUMO energy is related to both the twist angle and the number of 2 & 6 Cl atoms, log,([M]/[M-Cl]') is in turn related to the latter two parameters.

Fragmentation in ECNIC spectra of PCB congeners was found to be related to molecular parameter values calculated by the MOPAC program. The log,([M]/[M-H]') and log,([M]/[M-Cl]') fragmentation ratios were correlated with LUMO, twist angle and number of 2 & 6 Cl atoms. Correlation coefficients were higher for chlorine atom loss than for hydrogen atom loss.

The energies of the HOMO, LUMO, LUMO+1 and LUMO+2 orbitals all became increasingly negative as the number of chlorine atoms increased. This indicated that the PCB congeners with the greatest number of chlorine atoms have an increasing ability to stabilize an ionizing electron. This would explain the increased frequency of molecular ion occurrence in the spectra of PCB as the number of chlorine atoms increased. However, the LUMO energy increased in negativity to a lesser extent as the number of 2 & 6 Cl atoms increased. This provided a basis for explaining the observed greater PCB fragmentation in ECNIC spectra as the number of 2 & 6 Cl atoms increased. It is hypothesized that molecules exhibiting less difference between the LUMO and LUMO+1 energies are less able to stabilize the energy of an ionizing electron and therefore fragment.

The threshold values of the orbital energies that encourage fragmentation are currently being investigated. This is being done with respect to the energies anticipated to be present in the ECNIC process. This may provide additional information on the reaction processes involved in this type of ionization.

THE EFFECT OF EPOXIDE GROUPS ON THE ELECTRON CAPTURE NEGATIVE IONIZATION MASS SPECTROMETRIC RESPONSE OF STEROIDS AND RELATED COMPOUNDS. Helen K. Mayer1, William Reusch1, and J. Throck Watson1,2, Departments of Chemistry1 and Biochemistry2, Michigan State University, E. Lansing, MI 48824.

Under electron capture negative ionization (ECNI) conditions, certain combinations of double bonds, carbonyl groups, and halogens have been shown to either not affect, decrease, or greatly enhance the relative response of steroids and other cyclic compounds (1). The presence of an epoxide group also may be important for enhanced response.

All compounds were analyzed under similar conditions using a JEOL JMS-AX505H mass spectrometer coupled with a Hewlett Packard 5890 gas chromatograph. Methane was used as the reagent gas because it does not favor the ionization of any particular compound. The following instrumental conditions were used: source temperature, 200°C; pressure, 2 x 10⁻⁵ torr; and accelerating voltage, 3 keV. All compounds were analyzed first in the full scan mode to determine the major ions; then these ions were used for replicates analyses by selected ion monitoring.

For enhanced response, an epoxide group must be near an electrophilic group or alpha to a carbonyl (see Table 1). The position of this carbonyl group is not important; the electron-capture capacity is the same. In fact, an epoxide alpha to a carbonyl is much more electron-withdrawing than a comparable conjugated ene-one system. For example, A4-3,17-dione has a relative response of 1.2; however, if a 4,5-epoxide replaces the double bond, the relative response increases to 39. The stereochemistry of the epoxide group does not affect its response. In many cases, the other functional groups in the molecule have a limited effect on the overall response; for example, P-16α,17α-epoxy-3,20-dione and Pδ-16α,17α-epoxy-3,20-dione have almost the same response. The presence of an epoxy group in conjunction with a carbonyl must be the most important contribution to the overall response of the compound.

Electron affinities have been shown to correlate with reduction potentials (E1/2) in aprotic solvents (2). In many cases, the trend in E1/2 correlated with the ECNI relative response (see Table 1). However, a direct correlation is not always possible, as shown in the comparison of P-4α,5α-epoxy-3,20-dione, P-16α,17α-epoxy-3,20-dione, and C-4δ,5δ-epoxy-3-one. All three have the same E1/2, but only the pregnanes have a similar ECNI response. Other researchers have noted variations between electron affinity values and ECNI responses for a series of polyaromatic hydrocarbons (3).

It has been noted in a previous study (1) that the presence of a M⁺ ion rather than a [M-H]⁻ ion in the ECNI mass spectrum of a ketosteroid is indicative of a high-response compound. This is not necessarily true of steroid epoxides. Compounds that form M⁺ ions have relative responses ranging from 9 to 200; compounds that form [M-H]⁻ ion have relative responses overlapping this range.

Trichothecenes (Table 2) also have enhanced ECNI responses. The presence of an epoxide in deoxynivalenol acetate does not enhance its response in comparison to the unepoxylated DOM-1 acetate. In this case, the epoxide group is not near a carbonyl group; therefore, structural features other than the epoxide group must be responsible for this particular enhanced response.

**KEY**

A Androstane C19 structure

PRESSURE DEPENDENCE AND REGIOSELECTIVITY IN THE REACTIONS OF O\(^{-}\) WITH AROMATIC COMPOUNDS

Meg Annan, Paul Vouros;
Department of Chemistry, Northeastern University
Boston, MA 02115

The gas phase chemistry of the oxide radical anion, O\(^{-}\), has been found to be useful in several important areas of chemistry. For instance, O\(^{-}\) has been shown to react rather selectively with halogenated pesticides and other environmental pollutants and has therefore been used as a negative ion chemical ionization reagent species. It has also been employed in the area of gas phase ion chemistry as a reagent to form not readily accessible gas phase organic anions. Finally, O\(^{-}\) chemistry has also been shown to play an important role in electron capture devices. In studies performed by other investigators, the principal ionic products in the reactions of toluene and benzene with O\(^{-}\) were [M-2H]\(^{+}\) and [M-H + O]\(^{+}\). In the case of toluene, oxygen incorporation has been assumed to be on the aromatic ring. We report results of experiments including reactions performed at different pressures, CID experiments, and isotope labelling which provide interesting information regarding the nature of O\(^{-}\) reactions with simple aromatic compounds.

The high pressure studies were performed on a Sciex TAGA 6000 triple quadrupole mass spectrometer equipped with an atmospheric pressure ionization source. The O\(^{-}\) reagent species were generated via dissociative electron capture by the N\(_{2}\)O carrier gas. The carrier gas was a mixture of 1% N\(_{2}\)O in N\(_{2}\). The laboratory collision energy was 80V and the collision gas was Argon. The low pressure experiments were performed on a VG-Quattro triple quadrupole mass spectrometer using the negative chemical ionization mode. The source housing pressure was 1.5x10\(^{-4}\) Torr while the pressure in the ion volume was presumably on the order of several Torr. The O\(^{-}\) reagent ions were formed efficiently by the use of N\(_{2}\)O alone as a negative chemical ionization gas. The laboratory collision energy was 110V and the collision gas was Argon.

Under atmospheric pressure ionization (API) conditions, the observed products have been previously reported to be [OH]\(^{+}\), at m/z 17 and [M-H + O]\(^{+}\) at m/z 107. The formation of a mixture of isomeric C\(_{6}\)H\(_{5}\)O\(^{-}\) ions was demonstrated by comparison of the CID spectra of such ions from toluene and four reference compounds. The results suggested the formation of a mixture of benzyloxide and ortho, meta, and para-methylphenoxides. The isomeric composition of this mixture was estimated using the concept of linear superposibility of CID spectra. The four most intense ions in the CID spectrum of m/z 107 from toluene were used for the analysis. The intensity of each fragment ion relative to the most intense fragment is tabulated in Table 1. By making a few assumptions an approximate ratio of o-methylphenoxide to the combined contribution of m-methylphenoxide and p-methylphenoxide can be determined. In addition, an approximate ratio of benzyloxide to o-methylphenoxide can also be determined, the primary assumption is that the m/z 64 fragment ion is contributed solely by the o-methylphenoxide isomer. The results are shown in Figure 1.

When the reactions of benzene and toluene with O\(^{-}\) were studied under API and negative chemical ionization (NCI), the effect of pressure on the product distribution was found to be pronounced. Under API conditions, evidence for proton transfer and dihydrogen transfer ([M-H]\(^{+}\) and [M-2H]\(^{+}\), respectively) in toluene or benzene was not observed. The only products observed were [OH]\(^{+}\) and [M-H + O]\(^{+}\) ions. A possible reason for the absence of [M-2H]\(^{+}\) in the API spectra may be that some species is present which quenches the highly reactive C\(_{6}\)H\(_{5}\)H\(^{+}\) ion forming a nondetectable neutral product. An alternate possibility is that the equilibrium conditions under API, as a result of the high collision rate, should favor the formation of the thermodynamically more stable product. The second possibility may also apply to the absence of [M-H]\(^{+}\). Under NCI conditions, where the collision rate is lower, benzene exhibits dihydrogen transfer while toluene exhibits both dihydrogen transfer and proton transfer. The API and the NCI spectra of toluene are shown below in Figures 2 and 3.

Of particular interest was the effect of perdeuteration of the methyl group in toluene on the reaction with O\(^{-}\). Under API an apparent change in the reactivity of toluene with O\(^{-}\) upon perdeuteration of the methyl group was observed. In this case, no ions characteristic of the behavior of toluene in the presence of O\(^{-}\) were formed. This suggests that the formation of [M-H + O]\(^{+}\) occurs via an initial hydrogen abstraction from the methyl group. These results, coupled with the predominant formation of the benzyloxide isomer of C\(_{6}\)H\(_{5}\)O\(^{-}\), also suggest that the formation of the methylphenoxide isomers of C\(_{6}\)H\(_{2}\)O\(^{-}\) is a result of rearrangement of the initially formed benzyloxide. An alternative possibility may be the rearrangement of the initially formed C\(_{6}\)H\(_{6}\) neutral species to a 7-membered ring which upon recombination with O\(^{-}\) may collapse to methylphenoxide.

1588
Under NCI conditions, the lower collision frequency and shorter residence time allow observation of reaction products analogous to [M-H]⁻, [M-2H]⁻, and [M-H + O]⁻. The spectrum of d₃-methylbenzene under NCI conditions is shown in Figure 4. Ions at m/z 91, 92, and 93, presumably corresponding to [M-2D]⁻, [M-HD]⁻, and [M-2H]⁻ or [M-D]⁻, respectively were observed. This mixture of products indicates hydrogen/deuterium scrambling and is in agreement with the 7-membered ring argument presented above. In addition, the formation of an oxygen substitution product appears to be suppressed, with a small amount of [M-D + O]⁻ being observed. This is also suggests that oxygen incorporation occurs primarily via hydrogen abstraction from the methyl group. Finally, the CID spectra of the m/z 107 and m/z 109 ions formed under NCI indicate the formation of a mixture of benzyloxy and methylphenoxides and the initial removal of an alkyl hydrogen in the pathway of oxygen incorporation. This is demonstrated by the CID of m/z 109 [M-D + O]⁻ under NCI conditions, shown in Figure 5, by the clean loss of 17 amu (-CD₂H) yielding m/z 92. The fragment ions at m/z 77, 78, and 79 in the same spectrum indicate losses of CD₂O, CDHO, and CH₂O, respectively. This suggests hydrogen/deuterium scrambling in the formation of the benzyloxide anion.

GAS PHASE REACTIONS OF DITHIOLATE ANIONS WITH SELECTED LEWIS ACIDS

W.S. Taylor, L.M. Babcock; Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803.

Reactions of several dithiolate anions with BF₃ and SiF₄ have been carried out in the gas phase using the flowing afterglow technique. Specifically, the reactions of 1,2-ethanedithiol (HSEtS⁻), 1,3-propanedithiol (HSPrS⁻), 1,4-butanedithiol (HSBuS⁻), and 1,2-benzenedithiol (HSPhS⁻) have been examined. These species are of interest because they can react with the Lewis acid to form a monodentate addition product in a three-body step, and also present the Lewis acid center with a second functional group which can potentially react to form a bidentate product in a bimolecular step. In previous work several of the dioxo- analogs of these ions have been observed to form both monodentate and bidentate species in competing product channels. The observed mechanistic behavior of the dioxo- systems indicates that this class of reactions occurs on a double-well potential energy surface. The present work has been carried out in order to further examine factors influencing rates and product formation in these processes.

A summary of the products formed in these reactions is given in Table I. Upon examination of these results it is apparent that, in every reaction which proceeded, monodentate products were observed but no bidentate products are formed. Optimum geometries and single point energies for the monodentate and bidentate species for BF₃ + HSEtS⁻ have been obtained from ab initio calculations. These results indicate that, while formation of the monodentate product is energetically favored, bidentate product formation is near thermoneutral. This is likely due to the requirement that the large sulfur atoms be in close proximity to one another in the bidentate product. The only system which participates in bimolecular product formation is SiF₄ + HSEtS⁻ which forms SiF₃⁻ in addition to the monodentate product.

Figure 1
These two products are formed in parallel channels in a manner similar to that of the monodentate/bidentate formation in the dioxo- systems. The branching ratio between the bimolecular and three-body channels is influenced by the pressure. Thus, we conclude that in this system the double-well surface is also applicable. The general mechanism describing all the reactions studied here is given in Figure 1, where the bimolecular product channel is available only to the previously discussed reaction.

The lack of sulfide formation in the systems in which BF₃ is the Lewis acid is likely due to unfavorable energetics. In terms of bonds broken vs. bonds formed, sulfide formation when BF₃ is the Lewis acid is endothermic by 26 kcal-mol⁻¹, whereas the analogous process when SiF₄ is used is exothermic by 21 kcal-mol⁻¹. The fact that sulfide formation only occurs with HSeEtS⁻ can be explained if a mechanism involving fluoride attack on the α-carbon of the ligand is invoked. As the ligand chain length increases the α-carbon becomes less susceptible to nucleophilic attack by F⁻.

With the exception of the reaction of HSPhS⁻ with BF₃, the rates of these processes exhibit no significant pressure dependence and proceed at approximately 60% of their collision rates. The pressure dependent behavior of the observed rate constant for BF₃ + HSPhS⁻ is illustrated in Figure 2. The rate constants for this process range from 24% - 40% of the collision rate. Here also, we feel that this effect is due to the close proximity of the two sulfur atoms in this rigid ligand. The B-S interaction is weaker than in those systems where the second -SH group is free to move. Thus the dissociation back to reactants of the excited complex shown in Figure 1 occurs more frequently, resulting in a slower overall rate. This effect would also explain the lack of reaction of this anion with SiF₄ in which the Lewis acid center is even more crowded.

Gas Phase Electron Transfer Reactions Between Selected Molecular Anions and Halogenated Methanes

W. B. Knighton and E. P. Grimsrud
Department of Chemistry, Montana State University
Bozeman, Montana 59717

Ion-molecule reactions between eight halogenated methanes (RX), including CCl₄, CFCI₃, CF₂Cl₂, CHCl₃, CH₃I, CClBr₂, CF₃Br, and CH₂Br₂, with selected molecular anions (A'), including azulene (Az~), nitrobenzene (NB~) and several substituted nitrobenzenes using a pulsed high pressure mass spectrometer are reported. The electron affinities of the donor molecules (A) range from 16 kcal/mol for azulene to 46 kcal/mol for para-dinitrobenzene. The reaction rates show a steady decrease with increasing electron affinity of the donor molecule. The ionic reaction products were halide ions (X⁻) and clustered halide ions (A.X⁻). No molecular anions of the type RX⁻ were observed for any of the reaction systems.

In order to explain the products and rates of the reactions studied here (see Table I), a hybrid dissociative electron transfer mechanism is proposed. The overall process consists of two distinct reactions. The first reaction is rate determining and results in the transformation shown in Reaction 1:

\[ A' + RX \rightarrow A.X^- + R \]  \hspace{1cm} (1)

where the A.X⁻ cluster ion and radical (R) emerge from the reaction complex. Because the ionic product is a cluster ion, the proposed mechanism is called the CADET (cluster assisted dissociative electron transfer) mechanism. The second reaction involves the declustering-clustering equilibrium reaction:

\[ A.X^- \rightarrow A + X' \]  \hspace{1cm} (2)

The A.X⁻ cluster ion after emerging from the reaction complex is rapidly thermalized through collisions with the buffer gas. The relative intensities of X' and A.X⁻ observed in the mass spectrum reflect the equilibrium position of Reaction 2 which is governed by the gas temperature and partial pressure of NB.

The proposed reaction coordinate for the CADET mechanism is illustrated in Figure 1. Special stability for two intermediate species is envisioned, (A'.RX)' and (A.X'.R)'. The transition state which exists at the height of the energy barrier is thought to resemble a structure in which the C-X bond is being ruptured as an electron is being transferred from A' to the halide atom.

Many of the important features within the experimental results are readily explained in terms of the CADET mechanism.

1. The product ions observed were free halides (X') and their respective adducts (A.X⁻) which is consistent with the products anticipated by the decomposition of the (A.X'.R)' intermediate to A.X⁻ + R.

2. The decrease in the second order rate constants with increasing electron affinity of A is thermodynamically consistent with the proposition that Reaction 1 is the rate determining step. Figure 2 illustrates this point where the second order rate constants for the reactions of CCl₄, CClBr and CF₃Br₂ with various electron donors have been plotted against the enthalpy change of Reaction 1. The rate constants are found to decrease precipitously as \(-\Delta H^\circ\) approaches zero and are not detectable for any reactions where \(-\Delta H^\circ\) is less than zero.

3. The decrease in reactivity of the chlorofluorocarbons in the order CCl₄ > CFCI₃ > CF₂Cl₂ is only partially explainable based on the \(-\Delta H^\circ\)'s for Reaction 1. The stability of the transition state, and therefore the height of the internal energy barrier, is expected to be dependent on the polarizability of the radical leaving group. The polarizabilities of the radical leaving groups are predicted to decrease in the order CCl₄ > CFCI₃ > CF₂Cl₂. This decrease in polarizability leads to progressively less favorable transition states within this series, and thus lower reaction rates.

4. The low reactivity of CH₂Br₂ compared to CF₃Br₂ is thought to reflect the effect of dipole moment, as the differences in reaction exothermicity are too small, and the polarizabilities of the radical leaving group too similar to explain this observation. The anion-dipole interaction orients the CH₂Br₂ molecule within the transition state so that the Br atoms point away from A'. Electron transfer from A' is then more difficult than in the corresponding CF₃Br₂ ion complex where the Br atoms point towards A'.

5. The total lack of reactivity of CH₃I can be explained by a combination of both the low polarizability of the CH₃ radical and an unfavorable dipole-moment induced orientation of the CH₃I molecule within the transition state.

Isotope Exchange and Association Reactions of Hydroxide and Alkoxide Clusters

Thuy Thanh Dang, S. E. Barlow, and Veronica M. Bierbaum

Department of Chemistry and Biochemistry
University of Colorado at Boulder

Hydrogen/deuterium (H/D) exchange reactions of methoxide-water clusters with a variety of labeled water reagents were studied using the Tandem Flowing Afterglow Selected Ion Flow Tube (FA-SIFT). For these reactions, multiple proton transfers may occur within the complex. Table 1 summarizes the results of the exchange reactions. For those systems where more than one possible product was formed, the branching ratio for the endothermic channels was statistical while the exothermic channels were nonstatistical. The statistical results implicate formation of a relatively long lived complex which gives rise to complete scrambling.

a Number in parenthesis is one standard deviation of experimental rate coefficients.
b \( k_{\text{obsd}} / k_{\text{VAR}} \) and \( k_{\text{VAR}} \) calculated according to Chesnavich, W. J., Su, T.; Bowers, M. T. J. Chem. Phys. 1980, 72, 2641.
c BR_{\text{stat}} are the statistical branching ratios assuming complete scrambling within the complex.
d BR_{\text{expt}} are the experimental branching ratios.
e The absolute errors in the branching ratios are estimated to be less than 10% of the percentage reported.

The AH_{\text{rxn}} signs are qualitatively assigned. It is known that substituting a deuterium for a hydrogen in anions is energetically unfavorable. (Grabowski, J. J., DePuy, C. H.; Van Doren, J. M.; Bierbaum, V. M. J. Am. Chem. Soc. 1985, 107, 7384).

1594
In addition, the rate coefficients for the three body association reactions which form hydroxide-water, methoxide-water, methoxide-methanol and ethoxide-ethanol and their various deuterated analogs were measured as a function of helium pressure. Figure 1 gives the experimental data for the association reactions of hydroxide and alkoxides. The apparent bimolecular rate coefficient \( k_{app} \) of the following fourteen reactions is plotted against the helium pressure.

\[
\begin{align*}
H_0^- + H_2O &\rightarrow HO^-\cdot H_2O \\
D_0^- + D_2O &\rightarrow DO^-\cdot D_2O \\
CH_3O^- + H_2O &\rightarrow CH_3O^-\cdot H_2O \\
CH_3O^- + D_2O &\rightarrow CH_3O^-\cdot D_2O \\
CD_3O^- + H_2O &\rightarrow CD_3O^-\cdot H_2O \\
CD_3O^- + D_2O &\rightarrow CD_3O^-\cdot D_2O \\
CH_3O^- + CH_3OH &\rightarrow CH_3O^-\cdot HCH_3 \\
CH_3O^- + CH_3OD &\rightarrow CH_3O^-\cdot DOCH_3 \\
CD_3O^- + CD_3OH &\rightarrow CD_3O^-\cdot HOCD_3 \\
CD_3O^- + CD_3OD &\rightarrow CD_3O^-\cdot DOCD_3 \\
CH_2CH_2O^- + CH_2CH_2OH &\rightarrow CH_2CH_2O^-\cdot HOCCH_2CH_3 \\
CD_2CH_2O^- + CD_2CH_2OH &\rightarrow CD_2CH_2O^-\cdot HOCCH_2CD_3 \\
CH_2CD_2O^- + CH_2CD_2OH &\rightarrow CH_2CD_2O^-\cdot HOCD_2CH_3 \\
CD_2CD_2O^- + CD_2CD_2OD &\rightarrow CD_2CD_2O^-\cdot DOCD_2CD_3
\end{align*}
\]

The lifetimes of the clusters were determined. The results indicate that deuterating the alkyl groups significantly lengthens the lifetime of the clusters, while deuterating the bridging position has very little effect on the lifetime of the clusters. This implies that the methyl groups are nearly free rotors in the complex, thus providing large numbers of states to store the energy; on the other hand, the newly formed OH--O bond produces only vibrational modes with much lower density of states.
DEHYDROGENATION OF ETHANE BY CpM⁺ (M=Fe, Co AND Ni):
AN FTICR STUDY

Henglong Chen, Hung-Yu Lin, Karl Sohlberg and Douglas P. Ridge, Department of
Chemistry and Biochemistry, University of Delaware, Newark, DE 19716.
Dag Ekeberg, Georg Hvistendahl and E. Uggerud,
University of Oslo, P. O. Box 1033 Blindern, N-0315 Oslo 3, Norway.

The reactivity of transition metal ions with alkanes is influenced by the ligands on the
metal. Fe⁺, for example, does not react with ethane, but FeL⁺ (L=CH₂, CH₃, C₅H₆) does react
with ethane to give a series of products [1], [2]. In these cases the reactivity of Fe⁺ is enhanced
by participation of ligands in the reactions. CpCo⁺ has been found to dehydrogenate ethane[3],
but reactions of CpFe⁺ and CpNi⁺ with ethane have not been reported. Using FTICR
techniques we have found reactions of CpM⁺ (M=Fe, Co and Ni) with ethane as follows:

\[
\begin{align*}
\text{CpFe}^+ & \quad + \quad C_2H_6 \quad \rightarrow \quad \text{FeC}_3H_5^+ \quad + \quad C_4H_6 \quad \quad (1) \\
\text{CpCo}^+ & \quad + \quad C_2H_6 \quad \rightarrow \quad \text{CpCoC}_2H_4^+ \quad + \quad H_2 \quad \quad (2) \\
\text{CpNi}^+ & \quad + \quad C_2H_6 \quad \rightarrow \quad \text{CpNiC}_2H_4^+ \quad + \quad H_2 \quad \quad (3)
\end{align*}
\]

The ratio of \( k_{\text{Fe}} \): \( k_{\text{Co}} \): \( k_{\text{Ni}} \) is 0.01: 1.0: 0.4. In addition the following subsequent reactions at
high pressure in the Fe system were observed.

\[
\begin{align*}
\text{FeC}_3H_5^+ & \quad + \quad C_2H_6 \quad \rightarrow \quad \text{FeC}_5H_9^+ \quad + \quad H_2 \quad \quad (4) \\
\text{CpFe}^+ & \quad + \quad C_2H_6 \quad \rightarrow \quad \text{CpFeC}_2H_6^+ \quad \quad (5)
\end{align*}
\]

These observations raise the question of why CpFe⁺ reacts in such a completely
different manner from CpCo⁺ and CpNi⁺. We offer the following interpretation in terms of
Frontier Orbital Theory.

First consider an MO diagram for CpFe⁺ as shown in Fig. 1. From this diagram we see
that all bonding MOs are occupied and the LUMOs are ligand based \( \epsilon_1^\prime \) orbitals. The \( \epsilon_1^\prime \)
LUMOs are depicted in Fig. 2. Indicated are the coefficients of the \( 2p_z \) orbitals on the carbons
and the \( d_{xz} \) (\( d_{yz} \)) orbital on Fe. The 12 valence electrons occupy bonding orbitals giving a
strong metal ligand interaction and a LUMO with C-C antibonding character leading to C-C
bond cleavage on reaction. This is why for CpFe⁺ the Cp ring is involved in the reaction.

In CpCo⁺ and CpNi⁺ occupation of antibonding orbitals will weaken the interaction
between Cp and M⁺. The MO diagram for CpCo⁺ is shown in Fig. 3 (CpNi⁺ would be
similar). This diagram tells us that \( d \) orbitals are not strongly perturbed by the ligand and thus
occupation in a high spin sense is expected. The resulting LUMO becomes the \( a'' \)
orbital which is strongly metal 4s in character as depicted in Fig. 4. Indicated are coefficients of the
\( 2p_z \) orbitals on the carbons and 4s orbital on the metal. With 13 and 14 valence electrons the
CpCo⁺ and CpNi⁺ have occupied antibonding orbitals resulting in a weak metal-ligand
interaction. The LUMO has strong metal 4s character and the metal is more like a free metal
with \( d \) orbitals occupied in a high spin sense. The metal 4s LUMO leads to dehydrogenation
reactions.

**C₃H₄N₂O₃⁻ Anions Produced by Reaction of 2-Chloro-5-Nitropyridine with the Hydroxide Ion**

Gregory G. Dolnikowski  
USDA-HNRC at Tufts University  
711 Washington Street  
Boston, MA 02111

**Introduction**

In solution and also in the gas phase, the electron deficient nature of the pyridine ring makes the electrophilic aromatic substitution reactions that are typical of aromatic systems very difficult, but instead facilitates nucleophilic aromatic substitution reactions. Nucleophilic aromatic substitution occurs in solution by three separate mechanisms (1), the addition elimination mechanism, $S_N(\text{AE})$, the benzene mechanism, and the aromatic nucleophilic substitution by ring opening and ring closing mechanism $S_N(\text{ANRORC})$. The $S_N(\text{ANRORC})$ mechanism has received much less attention than the other two mechanisms and it has not been much investigated by mass spectrometry.

**Solution Reaction**

The particular reaction of interest in this study is the reaction of 2-chloro-5-nitropyridine with OH⁻ (2,3). In a solution of dimethylsulfoxide and water this reaction forms a stable, isolatable, ring-opened $C_3H_3N_2O_3$⁻ anion whose structure has previously been determined by NMR and is shown in Figure 1. Addition of excess OH⁻ closes the ring again and leads to the expected nucleophilic addition product, the 2-oxy-5-nitropyridine anion. Both products are salts and are isomers of each other. Negative ion fast atom bombardment using glycerol as the matrix successfully desorbs the molecular anions of both products. Neither low nor high energy negative ion CID of these ions differentiates the two isomers. However, negative ion fast atom bombardment combined with high energy charge inversion tandem mass spectrometry (4) in a Kratos MS-50 three sector EBE instrument is an excellent means of differentiating the two ions from the $S_N(\text{ANRORC})$ solution-phase reaction. Figure 1 shows the charge inversion tandem mass spectra of the two products. Probable formulas for the positive fragment ions of the negative ion precursors are shown above the appropriate peaks in Figure 1.

**Gas-Phase Reaction**

In a negative ion chemical ionization source, OH⁻ ions derived from water reacted with 2-chloro-5-nitropyridine in the gas phase to produce an ion with a charge inversion tandem mass spectrum (see Figure 2) that is identical to that of the 2-oxy-5-nitropyridine anion. Apparently this analogous gas-phase reaction follows an $S_N(\text{AE})$ mechanism since the ring-opened ion is not detected. Scheme 1 shows simplified mechanisms for both of the solution and gas-phase reactions of 2-chloro-5-nitropyridine with OH⁻.

**Acknowledgement**

I would like to thank M.L. Gross from the University of Nebraska-Lincoln, and J.T. Watson from Michigan State University for allowing me to use their tandem mass spectrometers for this research.

INTRODUCTION
Reaction of C_3H_3^+ with acetylene has received considerable attention in recent years. The high concentration of C_3H_3^+ ions in sooting flames has suggested that this cation plays an important role in the ionic root to the formation of the soot. Reaction of linear-C_3H_3^+ with acetylene and C_2D_2 in FT/ICR has shown that linear-C_3H_3^+ isomerizes to the cyclic form. Isomerization was shown to take place via a long-lived C_5H_5^+ collision complex by hydrogen exchange reactions between linear-C_3H_3^+ and C_2H_2. Better understanding of the isomerization of linear C_3H_3^+ was achieved using C_2D_2 instead of C_2H_2. C_3H_3^+, C_3H_2D^+, C_3HD_2^+ and C_3D_3^+ ions were produced by isotope exchange reactions. To further investigate this isomerization mechanism, i.e., to examine if this isomerization involves skeletal exchange, reaction of linear C_3H_3^+ with ^13C_2-acetylene was studied in a quadrupole ion trap mass spectrometer.

EXPERIMENTAL
A Finnigan ion trap mass spectrometer was used for this study. C_3H_3^+ was produced by charge-transfer reaction of propargyl bromide with Xe^+, formed by electron impact ionization. Ejection capabilities of the ITMS were used for this charge transfer reaction and for the isolation of the C_3H_3^+. Neutral gas pressures were measured with an ionization gauge. P_{C_3H_3Br}=2\times10^{-7} \text{Torr}; P^{13C_2H_2}=4\times10^{-7}; PXe=1.5\times10^{-6}. Pressure of helium was adjusted to a total ionization gauge reading pressure of 8\times10^{-5}, i.e., 1 \text{ mTorr}.

RESULTS AND DISCUSSION
Reactivity of C_3H_3^+. Reactivity of the C_3H_3^+ was monitored by observing reaction with precursor neutrals. Percentage of reactive (linear) C_3H_3^+ formed by chemical ionization charge transfer from Xe^+ was 75% (Figure 1), consistent with the FT/ICR study.

Isomerization of Linear C_3H_3^+. After ejection of all ions except C_3H_3^+ following charge-transfer chemical ionization by Xe^+ of a mixture of ^13C_2H_2 and propargyl bromide, the ion/molecule reactions as a function of time were monitored. It was observed that (see Figure 2): 1) Reactions with ^13C_2H_2 led to the isomerization of linear-C_3H_3^+ to the non-reactive cyclic-C_3H_3^+. 1600
2) Isomerization occurs through a C₅H₅⁺ reaction complex via skeletal exchange producing

\[ ^{13}\text{C}_2\text{H}_3^+, \; ^{13}\text{C}_2\text{CH}_3^+, \text{ and } ^{13}\text{C}_3\text{H}_3^+. \]

Collisional Stabilization of the C₅H₅⁺ Collision Complex

In the pressure regime of the FTMS, no C₅H₅⁺ ion was observed when C₃H₃⁺ reacted with acetylene, indicating that most of the C₅H₅⁺ collision complex dissociated to give the cyclic C₃H₃⁺, rather than linear isomer. Since quadrupole ion traps operate at higher pressure, effect of pressure on the C₅H₅⁺ formation was studied using helium buffer gas for third-body stabilization of the C₅H₅⁺ collision complex. Intensity of the C₅H₅⁺ increased, directly, when the system pressure was increased from \(2 \times 10^{-6}\) to \(5 \times 10^{-4}\) torr (uncorrected ion gauge reading), supporting the collision complex formation mechanism (Figure 3).

CONCLUSION

The results show that the isomerization of the linear-C₃H₃⁺ to the cyclic form occurs through a C₅H₅⁺ reaction complex via hydrogen and/or skeletal exchange. Third body stabilization of the C₅H₅⁺ occurs at pressures above 1 mtorr, supporting the collision complex formation mechanism.

Formation of Substituted Benzene Radical Cations via Ion/Molecule Reactions with Iodobenzene

Gary L. Glish and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

Ion/molecule reactions commonly occur in mass spectrometers. While in many cases such reactions are undesirable they can be useful for structure determination or for comparison of gas-phase chemistry with solution chemistry. In general, when an even electron ion reacts with a neutral molecule, the product ion formed is also an even electron ion due to the normally unfavorable energetics involved in electron unpairing. A notable exception to this is a system we have been studying, the reactions of iodobenzene with a variety of different even-electron ions.

As shown below, a variety of even-electron hydrocarbon ions react with iodobenzene to give alkyl benzene radical cations. The general reaction is

\[ R^* + I^- \rightarrow \phi + \phi + R^* + I^- \]

Thus, an ion is observed at \((R+77)\). Reactions are observed in cases in which the reactant ion is less than 15 kcal/mol or so more stable than the resulting alkylbenzene radical cation. The driving force for the reactions in which the odd-electron product ion is less stable than the even-electron reactant ion is the fairly unique situation of the radical product \((I^*)\) being about 15 kcal/mol more stable than the neutral reactant (iodobenzene).

We first observed the reaction of iodobenzene giving substituted benzene radical cations in the methane CI mass spectrometry of iodobenzene. With the ion trap, selected reagent ion CI demonstrated that \(C_6H_4I^+\) gives an ion at m/z 106, \(C_6H_5I^+\), which is ethylbenzene. While the fact that this reaction occurs is interesting, the product can reasonably only be ethylbenzene. However, the next higher ion in the series, the propyl cation, has two possible structures \(n-\) or \(i-\). Thus, m/z 43 is allowed to react for 100ms is shown in Figure 1. The major product ion is m/z 57 due to hydride abstraction from isobutane. The other two ions in the spectrum result from reactions of 43 with \(\phi\). The ion at m/z 205 is formed by the commonly observed proton transfer reaction while the species at m/z 120 corresponds to the substitution of \(C_6H_4I^+\) for \(I^-\) in \(\phi\). The thermochemistry of the system is that the proton transfer is exothermic by about 2 kcal/mol, \(\Delta H_{298}^0\) substitution is exothermic by about 5 kcal/mol and \(n-\) \(C_6H_4I^+\) substitution is exothermic by about 25 kcal/mol.

Figure 2 shows the MS\(^3\) experiment in which the MS/MS spectrum of the reaction product at m/z 120 is obtained. From comparison of this spectrum with MS/MS spectra of the two isomeric propylbenzenes, it can be determined that the expected isopropylbenzene is the major product (giving the product ion at m/z 105) but that there is some \(n-\) propylbenzene also formed (giving product ions at m/z 91 and 78). Continuing up in the series, \(C_6H_5I^+\) would not be expected to react if it is \(n\)-butyl but the other three isomers, \(s-\), \(i-\), and \(n-\) butyl should react. When m/z 57 is formed from 1 or 2-chlorobutane approximately 0.06% of the ions are reactive, giving m/z 134. The product ion spectrum of m/z 134 has only one ion, m/z 105, which is characteristic of \(s-\) butylbenzene.

The vinyl cation is an extremely reactive species which rarely is observed to form stable substitution products because of the high exothermicity of its reactions. However, when it reacts with \(\phi\) the substitution product is observed. An MS\(^3\) experiment was performed in which the MS/MS product ion spectrum was obtained on the vinyl cation reaction product with the vinyl cation being formed by CID of \(C_6H_4I^+\). This spectrum indicated that styrene is formed, as expected. This reaction is about 50 kcal/mol exothermic, which suggests that significant energy may be partitioned into translational energy of the products.

An ion with a higher degree of unsaturation than the vinyl cation, \(C_6H_5^+\), which is a major fragment from phenyl cations, has also been studied. In addition to the product ion formed from the \(\phi\) substitution reaction, the molecular ion and protonated molecule of \(\phi-I\) are observed. The protonated species comes about as discussed above. The molecular ion is formed by charge exchange with \(^{13}C_C_6H_4I^+\) isobaric which is also present at m/z 51 when that m/z is selected from the mass spectrum. (Isobarically pure m/z 51 can be generated by MS/MS if so desired.) The MS/MS spectrum of the product ion formed by \(C_6H_5^+\) is shown in Figure 3. MS/MS experiments generating \(^{13}C\) containing \(C_6H_5^+\) suggest that the structure of m/z 128 is that of naphthalene. The MS/MS spectrum of the molecular ion of naphthalene was obtained and is identical to Fig. 3.

