The rapidly increasing amounts of sequence data becoming available from a variety of organisms and the prospective availability of several complete genomes in the near future make mass spectrometry a method of choice for protein identification. It has been shown that protein on a gel can be enzymatically digested, whereupon the peptides can be extracted from the gel and analyzed with mass spectrometry. Identification is made either by searching the masses of all peptides against a protein sequence database or by using fragmentation information from a selected peptide in the search. The feasibility of using MS/MS information for protein identification has been demonstrated by others [1,2]. Here we describe a software tool (publicly available on the World Wide Web [3]) for protein identification by comparison of the masses of fragment ions of a peptide (from an enzymatic digest) to masses calculated from an available protein sequence database. It differs from previous protein identification tools in that it allows the user to specify certain information that is primarily observed in tandem MALDI-ITMS of peptides.

In particular, it has been observed that in tandem MALDI-ITMS tryptic peptides containing Arg dissociate preferentially on the C-terminal side of acidic residues [4]. This phenomenon proves very valuable for protein identification, especially when working with small amounts of material extracted from gels. The reduced number of available reaction channels serves to concentrate the fragmentation in those channels. The result is that a peptide containing Arg and Asp/Glu will produce an easily interpretable MS/MS spectrum that only contain a few intense peaks. In general, these spectra do not give part of the sequence as required by some protein identification algorithms [1], but the information that the cleavage occurs at an acidic residue is very valuable for identifying a protein. On the other hand, an MS/MS spectrum without any major fragment ion peaks (which would otherwise be unusable with previous algorithms) indicates that the peptide does not contain acidic residues. This information is also highly selective and usually the mass of a few peptides that do not contain any acidic residues is sufficient to identify a protein.

PepFrag allows for searching protein or translated DNA sequence databases (SWISS-PROT, PIR, GENPEPT, or OWL or dbEST) using any combination of the above-described mass spectrometric information. The databases have been taxonomically divided to allow for faster searches and to minimize the number of unrelated hits. A hypertext form containing the experimental conditions (enzyme, approximate protein mass, place in phylogenetic tree of the species, modifications of amino acids) and measurements (peptide mass, the fragment masses, and other information about the peptide including if it contains or does not contain certain amino acids) is submitted (Figure). The result is a list of proteins that each contain a peptide that satisfies the experimentally determined constraints. The page contains hypertext links to pages containing more information about the proteins.

4. J. Qin and B.T. Chait, J. Am. Chem. Soc. 117 (1995) 5411.

Figure. *PepFrag* is a tool for identifying proteins. It searches a protein sequence database when mass spectrometric fragmentation information is available for one or more proteolytic peptides. In this example proteins from *Saccharomyces cerevisiae* were separated on an SDS-PAGE gel and one band was digested with trypsin. The peptide mixture was analyzed with matrix-assisted laser desorption/ionization ion trap mass spectrometry [4]. Ions at mass/charge of 2329 ± 2.0 Da were isolated (marked with an arrow in the left spectrum) and fragmented into ions with masses 830.0 ± 2.0 , 1015.9 ± 2.0 , 1243.8 ± 2.0 , and 1705.7 ± 2.0 Da (right spectrum). All fungal proteins in SWISS-PROT were searched for tryptic peptides allowing fragmentation into b and y ions. Only one protein, a 71 kDa heat shock protein, match these constraints.

Peptide Fragment-Ion Tags from MALDI/PSD for Error-tolerant Searching of Genomic Databases

Karl R. Clauser, Peter Baker, and Alma L. Burlingame
Department of Pharmaceutical Chemistry, Box 0446
University of California, San Francisco, CA 94143-0446

Peptide sequence information in the form of a *fragment-ion tag* can be readily obtained by Post-Source Decay (PSD) with precursor ion gating directly from **100 fmol quantities** of material in the unseparated peptide mixtures recovered from in-gel digestions.

Under such conditions, the PSD spectra often contain a limited number of fragment-ions which may thwart efforts to manually determine even a cluster of consecutive partial sequence. However, all ions present constitute a tag that has very-high discriminating power for searching sequence databases. We have developed a computer program, **MS-Tag**, that uses these tags to fit the PSD data to a single peptide-sequence in a genomic database.