---

The 39th ASMS Conference on Mass Spectrometry and Allied Topics
During the course of the MS/MS experiments on the m/z 128 reaction product it was observed that the product ion at m/z 127 produced an ion at m/z 204. While this could be the molecular ion of I⁻, it is also (R+77) for R=127. An MS³ experiment demonstrates that it is the later species which is formed.

The reaction of m/z 127 indicated that cyclic ions would also react in addition to the linear hydrocarbons. Figure 4 shows the reaction of the phenyl cation with I⁻. Not only is the substitution product observed but also the reaction intermediate, m/z 281. From a kinetics plot for the reaction m/z 77 the rate constant for this reaction in the ion trap was determined to be 2 x 10⁻⁹ cm²/s/molecule, indicating that this is a very efficient reaction. The MS/MS spectrum of the reaction intermediate shows the expected dissociation, loss of I⁻. The MS/MS spectrum of the reaction product indicates that it is biphenyl.

We have observed this reaction with other halobenzenes. Crude bracketing of unknown heats of formation can be performed by observing if this reaction occurs with I⁻ and the analogs, Br and Cl. The reaction will occur with I⁻ if the difference in heats of formation of the reactant and product ion is less than 15 kcal/mol. For the reaction to occur with Br the product ion must be at least as stable as the reactant, while for Cl the product ion must be at least 15 kcal/mol more stable than the reactant.
ORIGIN OF [M+C_nH_{2n-2}] ANIONS IN THE NCI MASS SPECTRA OF SUBSTITUTED PAHs WHEN USING METHANE AS THE BUFFER GAS

Lee Q. Huang,
Department of Analytical Chemistry, The Connecticut Agricultural Experiment Station, Box 1106, New Haven, CT. 06504,
Colin Moore,
Kratos Analytical Inc., 535 East Crescent Avenue, Ramsey, NJ. 07446.

Polycyclic aromatic hydrocarbons (PAHs) have long been recognized as hazardous environmental pollutants because of their carcinogenic effect on man. Attempts have been made to utilize many chromatographic and/or spectroscopic techniques for the analysis of these compounds. Adduct ions of [M+14]' and [M+28]' were reported in mass spectra of many PAHs when the negative chemical ionization (NCI) technique was used, but their formation has been attributed to two totally different reactions occurring in mass spectrometer (MS) source. The first reaction involves the substrate and hydrocarbon buffer gas in the ion source and results in the formation of [M+C_nH_{2n}]' adduct ions (ref. 1). The second reaction is a result of a wall-catalyzed oxidation reaction (ref. 2) giving a [M+14]' adduct. In the GS/MS analysis of PAHs under methane negative chemical ionization conditions, we observed significant abundances of [M+12]', [M+26]', [M+40]', ...[M+C_nH_{2n-2}]' ions in the NCI mass spectra of substituted fluorenes (Fig. 1). The results from a detailed study as to the origin of these adduct anions are reported here.

The experiments were performed using Hewlett-Packard 5890 gas chromatographs coupled via a capillary direct interface to either a quadrupole MS (Hewlett-Packard 5988A) or a magnetic sector MS (Kratos CONCEPT IS). The relative intensities of the adduct ions were similar for both types of mass spectrometer. The compounds of interest were fluorene, 1-methyl-fluorene, 11H-benzo[a]fluorene, and 11H-benzo[b]fluorene. The benzene solution of the compound was injected in splitless mode onto a DB-17 column (30m x 0.25um i.d.) which was temperature programmed as follows: 90°C for 1 min, ramped at 20 °C min^{-1} to 250 °C and held for 10 min. Helium was used as the carrier gas after being filtered through an OMI-1 indicating purifier. The ion source was at 150 °C for all experiments. The indicated methane or argon buffer gas pressure was 1 x 10^{-5} torr measured in the source housing, corresponding to an estimated source pressure of 0.1 torr. For the accurate mass measurements, the sample was introduced into MS via direct insertion probe and the mass spectrometer resolution was set at 6000 (10% valley definition). Peak matching against pfk reference ions was then used to determine the exact mass of the ion of interest.

The [M+C_nH_{2n-2}] anions were not observed when argon was used as the reagent gas, which indicated that the adducts were probably due to reaction of substituted fluorenes to the species from the methane gas. The results from accurate mass measurements of these adduct anions were given in Table 1. These data confirmed that the [M+12]' was [M+C]', [M+26]' was [M+C_2H_2]', and [M+40]' was [M+C_3H_4]'. It is interesting to note that the most abundant adduct ion is [M+C]', and then [M+C+CH_2]', [M+C+C_2H_4]', ...[M+C+C_nH_{2n-2}]' and that substituted fluorenes have one unsaturated site on their aromatic rings; while other PAHs without unsaturated sites only form [M+C_nH_{2n}]' ions. This observation suggested that substituted fluorenes may react with hydrocarbon species in the methane buffer gas at the unsaturated site and rearrange to a saturated PAH as shown in the following equation.
Figure 1. NCI mass spectra of fluorene, 1-methylfluorene, 11H-benzo[a]fluorene, and 11H-
benzo[b]fluorene introduced through the gas chromatograph at a source temperature of 150° C using
CH₄ as the reagent gas.

Carbon Cluster Ion Reactivity with Aromatic and Polyaromatic Hydrocarbons

Jeffrey A. Zimmerman and William R. Creasy
IBM Corp., Dept. T67, P.O. Box 8003, Endicott, NY 13760.

The reactivity of carbon cluster ions (C_n^+, 10<n<25) has been studied with various aromatic and polyaromatic hydrocarbons in a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. Reactions proceed by one or more of three routes: charge transfer [1], adduct, and/or adduct minus a hydrogen atom ([adduct-H]) ion formation. Carbon cluster ions of this size are generally believed to be monocyclic rings which display limited reactivity due to the lack of exposed carbon atoms[2]. However, these cluster ions were discovered to react either by adduct or [adduct - H] ion formation dependent of whether the cluster contained an even- or odd-number of carbon atoms. This alternating reactivity suggests different structures and perhaps the presence of structural isomers.

Collisionally induced dissociation (CID) of the reaction products (adduct or [adduct-H] ions) produced limited fragmentation (loss of hydrogen atoms and molecules, C_2H_2(C_2)) for adducts formed with PAH's or styrene, and loss of HNC (HCN) and CH_3 from aniline and toluene adducts, respectively. No original reactants were created. At sufficient collision energies bare carbon cluster ions were formed (cf. Fig. 1, the CID of the [Cu.CioHg] ion). Similar results were obtained for the diadducts. These results imply the adducts are formed via multiple bonds with PAH type conjugation and are not loose associations. It was also possible to grow large adducts, associating to a maximum of four, that are rich in dehydrogentation. This suggests that carbon cluster ion/neutral reactions may contribute to the ion distributions observed in laser ablation of carbon containing materials.

Detailed investigation of the cluster ion reactivity with naphthalene reveals several interesting characteristics. All reactions (both products and reaction rates) were found to have a profound dependence on the kinetic energy of the cluster ion and on the pressure of a bath gas. Figure 2 shows both of these effects for the reaction of C_n^+ and naphthalene (all spectra obtained at the same naphthalene pressure and reaction time). The spectra shown start at high ion kinetic energies, with the center spectrum at ca. thermal ion kinetic energies. The last two spectra were acquired at background argon pressures of 1 x 10^-6 and 1 x 10^-5 torr, respectively. The rate constant for adduct formation decreased as the charge transfer rate increased as a function of increasing ion kinetic energy. Figure 3 shows computer modelled fits to the data for C_20^+ and naphthalene. The charge transfer and adduct rate constants were varied on the time scale of the experiment as a function of unreactive collisions.

The kinetics (in naphthalene reactions) indicate C_{11}^+, C_{19}^+ and C_{19}^+ have structural isomers, forming both adduct and [adduct-H] ions and exhibiting bi-exponential kinetics are observed for these ions. The lifetimes of the ion/molecule complex are estimated using a computer program that models the kinetics using radiative lifetimes ranging from 7 to 100 s^{-1} [3]. This produces lifetimes which are on the order of 0.1 - 3 ms, much longer-lived than
anticipated. These findings were verified by varying the argon bath gas pressure to collisionally stabilize the ion/molecule complex. In addition, experiments were performed to estimate the kinetic energy of the desorbed ions. Ions were first thermalized and then subjected to a single frequency excite pulse to increase their kinetic energy to a known value. Figure 4 shows the results for C_{15}^+. The enclosed area represents unthermalized results and was abnormally high, 4 - 6 eV. A 2 volt trapping potential was used, therefore considerable kinetic energy must be present as cyclotron motion.

GAS-PHASE MOLECULAR RECOGNITION:
ALKALI METAL ION TRANSFER REACTIONS OF CROWN ETHERS

Inhou Chu, Hong Zhang, Sam Leming, and David V. Dearden

Chemistry Department
The University of Texas at Arlington
Arlington, TX 76019-0065

Background. The special ability of crown ethers to selectively form complexes with alkali metal cations in solution is well known. This selectivity is generally believed to be the result of a size match between the ligand cavity and an alkali metal cation; cations which match the cavity size bind more strongly than those which do not. In addition, the stabilities of crown-cation complexes are known to have strong solvent and counterion dependence. For example, the complex of 15-crown-5 with K+ is more stable in aqueous and methanolic solutions than the corresponding Na+ complex, although calculations indicate that the intrinsic M+-crown bond strength is greater for M = Na than for M = K. These species have also been the subject of recent theoretical work.

Motivation. The present study is motivated in part by the need to obtain data which are directly comparable to theoretical studies, i.e., gas phase data where solvents and counterions are not present. Crown-cation complexes have been observed previously using FAB and 252Cf-plasma desorption techniques. However, in all of these studies it is unclear whether complex formation occurred in solution prior to volatilization or in the gas phase after volatilization.

Size- and shape-specific chemistry is rarely observed in the gas phase. Crown ether-alkali cation experiments provide an opportunity to probe the relationship between cation radius, crown cavity radius, and reactivity, since the alkali metal cations are chemically quite similar except for their size.

Experimental. We have successfully generated gas-phase complexes of Na+, K+, Rb+, and Cs+ with 15-crown-5 and 18-Crown-6 using laser desorption. Solutions of crown ether and cation salts (generally chlorides or nitrates) in methanol were deposited on a stainless steel probe. Solvent was removed and the probe was inserted into a vacuum chamber and located immediately adjacent to the trapping cell of a Nicolet/Extrel FTMS-1000 ion cyclotron resonance mass spectrometer. Complex ions are trapped in the cell following irradiation of the probe tip with the focussed output of an excimer-pumped dye laser. Very small pulse energies are required (less than the 0.5 mJ/pulse threshold of our detector), provided the probe surface lies within a few mm of the focal point of a 150 mm fl lens. Subsequent ion-molecule chemistry is carried out by admitting neutral reagents through a leak valve and monitoring ion populations as a function of reaction time. Collision-induced dissociation (CID) and threshold CID experiments were performed on a Finnigan TSQ-70 using fast atom bombardment-generated complexes.

Results and Discussion. We believe the species we are generating using desorption methods are intact crown ethers complexed to metals. Low-energy CID of the same complexes generated using fast atom bombardment gives only the alkali metal cation as a major fragment. Likewise, laser desorption produces primarily ions of the expected complex mass with little fragmentation.

All of the 15-crown-5/alkali cation complexes studied are observed to transfer the cation to 18-Crown-6 when neutral crown is admitted into the vacuum system. This is in good agreement with experiments in solution and with theory, all of which indicate that these cations bind 18-Crown-6 more strongly than 15-Crown-5. Rate studies indicate these reactions are relatively
inefficient, as seems reasonable since proper cavity-to-cavity orientation is probably essential for a reactive collision. The reverse reactions, transfer of cation from 18-Crown-6 to 15-Crown-5, are not observed after reaction times of 30 seconds.

Surprisingly, in addition to the expected transfer reactions, formation of \((\text{crown})_2\text{M}^+\) is observed. Evidently, these species can radiatively cool rapidly enough to stabilize the collision complexes. Kinetic plots support this idea, showing that simple pseudo-first order kinetics are not obeyed for these reactions. Species of the same stoichiometry have been observed in condensed media and have “sandwich” structures, with the cation lying between two parallel macrocyclic rings.\(^1\)

The formation of these alkali cation bound “sandwich” dimers can be understood in terms of the relative sizes of the cations and crown ether cavities, if it is assumed that the cation must protrude significantly from the ring cavity in order for “sandwich” building to occur. All of the studied cations form sandwiches with 15-Crown-5, consistent with the idea that none of them can fit within the cavity. Likewise, only Cs\(^+\) forms a sandwich with 18-Crown-6. Na\(^+\) and K\(^+\) have radii less than that of the 18-Crown-6 cavity, and Rb\(^+\) is only slightly larger, so these cations lie mostly within the ring cavity. Cs\(^+\) is much too large to fit within the cavity and therefore is accessible for “sandwich” formation. The mixed \((15\text{-Crown-5})(18\text{-Crown-6})\text{M}^+\) complexes are also explained by this model. Na\(^+\) and K\(^+\) can fit within 18-Crown-6 and do not form a mixed sandwich. Rb\(^+\) forms a mixed sandwich when it is initially complexed to 15-Crown-5, but not when it is initially bound to 18-Crown-6. Cs\(^+\) readily forms mixed sandwiches, since it is too large to fit within either macrocycle.

Attempts to measure crown-cation bond energies using threshold CID have so far had limited success. The threshold for dissociation of the 18-Crown-6/K\(^+\) complex is tentatively 1.1 eV, corresponding to a bond energy of about 25 kcal/mol, which seems reasonable. Work is in progress to improve the reproducibility of these measurements.

ION-MOLECULE REACTIONS OF GROUND AND EXCITED STATES
OF TRANSITION METAL IONS AND
THEIR RESULTING IONIC CLUSTER FRAGMENTS

J. V. Oriedo and D. H. Russell
Department of Chemistry, Texas A&M University
College Station, TX 77843

Atomic metal ions produced by electron impact ionization of transition metal carbonyls are formed
in both ground and metastable states and the distribution of states varies with the energy of the electron
beam\(^1\). Studies by various groups indicate that the state in which the reactant ion is produced can
significantly influence the chemistry of the ion-molecule reactions\(^2\).

This study focuses on the Fe\(^+\) system. Fe\(^+\) produced by EI of Fe(CO)\(_5\) reacts with neutral Fe(CO)\(_5\)
according to reactions 1-7. The charge transfer reactions (3-7) are endothermic for ground state Fe\(^+\) and
can only be a result of excited state Fe\(^+\). Generally, the relative intensities of the charge transfer products
increase from Fe(CO)\(^+\) (AP=11.52 eV) to Fe(CO)\(_5\)\(^+\) (IP=7.95 eV). The extent of electronic excitation can
be estimated from Table 1, and these data can be used to bracket the energy levels of the states giving
rise to charge transfer products.

The ligand exchange reactivity of Fe\(_2\)(CO)\(_3\)\(^+\) and Fe\(_2\)(CO)\(_4\)\(^+\) ionic cluster products formed by the
clustering reactions 1 and 2 are significantly different. For example, Fe\(_2\)(CO)\(_3\)\(^+\) readily undergoes ligand
exchange ion-molecule reactions with \(^{13}\)CO to displace all CO ligands; whereas only a fraction (ca. 40 %)
of the Fe\(_2\)(CO)\(_5\)\(^+\) ions are reactive toward ligand exchange\(^3\). The different reactivities of the Fe\(_2\)(CO)\(_5\)\(^+\) ionic
cluster fragment may be due to different structures for the Fe\(_2\)(CO)\(_3\)\(^+\) ions or electronic states of the
reactant Fe\(^+\) ions. If the Fe\(^+\) ions are formed with a distribution of long-lived electronically excited states,
the Fe\(_2\)(CO)\(_y\)\(^+\) ions may be formed with a distribution of internal energies.

\((\text{I})\) Clustering reactions

\[
\begin{align*}
\text{Fe}^{+} & + \text{Fe(CO)}_{5} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} + 2\text{CO} \\
\text{Fe}^{+} & + \text{Fe(CO)}_{6} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} + \text{CO} \\
\end{align*}
\]

\((\text{II})\) Charge transfer reactions

\[
\begin{align*}
\text{Fe}^{+} & + \text{Fe(CO)}_{5} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} + 2\text{CO} \\
\text{Fe}^{+} & + \text{Fe(CO)}_{6} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} + 3\text{CO} \\
\text{Fe}^{+} & + \text{Fe(CO)}_{7} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} \rightarrow \text{Fe}^{+} + 4\text{CO} \\
\end{align*}
\]

These experiments were performed in a differentially pumped two-section ICR cell. For instance,
Fe\(^+\) is initially formed by EI of Fe(CO)\(_5\) (in region 1 of the two-section cell). Fe\(^+\) is isolated by using ion-
ejection techniques and partitioned to region two of the cell where it is allowed undergo collisions with
various reagents (CH\(_4\), CH\(_3\)OH, He, Ar, etc.). The Fe\(^+\) ion is then partitioned back to the reaction chamber
(region 1) and allowed to react with the neutral Fe(CO)\(_5\) for 100 milliseconds. The effects of collisional
quenching on the reaction chemistry of Fe\(^+\) are probed by monitoring the branching ratio [Fe\(_2\)(CO)\(_3\)\(^+\) / 
Fe\(_2\)(CO)\(_5\)\(^+\)] of the two ionic cluster products (reactions 1 and 2).

The collisional relaxation rates (Table 2) show nitric oxide as the most efficient quencher (3x10\(^{-9}\) 
cm\(^3\)/sec). Methanol and methane collisionally quench excited states of Fe\(^+\) at the same rate (2x10\(^{-9}\) 
cm\(^3\)/sec). Inert gases show interesting results; the heavier inert gases collisionally quench the excited
states of Fe\(^+\) at a faster rate than the lighter inert gases.

1610
Differences in the quenching rates for various reagents can be explained in terms of the energy transfer processes between excited Fe\(^*\) and each quenching reagent. For inert gases the energy transfer process involves electronic-to-translational energy transfer (E->T). The higher collisional relaxation probability of excited Fe\(^*\) by heavier Kr compared to the lighter He could be due to intramultiplet relaxation mechanism discussed by A. B. Caller\(^*\). On the other hand, electronically excited Fe\(^*\) can induce, electronic-to-vibrational, rotational and/or translational energy transfer to the other reagents (E->V, R, T).

The depletion of Fe\(_2\)(CO)\(_3\)* ionic cluster fragment over extended collisional relaxation time of Fe\(^*\) with NO, CH\(_3\)OH, CH\(_4\), N\(_2\), H\(_2\), D\(_2\), He, Ar, and Kr is a clear indication of the effect of electronic excitation on the ion-molecule reaction chemistry of Fe\(^*\) with the neutral Fe(CO)\(_8\) (reactions 1-7). The initial energy of the Fe\(^*\) ion can greatly influence the internal energy of the Fe\(_2\)(CO)\(_3\)* product ions.

Table 2. Rate constants (corrected for ionization gauge sensitivity\(^*\)) for collisional relaxation of Fe\(^*\) by various reagents.

Ionization Potentials and Reactivity of Coinage Metal Clusters

M.A. Cheeseman and J.R. Eyler
Department of Chemistry University of Florida
Gainesville, FL 32611-2046

The ionization potentials of several homoatomic and heteroatomic coinage metal clusters have been determined utilizing charge transfer bracketing and Fourier transform ion cyclotron resonance (FTICR) mass spectrometry. The clusters studied were Ag$_n$, Au$_n$, Cu$_m$, and Ag$_k$Cu$_l$, where n=2-3,5, m=2,3, and k and l = 1, 2. Atomic ionization potentials were also verified for each of the above metals as a test of the overall bracketing method. This work represents one of the first measurements of adiabatic ionization potentials for any of the above clusters. A number of additional reactions were observed between several of the charge transfer agents and metal cluster ions, including some which resulted in metal-metal bond cleavage.

Table I shows the bracketed ionization potentials and estimated uncertainties of those metal clusters produced with sufficient intensity to be studied by charge transfer reactions. Previous experimental and theoretical determinations of ionization potentials for these species are listed in columns three and four of Table I, respectively. The agreement between this work and previous experimental results is good, particularly with regard to those ionization potentials which are well known. There is also qualitative agreement with the theoretical treatments. Both of these results supports the viability of this technique for determining the ionization potentials of small metal clusters.

Additional side reactions which occurred between some of the charge transfer agents (CTAs) and the metal clusters, and resulted in metal-metal bond cleavage, were also studied. These have been analyzed thermochemically to yield lower limits for the bond dissociation energies of the metal-CTA ion/molecule complex. These estimates are presented in Table II. Also presented in Table II are bond dissociation energies of some Ag-CTA complexes determined by collision induced dissociation (CID). These values agree well with our other estimates.

Reactions of Laser Desorbed Metal Ions With Benzene
Steven L. VanOrden, Brian T. Cooper, R. Marshall Pope, Steven W. Buckner, Department of Chemistry, University of Arizona, Tucson, AZ, 85721

Introduction
This work involves the reactivity of early transition metal cations (Y*, La*, Nb*, and Ta*) with benzene. These metal cations have been previously observed to be highly reactive toward hydrocarbons, exhibiting predominantly C-H insertion mechanisms. We have studied the product distributions, kinetic isotope effects, and subsequent reactions for these metal cations. It is found that these metals are highly reactive toward benzene, and that cleavage of the benzene ring competes with formation of the metal-benzyne complex by dehydrogenation.

One of the problems associated with performing laser desorption/ionization and photochemistry experiments with a pulsed Nd:YAG laser coupled to a Fourier transform ion cyclotron resonance spectroscopy is timing the laser and MS sequences. We have designed a new interface that coordinates the laser and mass spectrometer. This interface was used for the present laser desorption experiments.

Experimental
All experiments were performed on a Fourier transform ion cyclotron resonance mass spectrometer. Atomic metal cations were generated by focussing the fundamental output of a Spectra-Physics DCR-11-3 pulsed Nd:YAG laser (pulse energies of ~135 mJ) on pure metal blocks. Benzene pressure in the vacuum chamber was ~5x10^-8 torr (uncorrected). After initial ionization, the metal ions were trapped for 200-400 msec to allow for collisional and radiative cooling. After the cooling period the ions were isolated by swept double resonance ejection pulses. This cooling period should allow for nearly complete translational cooling (35-70 collisions). However, there is evidence that a small portion of the remaining ions might have some electronic excitation after this period.

Results
All four metals investigated were found to dehydrogenate at least one benzene to form a metal-benzyne complex. Scheme 1 shows the reactive pathways observed for each of the metal species. The relative branching ratios, listed for C,H6, are found to be very similar to those of C,D6. Only a small kinetic isotope effect is observed (~1.1) which could indicate that the dehydrogenation involves a tight transition state. The observed charge transfer reactions to form C,H7+ are endothermic and are probably due to incomplete collisional cooling of the metal ions. At very long reaction times it was found that 4 benzenes were dehydrogenated to form Ta(C,H5)+, but the reaction could be driven no further. The observation of C,H4 and C,H ligands for Nb* and Ta+ is the first observation of ring cleavage of benzene by transition metal cations. The lack of subsequent reaction by the Y-benzyne and La-benzyne complexes could offer insight into the mode of bonding. Consider structures I and II. For structure I both valence electrons are used in bonding and we expect little or no secondary reactions. A π-bonded benzyne such as in structure II, however, would still be capable of further reaction.

* Product Indicates Excited Metal Ion
INTRODUCTION

The photochemically induced polymerization of epoxides by cyclopentadienyl iron arene complexes is a commercially significant reaction used for photolithography. The FeCp* cation is thought to be a key intermediate in the reaction (1,2). We have previously investigated the gas phase ion chemistry of FeCp* with ethylene oxide, and with other cyclic ethers, to learn details of the mechanism of this reaction (3). We have now extended these studies to the reactions of cyclic ethers with other first row transition metal cyclopentadienyl cations, such as CoCp* and NiCp*. In addition, the effect of internal energy of the FeCp* ion on its reactivity with ethylene oxide has been investigated.

EXPERIMENTAL

The experiments were performed using a Fourier transform mass spectrometer with a 1-3/4" cubic cell, a 1 Tesla electromagnet and an Ionspec Omega data system. The vacuum system is pumped by a 330 l/s turbomolecular pump to a base pressure of 2x10⁻¹⁰ Torr. The vacuum system is equipped with two pulsed valves and a sapphire sealed leak valve for introducing volatile samples. CoCp*, NiCp*, and FeCp* were made by electron ionization of cobaltocene, nickelocene, and ferroocene introduced through a pulsed valve, opened for 10 ms. The metallocene pressure peaks 100 ms after the pulsed valve is opened, producing a maximum pressure of ca. 10⁻⁶ Torr, and fall to less than 10⁻⁸ Torr within 1 s. FeCp* was also formed by charge exchange ionization of ferroocene as described below.

FeCp* internal energy was varied using three methods (1) Adjusting the electron ionization energy between 20 eV and 70 eV demonstrated strong control on the observed reactivity of the FeCp* ion. (2) The internal energy of FeCp* formed by electron ionization was reduced by collisions with background ferroocene. The number of collisions a FeCp* ion experienced was controlled by changing the delay time of electron beam with respect to the pulsed valve event in which ferroocene was introduced. Short delay times produce cool FeCp*, because several collisions can occur between the FeCp* ions and the ferroocene vapor before it is pumped from the vacuum system. Increasing the delay between the pulsed valve introduction of the metallocene and the electron beam event yield ions with more internal energy. (3) Charge exchange ionization of ferroocene allows control of the energy deposited into the ions that are formed, through the selection of the appropriate reagent ion. As the recombination energy of the reagent ion increases, the amount of internal energy present in the FeCp* ion increases, for the reaction shown below.

\[
R^* + \text{FeCp}_2^+ \rightarrow R + \text{FeCp}_2^* \rightarrow \text{FeCp}_2^* + \text{Cp}^-
\]

RESULTS

The sole reaction between ethylene oxide and CoCp* or NiCp* is charge exchange. The odd electron ethylene oxide undergoes reactions with neutral ethylene oxide to form a protonated molecule, and other higher mass species. In contrast, FeCp* abstracts oxygen from ethylene oxide to form FeCpO*, and also undergoes charge exchange with the cyclic ether. However, CoCp* and NiCp* show the same reactivity as FeCp* toward the larger cyclic ethers, oxetane and tetrahydrofuran. The observed reaction for the latter ethers is a condensation of the ion and ether neutral. Also, CoCp* and NiCp* behave like FeCp* in reactions with ethylene sulfide. The abstraction of sulfur from one or two molecules of ethylene sulfide to form MCpS* and MCpS₂* is observed for the reactions of all of these cyclopentadienyl metal cations.
The two competing reaction channels of FeCp* with ethylene oxide, oxygen abstraction and charge exchange, can be individually enhanced by controlling the internal energy of the metal containing ion. With all three methods of changing FeCp+ internal energy, the same trend is observed. When the internal energy of FeCp* is increased, the ratio of oxygen abstraction to charge exchange is found to increase. At low internal energy, charge exchange is the major product, while at high energy, oxygen abstraction is the sole reaction, as shown in Figure 1.

REFERENCES

Figure 1. Mass spectra of the products of the reaction of ethylene oxide with FeCp* formed by 70 eV electron ionization of ferrocene admitted through a pulsed valve, delaying the electron beam (a) 80 ms and (b) 660 ms after the ferrocene is pulsed into the vacuum system. The C\textsubscript{2}H\textsubscript{4}OH* ion found in the top mass spectrum results from the odd electron molecular ion of ethylene oxide, formed by charge exchange, reacting with a second molecule of ethylene oxide.
ION-MOLECULE REACTIONS OF IRON PORPHYRINS WITH NO$_2$

Henglong Chen, T. E. Hagan, S. E. Groh and D. P. Ridge*
Department of Chemistry and Biochemistry and Center for Catalytic Science and Technology, University of Delaware, Newark, DE19716.

O atom transfer reactions between NO$_2$ and iron porphyrins in the gas phase have been observed. The neutral species 1, 2, 3 and 4 were introduced into the vacuum chamber of a Fourier transform ion cyclotron resonance (FT-ICR) spectrometer (FTMS-2000 Extrel, Madison, WI) at pressures on the order 10$^{-8}$ torr. The molecular anions of these species were formed by electron attachment and molecular cations by electron impact. NO$_2$ was introduced through batch inlet at a pressure of ca. 10$^{-7}$ torr. The anions of 3 and 4 (M) were found to react according to (1) and (2).

\[ k_1 \]

\[ M^- + NO_2 \rightarrow M(0^-) + NO \] (1)

\[ k_2 \]

\[ ------\rightarrow M(NO_2)^- \rightarrow M(NO_2)_{2}^- \] (2)

The variation of reactant and product ions with time are shown in Fig. 1. Also observed are M(NO$_3$)$^-$ and M(NO$_2$)(NO$_3$)$^-$. at small steady state concentrations. They are probably intermediates in the conversion of M(O)$^-$ to M(NO$_2$)$_2$$. (k$^1 + k^2) is about 2.3 \times 10^{-10}$ cm$^3$ s$^{-1}$

A two cell experiment where M$^-$ was prepared in one cell and then transferred to a second differentially pumped cell where it is exposed to NO$_2$ indicated that reaction (1) is promoted by internal energy in the reactant ion. Since M$^-$ is formed by electron attachment, its initial internal energy is the electron affinity of M. As the time that M$^-$ is stored in the first cell is increased allowing M$^-$ to cool, the relative amount of M(O)$^-$ observed in the second cell is diminished. CID of M(NO$_2$)$^-$ gives only M$^-$ and M(O)$^-$ as ionic fragments. These results suggest that Fe-O bonding is at least accessible to the adducts of anions of 3 and 4 with NO$_2$ in the gas phase.

On the other hand, 1 and 2 are not observed to extract O atom from NO$_2$. Instead charge transfer is the major process. This suggests that the chemistry of 3 and 4 is promoted by the ortho amido substituents on the porphyrin.

The reactions of the cation of 2 (M) with NO$_2$ are illustrated in Fig. 2. The products of this reaction are M(OH)$^+$ and M(NO)$^+$. The formation of M(OH)$^+$ must proceed by the intermediacy of either MH$^+$ or M(O)$^+$. A small amount of MH$^+$ is observed (the M+1 mass peak slightly exceeds the expected $^{13}$C peak). In the absence of NO$_2$, however, M$^+$ is undepleted and MH$^+$ does not grow at long reaction time. This suggests that M(OH)$^+$ results from reaction (3).

\[ \text{NO}_2 + \text{RH} \rightarrow \text{M}^+ \rightarrow \text{M(OH)}^+ \rightarrow \text{M(OH)}^+ \] (3)

M(OD)$^+$ was not observed in the presence of D$_2$O, (CD$_3$)$_2$C=O and C$_6$D$_6$ indicating that RH in reaction (3) is the neutral porphyrin. The resulting R$^-$ is a very stable radical.
The formation of M(NO)$^+$ in single bimolecular encounter between M$^+$ and NO$_2$ requires loss of an O atom. A free O atom is a most unstable leaving group. It is also observed that the ratio of M(OH)$^+$/ M(NO)$^+$ is proportional to the ratio of the pressures of RH and NO$_2$. This was tested in two kinds of experiments. In one experiment, the ions were formed by electron impact, the NO$_2$ pressure varied by controlling the batch inlet pressure and the RH pressure varied by controlling the probe temperature. In a second experiment, the M$^+$ ion was formed by laser desorption and M(OH)$^+$ is formed only at short delays after the laser pulse when desorbed neutral RH is present. M(NO)$^+$ is the only product at long delays after the laser pulse. Both of these suggest that M(NO)$^+$ is formed by the two step reaction (4).

$$\begin{align*}
\text{NO}_2 & \rightarrow \text{NO} \\
\text{M}^+ & \rightarrow \text{M(OH)}^+ \rightarrow \text{M(NO)}^+ \\
\text{-NO} & \text{-O}_2 \\
\end{align*}$$

Cations of 1 and 3 react with NO$_2$ to give the same products as 2. The cation of 4 does not react with NO$_2$. The conformation of cation of 4 has been characterized in the gas phase and the "tethered" imidazole base is found to be coordinated with the metal$^{[1]}$. The failure of the cation of 4 to react with NO$_2$ thus suggests that O atom transfer from NO$_2$ requires a coordinatively unsaturated metal (13 valence electrons) as is found in the cations of 1, 2 and 3.

Introduction
Protonated cluster ions can be generated following the ionization of neutral clusters containing protic hydrogens and lone-pair electron donor sites. In these systems, hydrogen-bonded networks can be extended indefinitely. The relation between energetics and distributions is of interest because ion cluster formation usually involves ionization with excess energy, often followed by strongly exothermic intra-cluster reactions, while the cluster binding energies are relatively small. In this paper, we report the results of a joint beam expansion/thermochemical study of blocked hydrogen bonding in acetonitrile - methanol binary clusters.

Experimental
Acetonitrile-methanol binary clusters, generated by pulsed adiabatic expansion in a supersonic cluster beam apparatus, were ionized by EI and subsequently mass analyzed in a quadrupole mass spectrometer. Equilibrium measurements were carried out using the NIST pulsed high-pressure mass spectrometer.

Results
Figure 1 displays a typical 70 eV EI mass spectrum observed from the ionization of a cluster beam generated from the expansion of a 1:1 vapor mixture of CH₃CN and CH₃OH in He carrier gas. The prominent peaks in the mass spectrum are due to the sequence H⁺MnA₂ (denoted as aₙ) where A and M are acetonitrile and methanol, respectively. This manifold is predominant over a wide range of vapor composition (30-80% A with respect to M) and stagnation pressures (1-6 Bar) and is strongly independent of the electron impact energy (20-100 eV), indicating that the cluster ions H⁺MnA₂ have a particularly stable structure independent of the distribution of the neutral clusters produced. In order to define the thermochemistry associated with the cluster sequences, we measured the enthalpies of the various clustering and exchange equilibria. The results for clusters containing up to four molecules are shown in Figure 2. The results show that the switching of CH₃CN for CH₃OH is favorable until the clusters incorporate two CH₃CN molecules and become blocked at both ends of the CH₃OH chain. Past this, further exchange becomes endothermic. In conclusion, the cluster ion distributions from beam expansion are sensitive to thermochemical differences as small as 1-3 kcal/mol. The sensitivity to thermochemistry is observed even when ionization and intra-cluster proton transfer can deposit large amounts of energy. This suggests that the final evaporation steps occur from clusters with little excess energy. Thermochemical data make it possible to correlate the cluster distributions with energetics, and will be useful also in calculating the rate constants for evaporation processes.

"LADDER" Algorithms for Constructing Equilibrium Affinity Scales

Daniel N. Sorensen and John E. Bartmess
Dept. of Chemistry, University of Tennessee, Knoxville TN 37996-1600

Many equilibrium affinity scales have thus far appeared in the literature, such as gas phase basicity and acidity scales. Creation and ordering of these scales from the original equilibria is tedious and somewhat arbitrary when done by hand. We previously reported a program that creates the scale, gives the best fitting absolute AG's for each member, and graphs the scale. We now report significant improvements to the program.

Prior to data analysis, the program discards pendant values (those linked to only one other compound) and breaks the data into fusion subsets, which are analyzed separately. The latter are defined as sections of the "ladder", bounded by compounds on which all equilibria values from either higher or lower in the ladder terminate. Both of these actions decrease computational time in data analysis, because computational time is a power function of the number of bases. The data can also be analyzed using a number of weighting schemes. A scheme with even weighting is best when unusual chemistry is not expected. If a wide range of AG values are present in the data, a Gaussian weighted fit can also be considered. The Gaussian fit is chemically reasonable since $K_{eq}$ is often not known to better than ±10%. While a measured AG < 1.0 kcal/mol is probably known ± 0.1, for a 3.0 kcal/mol process, the error is more likely ±0.5 kcal/mol.

Mathematically the problem is a slightly overdetermined one: typically the number of measurements is somewhat less or comparable to twice the number of compounds. The difficulty in assignment of the best fit lies in recognizing outliers in the measurement data. These outliers could be due to experimental error or to unusual chemistry. Unnoted, the outlying data may skew the solution that best fits the data.