A Fragment-Ion Tag can be obtained from an MS/MS spectrum and has 3 attributes:

1. A peptide **parent-ion** mass.
2. Masses of individual **fragment-ions** from the peptide. Currently supported ion types include:

a, b, y	a-H ₃ PO ₄ , b-H ₃ PO ₄ , y-H ₃ PO ₄
a-NH ₃ , b-NH ₃ , y-NH ₃	b-SOCH ₃ , y-SOCH ₃
b-H ₂ O, b+H ₂ O	N-term, C-term ladder
internal b, a, b-H ₂ O, b-NH ₃	
3. **Compositions ions** which indicate the presence of particular amino acids. This information can be from immonium and related low mass ions or high mass ions representing side-chain losses from the parent ion.

By considering each ion independently MS-Tag can simultaneously consider a variety of ion types, as does SEQUEST from the Yates group [1], while still enabling error tolerant searching to allow for single mutations, cross-species substitutions, isotope variations and modified amino acids, as does PeptideSearch from the Mann group [2].

Figure 1 shows two PSD spectra obtained with precursor ion gating directly from the unseparated peptide mixture recovered from in-gel digestion of a human placental protein isolated by 2D PAGE. Table 1 shows the results from database searches with MS-Tag.

Mass Spectrometry

PSD spectra were obtained with a matrix of α -cyano-4-hydroxycinnamic acid on a Micromass ToFSpec SE MALDI-TOF instrument equipped with a precursor ion gate. PSD was performed by making 10-12 steps of the reflectron voltage, at each step the voltage was reduced to 75% of the previous step. Segments from individual steps are stitched together to produce the complete spectrum. Data for each step is typically obtained from a separate position on the sample target with 50-75 laser shots per position. The spectra are smoothed so that partially resolved isotope peaks appear as single average-mass peaks.

Database Searching

To demonstrate the database discriminating power of the PSD data in Figure 1, the Genbank database was searched with minimal restrictions. Parameters common to all searches: search mode (no errors), protein MW (1-200kDa), parent ion tolerance (+/- 0.6 Da),

fragment ion tolerance (+/- 1.1Da), cysteine modification (acrylamide), ion types allowed (a, b, y, a-NH₃, b-NH₃, y-NH₃, b-H₂O, b+H₂O, internal). In trypsin specific searches; maximum number of missed cleavages (1). For the 1935 Da peptide *0 unmatched fragment ions* were allowed from the list: 255.1, 266.3, 272.2, 367.2, 480.2, 520.5, 921.9, 1819.7; composition ions for H, [L], and [R] included. For the 2000 Da peptide *2 unmatched fragment ions* were allowed from the list (518 and 535 could not be assigned): 175.1, 197.1, 226.1, 271.2, 339.6, 365.5, 458.4, 468.4, 518.5, 535.6, 671.7; composition ions for [L] and [R] included.

Deconvolution of Natural Isotopic Abundance Patterns by Least Squares and Maximum Entropy Methods

Zhongqi Zhang, Shenheng Guan*, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab, Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

* Department of Chemistry, Florida State University

The accessible surface area of a protein depends on protein conformation; therefore, the rate and extent of deuterium incorporation offer a powerful probe of protein shape in solution and gas phase. However, in order to determine the number of deuterium atoms in a peptide or protein from its mass spectrum, one must first eliminate the "natural" isotopic distribution due to less-abundant isotopes of C, S, O, N, etc. This paper describes least squares fitting and maximum entropy methods for deconvolution of natural isotopic abundance from mass spectra.

Direct Solution of Linear Equations. The conventional correction for natural isotopic abundance is by step-by-step reduction: a tedious procedure which is difficult for molecules with many atoms. One possibility is to solve the linear equations relating the natural isotopic distribution to the experimental spectrum. The calculation then reduces to a matrix operation performed by a computer. [1]

Least Squares Method. If the number of heavy-isotope peaks is larger than the number of sites for isotope labeling; the number of equations can exceed the number of unknowns. In this case, some peaks which contain useful information are not used for direct solution of the linear equations. Least squares fitting is best suited for seeking the set of deuterium abundances that gives the best fit to all of the equations.