Three different methods of analysis are used: least squares/sums, iterative smoothing, and simplex. For all three, the equilibrium pairs are first ordered as a matrix of all possible pairs, with the values for the measured energies entered at the appropriate points. For the first method, this matrix is then factored via Householder transformation with pivoting, and the least squares solution is obtained. The method gives a rapid solution. In addition, the same factored matrix can be re-used many times to test the effects of changing a questionable AG value. The disadvantage of the method is in predicting outliers. In the simple least squares method, true outliers can be missed, while good measurements can be indicated to be outliers.

The second method of data analysis, iterative smoothing, treats the data as a planar projection of the matrix and then tries to fit a smooth plane to the data. The method is best for predicting small AG's between nearby compounds that correspond to the smoothed gradient. Its disadvantages are that the solution is dependent on the ordering of the pairs and no weighting of measurements is possible.
The third method is primarily concerned with detecting the true outliers. The simplex method is used in conjunction with least trimmed squares. The squares of the residuals are first ordered, then the largest of these are discarded from the minimization function. This method is best for predicting outlying data, but is also time intensive. As long as the three solution qualitatively agree, the least squares routine is accepted as the best fit, and the simplex method as the method for detecting questionable data.

The program then splices the fusion sets together, reinserts the pendant measurements, and anchor the scale to the accepted AG for one base. Another short program graphs the scale.

We define three general classes of ladders. Pendant ladders involve many pendant measurements or a whole series of pendants. These ladders are only barely overdetermined (number of equilibria approaching the number of compounds) and the program cannot really help. Proper construction of a ladder requires two or more pathways between any two compounds. A ladder rich in multiple pathways can consist of a number of fusion sets, or be one fusion set in its entirety. The former are easier to calculate a fit for, but the latter are mathematically the best ladders. For a multiple fusion set ladder, once the outlying data has been re-investigated, complete scales may be formed by spanning the fusion set boundaries. The program runs on PCs, but a large scale (more than 70 compounds and 150 measurements) may require the use of a mainframe computer.

The program has been used to isolate problems in existing scales, can be used in the creation of new ones, and is available from the authors.

A small sample scale:

The Fourier Transform Ion Cyclotron Resonance (FTICR) mass spectrometer has been used to determine many gas phase physical quantities such as relative and absolute ion/molecule reaction rate constants, proton and electron affinities, and ionization potentials. Measurement (or at least an estimate) of the kinetic energy of ions in an FTICR instrument is important since any or all of the above mentioned quantities may be dependent on kinetic energy.

The kinetic energy of ions produced in an FTICR mass spectrometer has been estimated by two different means in this work. One method utilized kinetic energy dependent ion/molecule reactions and, by comparison with previous work, resulted in an ion kinetic energy. Ion kinetic energy is related to ion temperature by the equipartition theorem. The other method, based on thermodynamics, estimated ion temperatures using proton transfer equilibrium measurements on molecules for which standard free energies of proton transfer are known.

Investigations involving three different systems (two kinetic, one thermodynamic) are reported here. For all data presented here, a relaxation delay after ion formation and prior to the beginning of the data acquisition period was implemented to allow ions formed near the trapping plates time to be collisionally relaxed to the center of the cell where ion detection is the most efficient. The first ion/molecule reaction system used was \( \text{O}_2^+ + \text{CH}_4 \rightarrow \text{CH}_3\text{O}_2^+ + \text{H} \). Data obtained here resulted in a rate constant of \( 9.4 \pm 0.4 \times 10^{-13} \text{ cm}^3\text{s}^{-1} \). This value corresponds\(^1\) to an average ion temperature of 1600 K. The ion/molecule reaction studied most fully was \( \text{Ar}^+ + \text{N}_2 \rightarrow \text{Ar} + \text{N}_2^+ \). It was found to have a rate constant of \( 2.4 \pm 0.2 \times 10^{-11} \text{ cm}^3\text{s}^{-1} \) which indicates\(^2\) an average temperature of 690 ± 190 K. This reaction was also studied as a function of pressure and trapping voltage. The results of these experiments are shown in Figures 1 and 2. The final system examined in this work was the proton transfer equilibrium between toluene and ethyl benzene. Measurement of the equilibrium constant in conjunction with a known standard free energy change\(^3\) for this reaction of 1.0 ± 0.5 kcal/mol provided a temperature estimate. The equilibrium constant, which is independent of the chemical ionization reagent and total pressure over the range studied, was found to be 0.203 ± 0.022. The temperature indicated by this "thermometer" is 316 ± 160 K. A summary of the temperatures found and the pressures studied with each of the three systems is given in Figure 3.

None of the temperatures obtained from the ion "thermometers" presented here agree. One might conclude based on the disagreement that the measurement of ion kinetic energy through chemical reactions is not feasible. However, even though an absolute temperature still seems uncertain, some definite conclusions regarding ion kinetic energy can be made. From the \( \text{Ar}^+ + \text{N}_2 \) study two statements can be made. First, \( \text{Ar}^+ \) ions, if formed with excess kinetic energy, are collisionally relaxed to some temperature that additional collisions will not reduce. This occurs with an average of as few as 13 collisions (based on a Langevin cross-section). Since no effect of total pressure is observed on this base kinetic energy, one might conclude that during the relaxation period (a 100 ms delay after ion formation and prior to data acquisition) the excess z-kinetic energy is to a large extent removed rather than merely transformed into x- and y- kinetic energy. Finally, even if the ions are translationally excited by the trapping potential well, the same base kinetic energy is reached for all trapping voltages between 0.3 and 5 volts with 40 collisions or less.

At low pressure in the FT-ICR, association reactions of Si(CH$_3$)$_3$$^+$ with a number of species proceed by a radiative stabilization mechanism$^1$. The experimental efficiencies, $\Phi_{(exp.)}$ ($\Phi_{(exp.)} = k_a/k_c$, where $k_a$ is a bimolecular rate constant and $k_c$ is a collisional rate constant) measured at 300K are in reasonable agreement with Dunbar's theoretical values derived from RRKM theory$^2$. The model predicts that the radiative association efficiency depends on the bond dissociation energy, $E_b$, the temperature, $T$, and number of vibrational degrees of freedom, $N$. We examine here the effects of temperature and bond energy on the association reactions of Si(CH$_3$)$_3$$^+$. In order to broaden our study of association reactions, one other system, the formation of acetone proton-bound dimer, was also studied.

A number of oxygen-, sulfur- and aromatic compounds have been studied with Si(CH$_3$)$_3$$^+$. As shown in Fig. 1, all radiative association efficiencies decrease with increasing temperature over the range T = 300K to 420K (two species, acetone and dimethylether adducts, have been measured up to 510K), in qualitative agreement with theory. The slope of the plot of Ln($\Phi_{(exp.)}$) against $T$ gives the temperature coefficient, $\phi\prime$. $\phi\prime$ increases linearly with $E_b$ as shown in Fig. 2. The experimental efficiency, $\Phi_{(exp.)}$, increases with $E_b$, so Fig.2 indicates that highly efficient association reactions have lower temperature coefficient than less efficient association reactions. For species studied here, $\phi\prime$ of furan is 10 times larger than $\phi\prime$ of the c-hexanone adduct. The $\phi\prime$ of acetone proton-bound dimer does not fall on the line in the plot of $\phi\prime$ vs. $E_b$, which indicates that $\phi\prime$ varies with factors other than $E_b$.

Apparent bimolecular rate constants $k_a$ in slow association reactions ($\Phi_{(exp.)} \ll 1$) are pressure dependent. From a kinetic analysis$^3$ of plots of $k_a$ vs. reactant neutral pressure, one can get the dissociation rate constant $k_b$ and the radiative rate constant $k_r$ experimentally. In the case of the acetone proton-bound dimer (Table1), $k_b(\text{exp.})$ agrees well with $k_b(\text{theo.})$ from RRKM theory, and $k_r$ is nearly constant in the measured temperature range.

As the above studies have shown, the bond energy $E_b$ has a crucial effect on $k_b$ and consequently on the association efficiency. Bond energies from equilibrium constant measurement are listed in Table 2. Comparison of $E_b$ with P.A. and I.P. shows that $E_b$ increases linearly with increasing P.A. and decreasing with I.P. for compounds with similar functional groups. A difference is noted in behaviour between what we call closed aromatic hydrocarbons (at least one six-membered ring without H substituents) and open aromatic hydrocarbons (all others).

Fig. 2: Acetone proton-bound dimer

Fig. 1: Various compounds in the mass spectrometry study.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics.
The O* ion produced by solar ultraviolet photoionization of Atomic oxygen is the major ionic species in the ionosphere. Since the rates of radiative recombination of O* with electrons are several order of magnitude smaller than those for dissociative recombination of \( N^*, O^*, NO^* \) and \( CO_2^* \) with electron, the charge transfer reactions which convert O* into \( N^*, O^*, NO^* \) and \( CO_2^* \) constitute the most important ion-molecule reactions in the ionosphere.

Using a tandem photoionization mass spectrometer, we have measured absolute total cross sections for the following reactions:\(^1\)^\(^2\)

\[
\begin{align*}
O^*(^4S) + H_2 &\rightarrow O + H_2^* \quad (1) \\
&\rightarrow O + H + H^* \quad (2) \\
O^*(^4S) + N_2 &\rightarrow N + NO^* \quad (3) \\
&\rightarrow O + N_2^* \quad (4) \\
&\rightarrow O + N + N^* \quad (5) \\
O^*(^4S) + CO_2 &\rightarrow O + CO_2^* \quad (6) \\
&\rightarrow O + O + CO^* \quad (7) \\
&\rightarrow CO + O_2^* \quad (8) \\
&\rightarrow O + O_2 \text{ (or } O + O) + C^* \quad (9)
\end{align*}
\]

Preliminary results on the corresponding reactions involving excited \( O^*(^2D) \) and \( O^*(^2P) \) have also been obtained. Charge transfer is found to be overwhelmingly the major channel for reactions of excited \( O^*(^2D, ^2P) \).

GAS PHASE REACTIONS OF CF+, CF2+, and CF3+ WITH HALOCARBONS
Robert A. Morris, J. M. Van Doren, A. A. Viggiano, and John F. Paulson
Phillips Laboratory, Geophysics Directorate/LID, Hanscom AFB, MA 01731-5000

Ion-molecule reactions occurring in plasmas containing halocarbons have received little attention from experimenters. In this abstract we report results for the gas phase reactions of CF+, CF2+, and CF3+ with the halocarbons CF3Cl, CF3Br, CF3I, CF4, and C2F6. The investigation was conducted using a variable temperature-selected ion flow tube (VT-SIFT) instrument operated at 300 and 496 K. Few of these reactions have been studied previously. None has been investigated by the SIFT technique or as a function of temperature.

The ion CF+ reacts rapidly with CF3X (X = Cl, Br, I) producing the ions CF2X+. In the case of CF3Cl, CF3+ is also produced as a minor product. Rate constants for these and the other reactions studied are given in Table 1. Curvature was observed in the pseudo-first-order kinetics plots (logarithm of CF+ signal vs. reactant neutral flow rate) for the reactions of CF+ with CF4 and C2F6. In both cases the curvature is attributed to the presence of two CF+ states (vibrational or electronic) of differing reactivities toward the perfluorocarbon of interest. This conclusion is supported by our observation of efficient charge transfer from CF+ to NO, a reaction which is endothermic 3 kJ/mole for the ground state of CF+. For the reaction of CF+ with NO, we again observed curvature in the kinetics plots. Rate constants for the slow reacting state, kslow, and for the sum of reaction and quenching of the fast reacting state (kfast + kq) were obtained by fitting a double exponential function to the data. The values of kslow are 1.1 x 10^-11 and 4.2 x 10^-11 cm^3 s^-1 at 300 and 496 K, respectively. These values are assumed to correspond to the ground state of CF+. The activation energy derived from these data is 8 kJ/mole. The values of (kfast + kq) are 8.7 x 10^-10 and 6.8 x 10^-10 cm^3 s^-1 at 300 and 496 K, respectively, and are equal to the collisional rate constants within experimental uncertainty.

The reactions of CF2+ with CF3X yield CF3+ and CF2X+ for X = Cl and Br; for X = I, CF2I+ and CF3I+ are produced. Production of CF3X+ is exothermic for X = I only. The overall reactions proceed at the collision rate at 300 and 496 K, and the branching ratios are not strongly dependent on temperature. The reactions of CF2+ with CF4 and C2F6 produce CF3+ and C2F5+, respectively. The rate constants decrease significantly with increasing temperature. In the reaction of CF2+ with CF3X, the products CF3+ + CF2X (X = F, Cl, Br) may arise from transfer of either F or X. For the products CF2X+ + CF3 (X = F, Cl, Br, I), transfer of either X or F- may pertain. Similarly, the C2F5+ product of the reaction between CF2+ and C2F6 may arise from transfer of either F- or CF3. Experiments in which the reactant ion is 13CF2+ are planned with the hope of elucidating the reaction mechanism(s).

CF3+ reacts with CF2X (X = Cl, Br, I) via fluoride transfer producing CF2X+ as the only ionic product for all X. The rate constants, which are below the collisional values at both 300 and 496 K, decrease sharply with increasing temperature and increase for the heavier halides. These results are consistent with the reactions occurring on a double-well potential.
surface. The measured negative temperature dependences are: \( k(X = \text{Cl}) \sim T^{-1.9}; k(X = \text{Br}) \sim T^{-2.0}; k(X = \text{I}) \sim T^{-1.4} \). No reaction was observed for the \( \text{CF}_3^+ / \text{CF}_4 \) system. \( \text{CF}_3^+ \) appeared to react very slowly with \( \text{C}_2\text{F}_6 \) at 300 K, producing \( \text{C}_2\text{F}_5^+ \), but a reaction with an impurity in the \( \text{C}_2\text{F}_6 \) cannot be ruled out. No reaction was observed at 496 K.

INTRODUCTION:

Intermolecular H/D exchange experiments in mass spectrometers have typically been done in the ion source using chemical ionization (CI) and more recently using D₂. The application of tandem mass spectrometry to H/D exchange offers several advantages, including the ability to study specific compounds in complex mixtures and the ability to control the kinetic energy of the ion and the number of collisions it undergoes.

Beam induced H/D exchange using D₂ is a useful method for the analysis of non-volatile and thermally labile organic compounds. Because ND₃CI is a transparent matrix, it does not contribute any ions to SIMS spectra in contrast to the behavior of many liquid matrices. This work describes the analytical potential of two types of exchange experiments, both with respect to determining the number and types of active hydrogens and their implications for the mechanisms of I/M reactions.

EXPERIMENTAL:

A Finnigan model 4500 triple stage quadrupole (QQQ) and a custom-built pentaquadrupole (QQQQQ) mass spectrometer were used to carry out exchange experiments in the collision region. Mass-selected parent ions (either M⁺ generated by 70 eV EI or M+H⁺ generated by 70 eV CI) were allowed to collide with a deuterated reagent gas (pressure 2 mTorr) in the rf-only quadrupole at a collision energy of 1.5 eV.

D₂ experiments were performed using a Riber SIMS. Ar Ion beam of 4.5 keV bombarded a silver surface covered with a mixture of analyte and ND₃CI.

RESULTS AND DISCUSSION:

H/D Exchange in the Collision Region

The degree of D incorporation is dependent on the proton affinity difference between the analyte ion and the reagent (ΔPA) and also on the kinetic energy of the analyte ion. Reagents can be chosen which exchange all active hydrogens or only selective hydrogens. For example, CH₃OD (PA 181.9 kcal/mol) exchanges only with the carboxylic group of the radical ion of anthranilic acid (PA of benzolic acid 198.2 kcal/mol; of aniline 209.5). ND₃ (PA 204.0) exchanges both the amino and carboxylic hydrogens. The selective exchange of carboxylic hydrogen in the presence of amino hydrogens by CH₃OD was confirmed by pentaquadrupole experiments (Fig. 1). A reaction mechanism (Scheme 1) has been proposed to explain the experimental observations.

An investigation of the effects of collision energy reveals that (I) cluster ion formation (II) the H/D exchange process and (III) low energy collision activated dissociation due to reactive collisions are all intimately connected as shown in Fig. 2. Note that at very low energy (1-2 eV) argon does not cause any fragmentation to protonated ion of benzoic acid (Fig. 2A) whereas CH₃OH does (Fig. 2B). The % D incorporation (Fig. 2C) and the signals due to methanol clusters, I/M complexes and to the fragment C₇H₅O⁺ (m/z 105) decrease as the collision energy is increased. Although the formation of the I/M complex is initially driven by ion-dipole and Ion-induced dipole interactions, the exchange process is far more complicated and cluster ion formation plays a major role.

H/D Exchange during DI

The degree of exchange in the desorbed ions provides insights into the mechanism of interfacial chemical reactions occurring in the selvedge region during DI. For example, the intact cation (m/z 162) of carnitine HCl shows 2 active hydrogens whereas its trans-alkylated product (m/z 176) shows only one active hydrogens (Fig. 3) which is in agreement with the proposed mechanism.

The relative abundance of ions resulting from exchange is dependent upon the primary argon ion dose (Fig. 4). These data suggest that the exchange is induced by ion beam and does not occur in the matrix prior to ion bombardment.

CONCLUSIONS:

Both methods are valuable in counting the total number of active hydrogens and in obtaining mechanistic information on I/M reactions. Exchange in the collision region shows that counting certain types of active hydrogens in polyfunctional compounds is possible and cluster formation and endothermic reactive collision play an important role in the mechanism of H/D Exchange. Exchange in SIMS using ND₃CI shows that the exchange process is beam induced and hence this is a valuable tool in studying interfacial chemical reactions.

Substituent effects, steric effects, and both conformational and configurational effects play important roles in the outcome of organic reactions in both the solution and gas phase. We have undertaken a study of the effects of functional group interactions on the reactive and dissociative behavior of a series of alkenols and amino-alcohols using an ion trap mass spectrometer. In solution, hydroxy and amino groups may act as hydrogen bond donors and hydrogen-bond acceptors, and double bonds may act as hydrogen-bond acceptors, so the influence of these functional groups was of primary interest in gas-phase studies. The objectives were to examine the ion/molecule reactions of dimethyl ether ions with a series of aminoalcohols with varying functional group separation, to probe hydrogen-bonding effects in alkenol adduct ions, and to characterize the product ions of these ion-molecule reactions by using low energy collisional activation.

It has been proposed that the pπ electrons of a double bond may coordinate a proton attached to another site, so we undertook a study of the effects of this potential functional group interaction on the reactive and dissociative behavior of simple bifunctional molecules. We have examined the collisionally activated dissociation (CAD) spectra of the ion/molecule reaction products of a series of alkenols (allyl alcohol, 3-buten-1-ol, 4-penten-1-ol) to correlate functional group separation and hydrogen-bonding interactions.

Ion/molecule reactions of the alkenols with dimethyl ether result in two adduct ions of interest: (M + H + DME)+ and (M + H + DME - H2O)+. A mechanism proposed for the formation of (M + H + DME - H2O)+ from (M + H + DME)+ (Scheme 1) involves an ion-molecule complex as an intermediate step. The abundance of the dehydration product, (M + H + DME - H2O)+, relative to (M + H + DME)+ increases as the length of the carbon chain decreases. The ratio of (M + H + DME - H2O)+ to (M + H + DME)+ is 1:1 for allyl alcohol, 1:2 for 3-buten-1-ol, and 1:4 for 4-penten-1-ol. The heats of formation of each alkenol/DME complex were estimated and varied by as little as 3 kcal/mole, so it is unlikely that the exothermicity of the reaction alone can account for the large differences in stability of the adduct.

This suggests that intramolecular interactions between the double bond and the proton provide additional stabilization for the proton-bound complex relative to the dehydrated complex. The increased length of the carbon chain in 3-buten-1-ol and 4-penten-1-ol allows more favorable intramolecular interactions between the double bond and the proton because stable six and seven membered ring structures are formed. Likewise, the formation of a proton bridge within the allyl alcohol is presumably less favorable due to the smaller size of the resulting ring structure (a five-membered ring). For the (allyl alcohol + H + DME)+ adduct, however, the relative strengths of the hydrogen bonds between the allyl and DME portions are more equivalent, and this may enhance the lifetime of the proton-bound complex, allowing more time for the rearrangement resulting in (M + H + DME - H2O)+ (shown in Scheme 1B) to occur.

As a comparison, simple alcohol adduct ions were also examined to probe the importance of the double bond functional group on the formation and dissociative behavior of the adducts. Abundant protonated ions and proton-bound dimers were observed, although the formation of (M + H + DME - H2O)+ only occurred to a minor extent. This latter observation likely reflects the lack of favorable intramolecular hydrogen-bonding which assisted the rearrangement shown in Scheme 1, route B. Such interactions play an important role in stabilizing the ion/molecule complex and in enhancing entropically the extensive rearrangement needed for elimination of H2O.

Thus, the formation and dissociation of the alkenol/dimethyl ether and alcohol/dimethyl ether adducts is dependent on the propensity for formation of intramolecular hydrogen bonds within the adducts. For substrates with functional group separations that enhance formation of stabilizing intramolecular hydrogen bonds (such as within 4-penten-1-1-ol), adducts may preferentially dissociate via different routes than the adducts of those substrates (i.e. allyl alcohol) for which the intermolecular hydrogen bonds between the two molecules of the complex are more thermochromically equivalent.

We have also undertaken a study of the reactive and dissociative behavior of a series of amino alcohols and related molecules. In order to evaluate the significance of functional group interactions in gas-phase ion chemistry, compounds differing both in the separation of functional
groups and in their substitution patterns were chosen. The adduct ions of interest (M+13)+ were formed via ion-molecule reactions between neutral amino alcohols (M) and dimethyl ether ions (CH₃OCH₂)+ in a quadrupole ion trap mass spectrometer. The adduct ions were then characterized by CAD. Two mechanisms are proposed for the formation of these adducts. Both involve nucleophilic attack of the amino alcohol on the dimethyl ether cation, followed by elimination of methanol to give net addition of a CH group. The only difference between these two mechanisms is the reactive site (hydroxyl or amino group) of the amino alcohol.

To elucidate the justification for these competitive mechanisms, ethanolamine, N-methylethanolamine, and N,N-dimethylethanolamine were studied. All formed (M+13)+ adducts upon reaction with dimethyl ether ions. The CAD spectra for these adducts (Figure 1) show that both mechanisms may be operative. In the case of (ethanolamine + 13)+, the major fragment corresponds to loss of water. On the other hand, the spectrum for the tertiary amino compound shows only loss of 30 daltons (loss of formaldehyde). N-Methylethanolamine represents the intermediate case, in which both of these losses are observed in significant amounts.

The effect of functional group separation on the dissociative behavior of amino alcohol adducts is most dramatically illustrated by the differences in the CAD spectra of 3-amino-1-propanol and 2-amino-1-propanol (Figure 2). Whereas the CAD spectra for the simple protonated molecules are very similar, showing predominantly loss of water, the (M+13)+ adducts show strikingly different behavior. The 2-amino-1-propanol (M+13)+ adduct gives primarily loss of water and loss of formaldehyde. On the other hand, the 3-amino-1-propanol adduct gives only 44+ ions and a very slight amount of formaldehyde loss.

This investigation has shown that the effect of interfunctional distance on the reactive and dissociative behaviors of amino alcohols can be dramatic. Also, while the degree of substitution on the amine functionality is important in determining adduct formation and fragmentation patterns, the substitution of the carbon chain connecting the amine and hydroxyl functions seems to have little effect on the reactivity of the system.

Ionized Cycloalkane Formation from Ionized n-Butanol

Mohammed S. Ahmed, a Charles E. Hudson, b C.S. Giam, a and David J. McAdoo b
Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550 and Department of Marine Sciences, Texas A&M University at Galveston, Galveston, Texas 77553

Ionized cyclopropanes are common products of radical cation fragmentations in the gas phase [1]. Most of these reactions take place by the cyclization of distonic intermediates (Scheme 1) in which R is H or an alkyl group. Y can be OH, OR, NH2, etc., and n > 1.

Scheme 1

\[
\begin{align*}
RCH_2Y^+ & \rightarrow RCHY^+ \rightarrow RCH^+ + YH \\
\end{align*}
\]

Since the formation of ionized cyclopropane [1] and methylcyclopentane [2] is well established, a search for ionized cyclobutane was needed to define further the generality of Scheme 1. The objective of this investigation was to characterize C4H9+ product ions formed by water elimination from ionized n-butanol to define better the scope of ionized cycloalkane formation in gas phase ion chemistry. Formation of ionized methylcyclopropane from this ion has recently been proposed [3].

All experiments were performed on an Extrel FTMS-1000 equipped with a 3 T superconducting magnet and 5.08 cm cubical cell. Spectra were collected in the direct mode under broad band conditions. Ions were excited by a 40 Vpp chirp from 0 to 3.66 MHz at 2 KHz/us. Daughter ions were produced from butanols by electron impact at 12 eV. The trapping voltage was 2 V. The typical pressures for butanols and NH3 were 6-8x10^{-8} and 2-3x10^{-7} torr respectively.

We used reaction with NH3 to characterize C4H9+ fragments, as 1 and 2 react with NH3 to give characteristic products (Scheme 2). Formation of C4H9+ upon reaction with NH3 distinguishes 2 from 1.

Scheme 2

\text{CH}_3\text{CH}^+ \rightarrow \text{CH}_2^+ \quad + \quad \text{NH}_3 \\
\end{align*}
\]

Products formed by reaction of C4H9+ from 1-4,4,4-d and from 1-3,3-3-d with NH3 are given in Table 1. C4H9D+ from 1-3,3-3-d, the daughter ion expected following 5-membered ring H-transfer, gave products at m/z 30, 31 and 45 upon reaction with NH3. The m/z 45 demonstrates formation of 1. This is confirmed by the production of C4H9NH2+, C4H9D,N2+ and
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

C,H,D,N in the reactions of C,H,D, from 1-4,4,4-d with NH,. This reaction also produced m/z 30 (CH NH +), m/z 31 (CH NH or CH N'), m/z 32 (CH ND or CH,NH'). Our observations suggest formation of 1 as follows (Scheme 3):

Scheme 3

Considerable H shuffling is apparent in the products of the reaction of NH with C'H,D, formed from 1-4,4,4-d (Table 1). This is explained by H-exchange between the partners in an encounter complex rather than in "CH(CHCD),NH", since exchange does not occur between N and S-carbons in ionized amines. C,H,D, ions formed by 6-membered ring H-transfer from 1-3,3-d and 1-4,4,4-d formed substantial one carbon but no two carbon products upon reaction with ammonia (Table 1). The elimination of water from ionized 1-butanol produces 2 following 6-membered ring H-transfer and 1 following 5-membered ring H-transfer. The C,H,D:,C,H,D, ratio from 1-3,3-d (3.3) and C,H,D:,C,H,D, ratio from 1-4,4,4-d (3.2) indicate that 2 was produced from ionized n-butanol more than 3 times as often as 1 at 12 eV electron energy.

The formation of ionized cyclobutane and methylcyclopropane establishes that isomerization to a distonic intermediate followed by cyclization with elimination of a stable neutral fragment (Scheme 1) is a common mass spectral fragmentation. Ionized cyclobutane is formed from ionized 1-butanol more than 3 times as often as is ionized methylcyclopropane. The distribution of products in these reactions is largely determined by the relative rates of the H-transfers that form the distonic intermediates.

Results were obtained at 12 eV ionizing electron energy. Product distributions were determined as described in the text.
THE MECHANISM OF THE GAS-PHASE BASE CATALYZED ALDOL REACTION: REACTIONS OF SUBSTITUTED BENZALDEHYDES WITH ACETONE ENOLATE ANION.

George W. Haas, Roger N. Hayes, and Michael L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304.

Base-catalyzed aldol condensations have an important role in modern organic synthesis. Yet the gas-phase aldol condensations are not well-understood. Consequently, the goals of this study are (1) to establish a gas-phase analogy for the aldol condensation, (2) to investigate the extent of the tetrahedral complex versus loosely-bound complex (i.e., ion-dipole and proton-bound species), and (3) to look for substituent effects.

In two previous studies of the reaction of the acetone enolate and neutral acetone, it was found that the gas-phase adduct possesses three structures:

1. Tetrahedral in which there is a covalent bond between the nucleophile and the acetone.
2. Proton-bound in which two enolates are held together by a proton.
3. Ion-dipole in which the enolate and acetone are bound by electrostatic forces.

Structures (2) and (3) are regarded as "loosely-bound".

In this study, we have used the reaction of acetone enolate anion with a number of para-substituted benzaldehydes to probe the extent of tetrahedral adduct formation as a function of Hammett $\sigma$ substituent parameters. Accordingly, the system allows us to investigate the extent of the negative charge by various substituents in the formation of tetrahedral adduct. Furthermore, we can examine quantitatively the correlation of tetrahedral adduct formation and substituent effects by using the Hammett equation. Thus, the experiment can be viewed in both a qualitative and quantitative manner.

The data show that the losses of water from the adducts and from the reference compounds increase as the electron withdrawing character of the substituents increases. The CAD spectra of adducts from the most electron-withdrawing and the most electron releasing groups studied are shown in figures 1 and 2. The increasing propensity for the adduct to lose water is interpreted to indicate increasing extent of tetrahedral adduct formation. In this adduct, the negative charge is stabilized when the substituent is electron withdrawing.

As mentioned earlier, to test quantitatively the correlation of the extent of tetrahedral adduct formation with substituent effects, a Hammett plot was prepared (see figure 3). Figure 3 displays all the para-substituents used and has a correlation of $+1.48$, and a p-value (slope) of $+1.49$. The reaction constant ($p$) indicates the reaction is facilitated by electron-withdrawing groups and is moderately sensitive to substituent effects.

Thus from the data obtained, a couple of conclusions can be drawn:

1. The extent of tetrahedral adduct formation is greatest for systems in which an electron withdrawing group is introduced.
2. The Hammett plot shows that the reaction constant is positive, giving a quantitative measure of how the formation of tetrahedral adducts are facilitated by electron withdrawing groups.

Mass spectrometry played a key role in environmental research and environmental analytical chemistry during the 1980s. One major reason for the significant growth in applications of mass spectrometry in environmental studies was the development of analytical methods that were incorporated by the United States Environmental Protection Agency (USEPA) as approved methods into regulatory programs under the Safe Drinking Water Act, the Clean Water Act, and other environmental legislation. These approved analytical methods consisted of detailed cookbook-style descriptions of all the individual method steps from sample collection to production of qualitative and quantitative results. The methods were incorporated into the Federal regulations to ensure uniform and comparable analytical results from mandated environmental analyses.

During the 1980s three general USEPA mass spectrometric analytical methods came into widespread use, and slightly different versions of each evolved to meet the perceived different requirements of similar, but legally different regulatory programs:

- **Methods 624, 524.1, 524.2, 8240, 8260, and CLP/VOC.** Volatile organic compounds (VOCs) by inert gas purge, trapping of the vapors on a solid sorbent, and thermal desorption into a packed or capillary column gas chromatography/mass spectrometry (GC/MS) system.

- **Methods 625, 8250, 8270, and CLP/SEMIVOL.** Gas chromatographable compounds by methylene chloride (CH₂Cl₂) extraction, phase separation, concentration of the CH₂Cl₂ extract by evaporation, and injection of an aliquot into a packed or capillary column GC/MS system.

- **Methods 613, 513, 8290.** 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD) and some congeners (8290) by solvent extraction, phase separation, concentration of the solvent extract by evaporation, and injection of an aliquot into a capillary column GC/high resolution MS system operating in the selected ion monitoring mode at about 7500 resolution.

Although the regulated community had the choice (except for dioxin) of an approved mass spectrometric or an approved non-mass spectrometric method, the mass spectrometric methods became very popular because of their power and cost-effectiveness. The demand for mass spectrometric analyses provided a great boost to instrument sales which led to many improvements in commercial instrumentation.
During the 1990s, applications of mass spectrometry in environmental research and analyses should continue to grow. Some predictions of future directions in research and environmental applications of mass spectrometry are:

- The multiple but similar mass spectrometric methods, which developed during a period of changing technology (packed to capillary GC columns) and perceived differences in regulatory programs, will undergo consolidation and restructuring to fewer and more uniform methods across legally different but similar regulatory programs.

- Lower regulatory limits for metals and toxic elements in environmental samples will lead to further development and widespread application of mass spectrometric methods for these substances, e.g., inductively coupled plasma (ICP)/MS.

- Concern for environmental contamination by non-gas chromatographable (nonvolatile) organic and inorganic compounds will lead to extensive development and regulatory application of liquid chromatography (LC)/MS methods. An early indication is the recently developed USEPA Method 553 for the determination of benzidines and nitrogen-containing pesticides in water by liquid-liquid extraction or liquid-solid extraction and reverse phase high performance LC/particle beam/MS.

- Concern for water soluble and non-extractable organic and inorganic environmental contaminants will lead to new analytical methods based on semi-permeable membrane sampling systems and membrane mass spectrometry (M/MS).

- Process analytical chemistry will incorporate mass spectrometric methods, especially M/MS and bench-top tandem MS, for continuous monitoring of process and waste streams to feed back real-time analytical results to maintain process control and prevent pollution at the source.

- Concern for human and ecological exposure assessment will provide considerable research opportunities to apply emerging mass spectrometric methods to the study the interactions of biomolecules and environmental contaminants.

- Electron capture negative ionization mass spectrometry will become more widely used for environmental analyses. The advantages of high sensitivity and high selectivity for compounds with electronegative elements or substituents will be required and the problems of weak standardization among different laboratories and a lack of standard reference data will be solved.

Overshadowing all this promise is the question: where will all the analytical chemists and mass spectroscopists come from? Unless sufficient well-trained analytical chemists with mass spectrometry skills are produced, some or all of these and other promising areas will not develop.
There exists an analytical chemistry equivalent of the Heisenberger uncertainty principle of physics. As the concentration of the analyte being measured falls, the uncertainty of the result increases rapidly. In the 1980’s mass spectrometry displayed the quantum jump to routinely measure levels as low as parts per trillion (ppt) brought about mainly by such environmental issues as dioxins and polychlorinated biphenyls. Additionally the risk assessments pronounced by toxicologists have often placed ‘safe levels’ in the low ppb levels. The quest to determine whether a substance is present or not revolves around the ability to detect down to the ultimate level of one molecule - the search for zero. For the moment, however, the measurement of trace levels to the ppt level represents the lower limit of detection by mass spectrometry.

Scientists are not exempt from the mundane rigors of supporting their findings. In a court of law it is required to provide proof in a criminal case that is “beyond reasonable doubt” or in a civil matter that “the preponderance of evidence” supports the conclusion. Since methods of confirmation by mass spectrometric techniques are often developed on an ad hoc basis to deal with an emergency situation, they cannot be validated by interlaboratory testing. What has emerged over the last decade, however, is the evolution of a set of criteria generally recognized as scientifically sound (1).

HISTORICAL BACKGROUND

The highest level of confirmation that can be provided by mass spectrometry is the exact correlation between the full mass spectral scans of a reference standard and the sample performed within the same working day. Usually El spectra contain sufficient structurally related fragment ions to permit absolute identification. Under such conditions, the relative abundance ratios should experimentally fall within 5%. Quite often, however, the presence of background ions may severely interfere with exact comparisons. This practice of direct comparisons represents the highest level of specificity obtainable by mass spectrometry.

In the field of trace level analysis, however, the opportunity to employ full mass spectral scans as a means to confirmation of presence is often an impractical situation. To make full use of sensitivity of detection, the technique of multiple ion monitoring (MID) offers a convenient method of ignoring potential interferences and concentrating on ions belonging to the compound under investigation. It is in this particular sphere of activity that the evolving criteria for confirmation have received greatest deal of attention. Scrutiny has been focused on the exact number of ions to be monitored to provide proof of presence. This examination of criteria for confirmation has been complicated because of the myriad of mass spectrometric techniques available for analyzing food samples. It was argued more than a decade ago that a minimum of three structurally related ions would be necessary to provide proof of presence (2). To improve the criteria for confirmation the relative abundance ratios were required to be within 5% when compared with a reference standard recorded under similar conditions. Evolution of new techniques, particularly soft ionization methods, has prompted a re-investigation of supporting evidence for confirmation since little or no fragmentation is observed.

CRITERIA FOR CONFIRMATION

1. Full Mass Scans

In the case of full mass spectral scans derived under the various ionization techniques (El, CI, NCI, FAB, etc.), the reference standard and the sample recorded under similar conditions on the same instrument should agree with no less than a 5% agreement in relative abundance ratios. This logic, while obvious, is often difficult to practice experimentally. While reference standards are pure compounds, the sample extract can introduce interfering ions into the mass spectrum complicating the confirmation process. Using chromatographic separation prior to mass spectrometry can often guarantee that interfering ions are reduced to a minimum allowing direct spectral matching to take place. However, when probe samples are used for confirmation, then gross interference can occur. In the case of confirmation of aflatoxin B1 in peanuts under NCI, Park et al. (3) argued that although the three ions representing the compound (m/z 297, 311, and 312) were present in the correct relative abundance ratios, they could be fragment ions from higher molecular weight compounds. These authors have stated that when the interfering ions constitute greater than 20% of the total intensity of the mass spectrum, then confirmation cannot be deduced in spite of the three ions at the correct relative abundance ratios. This lower limit of 20% represented a responsible judgment by the authors based on practical experience, i.e. the expert opinion factor.
2. Multiple Ion Detection

Confirmation of trace levels are generally carried out using multiple ion detection techniques to lower the detection limit of the mass spectrometer to match the residue problem. This method of confirmation mandates that chromatographic separation of the sample be performed prior to mass spectral analysis to concentrate the compound of interest into an appropriate elution profile for analysis as well as potential quantification if desired. The literature contains a large number of documented case histories where more than three or four ions were adopted for the confirmatory process. For example, in the case of trace levels of dimethoate in mangoes (4), four ions under GC/MS using methane CI were selected for confirmation of the eluting peak believed to represent the pesticide in the extract. It would seem that the prevailing expert consensus prefers to adopt no less than four ions for confirmation. These case histories can therefore be considered to establish that a minimum of three structurally related ions are generally recognized as scientifically sound. In the case of quantification, however, a single ion is often used to further reduce the limit of detection, optimize dwell times and improve precision and accuracy. This method of approaching quantification is generally accepted only after confirmation has been performed or a deliberate study is underway using spiked samples in a recovery study.

3. Product Ion Chemistry

Soft ionization methods have become popular techniques for the analysis of trace level residues because they provide two distinct advantages over EI. First, the ionization process favors the production of solitary protonated molecule ions or adduct ions depending on the reagent gas employed. Second, soft ionization methods tend to suppress the background interference ions due to lack of fragmentation. Observation of protonated molecule ions can be considered the most important criterion for identification, but the burden of proof of presence placed on a single ion species cannot be regarded as sufficient for confirmation. The majority of residue samples analyzed by liquid chromatography/mass spectrometry (LC/MS) suffer from this same disadvantage that chemical ionization methods provide only protonated molecule ions for confirmation. Since molecules analyzed by LC/MS are usually thermally labile or non-volatile, the opportunity to use EI to obtain sufficient fragment ions is not an experimental option. Only two LC interfaces have the option to perform EI studies, the moving belt interface and the particle beam device. Therefore, the degree of specificity has been increased by using tandem mass spectrometry (MS/MS). In the case of etrimphos, both the EI and CI spectra did not contain sufficient fragment ions for the confirmation process. However, the product ion spectrum derived from the protonated molecule ion, m/z 292, did provide five ions to meet the confirmation criteria (5). Using the protonated molecule ion as the precursor ion, the product ion spectra usually contain sufficient ions to meet the criteria of a minimum of three structurally related product ions. Therefore, the recent shift in emphasis to the use of LC/MS interfaces has created a reliance on product ions spectra to satisfy the criteria for confirmation.

CONCLUSIONS

Although the variation in the application of MS methods to residue analysis is large, the underlying criterion that at least three structurally significant ions are necessary for confirmation has been experimentally established to be valid. Most members of the discipline, however, have elected to go beyond the minimum criteria whenever possible. With the increasing application of soft ionization methods established by the various LC/MS methods, the lack of specificity has been overcome by the use of LC/MS/MS. The use of product ion spectra derived from protonated molecule ions has become a practical solution to analyzing many thermally labile compounds. Most of the problems in analyzing food samples involve relatively low molecular weight compounds. The choice of criteria for confirmation outlined above have been selected with this molecular weight range in mind. However, the next generation of pesticides derived by biotechnology will involve much higher molecular weight compounds. With increasing molecular weight the criteria for confirmation must be expected to undergo a revision to increase the number of ions required. However, the increased use of collision experiments via MS/MS will be expected to eventually replace the conventional approaches to confirmation through product ions derived from molecule ions.

The Impact of Electrospray on Environmental Monitoring

*R. D. Voyksner, H. Y. Lin and T. Pack
Research Triangle Institute, P. O. Box 12194
Research Triangle Park, NC 27709 USA

Introduction

Environmental monitoring of many non-volatile or thermally unstable polar organics by LC/MS relies on the development of sensitive, specific and cost effective LC/MS techniques. Electrospray can meet these goals since it has the capability to generate molecular ions (i.e. [M+H]⁺ or [M+Na]⁺) from low pg quantities of many environmentally relevant compounds. Fragment ions for identification or confirmation can be generated by multiple mass analyzer instruments, but more cost-effective approaches such as collisional activation in the electrospray transport region or the use of ion trap mass spectrometry (ITMS) can provide this structural information. Collisional activation decomposition (CAD) in the transport region of the electrospray interface or in an ITMS can result in higher daughter ion yield than typically achieved from triple quadrupole MS. This paper reports on electrospray combined with MS for the determination of numerous small molecular weight compounds of environmental interest.

Experimental

An electrospray source (Analytical of Bradford) was interfaced to a Finnigan MAT 4500 quadrupole MS. Samples ranging from 1 pg to 100 ng/µL were introduced into the RS source at a flow rate of 2 µL/min using a syringe pump. The potential difference across the capillary and skimmer in the ion transport region of the FS source could be used to control the extent of fragmentation. An electrospray Interface (Vestec) was also mounted to an ITMS (Finnigan MAT) to analyze several of the same samples under analogous operating conditions.

Results and Discussion

The main goal in this study was to evaluate electrospray MS for generating of structurally relevant information on typical molecules of environmental interest. One compound included in this study was aldicarb. Aldicarb, a thermally labile carbamate pesticide, exhibits fragmentation (ion at m/z 116) for a very low capillary/skimmer potential difference of 10 V (Figure 1). At 50 V potential difference the [M+Na]⁺ and other adduct ions are dissociated and the fragment ion at m/z 89 and m/z 116 increase in intensity. At a higher potential difference of 85 V only low mass fragment ions such as CH₃Na⁺, C₂H₅⁺ and C₃H₇⁺ are formed. Other pesticides and herbicides investigated also exhibit significant structural fragmentation at various capillary-skimmer potential differences. In general, potential differences in the 0-20 V range do not exceed the activation energy for the lowest energy fragmentation process, but remove most cluster ions formed through hydrogen bonding. In the 60-100 V potential differences range significant breakage of covalent bonds occurs while the signal for the molecular ion is retained. Potential differences above 100 V usually result in low mass fragments. At a high potential difference (140 V) over 16 eV of internal energy can be imparted into the molecule.

Besides providing structural information, the sensitivity of electrospray for detecting environmentally significant compounds proved to be excellent. Transmission of ions throughout the transport region at various capillary-skimmer potential differences varied by less than 20%. This means that the sum of the daughter ion currents at a high capillary-skimmer potential difference (CAD conditions) was nearly identical to the [M+H]⁺ ion current for a low capillary-skimmer voltages (non-CAD). The efficient CAD process permits detection of daughter ion for the analysis of 10 pg of aldicarb when scanning from 10-500 daltons (Figure 2). The sensitivity and linearity for electrospray MS can be seen in Figure 3 for a calibration curve of aldicarb from 10 pg - 100 ng. Concentrations above 100 ng often result in saturation of the electrospray ionization process causing a drop or leveling in the MS response.

In order to achieve better sensitivity, the combination of electrospray with an ion trap mass spectrometer (ITMS) was evaluated. Preliminary data generated from the coupling of the techniques indicated slightly better detection limits could be achieved for aldicarb. However, we are still evaluating and optimizing the electrospray - ITMS interface and anticipate significant improvements in sensitivity compared to quadrupole MS.

Applications of Mass Spectrometry to the Analysis of
3-Chloro-4-(Dichloromethyl)-5-Hydroxy-2(5H)-Furanone (MX).

*M. Judith Charles, Rohini Kannaganti, Gong Chen and G. Dean Marbury, Department of Environmental Sciences and Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-7400

Introduction. Existing methods for the analysis of the potent mutagen 3-chloro-4-chloromethyl)-5-hydroxy-2(5H)-furanone (MX) are unsuitable because they either rely on external standardization or internal standardization. Improved accuracy, particularly when using mass spectrometry can be obtained by internal standardization because any changes in the response of the analyte, due to the presence of other compounds or changes in ion source conditions are normalized to the response of the internal standard. The internal standardization method is however a semi-quantitative method because the response of MX to the internal standard is determined by measuring the response of a single concentration of MX to a single concentration of the internal standard. The objective of this study was therefore to develop an internal standardization method for the analysis of MX in waters. Accordingly, the mass spectrum of the methyl derivative of MX was characterized, the need for high-resolution mass spectrometry was established and a method was validated and tested that uses isotopically labelled benzoic acid as an internal standard.

Experimental. Solutions of the methyl derivative of MX and the methyl ester of benzoic acid were prepared by reacting standard materials of MX with solutions of 2% H₂SO₄ in methanol, deuterated methanol for 1 hour or 14% (v/v) boron trifluoride (BF₃) in methanol for 12 hours in a 70°C mineral oil bath. The sulfuric acid and boron trifluoride was neutralized by the addition of 2% aqueous NaHCO₃ and the methylated products were extracted into hexane.

Experiments were performed on a Hewlett-Packard 5890 gas chromatograph interfaced to a VG70-250SEQ mass spectrometer operating at a resolving powers of 1,000, 10,000 or 20,000 (10% valley definition). A 30m, 0.32mm I.D., 0.25um film, DB-5 fused-silica capillary column was used in all experiments. The GC oven was held at an initial temperature of 115°C for 3 min. and then increased to 165°C at a rate of 6°C/min in experiments performed to characterize the mass spectrum of the methyl derivative of MX. In other experiments, the GC oven was held at an initial temperature of 50°C for 1 min. and then increased to a temperature of 170°C at a rate of 10°C/min. Mass spectra were acquired by using electron ionization at an electron energy of 70 eV, 200 uamp trap current, source temperature of 150°C and interface temperature of 250°C. Ions corresponding to the molecular ion of the methyl ester ¹³C₆ benzoic acid (m/z 142.0726) and a PFK lock mass ion m/z 142.9920 were monitored from 3-11 minutes and fragment ions of the methyl derivative of MX (m/z 198.9121, 200.9024) and a PFK lock mass ion m/z 192.988 were monitored from 11-13 minutes in analyses performed by selected-ion-monitoring. Mass spectrometry/mass spectrometry experiments were conducted by introducing standard material of the methyl derivative of MX through the gas chromatograph and acquiring the MS/MS spectrum during the elution of the MX peak. The ion at m/z 229 was transmitted from MSI at a resolving power about 500 to the collision region, where collisionally activated decompositions (CAD) to product ions occurred. Conditions in the collision-region were an indicated argon pressure on the Bayert-Alpert ion gauge of 5x10⁻⁵ mbar and a collision energy of 25 eV.

Results and Discussion. Previous interpretations of the electron-ionization mass spectrum of the methyl derivative of MX has suggested that the isotope cluster beginning at m/z 199 is due solely to the (M-OCH₃) fragment ion. Measured abundances of the isotope ratios at m/z 199, 201 and 203, however differ from the theoretical values for a three chlorine isotope cluster (Figure 1). We hypothesized that the cluster arises from two distinct pathways and is composed of two fragment ions, each containing three chlorine atoms. One fragment arises from the loss of the -OCH₃ from the molecular ion. The other is due to either the loss of -OCH from the molecular ion or -CO from the (M-1)⁺ ion to yield a fragment ion at m/z 201 that overlaps with the three chlorine cluster at m/z 199. Experiments were designed to test this hypothesis. Accordingly, we deconvoluted the original cluster at m/z 199 assuming the presence of a three chlorine isotope cluster at m/z 199 and another at m/z 201 with good agreement between calculated and theoretical relative abundances of ions. The
presence of these two fragment ions was confirmed by high-resolution gas chromatography/high-resolution mass spectrometry (HRGC/HRMS) at a resolving power of 20,000. The mass spectrum of MX, methylated with deuterated methanol showed two fragment ions, one which arose from the loss of \(-\text{OCD}_3\) (m/z 199) and the other from the loss of \(-\text{OCH}\) (m/z 204). Mass spectrometry/mass spectrometry (MS/MS) of the m/z 229 (M-1\(^+\)) fragment ion of the methyl derivative of MX showed a product ion at m/z 201. The fragment ion at m/z 201 therefore originates from the loss of \(-\text{CO}\) from the (M-1\(^+\)) ion.

Selected-ion-monitoring of the ions at m/z 199 and 201 is recommended in the analysis of MX and thus the use of high-resolution mass spectrometry was explored because we do not know the effect of instrumental parameters (e.g., ion source temperature) on the relative yields of the two fragment ions, and thus on the observed ratio between the ions at m/z 199:201. We do know however that at a resolution about 10,000 the ions at m/z 201 are resolved. Operating under high-resolution conditions then allows the use of confirming criteria based on the theoretical ratio of ions in a three chlorine isotopic cluster. Doubt about the presence of the compound, in situations where the compound is present near the detection limits of the method, can thus be reduced because one is comparing an experimental (variable) value to a known (fixed) value instead of two experimental values that are by definition, variable. Additional need for high-resolution mass spectrometry was demonstrated by comparing the results of analyses of a chloramination extract performed at a resolving power = 1,000 and 10,000. Under low-resolution conditions, identification and quantification of MX was impossible due to low signal:noise values. In this case, noise due to chemical interferences was eliminated by using high-resolution mass spectrometry resulted in an improvement in the S:N value of an order of magnitude. A high-resolution mass spectrometry method for the analysis of MX was therefore developed that uses isotopically labelled benzoic acid as an internal standard. Validation of the method was achieved by spiking a known amount of MX into lake water and into chlorinated lake water. The difference between the expected and measured values was less than 10%. The response of the methyl derivative of MX to the methyl ester of \(^{13}\text{C}_6\) benzoic acid was shown to be linear from 50 pg/ul to 1000 pg/ul. A deviation from linearity was observed at lower levels (10 pg/ul) and the method was shown to have a detection limit (S:N = 3:1) of about 20 pg/ul. Thus, the method is applicable to the analysis of MX in a broad range of waters.

Figure 1. Mass spectrum of the methyl derivative of MX. The fragment ion at m/z 199 has been attributed to the loss of \(-\text{OCH}_3\) from the molecular ion. In this case, the chlorine isotope cluster would be similar to that observed in the m/z 229 fragment ion.
CHEMICAL TRANSFORMATION BROADENS THE SCOPE OF MS: DNA Adducts

*Roger W. Giese, Wenni Li, Samy Abdel-Baky, Kariman Allam, and Manasi Saha, Barnett Institute and College of Pharmacy, Northeastern University, Boston, MA 02115

The measurement of biomarkers is one approach to monitoring presence and effects of toxic chemicals in the environment. DNA adducts, the consequence of covalent damage to DNA, are an important biomarker. However, the amount of DNA in biological samples is small, and the DNA adducts commonly are a trace component of the DNA.

Gas chromatography with electron capture negative ion mass spectrometry (GC-ECNI-MS) is a sensitive form of MS but its scope is limited to volatile, thermally stable compounds. It is most sensitive when a specific ion is formed in high yield. Some DNA adducts arising from simple alkylation damage to DNA can be determined by GC-ECNI-MS after isolation as modified nucleobases and then electrophoric derivatization (1). This approach fails for most DNA adducts because of the structural variety and lability of their functional groups.

In order to broaden the scope of GC-ECNI-MS for sensitive DNA adduct detection, we are applying or developing chemical transformation techniques which convert the DNA adduct into a product which can then be electrophore derivatized and detected with high sensitivity by GC-ECNI-MS. Our first example was to convert N7-(2-hydroxyethyl)guanine, an ethylene oxide DNA adduct, into a corresponding xanthine with nitrous acid. The xanthine form of the adduct was then easier to electrophore derivatize than the parent compound (2). As a second example, we used high temperature (160°C) hydrazinolysis to release 2-aminofluorene from the DNA adduct, N-(deoxyguanosin-8-yl)-2-aminofluorene (3). The 2-aminofluorene was then converted to N-pentafluorobenzylidenyl-2-aminofluorene, a sensitive analyte for GC-ECNI-MS.

Here we introduce potassium superoxide to achieve a third kind of chemical transformation reaction for DNA adducts. The proposed overall method is shown in Fig. 1. Benzo[a]pyrene diol-epoxide is known to react with DNA onto the N2 position of guanine and the subsequent adduct, shown as the starting material in this figure, can be released from the DNA by mild acid hydrolysis (4). Our analytical strategy is to conduct this known step, followed by oxidation of the released benzo[a]pyrene tetrahydrodiol with potassium superoxide, yielding 2,3-pyrenedicarboxylic acid. This diacid is then converted by pentafluorobenzyl bromide into a corresponding diester for detection by GC-ECNI-MS. The detection of 9.2 fg (14 amol) of a standard of this compound by this technique is shown in Fig. 2. The high sensitivity reflects the known tendency of pentafluorobenzyl esters to undergo dissociative electron capture yielding a carboxylate ion in high yield.

Chemical transformation in chemical analysis tends to give up some structural information about the analyte, and thereby some specificity in the analysis. A compensating advantage is that a given method may be applicable to an entire class of analytes. For example, we anticipate that the KO2 procedure will be a general method for diol-epoxide polyaromatic DNA adducts. We have demonstrated previously that a diversity of hydroxy- and keto-polycyclic hydrocarbons can be converted by KO2 into corresponding polyaromatic carboxylic acids (5).

APPLICATION OF GC RETENTION INDICES FOR ISOMER SPECIFICITY IN GC/MS MONITORING OF HALOGENATED DIOXINS

J. R. Donnelly and G. W. Sovocool

Lockheed Engineering & Sciences Co., Inc. 1050 E. Flamingo, Las Vegas, NV 89119 and
U.S. Environmental Protection Agency, EMSL-LV, P.O. Box 93478, Las Vegas, NV 89193-3478

Brominated dioxins (PBDD) have been found in flame-retarded thermoplastic resin pyrolysates, brominated phenols, brominated diphenylether pyrolysates, and vehicular exhaust. Bromochlorinated dioxins (PBCDD) have been detected in municipal and hazardous waste incinerator fly ash. Toxicological data suggest that the toxicities of these brominated and bromochlorinated dioxins (75 PBDD, 1550 PBCDD) are similar to the levels found for the 75 PCDD analogs. Because of toxicity concerns and the scarcity of analytical standards, environmental monitoring for halogenated dioxins (HDD) is usually performed with only a few standards. Because toxicity is dependent upon substitution pattern, isomer-specific analytical methodology would be desirable for HDD, based upon the traditional combination of GC retention time or RI and mass spectrometric data. For quality assurance, it is important that the retention time ranges be known accurately for each congener group, so that GC/MS selected ion monitoring (SIM) descriptors will be assigned the proper retention time ranges. It is also important that the GC column resolve 2,3,7,8-substituted isomers from the close-eluting isomers, and that those RI be well-defined, so that quantifications of the 2,3,7,8-substituted isomers will be accurate.

For this study, commercially-available standards were augmented by the synthesis of over 100 HDD. Retention indices (RI) for the HDD were determined against the normal hydrocarbons, using temperature programmed capillary column gas chromatography. Retention indices for the HDD were expressed as the sum of five contributors: (1) the index of single-ring A; (2) the index of single-ring B; (3) the index of a "ring interaction" effect, or "1,9-effect" which was observed in cases where both the 1 and 9 positions were halogenated. In the event the 1,4,6, and 9 positions all were halogenated, the total effect was experimentally observed to be approximately 1.5 times the magnitude of a single 1,9 effect; (4) the index increment from "buttressing" the 1,9-effect with additional substitution at the 2 and 8 positions; and (5) the index of a "phase interaction" effect. The single-ring RI values are listed in Table 1. In general, each additional bromine substitution incremented the molecular RI about 1.5 times as much as a chlorine substitution did. The 1,9-chloro ring interaction was found to average 12 RI units; when two 1,9-effects were present (i.e. all four 1,4,6,9 positions were occupied by chlorine atoms), the total ring-ring effect was approximately 18 units.

The 1,9-dibromo ring-ring interaction was also found to increase the RI by approximately 12 RI units. Buttressing at the 2,8-positions with chlorines increased the magnitude of the effect to 18 RI units. "Buttressing" the 1,9 positions with 2,3,7,8-tetrabromo substitution increased the 1,9- ring-ring interaction effect to 34 RI units; 2,8-dibromo-3,7-dichloro buttressing gave the ring-ring interaction effect a magnitude of 22 RI units.

In those molecules containing two or more bromines on one ring, it appeared that the ability of the second ring, if unsubstituted, chlorinated only, or monobromo-monochlorinated, to interact with the column phase was diminished, resulting in a reduction of RI. It is suggested that the reduction in RI was related to the molecule assuming a distance from the phase greater than the optimum distance for interaction with the phase by the second ring. The experimental magnitude of the RI decrease, suggested to be caused by a "phase interaction" (PI) effect, was found to be dependent upon the number of bromines and upon whether the second was unsubstituted, chlorinated, or monobromo-monochlorinated. These findings have been summarized in Table 2.

In this study, 69% of the 71 HDD used to test the model had experimental RI values which agreed with the predicted RI values within 3 RI units, over a RI range of ca. 2500-4300 units; 89% were within 5 RI units, and no predictions varied from the experimental values by more than 7 RI units.

The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Results of a Field Evaluation of the Bruker Mobile Mass Spectrometer Under the SITE Demonstration Program

S. Billets
U.S. Environmental Protection Agency
Environmental Monitoring Systems Laboratory
Las Vegas, Nevada

V.A. Ecker and D.J. Chaloud
Lockheed Engineering & Sciences Company
Las Vegas, Nevada

The Superfund Program was established by Congress in 1980 to identify, prioritize, and remediate the nation's uncontrolled hazardous waste sites. Because the scope of the problem has proven to be even more complex and widespread than anticipated, Congress enacted the Superfund Amendments and Reauthorization Act of 1986 (SARA). Under SARA, the U.S. Environmental Protection Agency (EPA) was charged with effecting more timely and cost-effective solutions for Superfund site remediations. As part of this legislation, the Superfund Innovative Technology Evaluation (SITE) Program was established to provide EPA with a program designed to accelerate the development, demonstration, acceptance, and use of promising alternative or innovative technologies targeted to meet the objectives of the overall Superfund Program.

One element of this program provides developers with the means to demonstrate innovative technologies that could be used as an alternative to the current systems for detecting and assessing the extent of pollution at hazardous waste sites. The purpose of these demonstrations is to evaluate fully developed technologies, thereby making information on the performance and cost effectiveness of such technologies available to interested parties. Superfund decision makers will thus have the information necessary to consider whether or not these technologies can or should be used in specific site characterization or remediation projects.

Bruker Instruments, Inc., of Billerica, Massachusetts, was selected to participate in this program, and its Mobile Environmental Monitor (MEM) was identified by EPA as a promising candidate for a field demonstration. The MEM, designed for the on-site analysis of organic contaminants, is a quadrupole mass spectrometer (MS), optionally coupled to a gas chromatograph (GC) or a thermal desorption sampling probe. Currently, full-sized, non-mobile laboratory GC's/MS's have been the preferred EPA approach to identifying and quantifying organic contaminants at Superfund sites. A GC/MS instrument provides information regarding the molecular weight, retention time, and characteristic fragmentation pattern of organic compounds. The primary disadvantages of conventional GC/MS systems for field use are instrument size, power demand, and sensitivity to external factors (e.g., temperature, humidity, and vibration). The development of the MEM, which is rugged enough to withstand a variety of field conditions, is of considerable interest to parties responsible for contaminant monitoring at Superfund sites. Newly developed mobile systems, such as the Bruker MEM, appear to have attained satisfactory levels of stability, power usage, and compactness for field applications and are appropriate for testing under the SITE Program.

The purpose of the demonstration was to evaluate the ability of the MEM to analyze polychlorinated biphenyls (PCB's) and polynuclear aromatic hydrocarbons (PAH's) in soils and to analyze volatile organic compounds (VOC's) in water under field conditions at Superfund sites. The demonstration focused on the capability of the instrument to generate rapid, cost-effective, and reliable PCB, PAH, and VOC data from real-world samples. The experimental design used in this study was to compare MEM performance to analytical method performance results as would be received under the EPA Contract Laboratory Program (CLP). Detailed project and quality assurance (QA) plans were prepared which defined the sampling and analysis protocols, the experimental design, the QA and quality control (QC) requirements, the data base management system, the health and safety considerations, and the proposed methods for data analysis.
For this demonstration, samples were collected from two sites in Massachusetts (EPA Region 1) on the National Priorities List (NPL). These sites were selected on the basis of documented (Record of Decision) presence of analytes of interest: i.e., PCB’s in soil and VOC’s in ground water at one site and PAH’s in soil at the other. A screening analysis by the MEM identified the collection points (i.e., low, medium, and high concentration levels) for five samples in each compound class (PCB, PAH, VOC). Bulk samples were collected, homogenized, and split into replicates. For each compound class, each of the distinct samples was split into seven replicates for analysis on site (or near site) by the MEM, and off site by standard EPA methods. In addition, standard reference materials and blank samples were sent to all analysis locations as a measure of variability, detection limits, and other data quality assessment criteria. This process worked well for the PCB and PAH soil samples; however, remediation activities at the chosen site precluded the collection of VOC-contaminated ground water samples. Instead, a surface water sample was collected from one site and spiked at different concentrations of VOC’s. These samples were then analyzed under field and laboratory conditions as originally planned.

The data from all analysis sites were compiled into one fully documented data base. Data were then subjected to a detailed verification process. Following verification, a variety of data analyses were performed, including intermethod comparisons (between the MEM and the off-site laboratory results), reproducibility was estimated (from replicate analyses on the same instrument), and an evaluation of various data quality indicators was made. Direct comparison plots and a variety of statistical routines were used to interpret the data.

The primary advantages of the MEM are its portability and ruggedness. Rechargeable batteries supply all power required, and the logistical requirements are minimal and easily fulfilled. The use of purified ambient air as the carrier gas eliminates the need to transport compressed gas cylinders. The operations plan called for the analysis of 13 samples per day, which is within normal performance expectations; however, the analysis team had difficulty meeting this sample throughput requirement. Although the MEM is easy to operate under normal conditions, a skilled operator is required to correctly diagnose and repair malfunctions.

On the basis of data collected and observations made during this demonstration, several issues have been identified that must be addressed before the MEM or other GC/MS instruments can be recommended for Superfund site monitoring, characterization, and remediation activities. These issues include: (1) method enhancement and procedural requirements, (2) development of standardized QA/QC requirements, (3) development of data reporting standards for field analytical measurements, and (4) development of detailed troubleshooting guides and training programs. These issues do not necessarily represent problems with the technology itself; several are external factors or policy issues that require attention before the EPA can use field mobile GC/MS instruments as reliable field analytical devices.

EPA is conducting additional mobile mass spectrometer research at the EMSL-LV under the SITE Program. Future laboratory evaluations will concentrate on (1) separating variability associated with the instrument from that associated with the methods, (2) formalizing QA/QC procedures, and (3) establishing consistent data reporting procedures for field applications. Additional field demonstrations and evaluations will follow.

NOTICE

Although the research described herein has been funded wholly or in part by the U.S. Environmental Protection Agency under Contract Nos. 68-03-3249 and 68-CO-0049 to Lockheed Engineering & Sciences Company, it has not been subject to Agency review and therefore does not necessarily reflect the views of the Agency, and no official endorsement should be inferred. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.
THE ULTRA-TRACE DETERMINATION OF LSD BY LC/MS/MS WITH ION FORMATION AT ATMOSPHERIC PRESSURE.

*Jack Henion and Timothy Wachs, Drug Testing and Toxicology, Cornell University, 925 Warren Dr., Ithaca, NY 14850, and Rodger Foltz, Northwest Toxicology, Inc. 1141 East 3900 South, Salt Lake City, UT 84124.

Social and analytical problems still remain with respect to LSD. Its identification in forensic samples continues to be an analytical challenge utilizing modern GC/MS techniques. Recent experience regarding confirmation of urine RIA positives collected within the military suggests that only about 10-30% of these samples can be confirmed by GC/MS techniques. This problem stems at least in part from sensitivity differences between RIA screening and GC/MS confirmation techniques. Confirmation of relatively low levels (sub-ppb) that LSD exists in these urine samples demands sensitivity requirements that challenges current GC/MS standards. A factor that contributes to the GC/MS confirmation problem includes the high polarity and thermal instability exhibited by LSD. An ultra-trace derivatization procedure prior to analysis of the urine extract is thus required. The chemical complexity of urine extracts adds to the analytical problems and hinders unequivocal identification of this important drug and its metabolites.

We have explored the use of both the ion spray (pneumatically-assisted electrospray) and the heated pneumatic nebulizer (APCI) LC/MS interfaces for the ultra-trace determination of underivatized LSD. A comparison of LC/MS results on the commercial SCIEX API III and a modified Hewlett-Packard 5970 MSD system using both 2.1-mm- and 1-mm i.d. packed-HPLC columns have demonstrated sub-nanogram LC/MS detection limits. This report summarizes our results with an emphasis on the commercial Sciex system optimized for high sensitivity using the ion spray LC/MS interface.

EXPERIMENTAL

A Sciex TAGA 6000E triple quadrupole mass spectrometer upgraded to an API III was used in this work. The system was operated in the selected reaction monitoring (SRM) mode using argon as the collision gas with a collision energy of 20 eV (laboratory frame) with positive ion detection mode. The HPLC system used included a 600 MS pump (Waters Chromatography Division, Milford, MA) operated in the isocratic mode at 0.1 mL/min with 35:65 acetonitrile:water with 5 mM ammonium formate as the sluent. The column was a 2.1 mm x 50 mm LC8-DB (Supelco, Bellefonte, PA) equipped with a Model 7125 injector (Rheodyne, Cotati, CA). Human urine samples (5 mL, pH-adjusted to 10) were treated using a simple n-butyl chloride liquid-liquid extraction procedure, and the extract analyzed without derivatization. Injection volumes of 10-20 μL were analyzed by the LC/MS/MS system. The internal standard was da-LSD spiked into the urine at the 500 pg/mL level. Spiked urines containing 500 pg/mL da-LSD were analyzed containing the following levels of LSD: 0, 20, 50, 100, 200, 500, and 1000 pg/mL.

The corresponding LC/MS/MS mass spectra for LSD, iso-LSD, and da_LSD are shown in Figure 1. The analysis of urine extracts was carried out under selected reaction monitoring (SRM) conditions that included three Ions for LSD and two ions for the internal standard. The conditions described were chosen to represent a combination of high sensitivity and practical utility.

RESULTS AND DISCUSSION

The results of this work demonstrate that LC/MS/MS analyses of human urine extracts may be be accomplished with short sample analysis times and LSD levels at least as low as 50 ppt. For example, the extract from 5 mL urine may be concentrated to 50 μL while 20 μL of this were injected onto the 2.1 mm i.d. column. Isocratic HPLC conditions allow elution of underivatized LSD and its metabolites within 6 min. Structurally characteristic product ions plus the precursor ion and the corresponding HPLC retention time allows unique specificity for the detection and, in principle, quantitation, of LSD in human urines.

An incurred urine sample obtained from an unidentified military personnel was
analyzed by this technique. The described LC/MSMS analysis using SRM and a spike of 500 pg/mL \textit{d}_3\text{-LSD} produced the LC/MS/MS ion current profiles shown in Figure 2. The LSD component is observed at a retention time of 4.2 min while a large peak for iso-LSD is observed at a retention time of 5.8 min. It is worthy of note that these two components are readily detected without derivatization in this experiment. Although it is possible to chromatographically distinguish LSD from iso-LSD by GC/MS following trimethylsilylation derivatization, the described LC/MSMS technique demonstrates good separation and easy differentiation of these compounds within 6 min. Prior analysis by GC/MS/MS following derivatization had determined a LSD level of 370 pg/mL and an iso-LSD level of 1000 pg/mL in this urine. Comparison of relative peak areas from these LC/MS/MS results revealed a quantitative determination of 389 pg/mL for LSD and 940 pg/mL iso-LSD, in good agreement with the GC/MS/MS results.

**CONCLUSIONS**

At the present time the 50 pg/mL level appears to be the practical limit of detection using this technique, but it appears this can be improved to at least the 20 pg/mL level. If a cut-off level of 100 pg/mL LSD is established for regulatory matters the present 50 pg/mL should be sufficient. However, an alternative deuterated internal standard is needed that has abundant product ions differing from LSD.

Diarrhetic shellfish poisoning (DSP) is a severe gastrointestinal illness caused by the consumption of shellfish contaminated as a result of feeding on toxic dinoflagellates [1]. While bivalve contamination by DSP toxins is particularly acute in Japan and northern Europe, there have been no confirmed reports of DSP incidents in North America. The toxins associated with DSP are lipid-soluble, polyether compounds which are difficult to analyze by conventional methods. Recently we have developed a combined liquid chromatography atmospheric pressure ionization mass spectrometry (LC-MS) method using an IonSpray (ISP) interface for the analysis of DSP toxins and reported the presence of okadaic acid (OA), the principal toxin associated with DSP, in natural populations of Dinophysis spp. from eastern Canadian waters [2].

In early August 1990, several people developed symptoms of nausea, vomiting and diarrhea after eating cultured mussels from the Mahone Bay area in Nova Scotia. DSP was suspected and extracts from samples of raw mussels from a restaurant and cooked mussels from a domestic residence were found to be toxic to mice (IP injection). Analysis by an improved gradient elution LC-API-MS method using selected ion monitoring quickly established the presence of a high level of the DSP toxin, dinophysistoxin-1 (DTX-1, a methylated homologue of OA), in the suspect mussels and not in control mussels (Figure 1). Interestingly, OA was not detected. The formation of chemical derivatives which gave the correct shifts in both retention time and mass by LC-API-MS provided additional supporting evidence. The toxin was subsequently isolated, purified and its structure confirmed by a variety of analytical techniques including full-scan ISP-MS, derivatization and HPLC with fluorescence detection, high resolution FAB-MS and proton NMR.

Extraction and handling procedures were improved during the investigation, allowing the quantitative analysis by LC-API-MS of survey samples from the affected area. It was found that the incident was highly localized to one mussel growing lease and that by the end of August, the mussels had depurated all of their toxin load. The most toxic mussels, containing up to 1000 ng/g whole tissue (the legal level in Europe is 200 ng/g), appear to have been harvested on August 3. This suggests that a bloom of toxic plankton may have occurred near the end of July and led to contamination of the mussels.

Microscopic examination of toxic mussel digestive gland contents revealed remnants of Dinophysis spp. (probably norvegica), an organism known to produce both OA and DTX-1 (although the ratio is known to vary, with documented instances in Norway where only DTX-1 is present [3]). Control, non-toxic mussels showed no recognizable remnants of Dinophysis spp. Plankton tows from the water adjacent to the affected area in mid-August did show several Dinophysis spp. (including norvegica as the dominant species), but at low levels in the water column. LC-MS analysis of these plankton samples provided only a weak, unreliable signal for DTX-1, and it is presumed that the plankton bloom had dissipated by the time of sampling.

To our knowledge this is the first proven case of DSP in North America.

Particle beam LC-MS Using The Jeol SX-102 Mass Spectrometer. Woodfin V. Ligon, Jr. and Steven B. Dorn, General Electric Co. Corporate Research and Development, Schenectady, N.Y. 12301

We have described the design and construction of a particle beam LC-MS interface specifically designed for use with magnetic mass spectrometers. (Ligon and Dorn, Anal. Chem., 62, 2573, (1990)). This early work utilized a Varian-MAT 731 which was relatively insensitive, slow scanning, and allowed only EI analysis. We have now successfully transitioned this interface to a JEOL SX-102 mass spectrometer. Using this instrument we have demonstrated sub-nanogram sensitivity using one second mass scans (40-800 amu) in EI mode. In addition, we have developed methods which allow acquisition of CI data at full accelerating voltage (10 keV) with excellent sensitivity using a wide range of reagent gases. When operating with an LC flow of 0.5 ml/min acetonitrile and isobutane reagent gas, the base pressure in the ion source region is about 2 x 10^{-6} torr. Because of the very low pressures obtained with our interface, the operation of the mass spectrometer is not compromised in any way. We have demonstrated detection of masses above 2000, high resolution scanning and high resolution SIM.