Maximum Entropy Method (MEM). Since all experimental data are corrupted by noise, the "best" result does not necessarily show the best fit to the experimental data. An ideal result should be a distribution that fits to the experimental data within the error range, and has least noise. The maximum entropy method (MEM) gives this solution. The MEM solution usually gives a smoother distribution and contains less noise than the least squares method. Entropy in this context is defined as [2]

$$S = - \sum_{n=0}^N A_n \ln \left(\left(\frac{A_n}{B} \right) - 1 \right)$$

in which A_n is the probability that a molecule contains n artificially introduced heavy isotopes: i.e., the abundance of species with n heavy isotopes. N is the total number of sites for isotope labeling. B is a user-defined parameter. When $A_n = B$, the entropy is a maximum. We need to maximize S subject to a constraint, C . The most often used constraint is χ^2 . The goal of MEM is to find a solution that has the maximum entropy and has a C value within a certain range. To find the maximum S in compliance with the constraint, one uses a multiplier, λ , ($\lambda > 0$) to form another function $Q = S - \lambda C$. Q is maximized with respect to λ until a user-defined C value is found. As a result, the maximum entropy method becomes a multidimensional function maximization problem. Function maximizations used here are based either on the direct search method or the conjugate gradient method.

Linear equations were solved by the routines provided with LabWindows/CVI (National Instruments, Austin, TX) for Windows. An example of deconvolution of natural isotope abundance using least squares method and maximum entropy method is shown in Fig. 1. Note that the maximum entropy method gives a smoother result which exhibits only positive deuterium abundances.

Fig. 1. Partially deuterated Substance P. Left: MALDI FT-ICR mass spectrum of partially deuterated substance P. Right: Deuterium distribution after deconvolution of natural isotope abundance by least squares (LSQ) and maximum-entropy (MEM) methods. In MEM, the standard deviation is calculated from four repeated experiments, and a confidence level of 99% in the χ^2 test serves as the constraint. The MEM result exhibits less noise than the LSQ result. The MEM result is preferred, because it minimizes noise and yields only positive deuterium abundances.

Direct solution of linear equations and least squares methods work well when the spectrum has a high signal-to-noise (S/N) ratio. MEM is most useful when the S/N ratio is poor, but requires much more computation time. If the spectrum has high S/N ratio, (i.e., the system has a very strong constraint), MEM should give the same result as the least squares method.

The present approach should prove especially useful for characterizing protein higher-order structure and dynamics by analysis of H/D exchange. An important advantage of mass spectrometry is that it can separate different conformational states of a protein in a H/D exchange experiment. Following H/D exchange, different conformational states have different deuterium incorporation levels, and thus different molecular weights. As a result, a mixture of different conformational states of a same protein, or a fragment from different conformational states of a same protein, can be separated in a mass spectrometer. By analyzing such isotopic patterns, one gains access to the kinetics of protein folding. In these experiments, different conformational states may often not be well-resolved due to overlap of natural isotopic abundance distributions. Correction for natural abundances facilitates resolution of different conformational states, because fewer mass spectral peaks are present. Peptide Sequencing by MALDI-TOF using Direct and Database Strategies.

Wade M. Hines, Dale H. Patterson, Edward J. Takach,
Marvin L. Vestal and Stephen A. Martin

PerSeptive Biosystems, 500 Old Connecticut Path, Framingham, MA 01701

Protein and peptide structural analysis methods have evolved with advances in analytical instrumentation. For instance, the ability to determine masses of peptides from a protein digest by simple time of flight (TOF) analyzers and matrix assisted laser desorption/ionization (MALDI) has changed the way many investigators approach structural questions including the use of peptide mass matching(1) strategies for database searching. Likewise, incomplete sequence data from the gas phase processes of post-source decay (PSD) and collision induced dissociation (CID) or ladder sequencing experiments can be combined with accurate masses to enable highly specific database queries(2). Many of these sequencing strategies are actively being pursued by the biotechnology industry in the characterization of recombinant proteins and novel factors. Resolution in excess of 9000 and mass accuracy better than 10 PPM are obtainable by rTOF with delayed extraction MALDI. This increase in performance translates to definitive results when searching databases, identifying post-translational modifications or fitting sequences together. MS/MS performance (PSD and CID) is also enhanced with delayed extraction, enabling the resolution of fragment isotopic peaks up to and beyond mass 1500 with corequisite gains in mass accuracy of fragment ions.

Through example, we document the application of these methods as used to solve a real problem. Database searching with accurate masses is demonstrated, in this case to prove that no matching sequences occur in the protein sequence databases. Digest products and limited sequence data are also used in database searching methods, again finding a lack of identical sequences. And PSD and CID are used to directly determine one peptide sequence using a computer program designed to peptide high energy CID mass spectra and PSD is also applied to complete a further sequence by resolving from among a small set of possible sequences determined through homology and exact mass measurements.