The Determination of Hydroperoxides, Peroxides and Other Labile Compounds by Particle Beam EI-MS/MS. Richard Hiserodt, Ming-Hua Yang, Thomas G. Hartman, Joseph Lech, Tarik Roshdy, Karen Schaich and Robert T. Rosen*. Center For Advanced Food Technology and Food Science Department, Cook College, Rutgers University, New Brunswick, NJ 08903

The inertness of the particle beam technique was highlighted in this presentation by showing EI spectra of the most sensitive and labile organics, hydroperoxides and peroxides. The compounds decompose with heat and by metal catalysis. Use of PEEK columns and tubing with HPLC, and the particle beam interface with EI-MS overcomes this disadvantage and spectra were presented of compounds which cannot be analyzed by any other MS technique. Lipid peroxidation products such as linolenyl hydroperoxide have been postulated as intermediates for years, and their decomposition pathways lead to flavors as well as toxic polymers. EPR has been the only standard of analysis for years. Now methodology is possible by both HPLC and HPLC-MS.

The EI-mass spectrum of a mono hydroperoxide of methyl linoleate was shown. Characteristics ions in this mass spectrum are the odd electron ions at $m/z=292$ and $m/z=308$. These result from loss of $H_2O$ and $H_2O_2$ from the molecular ion. The low mass ions for this compound consist of a series of ions separated by methylene units and are characteristic of linolenic acid, the analog with three double bonds. Also shown was the EI-spectrum of a dihydroperoxide of methyl linoleate. The primary fragments at high mass which characterized this spectrum include the ion at $m/z=325$ resulting from loss of $OOH$ from the molecular ion. The molecular ion can also lose a molecule of $H_2O$ to form the ion at $m/z=324$ which immediately loses $O$H and $OOH$ to form the ions at $m/z=307$ and $m/z=291$. Loss of a molecule of oxygen produces the ion at $m/z=316$ which can lose $O$H or $OOH$ to form the ions at $m/z=309$ and $m/z=293$ respectively.

Work was also done using this technique to determine the applicability to other peroxides. The EI-spectrum of 1-(hydroperoxycyclohexyl)dioxydicyclohexanol did not show a molecular ion nor did we detect ions for loss of $H_2O$, $H_2O_2$, $OH$, or $OOH$. The even electron at $m/z=115$ is formed by inductive cleavage at the peroxide linkage. Loss of $H_2O$ from this ion yields the even electron ion at $m/z=97$ and loss of ethylene from this ion yields the even electron ion at $m/z=69$. Triphenylmethylhydroperoxide did not show a molecular ion nor did we detect ions for loss of $H_2O$ or $H_2O_2$ but we did detect a ion at $m/z=259$ due to loss of $OH$ from the molecular ion. We detected the trityl carbocation at $m/z=244$. Triphenylmethylhydroperoxide did not show a molecular ion nor did we detect ions for loss of $H_2O$ or $H_2O_2$ but we did detect a ion at $m/z=244$ an odd electron ion and may result from an McLafferty rearrangement to the ionized ring with subsequent loss of a molecule of oxygen by alpha cleavage. Inductive cleavage of the ionized oxygen closest to the ring in ((2,3,5,6-tetramethyl-1,4-phenylene) dimethylenebis(t-butyl peroxide) yields the ions at $m/z=249$ and $m/z=73$. Loss of the second t-butyl group yields the ion at $m/z=176$, or $m/z=175$ if it is lost as t-butyl alcohol.

Solutions of these hydroperoxides and peroxides were prepared in acetonitrile and chromatographed on a Syncropack B10-C RP-P (C-18) HPLC column. The mobile phase consisted of water with varying amounts of acetonitrile. The samples were also chromatographed using normal phase conditions on a silica column using a mobile phase consisting of hexane / ethyl chloride / ethan. The hydrophobic nature of the hydroperoxides and their precursors indicate normal phase conditions to be preferable.

PARTICLE BEAM LC-MS SPECTRA OF QUATERNARY AMMONIUM SURFACTANTS

Bruce H. Solka, Helene Curtis, Inc., Chicago, IL 60639

The ability of particle beam (PB) LC-MS to provide useful analytical information for nonvolatile cationic surfactants is demonstrated. These compounds, usually in the form of quaternary ammonium salts, are often the primary active ingredient in hair conditioning products. In this application they are usually of the types

\[ R_1 N(CH_3)_3^+ X^- \] and \[ R_1 R_2 N(CH_3)_2^+ X^- \]

where the alkyl chain, \( R \), varies from 10 to 22 carbons. Analytical requirements for these materials usually include determination of the number and lengths of alkyl chains, and the chain length distribution.

We find that PB vaporization processes of these salts preserve the structural integrity of the analytes and that EI and CI techniques meet most analytical requirements. Use of PB-MS for this type of work has the advantage of allowing easy changeover to non-surfactant or even non-LC applications.

Figure 1 illustrates a typical EI spectrum for a monoalkyl quat. The ion at m/z 368 corresponds to flash desorption of the intact quaternary ion. The m/z 353 ion is the molecular ion of the tertiary amine formed by pyrolytic demethylation. Its intensity relative to the m/z 58 immonium ion is consistent with the normal EI spectra of long chain alkyl dimethyl amines. The methane chemical ionization spectra (not shown) are dominated by \( MH^+ \) and \( M-H^+ \) ions of this tertiary amine with much smaller amounts of the intact quat. A third feature of the EI spectra of these types of compounds is a series of fragment ions that correspond to alkane losses from the intact quat ion (m/z 352, 338, 324, 310, 296, ...). These appear to be due to charge-remote fragmentations occurring in the ion source. This mechanism has previously been seen in CID MS/MS spectra of these compounds. These features persist in the homologous series of C12 to C22 monoalkyl quats and chain length distributions can be determined from the molecular ion intensities.

Figure 2 illustrates typical EI and CI spectra obtained for dialkyl quats. Negligible amounts of intact quats are seen but dialkyls are easily distinguished from monoalkyls because \( \alpha \)-fission from the dealkylation amine product now produces a stable medium mass immonium ion with retention of the second alkyl chain. In addition the CI spectra exhibit...
intense hydride abstraction ions from the dialkylmethyl tertiary amine. Chain length and distribution are determined from either the medium mass fragment (EI) or the molecular ions (CI).

The competition between desorption and dealkylation seen in monoalkyl guats provides an opportunity to test the effect of ion source temperature on these volatilization mechanisms. A plot of the ratio of relative intensities (% TIC) of intact guat ions to tertiary amine molecular ions (masses 284 and 269 for hexadecyltrimethylammonium chloride) (Fig. 3) shows a threshold behavior with subsequent increase in intact guat desorption up to the 300 °C limit of our ion source.

These results indicate the PB volatilization processes seen here generate species which are directly related to the structure of the original nonvolatile salt and that increasing source temperature improves the likelihood of observing intact quaternary ions. This work was done on an Extrel ELQ 400-1 MS with the Thermabeam PB interface. The LC flow was usually about 0.6 ml/min of 50/50 water/methanol.
Sensitivity and ionization softness are used to gauge the settings for a particle beam LC/MS interface. The sensitivity is a measure of the relative efficiency with which the particle beam delivers the solute into the ionization chamber and the ionization softness a measure of the relative ease of delivery and subsequent ionization. Some of the variables that may influence the solute delivery include the mobile phase composition and flow rate, the choice of nebulizer and its flow pressure, the position of the fused silica tube in the desolvation chamber, the nature of the compounds being analyzed, the addition of volatile salts, the pumping capacity, the size of the skimmer in the momentum separator and the ion source temperature[1]. Normally, the optimization procedure involves adjusting each variable independent until a perceived optimum is reached. As with all optimization schemes this approach is subject to faults optimum. Additional, one may never reach the true optimum using the "one variable at a time" approach if the variables interact. There are several methods for optimizing a process including simplex algorithms and experimental design. A designed experiment is used to understand the process and map the relationships among the variables within an operating space through math models.

In prelude to running the experiments, all of the known variables were considered and evaluated for appropriateness for inclusion in the model. Some of the variables pertaining to the LC analysis method and the interface design characteristics were treated as constants. Under normal circumstances the LC method would be optimized for solute resolution. The organic mobile phase and LC flow rate were considered uncontrolled as far as the mass spectrometer in concern and were held constant during these course of the experiments. Likewise the pumping capacity, the position of the fused silica tube in the desolvation chamber, the skimmer size and the ion source temperature where treated as constants. Consequently, only five variables such as Acetonitrile mobile phase composition, second stage nebulizer flow pressure, nebulizer temperature, desolvation chamber temperature, and the ammonium acetate concentration in the mobile phase were evaluated for their effects on Extrel's ELQ-400-3 QQQ LC/MS system. P-methoxy-1-phenyl acetic acid (M.W. 166) was used as a model compound for this study. Ion source temperature and the LC flow rate were set at 280°C and 0.4 mL/min respectively throughout this work. The first series of experiments were based on a D-optimal design with inclusions to allow the examination of the main effects, interactions, and some of the quadratic terms. There were 74 points included in the model with each data point being an average of 3-5 replicates. The data were analyzed using the computer program RS/Discover running on a VAX 6410.

The results fit the quadratic model better than a simple interaction model. Figure 1 shows a normal probability plot of the residuals when a quadratic model is used. Note that some data points still deviate from the line, suggesting that the relationship between the response sensitivity and all five variables is not purely quadratic. The main effects found are nebulizer flow, nebulizer and desolvation chamber temperatures as shown in Figure 2, where the effects with 95% confidence level are plotted. The effect of salt on the response does not appear to be significant in this model. However, the effect of salt is coupled with desolvation chamber temperature, especially when the temperature is high (Figure 3). Other two-term couplings are found between the mobile phase composition and nebulizer flow, and between nebulizer flow and its temperature (see the low number on the "signif" column in Table 1). The relationship between the ionisation softness, measured by the area ratio of m/z 166 to m/z 121, and these five variables has not been analyzed by an appropriate model yet. The raw data suggests that the softness increase with the response sensitivity (Figure 4).
Supercritical fluid chromatography fills an important role in many industrial laboratories in the characterization of less-volatile, nonpolar mixtures. One goal of our research has been to provide on-line SFC-MS support for other SFC users, most of whom use capillary SFC, unmodified CO$_2$ as the mobile phase, and flame ionization (FID) or ultraviolet detection. We most generally use the direct-fluid-introduction interface in our SFC-MS work. In this interface, the entire capillary-column effluent is introduced directly into the ion-source ionization region. Unfortunately, we, as well as other researchers in the field (1), observe a substantial drop in SFC-MS signal-to-noise ratio (S/N) and an increase in fragmentation above SFC pressures of 300 to 350 atm, at typical capillary-column flow rates. This became a real limitation after the upper pressure limit of many of our SFC systems was increased to 560 atm (2).

We've used simple, liquid-nitrogen-cooled cryopumps to increase the pumping capacity of our triple-quadrupole mass spectrometer. This has made a dramatic improvement in the SFC-MS S/N and the spectral quality at higher SFC pressures. Previously, we presented our preliminary results (3). Since that time, we've continued our investigations of cryopumping and have made significant advances. The optimized cryopump arrangement consists of one cryopump in the ion-source-manifold region and two cryopumps in the analyzer-manifold region. Of the latter pair, one lies over the first quadrupole mass analyzer (Q1), while the second lies over Q3.

Figure 1 shows a plot of analyzer pressure vs. SFC pressure using the optimized cryopump arrangement. At an SFC pressure of 550 atm in the CI mode, the analyzer pressure is approximately 8 x 10^-6 torr with cryopumping (2 x 10^-3 torr before our most recent modifications), while it reaches nearly 7 x 10^-5 torr without cryopumping.

We've used a variety of samples as probes during our investigation of cryopumping. For example, we observed a 10-fold improvement in the abundance of the ammonium adduct ion of the oligomer of poly(ethylene) glycol with an ethoxylate value of 35 over our previous best results.

It has become increasingly clear that cryopumping consistently improves SFC-MS performance above 300 to 350 atm. Cryopumping has enabled us to routinely provide both electron and chemical ionization spectra through the full SFC pressure range. In fact, since we began using cryopumping we have not yet encountered an analyte which can be eluted and detected by capillary SFC-FID which we cannot likewise elute and detect by SFC-MS. The cryopumps are simple to use. They are filled with liquid nitrogen before a series of runs and "topped off" 2 to 3 times during the course of a day. The cryopumps warm during the night and the condensed CO$_2$ is pumped from the cryocooled surfaces. The use of the cryopumps is so straightforward and their benefits so clear that we now use cryopumping on a routine basis for all our SFC-MS work.

It has become increasingly clear that cryopumping consistently improves SFC-MS performance above 300 to 350 atm. The use of the cryopumps is so straightforward and their benefits so clear that we now use cryopumping on a routine basis for all our SFC-MS work.

Figure 2 illustrates our ability to now obtain a peak-to-peak match between the SFC-FID chromatogram and the SFC-MS reconstructed-total-ion-current chromatogram. Figure 2 compares the chromatograms obtained for an
alcohol reaction mixture residue. The first peak is residual octadecanol. The second multiplet consists of fatty-fatty esters and high-molecular-weight alcohols produced by condensation of fatty alcohols. The last multiplet of 6 peaks was not observed during an earlier GC-MS analysis. The methane-CI SFC-MS data revealed these peaks to be esters of the high-molecular-weight condensation alcohols with fatty acids. (Fatty acids were present at low levels in the reaction mixture.) Figure 3 shows the SFC-MS CH₄ CI spectrum of the last peak in the multiplet, corresponding to a 54-carbon ester. The spectrum appears to be a "normal" CH₄ CI spectrum of a fatty-fatty ester, despite the high molecular weight of this species and the presence of a significant quantity of CO₂ in the ion source during ionization. As expected, ions corresponding in mass to the loss of the acid moiety are present.

Unexpected results were obtained during the NH₃ CI SFC-MS run of a series of trimethylsilyl (TMS)-derivatized secondary amines. The apparent masses were 44 Da higher than expected. This suggested that the TMS-derivatized amines were reacting with the SFC mobile phase, CO₂. Such reactions have been observed with primary amines, but we have not observed the reaction of secondary amines with CO₂. We confirmed that the TMS-derivatized secondary amines were reacting with CO₂ by using N₂O as the SFC mobile phase.

Introduction

Combined liquid chromatography mass spectrometry (LC-MS) is now a well established technique for the detection, quantitation and identification of polar organic compounds. A variety of LC-MS interfaces have been developed, which can be applied in various ranges of analyte polarity. However, due to compatibility problems with respect to the mobile phase composition only reversed-phase LC is coupled to mass spectrometry. As a result of the expanding applicability range of MS, which is due to the introduction of powerful liquid-based soft ionization techniques, i.e., FAB, ESP and TSP, the analysis of ionic compounds by LC-MS methods now becomes feasible. However, the LC separation of ionic compounds is performed using ion-exchange, ion-pair or ion chromatography, where mobile phase are used that are generally not compatible to routine LC-MS operation.

In the past years we have been developing techniques, that can overcome the mobile phase compatibility problems. For target compound analysis, the phase-system switching approach was introduced. However, when the LC-MS analysis of mixtures is necessary, a more versatile approach is required. Pseudo-electrochromatography (\(\psi\)EC) has been developed and investigated for its potential in the LC-MS analysis of ionic compounds. Some important features of \(\psi\)EC in comparison with other separation techniques are given in the Table.

Experimental

\(\psi\)EC is performed using packed microcapillary columns (220 \(\mu\)m ID). A schematic diagram of the on-line combination of \(\psi\)EC and CF-FAB MS is given in Figure 1. A conventional reciprocating LC pump in combination with a pre-injector split is used for solvent delivery. The FAB matrix solution is added in the post-column mode by using a liquid-junction coupling. CF-FAB MS is performed on a Finnigan MAT 90 double focussing mass spectrometer.
Results and discussion

The vEC technique has been used in the analysis of nucleotides using CF-FAB MS. A typical example of the effect of applying a potential over the chromatographic column next to the pressure driven flow is given for the separation of AMP, ADP and ATP in Figure 2.

Conclusions

vEC is readily applicable for the analysis of ionic compounds. It avoids the use of non-volatile mobile phase additives, that are normally required in the separation of ionic compounds. Furthermore, it gives the possibility to further tune both the selectivity in chromatography and the chromatographic performance in terms of efficiency. Presently, 10-50 pmol full-scan detection for nucleotides in CF-FAB have been obtained. vEC shows great promise for future application in the LC-MS analysis of ionic compounds.

Future work aims at a more fundamental description of vEC as well as the use of voltage ramping during the chromatographic run. It is expected that continuously changing the potential during the run will give even more powerful ways to control the separation.
A NEW PROBE INSERT FOR A THERMOSPRAY INTERFACE THAT ALLOWS RAPID REPLACEMENT OF CLOGGED PROBES AT NOMINAL COST

TIMOTHY MACMAHON, IBM, HOPEWELL JUNCTION, NEW YORK, 12533.

One of the major problems encountered when operating a thermospray interface is the continual clogging of the approximately 100 micron opening in the vaporizer tip. The reason this tip clogs frequently is because of the nature of the thermospray process. The thermospray vaporization process deposits involatile species at the tip which degrade the performance and eventually clog the tip. There are other mechanisms that, also, lead to clogging. For example, if the solvent or analyte contain particles 100 microns or larger, they can lodge in the probe and clog it. To this end .2 micron filters are installed on the inlet to the probe. In the author's lab, compounds have been run which polymerize at about 200C. Analyzing these compounds can result in replacement of the probe 3 or 4 times in one day due to the polymerization reaction occurring near the tip. Once the probe has become clogged, one can try removing the clog by chemical means, but this author has never had much success with those methods. The design adopted by a number of instrument companies involves replaceable probe tips which can be removed and cleaned or discarded. If replacement of the tip does not solve the problem, then one must replace the entire probe. These probes are generally expensive and, if probes have to be replace a few times a day, the cost becomes prohibitive.

There have also been a number of designs in the literature which claim to solve the clogging problem. One uses laser drilled apertures which can be reused after cleaning. The insert closest to the design described in this paper has a very simple and straight forward probe replacement. The replacement requires the spot welding of the TCI and TC2 thermocouples onto a 1/16 inch piece of capillary tubing which is then inserted through a modified Swagelok fitting into the vacuum chamber.

The two probes that the author designed are similar to each other and are shown in Figures 1 and 2 respectively. With these designs no spot welding is needed when replacing the probe inserts, and the capillary tubing is supported into the probe handle to minimize vacuum leaks. In the first design, a 1/16 inch stainless steel tube with .005 inch I.D. (127 micron) is used to vaporize the sample. In the other design, a .21mm polyimide clad quartz capillary is used. The beauty of this technique is that when a probe clogs the old tubing is simply removed and for the price of two ferrules and a short piece stainless steel capillary tube ($10.00) the probe is repaired.

In the case of the stainless steel capillary, one can either heat the tube directly by placing the electrical connections on the 1/16 inch tubing or indirectly by placing the electrical connection on the guide tube. One might expect there to be a difference between heating directly and indirectly, but no difference could be observed. The quartz capillary could only be heated indirectly due to its lack of conduction.
The performance of the two probes was satisfactory, but the quartz capillary tended to be a little less stable than the stainless steel capillary. This instability was probably due to small vibrations near the tip caused by the evaporation of the solvent. The replacement of the quartz tube was also less convenient because of the very narrow diameter and the need for keeping it clear of obstructions. When compared to the commercially available probes from Kratos, the two probes were very similar even though the thermocouples are not directly mounted on the capillary that transfers the fluid and one might expect very sluggish responses to changes in temperature which would lead to less ion signal. In fact, the total ion currents with the new probes are as high if not higher than those obtained with the commercial probes.

4. These probes were built by Scientific Instrument Services, Ringoes N. J.
5. Quartz capillaries are available with ID from 25-100 micron.

VUV PHOTOIONIZATION MASS SPECTROMETRY: RAPID SCREENING FOR DRUGS OF ABUSE IN URINE

Jeffrey W. Finch* and M. Bonner Denton
Department of Chemistry, University of Arizona, Tucson, AZ, 85721
*Department of Pharmacology, Medical University of South Carolina, Charleston, SC, 29425

Introduction: A molecular hydrogen laser coupled to a time-of-flight mass spectrometer has demonstrated the ability to detect drugs of abuse in urine with minimal sample pretreatment. The laser output consists of 7.8 eV photons over a series of lines in the vacuum ultraviolet, which produces only parent molecular ions for many drugs and pharmaceuticals. In addition, due to the selectivity of 7.8 eV photoionization, drugs of abuse can be rapidly screened in urine samples by using a simple solid-phase extraction technique for sample clean-up, followed by direct MS analysis of the resulting extract. Photoionization mass spectra of extracts from pooled urine samples spiked with cocaine, codeine, morphine, phencyclidine, and methadone consist of parent molecular ions for the drugs with a few non-interfering ion signals from the matrix.

Experimental: The molecular hydrogen laser source, described previously (1,2) is a Blumlein discharge apparatus with a narrow discharge channel (330 μm) and a low-inductance spark gap switch purged with nitrogen. Voltage on the bottom Blumlein plate was 20 kV and a hydrogen pressure of 45 torr was maintained in the discharge channel. The laser was operated at a duty cycle of 10 Hz and has an average peak pulse energy of 30 μJ. For mass analysis, a linear time-of-flight mass spectrometer (3) was used, consisting of a 1.5 m drift tube with a Galileo Electro-Optics Z-stack microchannel plate detector (10^8 gain) mounted at the end. A LeCroy 9400A digital oscilloscope was used to store mass spectra averaged over 200 laser pulses and the data was then transferred to an IBM compatible 286 computer for analysis.

Urine samples were pooled from five healthy male graduate student volunteers. 5 ml samples were spiked with μl aliquots of 1 mg/ml drug solutions in methanol. Blank and spiked urine samples were then immediately extracted with Bond Elut Certify (Analytichem International) columns using the manufacturer's suggested procedure (4) for a particular drug class, however, no derivatization steps were applied. Effluent collected from the columns was evaporated to a residue and transferred to sample vials which were then placed in a direct insertion probe for mass analysis.

Results and Discussion: The photoionization mass spectrum of an extract from a urine sample spiked with 20 ppm cocaine is shown in Figure 1. A clear parent molecular ion at mass 303 is observed as well as a fragment ion at mass 182, due to the loss of benzoate. Cocaine was the only abused drug which yielded a fragment ion in the photoionization mass spectrum. For urine samples spiked with cocaine as low as 500 ppb, clear ion signals were recorded above the level of background. Figures 2 and 3 show photoionization mass spectra from extracts of urine samples spiked at 200 ppb with methadone (mass 309) and phencyclidine (mass 243), respectively. In each case, an intense parent molecular ion is observed with some peaks from the matrix which do not interfere with the M^+ signals. Similar results were observed for urine samples spiked at the 200 ppb level with opiates morphine and codeine.

The hydrogen laser/TOF system in its current configuration is capable of drug screening in urine at levels well below cut-off values listed for the technique of enzyme multiplied immunoassay (EMIT). In addition, the technique should be less subject to chemical interferences which produce false test results in EMIT. While background ion signals from the urine matrix are observed in mass spectra for extracts of blank and spiked samples, it is known that electron impact features give rise to background signals in spectra recorded without any sample in the source. These features, such as the low mass signals observed for residual air, are due to electrons which are generated from
interaction of the laser radiation with metal surfaces in the ion source. Currently, the laser radiation is directed into the ion source through a purge tube with two CaF$_2$ windows. Better focusing of the laser radiation into the ion source should significantly reduce the observed background from the urine matrix and improve sensitivity.

Reduction of alkyl halides to the trichloromethyl radical by liver microsomal P-450 is the initial event leading to hepatotoxicity. The reductive metabolism of BrCCI₃ by ferrous hemoglobin was used as a model system. This reaction leads to the alteration of the prosthetic heme to form products that can be dissociated from the apoprotein and others that are irreversibly bound to the apoprotein. Proteolysis of the irreversibly bound adduct with elastase overnight at 37°C gave two heme-peptides (HP1 and HP2) that were isolated by reverse phase HPLC, using a C₁₈ Vydac column. These were characterized by Edman sequencing giving the following amino acid residues C-D-K-L-H (residues 93-97 of the hemoglobin β-chain), positive ion plasma desorption mass spectrometry (PDMS) (figure 1, HP1) and fast atom bombardment. The spectra of the elastase digest fractions containing those modified heme-peptides show for:

An extended elastase digest, 72 hours at 37°C, when checked by PDMS gave for HP1 a peak at m/z 1097.8 (figure 2), while HP2 gave a peak at m/z 1061.5. Both heme peptides were digested with aminopeptidase. Aliquots of the digests were screened by PDMS and HPLC every 24 hours. Completion of the reaction varies between 72 to 120 hours. The results of the aminopeptidase digest of HP1 shows a peak at m/z 855.2 which corresponds to the attachment of the modified heme containing three chlorines to cysteine.

734.9 + 1210 = 855.9

The results of the aminopeptidase digest of HP2 shows a peak at m/z 818.8 which corresponds to the attachment of the modified heme containing two chlorines to cysteine.

698.4 + 121.0 = 819.4

The results would appear to firmly establish the attachment of the prosthetic heme group to cysteine 93 of the hemoglobin β-chain (figure 3).
Identification of an N-7 conjugate of hepsulfam

Robert T. Streeper, O. Michael Colvin, Robert J. Cotter
Department of Pharmacology and Molecular Sciences,
The Johns Hopkins University School of Medicine
Baltimore, Maryland 21205

Hepsulfam (NSC 329660) is a bifunctional DNA alkylating agent presently in phase I clinical trials as a treatment for chronic myelogenous leukemia. Hepsulfam is active against CML in patients who have undergone blast crisis and resistant to the standard therapy using busulfan (1). Hepsulfam has a much broader spectrum of antineoplastic than busulfan (1). Hepsulfam has been shown to produce crosslinks in DNA (2) but the nature of these crosslinks is not known.

We have shown that hepsulfam reacts with the N-7 nitrogen of guanosine using a combination of mass spectrometry, reversed phase HPLC and ultraviolet spectrophotometry. We have also determined a DNA sequence motif sufficient for crosslinking of a small oligodeoxyribonucleotide.

The N-7 nitrogen of guanosine has been shown to be the target for many of the antineoplastic DNA alkylating agents currently used. Busulfan, the structural analog of hepsulfam, has been shown to produce interstrand crosslinks DNA by successive alkylation of the N-7 nitrogen atoms of guanylic acid residues (3). To determine if hepsulfam reacted analogously we studied the reaction of hepsulfam with guanosine in DMSO solution at 45 °C. A Kratos (Manchester, UK) Concept 1 H mass spectrometer was used to analyze the reaction mixture. Figure 1 shows the mass spectrum of this reaction mixture after three days incubation. The signals at 345, 477, 574, 760, and 857 amu correspond respectively to 7-(n-sulfamoylheptyl)guanine, 7-(n-sulfamoylheptyl)guanosine (Figure 2), 7-(n-sulfamoylheptyl)guanosine + sulfamic acid anion + proton, 1,7-Di(7-guanosinyl) heptane + sulfamic acid anion (Figure 3), 1,7-Di(7-guanyl) heptane + two sulfamic acid anions + proton. No signal was observed for the doubly charged 1,7-Di(7-guanosinyl) heptane (332 amu) or for 1,7-Di(7-guanyl) heptane + proton (399 amu).

To determine the position on the guanosine that is alkylated by hepsulfam we separated the reaction mixture by reversed phase HPLC. A large peak eluting at 22 minutes was the first to appear over the course of the reaction and thus was thought to be the adduct of hepsulfam to one guanosine. The peak was collected and concentrated and analyzed by UV spectrophotometry. Tong and Ludlam (3) have shown that the UV spectrum of N-7 alkylated guanosine undergoes an irreversible change at high pH corresponding to the opening of the alkylated ring where guanosine does not. To determine if the isolated HPLC fraction contains N-7 alkylated guanosine we observed changes in the UV spectra of guanosine, N-7 methyl guanosine, and the 22 minute HPLC peak isolated from the reaction mixture. Comparison of the pH dependence of the UV absorption spectra of N-7 methyl guanosine to that of the isolated HPLC fraction shows that the absorption band sharpens and shifts to a shorter wavelength, and that when the solutions are brought back to neutrality, the absorption does not return to the starting profile but remains relatively sharp. Examination of the shifts shown by guanosine show that the solution regains the original absorption profile after being taken to high pH. Thus we conclude that the 22 minute peak is indeed N-7 alkylated guanosine. Figure 4 shows the product of the base induced ring opening of N-7 hepsulfamoyl guanosine.

To determine the sequence DNA that hepsulfam crosslinks we synthesized two palindromic hexanucleotides, one with guanylic acid residues directly adjacent (5'-ATGCAT #5651) and one with guanylic acid residues separated by both adenylic and thymidylic acid residues (5'-GACGTC #5652). The oligonucleotides were reacted with hepsulfam and analyzed by RP-HPLC. The reaction mixtures were briefly heated to 60 C to denature the paired strands and an aliquot was immediately analyzed by RP-HPLC. When #5652 was analyzed without heating, a peak at 22 minutes indicative of the dimer and a peak at 29 minutes for the monomer were observed. When the starting material was analyzed after heating a single peak at 29 minutes was observed indicating nearly complete conversion to the monomer. In the solution containing both the oligonucleotide and hepsulfam 3 days of incubation peaks at both 22 and 29 minutes were observed after the solutions were denatured by heating. Thus we conclude that the undenaturable peak at 22 minutes observed in the drug treated solution is a crosslinked dimer. Oligonucleotide 5651 with adjacent guanylic acid residues showed no evidence of reaction.
DEVELOPMENT OF NEW METHODS FOR RAPID ANALYSIS OF DRUGS IN BIOLOGICAL MATRICES

Michelle V. Buchanan, Marcus B. Wise, Robert L. Hettich, John Caton and Gregory B. Hurst
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

The determination of trace levels of drugs or other compounds in tissue and other physiological media requires analytical methods which are highly sensitive and yield confident compound identification. The goal of this work is to develop new approaches for the analysis of drugs and other organics in physiological samples which would be rapid, accurate and require a minimum quantity of sample. With respect to sample quantities, in the case of tissue samples, for example, it would be more desirable to sample a few milligrams of tissue obtained by needle puncture than harvest grams of tissue.

Previous work in our laboratory has demonstrated the ability to analyze picogram levels of drugs in one microliter aliquots of untreated urine in about three minutes total analysis time using thermal desorption directly into an ion trap mass spectrometer (ITMS). In a project for the Food and Drug Administration, we are attempting to extend this approach to other physiological media, such as milk and tissue. In this project, two anthelmintics, phenothiazine and piperazine, are being examined. Experimentally, the sample is thermally desorbed from a quartz wool bed directly into the ITMS with no chromatographic separation. The compounds are ionized using isobutane chemical ionization (CI), which selectively protonates these nitrogen-containing compounds to form (M+H)⁺ ions, greatly decreasing interferences from less basic compounds in the sample matrix. The (M+H)⁺ ions are isolated and collisionally dissociated to form characteristic fragment ions which confirm the presence of the targeted species. Initial studies with standards of phenothiazine, which yields a (M+H)⁺ ion with m/z 200 and is then dissociated to form ions with m/z 199 and 167, have suggested that detection limits of at least 50 parts per billion (50 pg in a 1 pL sample) are attainable. Piperazine, which yields a ((M+H)⁺ ion with m/z 87 with CAD ions with m/z 70 and 44, has yielded detection limits below 100 ppb in these initial experiments.

To assess whether samples could be analyzed with no sample preparation, milk and tissue homogenate were spiked with the drugs and analyzed directly by thermal desorption ITMS. Figure 1 shows the desorption profile for a 1 μL injection of a 5 μg/mL solution of piperazine in milk. Figure 2 shows a corresponding desorption profile for a 1 μL injection of a 500 ng/mL (500 ppb) solution of phenothiazine in milk. A study using beef tissue homogenate was also conducted with phenothiazine. An example of the resulting desorption profiles is shown in Figure 3, where 1 μL of tissue homogenate spiked with 10 ng/g of phenothiazine was examined. In these studies, no major interferences from the matrix were observed.

The required ppb (ng/g) detection limits for these drugs will require further development. In these initial studies, only one microliter aliquots of the solutions were used and larger aliquots could be injected to improve the detection limits. Also, a split open/split interface is used on the ITMS transfer line which allows only a few percent of the effluent to enter the ITMS. Adjusting this ratio might also improve the achievable detection limit.

In cases where sample preparation will be required for concentration of the targeted compounds to reach the specified detection limits or elimination of matrix interferences, methods based on countercurrent dialysis are being developed. Dialysis capillaries are used to separate the higher molecular weight materials in the samples, such as cell debris, proteinaceous material and lipids, from the smaller molecular weight compounds, which are deposited on a sorbent trap for subsequent thermal desorption. Initial experiments with this approach have shown that good isolation can be achieved in a few minutes with small quantities of samples.

In conclusion, these initial studies have shown that thermal desorption ITMS has great potential for the rapid determination of targeted drugs in milk and meat. Additional work is being conducted to extend the ultimate detection limits to the low ppb levels using small quantities of samples, including modifications in the thermal desorption device and transfer line into the ITMS, as well as development of rapid countercurrent dialysis methods to concentrate the drugs on a sorbent bed for subsequent analysis.

RAPID SCREENING TECHNIQUES FOR TAXOL AND OTHER TAXANES USING DCI-MS/MS.

Department of Chemistry, Purdue University

Department of Medicinal Chemistry and Pharmacognosy
Purdue University, W. Lafayette, Indiana 47907 USA

Taxol, a novel diterpene originally isolated from the bark of the western yew, Taxus brevifolia, is a potent antileukemic agent. It shows excellent activity in screens against many types of cancer, and has a unique mechanism of action as the only plant product known to induce assembly of tubulin into microtubules. These extremely promising characteristics of taxol as an effective anticancer drug are offset by the difficulty of synthesizing taxol and its natural shortage (30 pounds of bark to isolate 1 gram), which makes it critical to develop highly sensitive screening techniques to identify taxol in crude extracts. Alternative sources of taxol and related taxanes should also be screened. We use positive and negative desorption chemical ionization tandem mass spectrometry (DCI-MS/MS) to identify and approximately quantitate taxol in plant material, especially plant extracts, so as to direct isolation efforts towards the most appropriate samples. Tandem mass spectrometry combines separation power with capabilities for compound identification; this allows targeted compounds to be recognized in complex mixtures.

Mass spectrometric experiments were performed using a Finnigan TSQ-700 triple-stage quadrupole mass spectrometer. Samples were dissolved in either methanol or ethanol and ca. 1 µl aliquots were introduced on the rhenium wire DEP tip. The probe was then inserted into the chemical ionization source (ammonia, 0.5 torr) and rapidly heated (0-600°C at 100°C/s). Collision activated dissociation product-ion, parent and neutral loss spectra were acquired by leaking argon into the second quadrupole collision region (1.8 mtorr) and accelerating the ions to 20-40 eV (lab).

Taxol shows both an (M+H)+ ion, m/z 854, and an (M+NH4)+ ion, m/z 871, under positive ammonia desorption ionization conditions. The compound fragments in a structurally characteristic fashion (Fig. 1a) and the MS/MS product-ion spectrum of the (M+H)+ ion is also structurally diagnostic (Fig. 1b). When 10 micrograms of Taxus baccata bark extract was examined by DCI, it gave the featureless mass spectrum shown in Fig 1c. By contrast, the same amount of sample gave the MS/MS product-ion spectrum shown in Fig 1d.

Searches for taxol analogs which contain the biologically active side chain are made using selected parent and neutral loss scans. For example, analogs with modifications in the ester side chain were sought using negative chemical ionization and parent spectra of m/z 526, the ion corresponding to loss of the side chain in taxol, m/z 853. Candidate ions are then characterized by their conventional MS/MS spectra. Figure 2 displays a negative ion parent spectrum of m/z 525 acquired from the crude extract of T. baccata which shows several analogs of taxol are present. MS/MS product-ion spectra have identified m/z 831 as cephalomannine. In addition to searching for analogs with modifications in the ester side chain, analogs which contain the intact side chain are present. In this experiment (positive DCI), a constant neutral loss of 285 was chosen in order to seek analogs which have the intact C-13 side chain but differ elsewhere in the molecule. This spectrum of the same crude extract is reproduced as Fig 3. In addition to protonated taxol at m/z 854 and its NH4 adduct, at m/z 871, signals are seen at m/z 836, potentially a dehydrated analog, m/z 882, potentially an ethylated analog, and m/z 896, potentially the acetylated taxol and m/z 802, an unassigned taxane.