The upper figure presents the PSD and CID spectra of a peptide derived from a Lys-C digest of an analogue of GRF. The correct sequence for these spectra were determined by a computer program used for the interpretation of high-energy CID mass spectra. The lower figure presents the partial interpretation of another Lys-C peptide of GRF. Although insufficient fragment ions occur to determine the sequence directly, a combination of homology and accurate mass in combination with sequence ions shown provides enough evidence to confidently establish the sequence of this peptide.

Positive Identification of Proteins by Their Peptide Maps Through High Mass Accuracy and High Sequence Coverage

Q. Vorm*, O. N. Jensen, P. Mortensen, and M. Mann

European Molecular Biology Laboratory (EMBL), Heidelberg, Germany
* Dept. of Chemistry, Odense University, Odense, Denmark

Searching the masses of several proteolytically derived peptides against protein sequence databases has been proposed as an economical method for the identification of proteins. Experience in actual applications have caused some researchers to question the specificity of that approach and suggest that additional data must be obtained to identify proteins with certainty. Using improved techniques for peptide mapping by Matrix Assisted Laser Desorption time-of-flight MS, it is shown here that fast and positive identification of a very large percentage of samples can nevertheless be obtained by peptide mass maps alone. This significantly reduces the number of samples that need to be analyzed by tandem MS based strategies (see also MPN 332).

The improvements involve a one to two orders of magnitude higher mass accuracy and also the sample preparation procedure, which we introduced at this conference 2 years ago, where sample is deposited on micro-crystalline matrix surfaces formed by fast solvent evaporation, has been further enhanced by incorporating a nitrocellulose fiber structure into the microcrystalline structure. Thereby additional binding specificity for peptides and proteins is added.

The performance characteristics of the fast evaporation surfaces are retained, e.g.:

- mass accuracy in the 10 - 50 ppm range
- resolution to the limit of the instrument
- sub femtomole sensitivity for peptides
- sample washability

New advantages are:

- even higher peptide representativity and greater sequence coverage in peptide maps
- even greater tolerance towards contamination (esp. from polymer material)
- much improved detection of large proteins. Protein sensitivity in the 1 - 10 fmol range is obtained routinely

The Improved Sample Preparation Protocol:

- dissolve matrix material and nitrocellulose to a concentration of approx. 20 g/L and 5 g/L, respectively, in acetone/isopropanol (1:1 v/v).
- deposit approx. 0.5 μ L of matrix/nitrocellulose solution on the sample stage, where it spreads rapidly by itself, allowing fast evaporation of the solvent.
- deposit approx. 0.5 μ L analyte solution on the matrix/nitrocellulose surface and let the solvent dry.
- wash the sample by placing a 5 - 10 μ L volume of water on the matrix surface after the analyte solution is dry. Leave the liquid on the sample for ten seconds, then blow or shake it off. The procedure can be repeated.

Automation Scheme

Fig. 1. Automation overview.

All steps of protein identification from peptide maps have been automated. These include: data acquisition, calibration, peak labeling, database search, and documentation (see fig. 1). We have for the first time automated the critical adjustment of laser fluence control by means of fuzzy logic. This allows automated acquisition of MALDI mass spectra of a quality comparable to that obtained by a skilled user.

Fig. 2. From gel-separated proteins identified by peptide maps in actual biological projects.

The technique has now been applied to the identification of large numbers of proteins separated by 2D gel electrophoresis. Our experience with the latest 112 gel-separated proteins identified by peptide maps in actual biological projects, is:

- We matched an average of 12 peptides per protein and achieved an average sequence coverage of 26 %.
- Although the number of peptides found in the peptide maps generally increased with increasing protein molecular weight, the sequence coverage (in %) decreased.
- With >3 pmol starting material in the gel the success rate of protein identification by MALDI peptide maps is about 90 %. Ongoing improvements should lower this level to 1 pmol.

MALDI-ITMS as a Tool for Biomolecule Structure Analysis

Brian T. Chait and Jun Qin
The Rockefeller University, 1230 York Ave., New York, NY 10021

The quadrupole ion trap mass spectrometer (ITMS) is a potentially powerful tool for the analysis of biopolymers. The capacity of the ion trap for high sensitivity multi-stage tandem mass spectrometry (MS^n) is of particular appeal for biological applications that require the determination of the primary structures of proteins—e.g., the identification of proteins and the elucidation of posttranslational modifications. An attractive strategy for solving problems of this type involves enzymatic digestion of the protein, followed by mass spectrometric peptide mapping and tandem mass spectrometric analysis of individual components of the resulting complex mixture of peptide ions (Figure 1). This strategy, which does not require prior chromatographic separation of the peptides, is potentially fast and highly sensitive.