Using this methodology taxol has been identified and quantitated using standard addition in plant cell tissue cultures at the ppm level and taxol and several analogs have been identified in crude extracts from T. baccata and T. brevifolia bark. These studies demonstrate the benefits of the speed and low detection limits of tandem mass spectrometry and its applicability to complex mixtures.

Class Characteristic Fragmentation of Glutathiones Under
High Energy Collisionally Induced Decomposition
*Constance M. Murphy and Catherine C. Fenselau,
Department of Chemistry and Biochemistry,
University of Maryland Baltimore County, Baltimore, MD 21228

Both the enzymatically catalyzed and the chemical reactions of glutathione are important parts of the defense system of every cell against xenobiotic insult. Such conjugation often inactivates xenobiotic agents, and also causes significant changes in the activities of endogenous substrates.

Mass spectral analysis of this important and widely encountered family of metabolites was not satisfactorily achieved before the advent of desorption techniques. In cation spectra, abundant protonated and/or natriated molecular ions are usually observed, along with class characteristic ions of 306 or 308, comprising glutathione. Other fragmentation is usually minimal.

Recently various kinds of tandem mass spectrometry have been evaluated for the dual purpose of working with incompletely purified metabolites and of inducing fragmentation by collisional activation. Indeed, under collision activation more fragmentation is observed. Because of the strategic value of class characteristic ions, most investigators have proposed candidates, sometimes on the basis of a single glutathione sample. Thus Straub proposed the loss of 275 amu as class characteristic decomposition under his 29 volt collision; Pearson et al. proposed the loss of 129 under 0-100 ev collisions; Heeremans et al. recommended the loss of 146 amu under 45 ev collisions; Haroldson et al., analyzing low energy collisions of seven different conjugates, observed all three of these losses, however none in all seven spectra. Although the latter group favored 129 for constant neutral loss strategies, their report indicates that \([M+H]^+ - 232\) ions were observed in the daughter ion scans of all seven samples.

At least three papers in the literature report high energy collisionally induced decomposition of protonated molecular ions from glutathione conjugates on multisector instruments. Lay et al. reports the elimination of neutral molecules weighing 275 and 129 on a triple sector EBE instrument. In a study by Stock et al. using a four sector instrument of BEEB configuration, losses of 129 and 175 are observed, however the spectra were not recorded in low enough range to see loss of 275. Nelson et al have reported the losses of 75, 130 and 274 amu neutrals in two sector linked scans of a molecular ion radical formed by field desorption.

All mass spectrometric measurements in this study were obtained using a JEOL (Tokyo, Japan) HX110/HX110, four sector mass spectrometer with geometry of EEBE. The FAB gun was operated at 6 kV and the FAB gas was xenon. Tandem measurements were obtained by utilizing all four sectors (EBEB) on the instrument. In these experiments, helium was used as a collision gas at pressures sufficient to attenuate the precursor ion by 80%. The accelerating voltage was 10 kV, and the collision cell was floated at 4 kV. Resolution in both MS-1 and MS-2 was 1000. For both scanning modes, the compounds were dissolved in methanol (Fisher Scientific Co., Fairlawn, NJ) and the matrix was either thiglycerol (Sigma Chemical Co., St. Louis, MO) or 3-nitrobenzyl alcohol (Aldrich Chemical Co., Milwaukee, WI).

Fifteen glutathione conjugates were analyzed, including both mono and di-conjugates. The glutathione conjugates encompassed a wide range of compounds. All of the conjugates showed fragmentation resulting from the cleavage of the sulfur bond with the charge being retained either on the "R" group or the glutathione moiety. In addition to sulfur cleavages the vast majority of the conjugates showed fragmentation.
resultant from cleavages within the tripeptide. Cleavages at the γ-glutamyl carbonyl and at the amide bond of glycine were prevalent. The monoconjugate of dimethylbilirubin fragmented in a slightly different manner. Due to the fragility of the methylene bridge, the fragmentation was dominated by "R" group fragmentation. Furthermore, due to the basicity of the "R" group the charge was preferentially retained on the "R" group. None the less, this glutathione conjugate still exhibited class characteristic sulfur bond cleavage fragmentation.

Partial Characterization of Urinary Metabolites of U-78,875 in Monkey Urine by Tandem Mass Spectrometry

J.J. Vrbanac¹, P.E. Sanders, P.G. Pearson, R.W. Steenwyk, L. Baczyński² and I.A. O'Leary
Drug Metabolism Research and Physical and Analytical Chemistry¹, The Upjohn Company, Kalamazoo, Michigan 49001

Drug metabolite identification in humans and animals is of importance from both a scientific and product development perspective. The determination of drug metabolite structures has traditionally occurred after a compound has been selected for extensive preclinical toxicological evaluation since drug metabolism studies are expensive, relatively time consuming and, to be comprehensive, require the synthesis of a radioisotope labeled drug. It has been suggested that it is possible to characterize or partially characterize many drug metabolite structures relatively rapidly using "MS-MS" screening techniques and tandem quadrupole mass spectrometry. Here we report the rapid identification of metabolites of a novel anxiolytic drug candidate by tandem mass spectrometry.

U-78,875 (3-(5-cyclopropyl-1,2,4-oxadiazol-3-yl)-5-(1-methylbutyl)-imidazo[1,5-a]quinoxalin-4(5H)-one) is under development as a non-benzodiazepine anxiolytic and is presently in Phase I clinical evaluation. The purpose of the present study was to identify metabolites of U-78,875 present in monkey urine by LSIMS ionization and tandem quadrupole mass spectrometry. This was to be accomplished by obtaining high resolution electron ionization data for U-78,875, CAD spectra of U-78,875 and structural analogues and by the judicious use of parent and/or neutral loss scans suggested by these data.

Methods: ODS extracted urine was dissolved in water and chromatographed on ODS using gradient elution reversed phase HPLC. Fractions were collected every 5% change in solvent composition. High resolution El mass spectral data were recorded using a VG ZAB-2F high resolution mass spectrometer and direct probe electron ionization. Low resolution collisionally activated dissociation (CAD) mass spectra were obtained using a Finnigan MAT TSQ-70 tandem quadrupole mass spectrometer. Particle beam data were obtained using an Extrel designed interface and a Finnigan 4500.

Results: High resolution El analysis of U-78,875 and low-resolution CAD analysis of U-78,875 and structural analogues indicated that the only useful scan function for "screening" for metabolites using tandem mass spectrometry were parents of m/z 69 (cyclopropylcarbonyl derived from the substituted oxadiazole ring, Figure 1. Neutral loss of 68 daltons from MH⁺ was also observed but found to be far less sensitive in detecting metabolites). Several parent ions of m/z 69 were observed in drug related samples that were not observed in the control samples. Positive daughter ion mass spectral data obtained for parent ions m/z 336, 295, 352, 310, 433, 390, and 528 indicated the presence of U-78,875 and N-deisopropyl U-78,875 and partially characterized aryl hydroxyl, aryl hydroxyl-N-dealkyl, aryl glucuronide, aryl glucuronide-N-dealkyl, aryl O-sulfate and aryl O-sulfate-N-dealkyl metabolites. From these data it was concluded that metabolic pathways involved in the biotransformation of U-78,875 include N-dealkylation, aryl hydroxylation and subsequent sulfation or glucuronidation of hydroxy metabolites. Balance data was not obtained by this method. These data clearly demonstrated both the 1) utility and the 2) limitations of tandem quadrupole mass spectrometry in characterizing important metabolic transformations of a drug prior to the synthesis of radioisotope labeled drug, in that 1) rapid metabolism information was obtained, however, 2) a number of metabolites (characterized at a later date using radioisotopes) were not detected using this methodology.
In a related study, metabolites of U-78875 were detected and characterized by particle beam LC-MS. This technique was able to characterize U-78875, N-dealkyl metabolites, hydroxy metabolites, and the highly polar glucuronide conjugates. These and other data strongly suggested that the design of PB-MS used in these studies has utility in the structural characterization of highly polar drug metabolites, especially if a heated target is used.

Figure 2: Observed metabolic transformations of U-78875 in the rat.

Characterization of Stereoselective Benzylic Glucuronidation of the Antipsychotic Agent BMY-14802 Using Mass Spectrometry

*Ian A. Blair, Amin Kamel, 1Lewis J. Klunk, 1Umesh Shukla and 1Robert F. Mayol
Department of Pharmacology, Vanderbilt University, Nashville, TN 37222 &
1Pharmaceutical Research and Development, Bristol-Myers Squibb, Wallingford, CT 06492

Introduction
BMY-14802 (±)-(±)-1-(4-(4-fluorophenyl)-4-hydroxy-1-butyl)-4-(5-fluoro-2-pyrimidinyl) piperazine hydrochloride is currently undergoing evaluation as a new antipsychotic agent. In vitro studies using rat liver microsomes have established two potential routes of metabolism: cytochrome P-450-mediated N-dealkylation and oxidation, thought to be mediated by alcohol dehydrogenase. N-dealkylation was a major route of metabolism seen previously with structurally related drugs buspirone and tiospironem vivo (1) and in vitro (2). The present study was initiated in order to determine whether these two routes of metabolism could be observed in human subjects. The presence of a free hydroxyl group in the molecule suggested that conjugation could also occur. Urine from patients dosed with BMY-14802 was analyzed by HPLC before and after hydrolysis with β-glucuronidase/sulfatase derived from helix pomatia. This enzyme was previously demonstrated to efficiently hydrolyze urinary conjugates of buspirone (1).

Results and Discussion
Urine from a subject who had been dosed with 400 mg of BMY-14802 was extracted using a C18 solid-phase extraction column. The extract was analyzed by a reversed-phase HPLC system on a C18 column using methanol/0.1 M aqueous ammonium acetate/ triethylamine gradient. A small amount of BMY-14802 was observed (retention time 36 min). There was a large peak at a retention time of 26 min which appeared to consist of two components. This peak did not correspond in retention time to any of the known analogs or metabolites of BMY-14802. The urine was hydrolyzed with helix pomatia β-glucuronidase/arylsulfatase and the products were isolated using a C18 extraction column. In the 2-4 hr post-dose urine it was evident that hydrolysis had reduced the amount of the polar metabolite observed previously and that it now appeared to consist of a single component. There was a concomitant sizeable increase in a peak with a retention time corresponding to authentic BMY-14802. If the peak remaining with a retention time of 26 min was also conjugate, it was not clear why the de-conjugation had failed to go to completion.

BMY-14802 had been administered to the human subjects as a racemic mixture. This raised the possibility that the polar conjugates were glucuronide diastereomers and that one of them was a poor substrate for the helix pomatia β-glucuronidase. If both polar metabolites were indeed glucuronides, it was reasoned that it should be possible to methylate the carboxylic acids on the sugar moiety. To test this hypothesis, the urinary metabolites were dissolved in aqueous methanol and treated with ethereal diazomethane. HPLC analysis showed that diazomethane treatment increased their retention times from 26 mins to 33 mins. This confirmed that the conjugates contained free carboxyl groups. Interestingly, the HPLC characteristics of the methyl ester derivatives improved considerably when compared with the free acids so that they could be readily separated into components A and B using an isocratic system. The urine was hydrolyzed with β-glucuronidase, extracted and treated with diazomethane. HPLC analysis revealed that peak A was lost on hydrolysis and that peak B was unaffected. The two methylated derivatives A and B were isolated from the urine, purified by preparative HPLC and analyzed by DCI/MS (Figure). A protonated molecular ion appeared at m/z 421 in both methylated metabolites and significant fragment ions were observed at m/z 519 (MH - F), 347 (MH - glucuronide) and 331 (MH - O-glucuronide). Saponification of the individual methylated glucuronides and analysis by FAB/MS provided confirmation of the metabolite structures as BMY-14802 glucuronide diastereomers. The configuration of the diastereomers was assigned from biosynthetic studies with individual BMY-14802 enantiomers and UDPGA-fortified human liver microsomes. (+)-BMY-14802-glucuronide methyl ester
corresponded to compound A and (-)-BMY-14802-glucuronide methyl ester corresponded to compound B. (-)-BMY-14802 was a better substrate for human glucuronosyl transferase than (+)-BMY-14802. This was due to a lower apparent \( K_m \). Interestingly, there was an even greater difference in the apparent \( K_m \)s for the (-) and (+)-enantiomers with bovine liver glucuronosyl transferase. Paradoxically, (-)-BMY-14802-glucuronide was a very poor substrate for \( \beta \)-glucuronidases whereas (+)-BMY-14802-glucuronide was a very good substrate. This provides evidence to suggest that caution should be exercised when quantitative estimates of metabolite excretion are obtained after de-conjugation of human urine with \( \beta \)-glucuronidases. SENSITIVE AND SPECIFIC ANALYSIS OF HEXOBARBITAL ENANTIOMERS AND THEIR METABOLITES BY GC/ELECTRON CAPTURE NICI MS

Department of Pharmacology, Vanderbilt University, Nashville, Tennessee 37232

Hexobarbital (HB), a sedative/hypnotic and anesthetic drug, is used as a model substrate for the assessment of changes in the oxidative activity of hepatic CYP in human subjects and in animals (1). It is metabolized by alicyclic oxidation to 3'-hydroxyhexobarbital (3'-OH-HB), which is then oxidized to the 3'-keto metabolite (3'-keto-HB). On the other hand, epoxidation of the 1',2'-olefinic bond ultimately produces 1,5-dimethylbarbituric acid (1,5-DMB), and there are additional minor routes of metabolism, including N-demethylation. HB is a chiral drug and its metabolism is polymorphic, cosegregating with the stereoselective polymorphic oxidation of mephenytoin. This raised the possibility that there may be subtle difference in the stereoselective metabolism of HB by PMs, IMs, and EMs of mephenytoin. In order to investigate this possibility, an assay was required that could simultaneously monitor the individual HB enantiomers together with their metabolites. We have developed a highly sensitive and specific assay, based on gas chromatography/electron capture negative ion chemical ionization mass spectrometry (GC/NICI MS), for the analysis of HB enantiomers and their metabolites in plasma and urine as pentafluorobenzyl (PFB) derivatives. The PFB derivatives of HB enantiomers and their metabolites had excellent GC properties except for 3-OH-HB-PFB which gave a rather broad peak, however, conversion to the TMS derivative markedly improved its GC characteristics. All of the derivatives were readily separated by capillary GC (Fig. 1). Intense NICI spectra were observed for the HB derivatives. One major ion corresponding to [M-PFB]$^-$ was observed for each derivative except for 1,5-DMB where M$^+$ was observed. S-(+)-[5-2H3]-HB and R-(−)-[5-2H3]-HB were synthesized for clinical studies along with (±)-[1,5,5-2H3]-hexobarbital. Deterated analogs of the major metabolites were also synthesized for use as internal and reference standards. NICI spectra of S-(+)-[4-2H6]-HB-PFB, R-(−)-[4-2H6]-HB-PFB and [4-2H6]-HB-PFB showed intense ions at m/z 235, m/z 238 and m/z 241 respectively (Fig. 2).

The availability of all the relevant deuterated standards and a highly sensitive and specific method of detection allowed the quantification of HB enantiomers and their major metabolites in biological fluids to be carried out after administration of a small oral dose of HB. Four internal standards were employed in the assay: [4-2H6]-HB was used as a standard for HB and N-desmethyl-HB, [4-2H6]-3'-keto-HB for 3'-keto-HB, [6-2H6]-3'-OH-HB for 3-OH-HB and [6-2H6]-1,5-DMB for 1,5-DMB. The lowest detection limits were 50 ng/ml for 3-OH-HB and 1.0 ng/ml for the other compounds (signal to noise ratio, 5:1). Standard curves were linear between 1.0 ng/ml and 10 μg/ml; linearity beyond these limits was not tested because they were considered out of range for likely clinical doses. Recovery of HB and metabolites ranged from 25-65 % and intra- and inter-day variability was in the range 7.7 % to 17.6 %. The assay was applied to the analysis of HB and metabolites in the plasma and urine of a subject given a 100 mg oral dose of pseudoracemic HB containing equal amounts of S-(+)-[4-2H6]-HB and R-(−)-[4-2H6]-HB. This preliminary investigation confirmed the stereoselective disposition of HB in humans as reported previously. The two enantiomers demonstrated very rapid absorption which was completed within the first half hour after administration. (-)-HB was eliminated much more rapidly from the plasma than (+)-HB resulting in higher plasma concentrations of (+)-HB over time. This difference in elimination also resulted in significantly higher plasma concentrations of the 3'-keto and DMB metabolites from the (-)-enantiomer. Only low plasma levels of the N-desmethyl metabolite were detected while the 3'-OH metabolite was present only in trace to unmeasurable amounts from both enantiomers. Pharmacokinetic parameters from these data revealed that R-(−)-HB had a tenfold greater oral clearance than S-(+)-HB (147.5 versus 16.8 L/hr) and a threefold shorter terminal half life (0.93 versus 3.11 hr). Urinary excretion data showed 1,5-DMB as the major urinary metabolite of both enantiomers. More of the (-)-HB was excreted as the 3'-OH, 3'-keto and DMB metabolites than (+)-HB, while the reverse was the case for unchanged drug and N-desmethyl-HB.

Secondary ion mass spectrometry offers the possibility of determining the spatial distribution of selected compounds in biological tissue. We have developed an ion microprobe to perform this type of analysis. The instrument consists of a focused Cs* ion gun, sample stage, secondary ion source, quadrupole mass analyzer and detector with a 80286-based computer system to control the components, collect data, and display image data in real time. Distributions are determined by rastering the Cs* beam across the target, while monitoring the intensity of selected ion(s) at each raster position. Distributions are displayed as color images (using a modified thermal scale) and cartesian plots of intensity vs. position in either X or Y coordinates.

In this paper, we report on the characteristics of the instrument using samples that can be readily identified by other methods. Historically, grids of one form or another have been used to establish image fidelity and spatial resolution of different microprobes. Figure 1 is the secondary ion image observed from a hexagonal grid with 75 micron wire diameter and 2 mm spacing between parallel wires. From this image, it is apparent that the spatial resolution of the instrument is about 75 microns. Specifically, the apparent ratio of spacing-to-wire diameter (16.7), to the known ratio (26.7), indicates that the wire appears to be approximately twice its actual width. The hexagonal shape of the grid attests to the fidelity of the image system. The cartesian plot at the bottom of Figure 1 is a quantitative display of the ion intensity along the horizontal cursor line. Note that the color micrograph of Figure 1 suffers in the translation to grey shades in reproduction. This is evident from the cartesian plot in the lower portion of Figure 1.

Figure 2 shows the m/z 170 image taken from a mushroom that had been doped with an ethanol solution of methylphenylpyridinium (MPP*) iodide; in the image, black represents the highest intensity and shades of gray are used to represent relative intensity. When a drop of the ethanolic solution was deposited onto the mushroom slice, most of the solution ran to the sides of the sample stage, where the solution was subsequently absorbed by the mushroom. Consistent with this, the intensity of m/z 170 is greatest at the sample periphery. The dark right angle near the top of the image shows the effects of the knife that was used to slice and quarter the mushroom. The field of view of the microprobe is about 1.5 centimeters, which is approximately the size of the sample shown in Figure 2. Most ion microprobes have fields of view and maximum image size of 0.5 mm. or less, consistent with the transmission requirements of quadrupole and sector mass analyzer. For the microprobe described here, the secondary ion optics are rastered with the primary ion beam to permit a much larger field of view. To prove this point, a special, moveable electron impact ion source was built to mimick secondary ion emission. With the Cs* gun off, the secondary ion optics were rastered across the exit of the electron impact source. The image of acetone molecular ions emitted from the source is shown in Figure 3. The profile of the beam clearly shows a resolution element of approximately 100 microns. This resolution element reflects the field of view of the secondary ion source/quadrupole assembly at any particular spot on the sample. Were the field of view larger, the cartesian plot in the lower portion of Figure 3 would show a broader peak.

Improved Sensitivity for FAB-MS on Magnetic Sector Instruments Using Pulsed Bombardment and Array Detection

J. Tamura, M. H. Frey, and R. B. Cody
JEOL USA, Inc., 11 Dearborn Road, Peabody, MA

It has long been recognized that the ionization events immediately following the initiation of pulsed bombardment may be quite different from subsequent events. This observation may be noted by using a number of instrumental designs and configurations. With regard to our studies a particularly important observation is that for certain preparations, the intensity ratio of sample to matrix ions is significantly enhanced in the initial stages of bombardment. We have used an array detector fitted to a double-focusing mass spectrometer to study this phenomenon.

Our equipment lacked the circuitry to synchronize atom bombardment pulses with the collection of data by the array detector. To simulate the effect of pulsed atom bombardment, samples were prepared on one side of a double-sided FAB probe which allowed the sample to be manually rotated in and out of a stable 6 keV xenon atom beam. The array detector was set to detect and log data at regular intervals. The detection cycle time with that equipment was typically in the range 65-100 ms.

Figure 1 shows the molecular region mass spectra obtained at 100 ms intervals from 400 attomoles of the peptide eldeoisin (sequence pyro-EPSKDAFGLM-NH$_2$) in glycerol. Differential ionization of the protonated molecular signal at m/z 1188 and the glycerol matrix cluster ion at m/z 1197 are observed with the peptide signal diminishing and the glycerol cluster increasing in intensity as bombardment ensues. The quantity of peptide required to produce the signal/chemical noise ratio observed for the protonated molecule in these spectra represents an enhancement of better than four orders of magnitude over the quantity required to yield similar enhancements for all classes of molecules that we have examined that show the pulsing effect upon the initiation of bombardment.

Sample preparation is the key factor in optimizing for pulsed FAB. In contrast to sample preparations in glycerol, very few samples exhibit any pulsing behavior when prepared in nitrobenzene alcohol (NBA) matrix. While NBA is often superior as a matrix for conventional FAB, glycerol is usually superior for pulsed FAB. We attribute this observation to the higher surface tension of glycerol compared to NBA, and the formation of surface layers of analyte that are removed in the first few hundred milliseconds of particle bombardment.

In our studies, we have noted that the ions observed immediately following the initiation of bombardment may be of a different nature to those evolved subsequently. For example, the FAB mass spectrum of Prostaglandin A$_1$, obtained under steady bombardment conditions shows a signal corresponding to the ion [M+H-H$_2$O]$^+$ and no significant [M+H]$^+$ ion$^3$. Figure 2 shows three exposures of a sample of Prostaglandin A$_1$ in glycerol. The relative intensities of the protonated molecule and the water loss signals are quite different in the three exposures. These data were recorded for equal durations and all masses in the observed mass range are recorded simultaneously. This suggests that the sample was rotated into the atom beam at differing points in the integration window. Therefore the data actually reveal the effects of phenomena of shorter duration than the 65 ms cycle time of the array detector. This in turn suggests that differential ionization events occur on a time scale faster than we can presently detect.
Figure 1. Molecular ion region of eledoisin obtained for 400 attomoles of eledoisin in glycerol. Successive mass spectra were obtained at 100 ms intervals. These mass spectra illustrate the differential evolution of the analyte species and the matrix chemical background. The differentiation between analyte and chemical background, coupled with array detection, leads to improved sensitivity.

References:
In 1987 we proposed a new instrument incorporating wide angle multichannel array focal plane detection with high field high resolution capability for ultrasensitive high mass analysis of Biopolymers by FAB and FD. The concurrent requirements of Gross et al. (Nebraska) for four sector tandem MS with low noise systems for post-translational modification in proteins. A two sector version of the ZAB, the ZAB-2SE FPD, has now been constructed incorporating one wide angle (1.5:1) array for high sensitivity, low resolution survey analysis up to 15 kilodaltons, and the option of a second array (1.05:1) for narrow angle (5X window) high resolution analysis. The instrument also retains the off-axis multiplier detection of the ZAB 2SE together with its Linked Scan, CAD sequencing capabilities.

The basic specifications we proposed in 1987 are summarised in Figure 1, and these include the foreseeable requirements for biopolymer MS analysis of unknown structures, with respect to mass accuracy, mass range and sensitivity, for the next 5-10 years.

The instrument is in the final stages of construction, and in this paper we present preliminary data which illustrate the basic capabilities which will be routinely available. Refinements in data collection and in hardware and software related to mass calibration and assignment are still in progress, and therefore the mass scale and mass assignments in the figures shown, serve only as a guide at this stage of construction.

The significant increase in sensitivity of analysis of high mass (2-14kDa) biopolymers from the combined use of high field magnet large geometry instruments with focal plane array detection is expected to be achievable only with the use of low chemical noise ionisation systems (see later). Nevertheless, using conventional FAB ionisation without low chemical noise modifications (e.g. continuous flow FAB) one expects to achieve equivalent sensitivity of detection to that obtained scanning across the point detector, and over shorter ionisation times. This is illustrated with the array detector spectrum of 1 picomole of insulin in Fig 2 illustrating a 2 x 1 second picture of simultaneous detection over the 4,500 to 6,900 mass range.

The spectrum is background subtracted using an acquisition of matrix alone to remove some of the chemical noise derived artefacts, and it compares favourably in quality with the 1 picomole point detector spectrum obtained by summing and averaging over 20 seconds, followed by peak detection and smoothing. The ability to obtain the required equivalent data in a 1 second timescale, with the majority of sample still remaining can clearly be exploited. The major advantage of the wide angle array is of course expected to be seen with low chemical noise ionisation systems such as F.D. We introduced the use of high field F.D. analysis in particular in the glycoprotein/carbohydrate field some 15 years ago in the study of post-translational modification in proteins. A two sector version of the ZAB, the ZAB-2SE FPD, has now been constructed incorporating one wide angle (1.5:1) array for high sensitivity, low resolution survey analysis up to 15 kilodaltons, and the option of a second array (1.05:1) for narrow angle (5X window) high resolution analysis. The instrument also retains the off-axis multiplier detection of the ZAB 2SE together with its Linked Scan, CAD sequencing capabilities.

The spectrum shown in Fig 3, labelled as "No Dilution", is estimated as 5 picomoles from carbohydrate analysis. Dilutions of 1 in 5 and 1 in 50 confirmed the minimum level of point detection. Figures 4 and 5 illustrate the production of clear strong data on the array detector for the F.D. experiment on 1 in 5 and 1 in 50 dilutions respectively, showing summed pictures over the desorption profile from 25 to 35 milliamps. Interestingly, a single 1 second shot shown in Figure 6 for the 1 in 100 dilution is again of recognisable quality to the summed picture in Fig 5. Figures 7 and 8 illustrate the array spectrum of the F.D. of a 1 in 100 dilution of the sample, showing better quality data both for summed and individual pictures than the "no dilution" point experiment.

These data illustrate the potential of the new instrument for wide mass range high sensitivity detection applied to real problems in the field of biochemistry, biotechnology, and molecular biology, allowing increased sensitivity up to a factor of 100. This takes analysis of carbohydrates and peptides into the low femtomole region when low chemical noise ionisation systems are used, allowing retention of the majority of sample for other purposes even where high chemical noise ionisation is used. The mass accuracy specifications together with testing of the high resolution (10,000 R.P.) array at the double focussing...
position, are expected to be achieved within the next few months.

OPTIMIZATION OF MICROCHANNEL PLATE ARRAY DETECTORS USING ONE-DIMENSIONAL PHOTODIODE ARRAY READOUT

S. Rubel, M. Dixon, D. Edwards, J. Horton
Galileo Electro-Optics Corp., Sturbridge, MA

Microchannel plates (MCPs) are a popular component of many spectrometers, enough so that their performance has been extensively reported in the literature\(^1\)\(^2\). Common configurations use a single plate, or two in tandem, with a one-dimensional readout system such as a photodiode array (PDA).

Despite this research, the behavior of many MCP configurations have not been explored, mainly due to the number of design factors. What possible improvements in resolution and gain can we achieve with some of these untested devices? How critical is MCP performance to overall spectrometer performance?

To avoid testing a prohibitively large number of detector configurations, we turned to statistical experimental design. This permitted us to predict MCP detector behavior using a smaller sample size. Experimental design allowed us to determine the relative importance of each factor studied, and to make a preliminary choice of the configuration providing highest gain and/or spatial resolution.

Resolution is determined by the size and compactness of the charge cloud exiting from the MCP, and is affected by many of the same parameters which influence MCP gain. We chose to study the following factors: MCP pore size, separation between the MCP output and the phosphor screen (thus the electric field in that region), bias angle of the MCP pores relative to the detector axis, a proprietary Galileo image enhancement process, and the length to diameter (L/D) ratio of the pores. Note that even with only two levels per factor, the experimental space has \(2^5 = 32\) possible configurations; using a fractional factorial design we covered the same experimental space with only eight trials. The effect of bias voltage across the plates is well-documented for a wide variety of configurations\(^3\)\(^4\); therefore we omitted it as a factor from our study. For reasons of experimental economy we also used only UV photons as input.

When analyzing the experimental design one assumes that the response of interest (or its logarithm, square, etc.) can be well-described by a polynomial with a finite number of terms. In our analysis we include only linear terms; higher order and interaction terms are confounded. While such terms may be significant and distinguishable from noise, confounding prevents their being quantified individually without further trials. For example, lack of fit between the empirical model and the data could be due to a quadratic term in bias angle, or to the interaction between L/D ratio and pore size, or to some combination of the two; it is impossible to say which. Fortunately, statistical design also provides the means to evaluate how well the empirical model performs. In this study we focus on determining the most important effects. Future studies will determine the response polynomial in more detail.

The experimental apparatus comprises a UV deuterium lamp, a resolution mask, an MCP assembly, P20 phosphor screen, and a Princeton Instruments 1024 element PDA with 25 lira pitch pixels (\(<0.001\)^\text{\textasciitilde}). The resolution mask consisted of 0.001" slits separated by gaps ranging from 0.001" to 0.010". The MCP assembly was operated in a turbo-pumped vacuum chamber at a pressure of \(2 \times 10^{-6}\) torr or better.

For the purposes of our study we defined MTF as:

\[
\frac{\text{Peak height} - \text{Valley height}}{\text{Peak height} + \text{Valley height}},
\]

at 13 mm\(^1\) spatial frequency. At this frequency we found the MTF to cover a reasonable range of values, from zero to 0.39.

Figure 1 shows the relative
effect on resolution of the factors we studied. The empirical model described the data reasonably well, having an $R^2$ coefficient of 0.47. Analysis of the residuals showed that the model needs more terms, as we would expect. We believe we understand the role of the terms which we did include. Anode gap is inversely proportional to electric field strength, and consequently controls the time in which the charge cloud spreads. Bias angle also influences charge cloud spreading. L/D ratio probably influences resolution by affecting the energy distribution of the output electron cloud. We plan a theoretical study to investigate this hypothesis. Finally, we find the effect of image enhancement and of pore size to be negligible in this experiment. Note however that the best-performing MCP configuration had a resolution equal to that of the PDA (25 μm); a readout system with better resolution may well have exposed an effect from these factors.

Gain effects are shown in Figure 2. Again, for a screening experiment the empirical model provides a reasonable fit, with an $R^2$ coefficient of 0.49. The influence of L/D ratio and pore size is well-understood: longer pores of smaller diameter provide more multiplying strikes for secondary electrons. Image enhancement also improves the multiplication process, leading to higher gain. Finally, bias angle does not play a large role, but the increase in gain is expected: smaller bias angles provide higher secondary yield on the first strike. The measured increase agrees well with theoretical predictions.

CONCLUSIONS:

For a given MCP to anode spacing one can improve both resolution and gain with a larger L/D ratio and by using the image enhancement process.

The choice of bias angle presents a tradeoff between higher gain and better resolution. For most purposes, however, one can pick a larger angle for better resolution, and then make up for gain losses using a larger L/D ratio.

Pore size may present a similar choice in systems which have a better resolution, but no effect was apparent in our experiment.

Finally, we note that a fully optimized MCP configuration easily resolves features at the limit of the PDA, and thus is not the limiting component of the system.

A novel tandem quadrupole acceleration-deceleration mass spectrometer

Frantisek Turecek* and Ming Gu
Department of Chemistry, University of Washington, Seattle, WA, USA

A tandem quadrupole acceleration-deceleration (QADQ) mass spectrometer for neutralization-reionization studies is described (Figure 1). The MS-1 stage of the instrument consists of an Extrel combined EI/CI ion source, and an EXM-2000 quadrupole filter (Q1) of 2000 a.m.u. mass range. MS-1 is differentially pumped by a 1200 L/s diffusion pump. Mass selected ions are accelerated to 5-10 keV and collimated by a six-element lens (Lens 1) to form a beam of a 4 mm cross section and a 1.5° convergence angle. Lens 1 is furnished with a quadrupole electrostatic lens floated at the accelerating voltage and adjustable to ±120 V to move the ion beam at about 4° space angle. The beam is neutralized by collisions in the first collision chamber (Cell 1), floated at the nominal accelerating voltage and differentially pumped by a 1200 L/s diffusion pump, and allowed to drift through a floated screen-metal conduit to the second collision chamber (Cell 2) positioned 30 cm from Cell 1 and kept at a low potential of opposite polarity to defocus the remaining ions. Cell 2 is differentially pumped by a 60 L/s turbomolecular pump. The neutral products are finally reionized by collisions in the third collision chamber (Cell 3) positioned 61 cm from Cell 1, and floated at a variable high voltage. Cell 3 is differentially pumped by a 1200 L/s diffusion pump. The ions formed are decelerated by a special lens (Lens 2) and collimated to a convergent beam by an einzel lens. The decelerating potential is link-scanned with the final quadrupole mass analyzer. After deceleration the high kinetic energy ion fraction is filtered out by a chicane lens (Lens 3) of a -5 eV energy bandwidth. The optical stop of Lens 3 is mounted on a linear motion feedthrough to allow fine tuning and beam profile measurements. Lens 3 is also furnished with four pairs of deflection plates to aim the beam at the aperture of the MS-2 injection lens. The survivor ion and its reionized fragments are mass analyzed by a second EXM-2000 quadrupole mass analyzer (Q2) as MS-2, and detected by an off-axis electron multiplier furnished with a conversion dynode. The MS-2 part is differentially pumped by a 60 L/s turbomolecular pump.

Figure 1. Ion optics scheme and electrostatic potential diagram of the QADQ tandem mass spectrometer.

1697
Normal mass spectra are obtained by setting MS-1 in the RF-only mode and scanning MS-2, while keeping the collision chambers and the ion conduit at the accelerating potential. In the neutralization-reionization mode Cell 2 electrically isolates MS-1 and MS-2 and reflects back ions escaping from Cell 1. In the reionization step, the survivor and its reionized fragments are formed from keV neutrals at kV potentials and then decelerated to a low kinetic energy (40-60 eV). Consequently, Lens 3 and the detector can be operated at the ground potential which greatly simplifies both instrument design and data acquisition. Q1 and Q2 are operated at d.c. offsets 2-5 V below the ion kinetic energy in order to maintain high mass resolution.

In preliminary experiments the instrument showed >10% total ion transmission at 4-7 keV acceleration voltage. Unit mass resolution is readily achievable at both MS-1 and MS-2 without severe transmission losses. Relative ion abundances of \(^{124}\text{Xe}\) through \(^{134}\text{Xe}\) were measured by scanning MS-2 at unit mass resolution (<1% valley, Figure 2) and showed good agreement with the tabulated values. The beam cross section, measured at the optical stop of the chicane lens, matches that predicted by ion-trajectory simulations.

DESIGN OF AN ULTRA HIGH RESOLUTION ENERGY RESOLVING TANDEM MASS SPECTROMETER

A Gareth Brenton and Christopher S Enos

Mass Spectrometry Research Unit, University College of Swansea, Singleton Park, Swansea SA2 8PP, UK.

Anthony R Lee

Physics Department, La Trobe University, Bundoora, Victoria 3081, Australia.

We have previously proposed [1] ion optical arrangements, comprising a pair of symmetrically positioned electrostatic analysers for achieving very high energy resolving properties in tandem mass spectrometers. An instrument of this design has been constructed and is used to directly measure the electronic and vibrational structure of molecular ions by the technique of Translational Energy Spectroscopy (TES) [2]. In these particular applications, the ion spectrometers are operating with ion beams of kilo electron volt energies (typically 2 – 8 keV) and thus to record electronic and vibrational band structure, very high energy resolving power is required (>20 000). To improve existing instruments to have performance similar to photoelectron spectroscopy, (but for fast ion-molecule collisions), a new TES spectrometer of higher energy dispersion has been designed and is currently under construction.

The basic geometry and associated lenses for this equipment are shown in Figure 1. The principle features of the instrument are the electrostatic analysers which are 0.960 m in radius (an increase of 2.5 on the current instrument) which leads to a similar increase in energy dispersion. These particular sectors were chosen as they were available from a commercial mass spectrometer design. The geometry has been run through the TRIO programme [3] to check that the image aberrations are at an acceptable level (see Table 1). From our experience with our smaller instrument (R = 0.381 m electrostatic analysers) less auxiliary lenses are preferable in the instrument. Einzel lenses are necessary to provide first order focus (Y lenses, Fig. 1) which is a critical parameter to minimise, as the ESA’s are fixed (ie they cannot be moved tangentially to the ion beam, as a magnetic sector can, to achieve first order focus). Hexapoles (H, Fig. 1) are also necessary to carry out minor second order correction and, more importantly, to rotate the image for precise alignment with the collector slit which cannot be mechanically guaranteed. We also plan to include z-focusing Einzel lenses to increase the overall sensitivity as the symmetrical ESA arrangement has no focussing action in the z direction. TRIO indicates a B value of 4.69 for this geometry and therefore use of z focusing would help restore any loss of sensitivity. As this geometry has very low image aberrations for aberrations connected with the height of the ion beam (refer to Table 1 ie YY, YB, BB ....) it is planned to use long slit length (<20 mm to further increase sensitivity. The overall increase in transmission at a fixed energy resolution (compared to the current instrument) is expected to be a factor of ten. The ultimate energy resolution (currently 0.015 eV for a 3000 eV beam, E/ΔE ≤ 200 000) will probably not improve by more than a factor of 2.5 but the increased sensitivity afforded will make measurement feasible at these energy resolutions of 10 meV, allowing photoelectron type spectra of fast ions to be recorded directly.

Data from the current instrument has shown that band structure of ions can be obtained and by varying the target gas singlet, triplet (doublet, quartet) states can be selectively measured [4]. Areas we envisage to investigate are different collision cell designs, in particular, one reported at this meeting where the energy given to the collision gas can be monitored in coincidence with the energy loss of the projectile ion. This method will greatly enhance the resolution of spectra by immediate deconvolution of the energy distribution taken up by the target. Another area in which we have made some preliminary investigations is toward the electronic and vibrational bands of neutral compounds. Figures 2 and 3 show TES spectra for H⁺ on acetone (Figure 2) and H⁺ on propionaldehyde. TES spectra are highly reproducible and the differences between these isomers is easily seen. For propionaldehyde we are picking up a vibrational band at ~-10 eV. By changing the fast ion to another species such as He⁺, N⁺, O⁺ etc. these TES spectra vary significantly allowing a given compound to be mapped. We are currently looking at structural differences down to chiral species and will report these soon.

A quadrupole mass spectrometer can be constructed in which only time variant fields are used to produce mass specific detection. This is accomplished by using an r.f. only quadrupole field to which an auxiliary transverse dipole field is added. This auxiliary field is tuned to the natural oscillatory motion of ions near the high q stability limit. Ions in resonance with this stimulus gain transverse velocity and are ejected. The frequency or amplitude of this resonant excitation can be modulated such that the mass specific instability thus produced results in an a.c signal at the detector that is proportional to the ion flux. Phase sensitive detection can then be used to extract mass-intensity information characteristic of a mass spectrum.

There have been many prior implementations of r.f. only quadrupole systems. Many of the drawbacks encountered in prior r.f. only quadrupole systems can be avoided if an alternative method is used to provide the high q cutoff. Ions near the high q stability limit can be selectively excited by application of an auxiliary dipole or quadrupole field. Ions in near-resonance with the excitation field will gain transverse kinetic energy and be rejected if their radial displacement exceeds $r_0$ in less than the time it takes them to traverse the length of the quadrupole structure.

At low values of $\beta$, the ion trajectories may be simply described as a primarily sinusoidal motion. The change in $\beta$ with respect to $q$ is approximately 0.7 up to $\beta = 0.4$ where the slope in this relationship begins to increase. It continues to increase asymptotically until, at the stability limit, where $\beta$ equals one and $q$ equals 0.908, the slope is infinity. Ions near $\beta = 1$ have a motion composed primarily of a pair of frequencies equally spaced on either side of one half of the main r.f. frequency. The addition of an auxiliary field in resonance with either of these frequencies causes the maximum radial displacement of the ion trajectory to increase.

When such a resonance induced cutoff is utilized during a r.f. only mass analysis scan, the observed detected ion current stair steps have steeper transitions than would be otherwise observed. Since the influence of the auxiliary field on ion motion, and therefore ion transmission, is strongly dependent upon differences in the resonant frequency of ions and the frequency of the auxiliary field, small differences in ion masses correspond to large differences in ion transmission. This technique exploits the large value of the change in $\beta$ with respect to $q$ at high $q$ to achieve relatively high resolution with good ion transmission.

Any previously described r.f. only operating mode would benefit by use of a resonance enhanced high $q$ ion transmission cutoff. A further improvement is realized by modulation of the $\beta$ corresponding to the cutoff by modulation of the frequency of the auxiliary field. The detected ion current carried by ion masses which have effective path stability altered by the changing frequency of the auxiliary field will have an a.c component that has a frequency equal to the modulation frequency of the auxiliary field. Mass resolution is a function of the magnitude of the frequency modulation, as this directly determines the range of ion masses that will produce encoded ion current signals.

A simplified block diagram is shown which uses full wave modulation to excite both frequencies of ion motion in quadrature in both dimensions to prevent frequency beating, an obscure but important characteristic of resonant excitation beyond the scope of this discussion. Mixing one half of the main r.f. frequency with an audio frequency produces the needed waveforms. The amplitude is set and inductively coupled to the quadrupole structure. All that remains is to modulate the position or $\beta$ at which resonance occurs, which is accomplished by frequency modulation of the audio frequency generators. The amplitude of the auxiliary field, the chosen average $\beta$, the number of r.f. cycles and the amplitude of the auxiliary field frequency modulation determines the resolution setting of a given device.

MS/MS is possible by using this method to modulate the parent mass.
intensity in the first quadrupole of a tandem instrument. All daughter ions formed in the collision cell will also be modulated. Operating the final quadrupole with a different modulation frequency permits the selective detection of daughters at the appropriate sideband frequencies.

Resonant excitation at low $\beta$ produces notches in the transmission band which may also be modulated. Multiple notches modulated at different frequencies permit simultaneous multiple ion detection. MS/MS with multiple notches in Q1 and Q3 permits simultaneous multiple reaction monitoring.

The most encouraging result is the resolution of mass 1466 using an r.f. quadrupole operated at 1.002 MHz. Similar resolution is achieved in the r.f./DC mode only at the expense of sensitivity. By comparison, the r.f. only mode has more than 50 times as much intensity in terms of ion current at the detector. This result clearly demonstrates the projected advantages of increased sensitivity and resolution at high mass.
In all time of flight (TOF) mass spectrometers it is necessary to measure the time differences between ion production and ion detection. Two methods are mainly used for time measurements, that depend on the number of ions of the same mass striking the stop detector simultaneously. If the output signal from the detector is large a transient waveform recorder is generally used. Most of the time measurements in laser desorption mass spectrometry are performed with such an electronic equipment. Pulse height signals from detectors signal are measured as a function of time over several tens of microseconds with time bins of 5 ns (or much less) according to the frequency of the system (200 MHz or more). Digital values are stored in the computer memory and a complete TOF spectrum may be obtained for only one laser shot. However, several problems may occur such as time precision, uncorrect time-amplitude digital conversion, etc... although excellent commercial devices are available.

When the number of identical ions is very small (around one), single ion counting is more advisable. This is achieved by using a time digital converter (TDC) and a low threshold constant fraction discriminator. The most recent TDC built at the Institut [1] has a time bin of 0.5 nsec and can accept, for one start signal, 255 stops delivered by one or three different detectors (3 stop input signals). The dead time is 22 nsec. A smaller time bin, more stop signals and a smaller dead time will be possible. The time accuracy of a TOF peak centroid can reach 50-60 ps.

Event by event TOF coincidence measurements can be performed with single ion counting. For example time windows can be defined on a time of flight spectrum and used as time origins to generate (during data acquisition) time of flight spectra of correlated secondary ions produced by desorption processes following the main first desorption process. Delayed emission has been measured by this technique [2]. Multidesorption events associated with the same start signal provide a complex TOF spectrum that is the sum of several TOF spectra due to each event. The "time windows" technique allows to obtain these TOF in real time. A TDC, a microprocessor, a DMI card in a PC and a PC386 are used for these data acquisition [3].

Recently a charge digital converter (CDC) has been coupled to a standard TDC. This new device is very useful when several ions of the same mass hit a detector. As soon as a signal from the detector is seen by the discriminator, the total electric charge is measured for a time roughly equal to the dead time of the TDC. The amount of charge is proportional to the number of ions that has hit the detector and a digital value is added in the TOF histogram. It is necessary to measure a calibration curve of the detection system that depends on the energy and mass of the ion and also on both the discriminator threshold and the detector voltage (Fig. 1). Fig. 2 a-b shows matrix assisted laser desorption TOF spectra of a mixture of insulins measured with the TDC alone and the new electronic device. These spectra were recorded with the multidesorption probes TOF 23 ($^{243}$Cf, Cs or cluster ion gun, N2 laser) built at the Institut and commercially available. A double grid mirror is used [4]. The apparent mass resolution in matrix assisted laser desorption is around 2500 in the mass range 1000-2000 compared to 3500 with $^{244}$Cf. At the laser irradiance threshold and with low detection voltage values an apparent M/AM of 1500 is obtained for insulins. The isotopic mass distribution width is in fact the limitation factor. With TOF 23, the neutral spectrum and ion spectrum are recorded simultaneously. It is observed that metastable decay processes are very important in LDMS.

The secondary ion multiplicity can be, in principle, measured with the new CDC-TDC electronic system. Various tests of this module are being made at our laboratory.

A number of schemes have been described which allow the diversion of solvent or major components between the gas chromatograph and the mass spectrometer but most compromise chromatographic resolution or do not really switch cleanly. Because of these problems, many if not most mass spectrometers today utilize the so-called direct connection in which there effectively is no interface. Large components such as solvents are managed by simply turning off the mass spectrometer electronics. Unfortunately, turning off the electronics does not fully protect the spectrometer from the contaminating effects of large amounts of substances.

We have developed an interface which switches cleanly and completely in fractions of a second between a clean helium stream and GC effluent. This is accomplished without compromising GC resolution or sensitivity. In addition to on/off switching the device is also capable of partial splitting. Moreover, the device allows GC column exchange or other chromatographic maintenance without affecting the integrity of the mass spectrometer's vacuum and allows postcolumn derivatization as described in Anal. Chem. 63, 255 (1991).

These improvements are obtained by utilizing a modified open-split design in which the restricting (or inlet) capillary is arranged so that it can be positioned to sample either GC effluent or clean helium. In Figure 1, we provide a schematic of the interface. The inlet capillary is supported by a compression fitting supported on a bellows. This bellows is driven up and down by a mechanical screw arrangement. Clean helium flows into the interface via the bellows and exits via the vent. The flow from a variety of inlets flows through a manifold constructed of 0.3 mm i.d. glass lined tubing and exits through the vent. When the bellows is compressed the inlet capillary samples flow coming from one of the inlets. When the bellows is decompressed the inlet capillary samples only clean helium. The vertical motion required to accomplish switching is less than 2 mm and the time required to switch is less than 1 second. Intermediate vertical positions of the sampling capillary provide partial sampling of the GC flows.

Figure 1. Fast switching interface.
In our prototype the manifold is interfaced to two independent GC columns and to an auxiliary split-type capillary injector which is used to introduce reagents for postcolumn derivatization. The inlets which are not in use are provided with very low flows of helium to eliminate dead volumes.

The advantages of this system include the fact that switching of the interface has no effect on the pressure seen by the outlet of the GC column and no effect on the pressure seen by the mass spectrometer's ion source. As a result switching has no effect on GC retention times and no effect on ion source conditions. Column exchange on this system requires only that the bellows be decompressed after which the GC columns may be changed at will.

Figures 2. and 3. provides examples of the performance of the system.

INTRODUCTION

In a cryocooler, gas flows in a closed-loop from a compressor through interconnecting line(s) and the regenerator to an expansion volume and, then, returns back to the compressor. The displacer which embodies the regenerator matrix has a temperature range, across the length of its body, from as low as 10 K up to 300 K. Any contaminants which are condensible in this temperature range will be condensed on the surface of the regenerative materials or in the gap between the displacer and its outer enclosure. Consequently, the build-up of the condensate results in a loss of refrigerator performance. Because of the relatively large gas volume being circulated in the system, the concentration of contaminants which is needed to impair the cryocooler performance is usually low enough that they elude detection by any direct analysis technique. A preconcentration step is required.

This paper describes a specially-modified sample inlet system for preconcentrating contaminants in gases from a pressurized system and, subsequently, allowing their detection by the GC/MS technique. The gas volumes being analyzed can range from a few std. mL to tens of std. liters with a corresponding pressure from ambient up to 50 atm. The evaluation of this inlet design was performed on a reference standard gas cylinder which is comprised of a mix of four halocarbons in a balance of nitrogen. The limit of detection for the halocarbons is found to be a few nanograms for the operating conditions under EI in the scan mode. The linear dynamic range extends to a few micrograms being studied. The introduction of this reference standard as an internal standard for semi-quantifying contaminants in cryocoolers is demonstrated.

EXPERIMENTAL

Figure 1 illustrates the block diagram which depicts a sample selection valve, gas switching valves, a cryofocus, mass flow controllers (MFC), and an on-line moisture analyzer. The sample gas volume can be directed solely to the GC/MS or split, with variable split ratios, between the GC/MS and the moisture analyzer. The moisture analyzer, if used, operates under a fixed flow at 100 seem which enables a direct readout of moisture content, in ppmv. The preconcentrating gas flow rates were normally from 5 to 70 seem of helium whereas the desorb flow through the cryofocus was fixed at 5 seem. Various functions can be performed depending on the selected valve position, such as: manifold purging, contaminant preconcentrating in the cryofocus, reference standard and/or internal standard introduction, and contaminants desorbing for GC injection.

The cryofocus, Tekmar Capillary Interface Model 1000, which embodied a deactivated 530 μ fused silica column was cooled to -150°C or below in order to preconcentrate gaseous contaminants. An HP split/splitless capillary inlet injector was modified to be interfaced with this preconcentration column. In the desorb mode, the condensates were flash evaporated, injected, and then refocused at the head of GC column before final elution to the MS detector. Gases exiting from the cryofocus split: one to the GC column with a fixed flow at 0.8 sccm and the other to the split vent with the remainder of flow which is controlled by a mass flow controller. The GC column is a 25 m long by 0.25 mm ID, DB-1 from J&W Scientific. The instrumentation includes an HP 5890A GC interfaced to an HP 5988 MS.

The reference standard cylinder, from Restek Corporation, is comprised of 2.5 μg/μl of chloromethane, vinyl chloride, bromomethane, and chloroethane in a balance of nitrogen. The gas flow manifolds including the sample vessel are kept at 55°C for volatilizing the contaminants.
RESULTS AND DISCUSSION

Table 1 summarizes the results of variable volume sampling of the reference standard. The calculated quantity in Table 1 was derived by multiplying the gas volumes being introduced by the certified concentration at 2.5 μg/μl of the respective halocarbons. Forced zero linear regression of test data indicates that the area response of quant ion vs the quantity of halocarbons is linear, from a few nanograms up to several micrograms being introduced, as shown in Figure 2. The limits of detection, which are defined to be 3 times the signal to noise ratio, are found to be 3, 3, 3, and 8 ng for chloromethane, vinyl chloride, bromomethane, and chloroethane, respectively.

The utilization of this reference standard as an internal standard for the purpose of semi-quantifying the contaminants in cryocoolers is demonstrated in the chromatograms in Figure 3. Figure 3a exhibits contaminants present in a small cryocooler with a static pressure of 50 atm and a void volume of 200 cc. Figure 3b is an example of results from a large cryocooler with a static pressure of 18 atm and a void volume of 800 cc. Future efforts are to replace the use of halocarbon internal standards with a standard gas generator which is capable of providing a known blend of contaminant mix at varying concentrations.

Theoretical and Practical Aspects of
Short-Column Gas Chromatography/Mass Spectrometry
Sample Injection Methods

Stacy-Ann Rossi and Richard A. Yost, University of Florida,
Department of Chemistry, Gainesville, FL 32611

Theoretical and practical aspects of different sample injection methods used in short-column gas chromatography/mass spectrometry (GC/MS) have been investigated. It has been shown previously that for short-columns (< 5m), the experimental chromatographic resolution at high carrier gas velocities is not as good as that predicted by theory (1). The differences between experimental and theoretical values can be attributed to extracolumn variances from the sample injection method. If optimum short-column GC/MS performance is to be obtained, the development of a high-speed injection method is necessary to eliminate this extracolumn band broadening. We have investigated the use of Curie-point thermal desorption as a potential high-speed injection method for short-column GC/MS.

Experimental:
All experiments were performed on a Finnigan MAT TSQ45. Sample injection methods including standard syringe injection and Curie-point thermal desorption were investigated. Chromatographic separations were performed on a 4m, 0.25mm i.d. SE-54 capillary column using helium as the carrier gas. Both pressure regulation and flow-control of the carrier gas flow rate were used via a modified gas chromatograph (1). A homebuilt Curie-point unit was used for the thermal desorption experiments with 610 °C wires (2). The first quadrupole (Q1) of the mass spectrometer was scanned over a 2 amu window at a scan rate of 0.05s/amu to minimize the time constant associated with the detector. The anabolic steroid, methyltestosterone, was used in all studies with methylene chloride as the solvent.

Results and Discussion:
Results for standard syringe and Curie-point thermal desorption injection methods were compared to predicted theoretical data in order to evaluate the contribution of these two injection methods to extracolumn band broadening. It was originally believed that the input bandwidth for Curie-point desorption would be narrower than standard syringe injection methods

\[ \sigma_{\text{desorption}} < \sigma_{\text{vaporization}} \]

where \( \sigma^2 \) is the variance associated with the input bandwidth. As shown in Figures 1a and 1b, it is clear that both methods exhibit some degree of band broadening at high carrier gas velocities; however, the syringe injection method appears to yield narrower peak widths than the desorption method.

For the syringe injection method, the extracolumn band broadening results in an additional 0.4s to the theoretical bandwidth at 50% peak height. For Curie-point desorption, the contribution to extracolumn band broadening is three times that of the syringe method, adding 1.2s to the theoretical bandwidth. For plate height comparisons, an additional term \( (Du^2) \) is required in the Golay equation to account for the extracolumn band broadening. In Figure 1b, this is shown as an extracolumn broadening of \( \sigma = 2.5s \) for the syringe injection method and \( \sigma = 5s \) for Curie-point desorption compared to the theoretical plate height (\( \sigma = 0s \)). At this time, we believe that the input bandwidth for Curie-point desorption is not as much a function of the linear velocity, but is limited by the RF power supply used to heat the Curie-point wire to its final temperature. It should also be pointed out that the peaks obtained in these studies were non-Gaussian. To correct for this, the Foley-Dorsey equation was used so that chromatographic figures of merit could be obtained for both ideal and skewed peaks (3).

Considering the practical aspects of these injection methods, Curie-point desorption has been shown to be advantageous over syringe injection methods since there is no solvent background or interferences from solvent tailing, as seen in Figure 2. This allows Curie-point desorption to be used more effectively with isothermal column temperatures since solvent overlap is not a problem. It is also apparent from these chromatograms that for both methods mixture separation capabilities are equivalent and thermal decomposition is minimal; however, interferences from column or septum bleed is evident in the syringe chromatogram but not in the Curie-point desorption chromatogram.

DESIGN OF AN OPTO-ISOLATED DETECTOR FOR MASS SPECTROMETRY

*John W. Gray, Joan M. Green-Cardin, and John B. Hooper
Galileo Electro-Optics Corp., Sturbridge, Massachusetts 01566

The objective of the present work is to demonstrate the feasibility of a practical, cost effective, channel electron multiplier (CEM)-based, opto-isolated detector for mass spectrometry applications, and to identify and characterize the critical operating parameters of such a detector.

Detection of negative ions can be complicated by the fact that the signal is often obtained at high potential. Two methods of dealing with this problem are: 1) use of a conversion dynode to convert the negative ions to positive ions, and 2) pulse counting, which enables capacitive decoupling of the high voltage from the signal.

An opto-isolated ion detector has the advantage of being able to detect either positive or negative ions in the analog mode while still maintaining a signal at ground potential. In addition, it may be possible to float the CEM at a high potential for improved detection efficiency at high mass without resorting to a separate and costly conversion dynode. Figure 1 below illustrates the basic configuration of the device. There are four major system elements important to proper operation:

1) The channel electron multiplier for detecting and converting positive or negative ions to secondary electrons,

2) A phosphor for converting the high voltage electron signal to a photon signal,

3) A single glass fiber for transmission of the photons with minimal loss, and

4) A photodiode to sense the photon signal and convert it to a ground referenced electrical signal.

The photodiode output is directly compatible with most mass spectrometer signal processing electronics and may thus be directly retrofitted into existing systems without modification of the instrument. Two basic mechanical configurations have been constructed: 1) a flange mounted device in which the signal is transmitted through the vacuum housing via the glass fiber and 2) an integrated CEM/collector very similar in appearance to a standard CEM detector in which the photodiode is placed inside the vacuum.

Results of preliminary characterization of system elements will be presented as well as recommendations for future optimization of an integrated detector. The major effort will focus on optimizing the interface between the various components as well as selecting the most appropriate phosphor and photodiode.

President Robert Murphy welcomed the attendees and called the Business Meeting to order at 11:00 a.m. He reported that ASMS is a healthy organization with a growing membership. He announced the topics, dates and organizers for three affiliated meetings: The Fall Workshop on "Elemental Mass Spectrometry", November 14-15, 1991, organized by Willard Harrison and Gary Hieftje; the Sanibel Conference on "Lasers and Mass Spectrometry", January 25-28, 1992, organized by Tomas Baer and Klaus Blemann; the Asilomar Conference on "Trapped Ions: Principles, Instrumentation and Applications", September 27-October 1, 1992, organized by Graham Cooks and Alan Marshall.

Secretary Veronica Bierbaum introduced and congratulated the newly elected members of the ASMS Board of Directors: Sanford Markey, Vice President for Arrangements; Brian Chait, Secretary; Alan Marshall, Member-at-Large. She extended special thanks to the other candidates: Ann Goetz, Sharon Las and Jeffrey Shabanowitz. Bierbaum congratulated the recipients of the Student Travel Stipends to the ASMS Conference: Fred Bouchard, University of Waterloo; Bernd Bruenner, University of California-Davis; David Bunk, Texas A&M University; John Elling, University of Wisconsin; Jeremiah Hogan, University of Texas–Austin; Denise MacMillan, University of Nebraska; Ashley McCormack, University of Virginia; Patrick McKeown, University of Delaware; Yuan Mei, University of Florida; Mark Proefke, University of Illinois; Stacy-Ann Rossi, University of Florida; Lynn Teesch, Emory University; Steven Van Orden, University of Arizona; Josie Visentini, University of Montreal; Michael White, Texas A&M University. Bierbaum was saddened to announce the deaths of four long-term ASMS members: Philip Issenberg, Malcolm Dole, Michael Barber and Thomas Aczel. On behalf of ASMS, she extended sincerest condolences to their families.

Treasurer Jane Gale reported that the annual ASMS budget has increased from about $100,000 to $550,000 in the last ten years. The current net assets of $320,000 provide ASMS with financial security and allow the initiation of special projects, most notably the Journal of the American Society for Mass Spectrometry. Gale itemized the income and expenses for 1990 as well as those projected for 1991. There was a net loss of $30,000 in 1990, due primarily to JASMS and the necessity for buses at the 1990 Conference in Tucson. She noted that, since two-thirds of ASMS members attend the annual conference, it is appropriate that conferences represent the major ASMS expenditure.

Kelsey Cook, chair of the Audit Committee, announced that the Auditor’s report for 1989 was convincingly accurate and no irregularities were noted. The audit of the 1990 books has been completed and will be reported to the membership after review by the Audit Committee.

The Vice President for Programs, Henry Fales, expressed appreciation to the many people who contributed to the success of this year’s program. He acknowledged the chairs of the symposia, the oral sessions and the poster sessions, and thanked the members of the Program Review Committee. The 1991 Conference has 315 oral and 632 poster presentations, with about 1850 attendees.

The Vice President for Arrangements, Robert Lattimer, acknowledged the graduate students who served as program assistants. He summarized the results of the 1990 Arrangements Survey which indicated that meeting facilities, the scientific program and reasonably priced accommodations are the most important factors in evaluating the annual conference. Lattimer announced the locations and dates for the next six ASMS meetings: Washington DC Hilton, May 31-June 5, 1992; Seattle Convention Center, June 13-18, 1993 (the 1993 contract with the Las Vegas Riviera Hotel has been cancelled since the planned expansion will not take place); Chicago Hyatt Regency, May 29-June 3, 1994; Atlanta Marriott Marquis, May 21-26, 1995; Anaheim Disneyland Hotel, May 19-24, 1996; Kansas City Hyatt-Westin Crown Center, June 1-6, 1997.

The Member-at-Large for Education, Robert Cotter, acknowledged the members of the Education Committee and the Sanibel Conference Committee. He described the current ASMS Short Courses (Interpretation of Mass Spectra; Advanced MS Interpretation; GC/MS in Drug Testing; Fundamentals of Protein Analysis; LC/MS) as well as courses under consideration for future meetings (Fundamentals;
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Mass Analyzer Basics; Mass Spectrometry in Environmental Issues; Ion Optics; Quantitative Mass Spectrometry).

The Member-at-Large for Measurements and Standards, Michael Bowers, thanked the members of the Measurements and Standards Committee. He reported that the "Standard Definitions of Terms Relating to Mass Spectrometry" will appear in the July-August 1991 issue of JASMS and should serve as a living document. The Committee sponsored a workshop at this conference on the nomenclature for multiply-charged ions.

Past-President Ronald Hites announced that fifteen travel awards have been made to students and postdoctoral associates for the 12th International Mass Spectrometry Conference to be held in Amsterdam August 26-30, 1991: Duncan Bryant, University of Maryland, Baltimore County; David Bunk, Texas A&M University; Kenneth Caldwell, University of Nebraska; Xueheng Cheng, Harvard University; Susan Graul, University of California at Santa Barbara; Steven Hofstadler, University of Texas; Kathleen Kayganich, National Jewish Center for Respiratory Medicine; Jeffrey Klingler, University of Florida; Tapio Kotiaho, Purdue University; Jeffrey Kowalak, University of Utah; Thomas Shaler, University of California at Riverside; Douglas Sholley, Harvard School of Public Health; Lynn Teesch, Emory University; Evan Williams, Stanford University; Susan Wolf, Northeastern University. ASMS and the National Science Foundation each provided $10,000 towards these awards.

The Member-at-Large for Publications, Richard Caprioli, announced that the unit cost of the 1991 volume to the society is $13, representing excellent value.

Murphy then thanked the retiring members of the Board of Directors, Bierbaum, Caprioli and Lattimer, for their service to ASMS and presented each with a plaque. Murphy gratefully acknowledged the continuing support of Judith Watson, Executive Director of ASMS.

The 1991 ASMS Research Award, sponsored by Fisons/VG Instruments, was presented by Lance Nicolaysen to Hilkka Kenttamaa of Purdue University. George Stafford presented the ASMS Research Award, sponsored by Finnigan MAT Corporation, to Chrys Wesdemiotis of the University of Akron.

Murphy announced that JASMS will expand to eight issues in 1991 and that the library subscription rate will be maintained at $250. He thanked Editor Michael Gross for the high quality and excellent value of JASMS.

Murphy then discussed the possibility of initiating a Fellows Program as an avenue for recognizing individuals for their sustained contributions to mass spectrometry and to ASMS. About 8-10% of the ASMS membership would be honored by this program within ten years if there were 75 inaugural fellows and annual induction of 0.5% of the membership. Murphy acknowledged that the program may have negative aspects and be divisive. He welcomed discussion and suggested an informal poll to determine whether a committee should pursue the idea and recommend guidelines. A mail ballot of the membership would be required to amend the constitution and initiate a Fellows Program. Fred McLafferty cautioned that the mechanism of selection is extremely important and that secrecy and continuity must be preserved. Michael Bowers strongly supported the Fellows Program and encouraged ASMS members to applaud the achievements of one another and emphasize a positive spirit; he noted that the APS Fellows Program functions well and benefits the society. Robert Lattimer expressed the concern that certain groups within ASMS would be overlooked; he added that ASMS is a grass roots society that would not benefit from a two tier membership. James McCluskey encouraged the Board to base a decision on the members' wishes. Murphy re-iterated that this is the Board's intention. A hand vote of the attendees indicated that the membership is overwhelmingly opposed to pursuing the inception of a Fellows Program. Chris Enke encouraged the Board to explore other mechanisms for honoring and celebrating the achievements of ASMS members.

The meeting was adjourned at 11:58 a.m.

Respectfully submitted,

Veronica M. Bierbaum
Secretary
Manufacturers' Forum

Have you ever had a flash of insight about how something should be done, but didn't know who to tell your idea to? Or have you ever wondered about how some of the manufacturers feel about a particular topic near and dear to your heart? This year's workshop, sponsored by the Academic Lab Managers' Interest Group, was intended to give you the opportunity to make that earthshaking suggestion, or ask all the manufacturers how they really feel about it.

Larry Mallis (U. of Iowa) organized this year's workshop by contacting 13 primary and secondary mass spectrometry manufacturers to solicit their participation in a Manufacturers' Forum. (Primary manufacturers are the vendors who actually produce mass spectrometers, while secondary manufacturers are those who provide accessory equipment — e.g., chromatographs, parts and services.) Our intent was to provide the atmosphere for a "round-table discussion" in which manufacturers and users could ask questions and trade ideas about perceived problems, general concerns, and suggestions for future development. The forum was neither intended to be yet another sales pitch by the manufacturers, nor a complaint session from users. Representatives from 9 companies attended the forum: Finnigan, JEOL, VG-FISONs, Hewlett-Packard, KRATOS, Hitachi, Perkin Elmer-Sciex, Waters, and Scientific Instrument Services.

The discussion began with each manufacturers' representative introducing himself and his company, and offering a brief statement. A comment made by Finnigan during this opening phase was a statistic attributed to Sun Systems, who report a cycle time of approximately 9 months from release of a product onto the market until it is superseded — and thus is no longer actively supported. This makes it difficult for mass spectrometer manufacturers and users alike to keep pace with computer innovations.

Karl Wood (Purdue U.) asked about policies on support of elderly instrumentation. How long do manufacturers feel the responsibility to support their old products? Hewlett-Packard said their policy is to support a product for 10 years after declaring it obsolete. Their mechanism for deciding to declare a product obsolete is that customers stop buying it in favor of newer products. Finnigan feels both a legal and a moral obligation. The legal obligation is defined absolutely in some countries — e.g., 10 years in Sweden, 5 years in the U.S. Their moral obligation is a compromise between supporting a machine as long as the customer needs and uses it and what is economically feasible.

Larry Mallis (U. of Iowa) asked the manufacturers' feelings on the turn of events following a merger or takeover of an instrument vendor. This is an important consideration if one is in the market for a new instrument or has recently bought one, and is appropriate in light of the fact that four major manufacturers have recently been purchased by larger companies. Finnigan's takeover has resulted in some price adjustments and improvements in production scheduling for the factory. VG's purchase by FISONs marks acquisition by a parent company which appears to be more interested in the scientific instrumentation business than its predecessor. Perkin Elmer-Sciex suggested that their merger would only strengthen the position of the two component companies. KRATOS suggested examining the character of the company itself to assess long-term security rather than trying to generalize about all mergers.

Jack Simpson (NIMH) asked about manufacturers' plans to integrate more completely the control of liquid chromatographs by the mass spectrometer data system, as has been done with gas chromatographs. All manufacturers said they presently have some control, and are working on more.

Bob Minard (Penn. State U.) raised the issue of manuals and schematics. All of us at one time have been more confused than enlightened by a poorly written manual or incorrect schematic. Hank Fales (NIH) emphatically seconded the manufacturers' giving serious consideration of this problem. KRATOS has adopted a policy that new software releases will not be distributed to customers until the manual is ready to go with it. Hitachi, a company re-entering the mass spectrometry market, stated that their manuals are being written in English by native English-speaking authors, not being translated from Japanese. Perkin Elmer countered with the question of how many actually read the manuals. Over 50% in attendance indicated they did!

Tom Karns (U. of Oklahoma) suggested that the manufacturers should be more efficient about informing customers about hardware/software updates, and what new features/fixes are incorporated in those updates. We customers need to know in a timely manner when updates are available, and need the information to make a decision whether an update will improve capabilities sufficiently to justify expenditure of funds. Tom also suggested that, because all the manufacturers depend on computer capabilities, an
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

electronic mail connection would be a good communications channel to open. Finnigan reported the availability of an electronic bulletin board at the Finnigan Institute. KRATOS, in addition to their electronic bulletin board, offers a new telephone FAX tablet machine that allows two-way interactive communications that they are trying out.

Hank Fales (NIH) and Sandy Markey (NIMH) made the strong recommendation to the manufacturers, endorsed by the entire audience, that they dedicate themselves more to listening to users' comments and criticisms. The users' group meetings preceding ASMS have become in recent years more a sales pitch and less a problem-solving session. The manufacturers should not feel threatened so much by this kind of dialog. The buyers of their instruments have staked much of their own reputations on these large dollar amount purchase, and don't want the manufacturers to go away. Indeed, they suggest the manufacturers should put more effort into summarizing engineering updates to existing instruments in order to make them work better. Charlie Judson (U. of Kansas) offered the comment, from the viewpoint of a former CEC representative on the receiving end of users' comments, that this type of dialog is extremely productive for the manufacturers. Larry Mallis (U. of Iowa) offered that he likes both the informal one-on-one conferences and the public "gripe" sessions. Both have an important role to play.

Rick Thompson (Merrell Dow Research) asked the manufacturers how they track information coming in from the field on problems and complaints from their service engineers and customers. Hewlett-Packard tracks warranty repair reports very closely to identify recurring faults. Field engineers' reports are computerized and tracked back into the factory as much as possible. Finnigan tracks the number and kind of parts being drawn for service, and tracks telephone support requests and problems. JEOL writes reports on customer comments from demonstrations and training courses. VG and KRATOS have had a relatively small customer support organization in the past and have used communication among the group members, but both are now implementing formalized problem logging and tracking systems based upon H-P's model.

Interest Group Business:

This year's workshop was attended by approximately 75 people. We hoped that the topic would have a wider appeal than to just those affiliated with the Academic Lab Managers' Interest Group. Indeed, a number of people participated who are not directly affiliated with our Interest Group.

Suggestions were collected for future activities for this interest group, and for future ASMS meetings forwarding to the ASMS board. Suggestions for the group were: to continue developing the instrument list; to conduct surveys again for new and changing information; a workshop on hints and tips for evaluating instrumentation. Larry Mallis has reported some statistics from his work on the instrument list, which are given below. Contact him directly for details. Because of my recent change of affiliation from an academic Institution to a pharmaceutical manufacturer, the issue of my finishing my term of office as group coordinator was discussed. Those present agreed to my finishing my term of office.

The ASMS Board has suggested that we expand our purview to include our colleagues who do a similar job in industry. Speaking on behalf of several of our members (including myself) who have crossed this border in both directions, the problems we deal with -- both scientific administrative -- are very similar. I think expansion of our group definition will prevent the group from becoming insular, and further foster the breakdown of the barrier between the academic and industrial worlds. Forthcoming publications from ASMS will show the name of our group as the Analytical Lab Managers' Interest Group, whose stated purpose is to address "problems and solutions encountered by those responsible for mass spectrometry service facilities in both academics and industry."

1757
Biomedical Interest Group Report

The Biomedical Interest Group meeting was held on Thursday, May 23. The meeting was focused on Strategies for Natural Products Structure Elucidation with ca. 35 people in attendance. The meeting was opened with a request from Steven Carr (SmithKline Beecham), who has accepted the responsibility for chairing the interest group for an additional two years, for suggestions for symposia topics, workshop topics, plenary lecture topics, and possible speakers for any of the above.

After initial opening comments on a general scheme for natural products structure elucidation by Mark Hemling, Tony Thompson (U. Illinois) discussed the utility of high resolution methods. Molecular formula that are generated can be constrained by other available information such as $^{13}$C-NMR or the number and type of heteroatoms determined by derivatization. Selection of the best elemental composition can also be aided by comparing the observed isotope pattern with those calculated for each of the possible compositions. It was noted by Marshall Siegel (Lederle) that computer programs have been described in the literature (K. Blom et al.) which automatically correlate the elemental compositions with the observed isotope patterns to provide a rank ordered list of most likely compositions. With regard to suitable reference standards, the audience was directed to Vol. 193 of Methods In Enzymology (J. McCloskey, Ed., Academic Press, 1990).

The use of derivatization to aid in characterization of natural products was discussed by Jim McCloskey (U. Utah). The topic is so broad that one should go to special sources (Knapp, Handbook of Anal. Deriv. Reactions, Wiley, 1979; Blau & King, Handbook of Deriv. for Chromatog., Heyden, 1978; Anderegg, MS Reviews 1988, 7, 395). While derivatization is used for many purposes, several are of particular value in elucidating structure. These include modification/enhancement of fragmentation to enhance molecular ion yield or to produce structurally informative ions and the identification of specific structural groups. A good derivatization reaction is high yielding with one predictable product which produces an informative mass spectrum. It is also desirable that the product be stable, that labelled reagents are available, that the reaction be microscalable, and that the reagents be commercially available. Two useful derivatizations are trimethylsilylation and methylation. TMS-derivatives are readily made with BSA (BSTFA may be too reactive/unpredictable, e.g., in the presence of CH$_3$CN) although the derivatives of primary amines are relatively labile, especially in FAB matrices. Methylated compounds tend to be fairly stable and are easily made using the Kerek procedure (Ciucanu & Kerek, Carbohydr. Res. 131, 209-217). Hank Fales made several useful suggestions including the use of special narrow bore vials (Wheaton and possibly Peninsula Labs) to prevent the complete evaporation of small solvent volumes and the use of cardboard backed/thick Teflon septa to prevent the leaching of plasticizers from silicon-backed septa.

H/D exchange to determine the number of active hydrogens in an unknown was also addressed by Jim McCloskey. H/D exchange can be done in EI by adding a drop of D$_2$O to the sample on the probe although back exchange can occur with H$_2$O on the source walls. H/D exchange in FABMS/LSIMS is readily done with labelled matrices which are commercially available or may generated as needed by exchange with D$_2$O. H/D exchange in NH$_3$-DCI using ND$_3$ should be done with care as it is possible to exchange aromatic hydrogens and other relatively acidic protons due to the relative gas phase basicity of ND$_3$. The same is true in thermospray. Up to ten hydrogens may be counted directly and computer programs (Sethi et al. or Verma et al.) are capable of dealing with higher numbers by correcting for the extent of labelling in the glycerol peaks from FAB experiments.

A perspective on the proper role for LCMS in natural products structure elucidation was presented by Brad Ackerman (Marion Merrell Dow). LCMS is most generally useful for characterizing similar compounds in a series; otherwise, compounds normally need to be isolated in order to get other spectroscopic data. LCMS may also be useful when chromatophores are not present for UV detection. For molecules below MW 1000, thermospray is acceptable and allows for flow rates in the 1 mL/min range. LC/continuous flow FABMS works for compounds below MW ca. 5000 but sensitivity is compound and mass dependent. LC/CFFAB is amenable to low flow rates and provides a good balance between molecular ion and fragment information. LC/ESI/MS is also amenable to low flow rates with good sensitivity. It may be a nearly universal ionization technique and provides primarily MW information in the normal operating mode. Several examples (castanospermine, telocoplanin) were presented to demonstrate the utility of LC/MS.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

The ability to generate and observe fragment ions from natural products by CAD-MS/MS was discussed by Mark Proelke (U. Illinois). This can be particularly in FABMS when matrix background peaks are obscuring possible fragment ions. Experience in the UI MS lab suggests that CAD with Ar in a grounded collision cell is most useful for compounds of MW > 1000, while He in a floated cell (4 kV) produces the best results for compounds of MW < 1000. As examples of the utility of MS/MS, Mark showed that a suspected glycosylation of an insect neuropeptide was occurring on a Trp residue with relevant fragment ions being shifted the incremental mass of hexose. In the analysis of novel ectinosidins, the similarity of the MS/MS spectra to previously characterized compounds reduced the time required for analysis of the NMR data. In a similar way, the MS/MS spectrum of an unknown derived from a mummy resin was compared to the MS/MS spectrum of the compound proposed from all of the spectroscopic data, and identity was thus established.

Computer tools which might aid in the analysis of natural products were presented by Marshall Siegel (Lederle). These programs can be used to correlate the mass spectrum of compound with a structure proposed from all of the spectroscopic data. Once this has been done, one can more rapidly assign the mass spectra of related compounds. The program takes as input the atoms or superatoms ("indivisible" substructures) of the proposed structure and breaks bonds in all possible ways to attempt to match masses in the spectrum. The output lists the possibilities with the number of bonds that were broken to produce the ion since the most intuitive answer has the fewest number of bonds cleaved. Programs similar to that described by Marshall are available on the VQ Opus data system and from Trinity Software.

As an example of the way various of these methods can be used for analysis of natural products, Justin Stroh (Pfizer) presented the structure elucidation of a spider venom toxin. He pointed out several general issues including a) the need to resolve apparently conflicting data; b) that assumptions are dangerous but necessary at some point; and c) that lack of purity can lead to problems. After analysis of all of the data at hand, a structure was proposed and synthesized. MS characterization of the synthetic material showed that the proposed structure was wrong. Further analysis of the data and reconsideration of certain assumptions resulted in a second structure being proposed and synthesized; this also proved to be incorrect. Reevaluation of the data and the assumptions made and resolution of the conflicting data allowed for synthesis of a final proposed structure which proved to be correct.

Finally, Bob Boyd (NRC, Halifax) presented the bioassay-directed isolation, purification, and characterization of domoic acid, a marine neurotoxin which is occasionally present in mussels in sufficiently high amounts to cause neurological effects including coma and death. This is an elegant example of the power of various mass spectrometric methods when combined with other techniques to rapidly identify the nature of biologically active compounds.

MEETING NOTES

Suggestions for future activities by the Biomedical Interest Group include:

Plenary Lecturers or Topics: Forensic chemistry; NMR spectroscopy (Ad Bax, NIH or Kurt Wutrich, ETHZ, Zurich); posttranslational modifications of proteins (Finn Wold, Univ. of Texas); funding of biomedical research (Bernadine Healy, NIH); frontiers of immunology (John Smith, Merck or Lee Hood, CalTech); chemical mutagenicity and carcinogenicity (Bruce Ames)

Symposia Topics: Mass spectrometry in environmental toxicology

Workshops: No suggestions

Respectfully submitted,

Mark E. Hemling
Steven A. Carr

1759
A workshop to discuss current priorities and goals in NIH funding of academic research, and their real or perceived effects on the academic community of mass spectrometrists, was held on Tuesday evening, May 21. The workshop format was a panel with audience participation. Panel members were the two organizers, Catherine Costello and Charles Coulter, joined by Dennis Bier, Dept. of Internal Medicine, Washington University School of Medicine, Michael Gross, Dept. of Chemistry, University of Nebraska, and Kenneth Standing, Dept. of Physics, University of Manitoba.

Dr. Costello summarized some of the areas that the workshop was intended to cover, and most of them received at least some attention during the following two hours: New ideas and approaches that are becoming available or are on the horizon; potentials for interdisciplinary research; sources for instrumentation funding (Resources, Shared Instruments, Project Grants); effects of funding levels on staff, training, development, access for biomedical and other researchers to state-of-the-art instrumentation, career development of young investigators; grants management and review; methods for effecting changes inside/outside NIH; other sources of support.

Dr. Coulter opened the workshop discussion with a summary of the report "Technologies for the Future: Opportunities and Needs in Structural Biology and Molecular Medicine" which resulted from a recent BRTP workshop. In many areas (MS, NMR, X-ray, 2D gels), this report concludes that the technology presently leads the applications, and recommends that more funding, in the short-term, should be available for applications in the areas of immunology, gene transformations and specific diseases (AIDS, Alzheimer's) than for instrument development. He emphasized the need for program relevance, i.e. a contextual relationship is important - one is better off addressing the problem of 'cellular recognition' rather than 'carbohydrate chemistry.' At the present time, few Study Sections are giving much priority to funding for new major instrumentation. The only funds being approved are those with very apparent program relevance, that is, likely to provide answers to specific biochemical questions, rather than geared toward development of generally applicable new techniques.

Dr. Bier described the NIH MS Resource at Washington University. Here there is much quantitative analysis done to support clinical studies of investigators from many institutions. It is presently difficult to get fixed costs for these studies (support for the instrumentation and staff) from the NIH Divisions that otherwise support the disease-related investigations. He discussed how Core Research (Technological Research and Development) contributes to all other activities, but its role is not perceived by investigators who are interested in solving their research problems by any available means, not interested in MS per se.

Prof. Gross addressed his comments to the review process - specifically the routing of a large number of MS-based proposals to the Metalllobiochemistry Review Committee, a group whose overall composition is not appropriate for review of MS proposals. He suggested that a Bioanalytical Chemistry study section be formed. (This suggestion was heartily approved by most attendees.) Mike also pointed out that NSF no longer funds Resources. Attitudes within the NSF Biology Division presently seem more progressive and open to new approaches than are those of Chemistry.

Prof. Standing commented that the 2-year funding cycle leaves only a narrow time window for an investigator to demonstrate the success of a project. Longer grants, especially when instrument development is involved, would be more practical for both agency and grantee. The Canadian system tends toward longer-term funding of individual researchers.
The general discussion involved panel members and many in the audience, which numbered 60-160 participants during the course of the workshop, and brought out several themes: (1) Instrumentation funding without concomitant staff support is not cost-effective nor is nursing old instruments beyond their reasonable lifetimes. (2) The mass spectrometry community as a whole - users and manufacturers alike - does little in the way of public relations to advance its own cause, when compared to other groups - we should become more active and more sophisticated in focusing the attention of NIH administration, Congressional members and staffs, and our biochemical collaborators on the requirements for consistent support for major instrument development, purchase, and operation, and on making our contributions visible outside the MS community. (3) More active involvement of the manufacturers' group in ASMS through formation of a committee having its own agenda and open to considerations such as the sponsoring of fellowships, etc., might be helpful to all. (4) Some academic support is available through fee-for-service work for local industry, but one must take care to avoid competition with commercial laboratories and to include a research component if academic-industrial projects are included in NIH funding requests. (5) Interest is high for involvement of mass spectrometrists in a future Workshop similar to the one described for Structural Biology. (Omission of mass spectrometrists from inclusion in the Structural Biology workshop was a bit disheartening, but perhaps future programs will compensate.) (6) In some areas, technology does not presently lead the needs of the pharmaceutical industry. The pharmaceutical industry, in particular, has problems for which existing technology is inadequate. (7) Remedying the situation with regard to the Metallobiochemistry Study Section should receive very high priority, with members, including the ASMS board, encouraged to take an active role in effecting change.

Item (2) struck a responsive chord with many attendees and was the focus of numerous post-workshop discussions. Most seemed to feel strongly that ASMS should be looking into ways of collaborating with other science societies to promote, via lobbying efforts, research funding in the US.
An audience of about 170 attended the workshop of the Desorption Ionization interest group, which focussed this year on the subject of sample manipulation in FAB mass spectrometry. Following a few opening remarks, Richard van Breemen of North Carolina State University discussed some of his work with nitrocellulose films in the FAB determination of peptide mass spectra. Monolayer coverage of the nitrocellulose as a film deposited from an acetone solution onto the FAB platform was optimal. Too much nitrocellulose actually increased the level of chemical noise in the mass spectrum. Variation of the sample platform material from gold to copper to stainless steel did not produce any spectral effect. The nitrocellulose may act to prevent the irreversible adsorption of the sample molecule on the metal surface, and aid in the dissolution of the sample in the FAB solvent matrix which is applied after the sample has been applied to the film. Nitrocellulose also seems to act to reduce the extent of (M+Na)+ ion formation, although the cause of this effect is not yet clear. The signal-to-background levels in the mass spectra of several peptides were shown to increase with the use of the nitrocellulose surface modifier; absolute signal levels did not change appreciably. The nitrocellulose used in this work was obtained from Hercules, and dissolved in an acetone solution at a concentration of about 1ug/ul. Nitrocellulose from other sources may contain modifiers and surfactants. As a result, it may not dissolve completely, or the presence of the wetting agents may corrupt the FAB mass spectrum.

Susan Richardson of the US Environmental Protection Agency in Athens, GA discussed the use of liquid secondary ion mass spectrometry (FAB) in the negative ion mode for the determination of sulfonated azo dyes in wastewater. These dyes were either mono or di-sulfonated. The dyes were purified by liquid chromatography and prepared as standard solutions in a number of solvent matrices, including meta-nitrobenzylalcohol, glycerol, thioglycerol, diethanolamine, hydroxyethyldisulfide (HES), and a mixture of HES and thioglycerol, and the eutectic mixture between dithiothreitol and dithioerythritol. Comparative rankings of the signal intensities for the (M-Na)- ions of the dyes investigated showed that nitrobenzylalcohol was the preferred matrix for these compounds. A molar ratio of 100-200/1 provided the best signal quality, and in most cases, solubility of the dye in the matrix seemed to be the limiting factor. The effects on the mass spectra of changes in the primary ion energy (a cesium ion gun was used as the primary particle beam source) showed that for most of the dyes, a beam energy of about 10-15 keV provided the best signal, and this optimum energy was about the same for both the lower and the higher molecular weight dyes. Discussion from the audience suggested that the more highly sulfonated dyes do work better in the diethanolamine matrix than in the nitrobenzylalcohol, although the sensitivity is lower than might be expected for compounds that exist in the solutions as pre-ionized species.

Ken Busch presented the brief story of FAB flakes, which is the characterization of the product formed on the surface of meta-nitrobenzylalcohol on irradiation by the primary particle beam. This project was the research project of F. A. Byrdy, who first characterized nitrobenzylalcohol as obtained from the manufacturers (it includes trace levels of aldehydes and several other related compounds, as well as BHT anti-oxidant), and then used FAB in a synthetic mode to prepare and collect several hundred mg of the product. No FAB spectrum could be obtained, nor could a solvent be found in which NMR spectra could be measured. It was concluded that the product is the result of a condensation polymerization reaction (loss of water) between molecules of the nitrobenzylalcohol. It was noted that the use of NBA in a continuous flow FAB probe can lead to plugging of the line, presumably due to formation of this polymer at the tip of the entrance capillary.

Respectfully submitted,

Kenneth L. Busch
The Environmental Applications Interest Group held its annual workshop on Wednesday, May 22 at 1:00 pm. The topic for this year's workshop was "Methods for Environmental Field Analysis" which dealt with the application of transportable mass spectrometers for on-site environmental monitoring. Various aspects of field analysis were addressed during short presentations by five different invited speakers. Overall, the workshop was well attended with approximately 120 participants. The workshop speakers and the topics of their presentations are listed below.

Stephen Billets of U.S.E.P.A. Las Vegas, NV.

Presented a summary of the EPA Superfund Innovative Technology (SITE) Program and talked about the need for new technologies which could be used for rapid field screening and site characterization. Discussed the potential role of mass spectrometry as a tool for on-site environmental measurements and encouraged ASMS members to play an active role in this endeavor.

Phil Hemberger of Los Alamos National Laboratory, Los Alamos, NM.

Discussed the development of a transportable GC/Ion Trap Detector and its application to the on-site measurement of volatile organic compounds in water. Emphasized the successful use of commercially available components as opposed to the need to custom design and build instruments for field use.

John Wronka of Bruker Instruments, Billerica, MA.

Talked about actual results from the evaluation of a mobile quadrupole mass spectrometer at an EPA Superfund site. Results which were reported demonstrated that a mobile mass spectrometer could indeed perform rapid screening and quantification of a variety of different target analytes and compare favorably with established laboratory procedures.

Brian Eckonrode of Viking Instruments, Reston, VA.

Provided a summary of the capabilities of a new portable GC/MS (quadrupole) instrument for environmental monitoring applications. Discussed the performance of a thermal desorption sampling interface for semivolatile compounds.

Greg Hurst of Oak Ridge National Laboratory, Oak Ridge, TN.

Reported on the use of a direct sampling ion trap mass spectrometer for the rapid screening of volatile organic compounds in water and soil. Presented results showing that screening and quantification of target analytes could be accomplished at low part-per-billion levels at less than 3 minutes per sample by performing direct purge into the mass spectrometer.

Marcus B. Wise
Oak Ridge National Laboratory
The 39th Annual Conference saw a lively interest in the topic of quadrupole ion traps, beginning with the plenary lecture of Professor Paul, Bonn, and continuing with a number of presentations which covered improvements in ion isolation, mass resolution, combinations with chromatography and simulations of ion motion. This made it particularly appropriate that, late in the week, there should be a workshop devoted to the topic of fundamental aspects of ion traps. Interest in the topic was reflected in the fact that approximately 250 people attended.

The workshop started with a discussion of current capabilities of the instrument in chemical analysis, Rick Yost reviewing scan modes and performance capabilities in a variety of applications. Some figures of merit were then discussed, with considerable audience participation. Included were questions of dynamic range, injection efficiency, CID efficiency, ion temperatures and alternative activation methods.

Perhaps the topic of most intense interest was that of ion motion in the trap. Hans-Peter Reiser described results of a simulation program which displayed ion motion and Randy Julian discussed a large scale simulation which includes the effects of space charge and collision dynamics. Michel Weber-Graubau, John Todd and several others also contributed to this discussion.

The organizers appreciate the fine response, especially the audience participation in this workshop.

Graham Cooks and Rick Yost
In the first 5 months of 1991, over 130 papers dealing with the chemical and physical properties of buckminsterfullerene and its congeners were submitted for publication, corresponding to an incredible rate of nearly one new report per day. The flurry of research activity dedicated to this new form of carbon comes on the heels of the discovery by Krätschmer and Huffman that bulk quantities of C_{60} and other fullerenes could be easily extracted from synthetic soot. The physical characterization of these new materials is a vital task that has rallied together researchers from otherwise disparate corners of chemistry. Mass spectrometry continues to play a key role in these efforts, and it is therefore entirely appropriate that the ASMS provide a forum in the form of this workshop for presenting new results related to the mass spectrometry and gas phase chemistry of fullerenes.

Steve McElvany of the Naval Research Lab inaugurated the workshop with a brief chronology of progress in fullerene research since Smalley first proposed the "Bucky-ball" structure for C_{60} back in 1985. A listing of reviews and current achievements in this field is available through INTERNET at the e-mail address below:

BUCKY@SOL1.LRSM.UPENN.EDU

A. G. Marshall, J. V. Coe and co-workers at Ohio State University and Bob Hettich and his colleagues at Oak Ridge National Lab independently reported the observation and identification of the doubly-charged fullerene anions C_{60}^{2-} and C_{70}^{2-}. Both groups utilized laser desorption of fullerene extracts from synthetic soot in conjunction with FTICR. The identity of these ions was verified through a combination of high resolution mass measurements, double resonance ejection experiments, and by comparing frequency shifts for singly- and doubly-charged ions as a function of ICR trapping voltage. The origin of the doubly-charged ions was proposed to be thermionic emission from the laser-heated graphite surface rather than multiple electron attachment in the gas phase.

Lee Sunderlin and this author in collaboration with Bart Kahr and Dor Ben-Amotz of Purdue University described the gas phase reactivity of C_{60} and C_{70} under flowing afterglow conditions. These ions react slowly, if at all, with O_{2}, the strong Lewis acid BF_{3}, the strong Bronsted acid CF_{3}COOH and NO. However, both fulleride anions do react efficiently with NO to form the monoadducts.

Mark Ross summarized the past and on-going studies of carbon cluster chemistry at NRL using FTICR and other methods. Recent research on fullerenes has yielded measurements of ionization potentials, proton affinities and information about unimolecular and bimolecular reactions. In particular, CID of multiply-charged fullerenes produces lower charge-state fragments as well as charge-stripping and electron capture. Surface collisions of fullerene ions are found to be surprisingly ineffective in producing fragmentation.
R. Graham Cooks, Bart Kahr and Dor Ben-Amotz of Purdue described the higher mass fullerenes that can be observed from soot extracts under El and CI conditions. Satellite peaks at 14, 15, 16, 17 mass units higher are observed for C_{60}, C_{70} and other clusters; the M + 16 signals are attributed to monoxygenated cluster ions. It was proposed that these carbon cluster derivatives are created during the arc-welding process and/or during solvent extraction of the soot. Irradiation of the benzene extract from the synthetic soot yielded sequential addition of methylene groups to the oxygenated clusters, while irradiation of ether extracts produced multiple oxygen atom additions.

Alex Harrison and colleagues of the University of Toronto reported that collision-induced dissociation of C_{60}^+, C_{70}^+, C_{72}^+ and C_{74}^+ occurred by loss of an even number of carbon atoms, in agreement with photodissociation studies of C_{60}^+ and C_{70}^+. By contrast, upon collisional activation C_{60}^+ and C_{70}^+ fragment by loss of 1, 2 and 4 carbon atoms. Collisional charge inversion of C_{60}^+ and C_{70}^+ leads to positive ions which fragment by loss of an even number of carbon atoms.

In a collaborative effort, Helmut Schwarz, Thomas Wieske (Berlin), Wolfgang Krätschmer (Max Planck), and Diethard Bohme (York University) carried out high-energy (8 keV) CID experiments with C_{60}^+ and C_{70}^+ in a four sector instrument. With most common target gases (H_2, D_2, Ar, Ne, etc.) the familiar C_{60}-loss fragments were observed. However, with He targets new signals appear 4 mass units higher than each of the C_{60}-loss products, and with "He [M - C_{60} + 3] signals are observed. Analogous results were obtained with C_{70}^+ . These results clearly indicate that a helium atom has been incorporated into the carbon clusters in the course of the collisions. These remarkable observations constitute the first evidence for formation of endohedral cluster compounds from a bimolecular reaction.

Kenny Caldwell and Michael Gross (University of Nebraska) in collaboration with Sam Hsu (Exxon) reported on the measurement of the second ionization energy of C_{60} obtained by charge stripping. A value of 12.5 ± 0.5 eV was obtained. The curious doublet for the loss of C_7 (MIKES scan) was also noted and explained as formally being loss of C_7 and (C_7 + He) from the parent (or precursor) ion, consistent with the results from Schwarz’s laboratory in Berlin.

Mike Bowers (UC Santa Barbara) described a new ion chromatography method that can separate geometric isomers of ions, and its application to positively charged carbon clusters formed by laser ablation. The method relies on the measureable differences in mobility of ions with different shapes. Seven different families of carbon cluster cations have been observed. Small clusters (n > 10) tend to be linear; intermediate size clusters (n = 10 to 40) are primarily two-dimensional ring structures; larger clusters tend to be fullerenes (n > 40 for n even), although odd clusters retain substantial fractions of planar structures above C_{60}^+ .

Meeting Notes: Before beginning the workshop, suggestions for future plenaries and symposium topics that fall within the "Fundamentals Interest Group" purview were solicited from the gathering (75 - 100 attendees). Topics of interest for next year include metal ions, ion spectroscopy and interstellar chemistry. Additional suggestions may be sent to me at Purdue.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics

Workshop for History of Mass Spectrometry Interest Group

There were two announcements of general interest made before the more formal part of the program. First, Mike Grayson announced the completion of the oral history he has made from conversations with A.O. Nier. The document looks marvelous. Second, George Waller announced that his donation to the Smithsonian of the last remaining prototype of the LKB 9000 mass spectrometer, out of 3 that were originally made, has been accepted by that institution.

The interest group organized a workshop on "Oral History: What It Is and How to Take One" on Monday evening of the meeting. The workshop was in the form of two sequential presentations, both made by Dr. James Bohning of the National Center for History of Chemistry, of which the ASMS is an affiliated member. Dr. Bohning was trained in chemistry, but became interested in the history of chemistry, developed techniques in taking oral history and finally, in 1990, retired from a 30 year teaching career at Wilkes College to join the NFHC Staff as Assistant Director for the History of Chemistry. His first presentation was a definition of Oral History as well as excerpts from interviews with prominent chemists which he or his colleagues at NFHC have conducted. Oral history, as defined by Jim and in brochures from NFHC, is a tape recorded structured conversation that attempts to construct an "orchestrated autobiography" of the narrator. The results are intended to be part of the historical record and available for future use by researchers. Interviews are designed to obtain insights into what lies behind the public face of science that is preserved for posterity in publications, etc. Family background, factors that influenced career decisions, personal recollections that are tied to publication of experimental and theoretical work, etc. are all appropriate topics for the interview. Each interview is designed to integrate the personal aspects with public aspect of a career, and to place both within the context of broad developments of science.

The second presentation that Dr. Bohning made was directed toward introducing people to the techniques of taking an oral history. The goal of this presentation was to begin developing a small pool of ASMS members who will be willing to do oral history interviews, as Mike Grayson has completed with Al Nier and has begun with Sy Meyerson. Jim made this presentation by walking the audience through a set of notes he has prepared. The notes outline the interview process in terms of preparation, equipment necessary, areas to cover in the interview,
guidelines for intelligent listening, transcription and editing of the taped interview, obtaining final documents and releases, etc. This remarkable instructional period was followed by questions.

As Jim Bohning said during his presentation, the major developments in mass spectrometry are relatively recent, and thus The History of Mass Spectrometry Interest Group, and the Society as a whole, have a unique opportunity to capture history from its living participants. He feels that if the ASMS can develop a list of of potential interviewees that is mutually acceptable to both the Society and to the NFHC, then the NFHC and the staff of the Beckman Center for History of Chemistry will do the transcriptions of the interviews, with the interviewer doing the subsequent editing. (As Mike Grayson will gladly verify, the transcription is a major component of any oral history, and the NFHC's offer to perform this task could represent the difference between an effective oral history project in the ASMS or having no project at all.) Completed, edited interviews would be integrated into the Center's catalog of oral histories. In addition to several people stating interest in participating in such projects, and proposing names of potential interviewees, it was the sense of the workshop that the ASMS should solicit names of potential interviewees from the membership at large with the goal of developing the list proposed by Dr. Bohning. At the present time, it will be proposed to the Board that this solicitation be made in the fall issue of the Spectator. Copies of the outline notes for conducting interviews may be obtained by request from:

Al Yergey  
NIH  
Building 10, Room 6C101  
Bethesda, MD  20892  
301/496-5531

Signed:  
Alfred L. Yergey, Chairman of Interest Group on History of Mass Spectrometry.
A brief business meeting and the workshop were held on Tuesday, May 21 at 8:00 pm. About twenty people attended. Attendance was limited because many of the group’s members attended the Alfred O. Nier Symposium two weeks earlier and did not come to the ASMS meeting.

The workshop addressed the precise measurement of noble gas isotopic ratios. Philippe Chastagner, Westinghouse Savannah River Co., reported that there is increasing emphasis on the development of methods of measuring the concentrations of the stable fission product isotopes of Kr and Xe that are precise and accurate within ±20 ppm. These measurements are needed for: monitoring atmospheric dose levels; nuclear emergency response; treaty verification; and meteorological transport studies. Current analytical limitations include isobaric interferences, "memory" problems and lack of agreement on the global isotopic composition of natural Kr and Xe.

John Wacker, Pacific Northwest Laboratory reported on experiments in which degassed quartz was exposed to noble gas mixtures (0.02% Kr & Xe in 32% Ar, balance Ne) for 24 hours at 25°C and atmospheric pressure following which the gas was pumped out. After one hour of pumping, the quartz retained 0.3% of the gas-phase Xe and ~10 ppm of each of the other gases. Baking at 1000°C was required to reduce the trapped gases to background levels. Following these tests, he redesigned his equipment and used borosilicate glass, Inconel and stainless steel, materials that had lower gas retention than quartz. And, he followed rigorous cleaning and baking procedures to reduce the blank level to acceptable levels.

Richard Rankin, Idaho National Engineering Laboratory, reported that the Westinghouse Idaho Nuclear Company (WINCO) Gas Analysis Lab performs an average of 130 high precision noble gas analyses per month with a hybrid Finnigan MAT 271/251 gas mass spectrometer. Sample sizes range from 0.07 to 4 cm³@STP and are contained in breakseal tubes. The instrument is equipped with a dual viscous flow, ratioing inlet system and 3 ion collectors. In this system, the samples are compared with a laboratory reference sample - a large supply of which is available. Internal precision has been as good as 10 ppm. Typical sample analysis precision ranges from 20 to 50 ppm.

Submitted by Philippe Chastagner, workshop organizer.
Nomenclature for Mass-to-Charge Ratio

A Workshop Sponsored by the Measurements and Standards Committee

The Measurements and Standards Committee sponsored a workshop on nomenclature for mass-to-charge ratio. After a welcome by Michael Bowers, Alan Rockwood gave a short presentation. This was followed by an open discussion. At the end of the workshop, participants returned an informal survey which has been forwarded to the Measurements and Standards Committee for further consideration.

It was proposed that mass spectrometrists adopt a unit for mass-to-charge ratio to be called a thomson (in honor of J. J. Thomson) or some other suitable name. The $^{12}$C$^+$ ion would have a mass-to-charge ratio of $11.9994514198$ thomsons and the $^{12}$C$^-$ ion would have a mass-to-charge ratio of $12.0005485802$ thomsons. Thus, the thomson would have a value of $1.0364272 \times 10^{-8}$ kilograms/coulomb with the polarity of the ion included in the scale. A proposed abbreviation for the thomson was also discussed, and it was pointed out that the originally suggested abbreviation, Th, conflicts with the abbreviation of thorium so something like Tn might be a better choice.

Supporters of the nomenclature proposal generally felt that present nomenclature has encouraged (or at least failed to discourage) imprecise usage, particularly the use of terms related to mass when mass-to-charge ratio is meant. In part this may be attributed to the lack of a convenient name for a unit of mass-to-charge ratio. Imprecise usage may lead to faulty communication or worse, particularly when one is dealing with multiply charged ions. In the past this imprecision has not been a great problem because multiply charged ions were relatively uncommon, but with the advent of techniques capable of producing tens or even hundreds of charges on an individual ion the distinction between mass and mass-to-charge ratio must be more strictly maintained. For example, according to one anecdote given at the workshop, the confusion between charge and charge-to-mass had led to false conclusions about the upper molecular weight limit of a particular analyzer when used with electrospray ion sources. It was argued that defining and naming the thomson as an explicit unit of mass-to-charge ratio would help enforce a strict distinction between mass and mass to charge ratio and lead to clearer and more concise communication. A second reason for supporting the proposal is that given the central role of mass-to-charge ratio in the field of mass spectrometry as the quantity actually measured in mass spectrometers, it makes sense that the unit for this quantity be given a convenient name.

Opponents of the proposal countered that $m/z$ is already a very clear, well defined and convenient terminology. It was also pointed out that the "thomson" is not self defining, that like the hertz, the units are not explicitly conveyed by the name. This could confuse some readers, particularly the uninitiated. (Whether $m/z$ is a self defining unit was not discussed, but at least it has become understandable through wide and long usage). It was also pointed out that imprecision is not inherent in present nomenclature and that by a combination of present nomenclature and careful language one can write and speak without ambiguity, although at times some extra wordiness might be required.

Both sides presented good reasons for their respective positions, and this seems to have been reflected in the vote. Forty-seven response forms were returned with 57% in favor of the proposal, 34% opposed, and 9% uncommitted. (Not counted in the balloting were letters of support from two editors, and the moderator (ALR) clearly advocated the proposal but didn't vote.) Regardless of the positions on the proposal itself, there was widespread agreement that imprecise communication is sometimes a problem and that mass spectrometrists should be encouraged to avoid incorrect or ambiguous usage.
A surprising part of the workshop was a widespread disagreement on the correct dimensionality of \( m/z \). Three opinions were expressed. The view of the workshop leader going into the workshop was that \( m/z \) represents mass-to-charge ratio so the proper dimensionality would be mass divided by charge. This would be the correct dimensionality to use in the equations of motion for a charged particle in a mass spectrometer and it would be analogous to the usage in tables of fundamental constants in which (for example) the charge-to-mass ratio of the proton \((e/m_p)\) is given as \(9.578309 \times 10^7\) coulombs per kilogram. This is also closely related to the terminology of "grams per equivalent" and "equivalent weight" from electrochemistry. A second more popular view was that \( m \) is a mass but \( z \) is a pure number (being charge number, not charge), so \( m/z \) would have dimensionality of mass. A third view held that both \( m \) and \( z \) are dimensionless so \( m/z \) is a dimensionless number. The official definition of \( m/z \) is that it is a dimensionless number that is proportional to the charge-to-mass ratio. In this respect it somewhat resembles other dimensionless numbers such as reduced parameters from thermodynamics (e.g., reduced temperatures) and dimensionless groups from engineering (e.g., Reynolds numbers). Calling \( m/z \) the mass-to-charge ratio is a bit of convenient linguistic shorthand that is not strictly correct. (A subtle difference between the thomson and \( m/z \) then would be that the thomson has the dimensionality of mass/charge while \( m/z \) is dimensionless, although in magnitude the two are identical.) This widespread disagreement on the correct meaning of such a widely used symbol as \( m/z \) indicates a possible need (or opportunity) for an effort in education or self education. The nomenclature summary that will soon appear in J. Amer. Soc. Mass Spec. is a significant effort in this direction, and it should be read by all mass spectrometrists.

In one of the lighter moments of the workshop, it was pointed out that a natural form to plot electrospray mass spectra would be intensity versus charge-to-mass ratio (rather than the mass-to-charge ratio) resulting in almost evenly spaced peaks. The unit of charge-to-mass ratio could be called a nosmoht which is thomson spelled backwards. (This is analogous to the unit of inverse resistance, the mho, which is ohm spelled backwards.) However, support for the nosmoht appeared to be minimal.

Alan L. Rockwood
Battelle, Pacific Northwest Laboratory

Young Mass Spectrometrists Interest Group

The topic for the Sunday evening workshop was "Successful Grant Writing." This topic was covered in the workshop four years ago, but the increasing difficulty in obtaining funding made the subject appropriate to revisit. The workshop was well attended by both young and "more mature" mass spectrometrists. Five speakers gave excellent presentations which are summarized below.

Jon Amster from the University of Georgia gave an overview of the technical aspects of grant writing. He prepared two tables, shown on the next page, that detail the overall budget, review process, typical funding level, and hit rate (percentage of grants funded) for most funding agencies. He described the benefits of grant writing, especially the focus it brings to one's research ideas. Jon suggested applying for smaller, higher hit-rate grants during the first few years to gain experience in grant writing and to generate publications that will help in obtaining larger funding from agencies such as NSF or NIH.

Jennifer Brodbelt-Lustig of the University of Texas at Austin gave tips on things to do: give details on planned experiments, be focused on a specific problem, show a time line for progression of experiments, show preliminary results, and give thorough literature citations. Have a friend who has successfully received funding critically read the grant. Study carefully comments from past grant reviews. Finally, try to maintain a high degree of persistence, resilience, and humility.

Mark Ross of the Naval Research Lab gave the perspective of a program reviewer for the office of Naval Research. He emphasized that the major, well-known funding agencies are only part of the funding sources. He highly recommended a booklet published by NSF, "Grant Opportunities for Chemists," as a valuable resource for identifying sources of funding. This booklet may be obtained by writing to the Director, Chemistry Division, National Science Foundation, Washington, DC 20550. Mark gave an outline of an ideal proposal and emphasized that proposal guidelines should be followed closely. He was adamant about not exceeding page guidelines; excessively long proposals have much lower chances of favorable review. He reiterated the need for focus in the proposal, presentation of key experiments, and (for certain granting agencies) the relevance to the agency's mission.

Robert Cotter from the Johns Hopkins University gave the perspective of both an experienced grant writer and reviewer. One should make sure a grant is submitted to the appropriate agency and program, then check to make sure it is really received for review at the proper program. The directions for proposal preparation should be carefully followed, and each section should be distinct; each section should not contain the same material reworded. It is important to keep colleagues (potential reviewers) informed of your research so they can better judge your proposal. Finally, don't burn bridges -- the person whose work you criticize may be a reviewer.

Brian Musselman of JEOL gave suggestions for budgeting and obtaining quotes for grants that request funds for building, modifying, or purchasing instrumentation. He emphasized the need to make sure that all costs are included (e.g., even nuts and bolts where appropriate). Furthermore, he suggested that it is important to state explicitly when contributions are made by a university or department, e.g., institutional funding, machine/glass shop, etc.

Although it was acknowledged the funding is difficult and often frustrating to obtain, there are many ways, some given here, to increase one's chances of getting a piece of the pie.

Respectfully submitted,

John T. Stults,
Genentech, Inc.
The 39th ASMS Conference on Mass Spectrometry and Allied Topics