At present, the most efficient methods for ionizing peptides are electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI). MALDI has a number of properties that make it particularly attractive as an ion source for ion trap mass spectrometry of complex peptide mixtures that are produced by enzymatic digestion of proteins. First, the pulsed nature of the MALDI source matches well with the pulsed operation of the ion trap mass spectrometer. Second, the low sample consumption per laser pulse allows interrogation of a single sample (containing ≤ 1 pmol per component) by many thousands of laser pulses. These features allow large numbers of experiments to be performed on a single low-abundance sample of a mixture of peptides, and also enable judicious tuning of experimental parameters. The capabilities given above are advantageous for biological applications in which the proteins of interest are in low abundance. Additional properties of MALDI that make it well suited for the analysis of protein digests include its proclivity for producing abundant yields of ions from the components of complex mixtures of peptides, the easily interpretable spectra obtained from mixtures of peptides (as a result of the dominance of singly protonated species), and the tolerance of MALDI for salts, buffers, and other common biochemical additives and impurities.

We have recently interfaced a MALDI ion source with an ITMS¹ (Figure 2) and developed means for trapping MALDI peptide ions with $\sim 40\%$ efficiency², isolating selected ion species with $> 95\%$ efficiency³, inducing extensive collision-induced dissociation of selected ions with m/z up to 3,500³, and measuring ions with $m/z > 2500$ with improved resolution and mass accuracy². The achievement of these design goals has paved the way to a practical, sensitive ITMS that can be used for the solution of challenging and important biological problems⁴.

In the present paper, we illustrate the performance and utility of this new tool for site specific identification of posttranslational modifications (e.g., phosphorylation, glycosylation and disulfide mapping), probing protein-DNA interactions, and identification and characterization of gel-separated proteins⁴.

Real Time Protein Identification to Guide Tandem MS Investigation of Unseparated Peptide Mixtures

Matthias Wilm, Andrej Shevchenko, Matthias Mann

European Molecular Biology Laboratory, Meyerhofstr. 1, 69 117 Heidelberg, Germany

Protein characterization from polyacrylamide gels is a key requirement in molecular biological research. Mass spectrometry can now routinely be used for this purpose. Proteins are digested with trypsin and the tryptic peptides are extracted from the gel material. We identify them either by an accurate mass measurement of their peptides by MALDI TOF (peptide map) or by sequencing some of the peptides with an Electrospray Tandem Mass Spectrometer using sequence tags. With the Nano-Electrospray source sensitivities of less than 100 fmol protein starting material from Coomassie or silver stained gels can be reached¹. Both techniques are now used to tackle large scale protein characterization projects from 2D gels comprising hundreds of proteins. Real time identification of proteins would be highly desirable in these projects.

To this end the peptide mixture is first analyzed to identify peptides as opposed to chemical background which originate from the digested protein(s). "Parent ion scan" of the immonium ion of leucine/isoleucine can be used to distinguish the peptides from the chemical noise². Peptide peaks are selected in the spectrum and - by activation of an Apple Script - their m/z values are communicated to a database file ("FileMaker Pro"). This file serves as a graphical interface to the mass spectrometer. By pressing a single button a high resolution scan or a high resolution parent scan of the selected peptides is acquired. A tandem MS spectrum of a any peptide can be recorded by pressing another button. The buttons activate Apple Scripts which manipulate the acquisition software. Complex functions - such as choosing different collision energies depending on the weight of the peptide and on the scanned m/z range of the fragment spectrum - are performed without further intervention by the user (figure 1). When the tandem MS spectrum of the first peptide is acquired the spectrum can be interpreted automatically. The generated sequence tag is sent to a remote database server to identify the protein. 10 seconds later the result is sent back. The masses of the tryptic peptides of an identified protein are then compared to the selected peptide masses and sequence proposals are displayed to the investigator. Peptides which could be associated to the protein can be fragmented and their tandem MS spectra can be compared to the proposed sequences to rapidly confirm the protein identification. Subsequently, attention can be focused on peptides whose mass does not correspond to that of a tryptic peptide of the identified protein.

Therefore, unexpectedly modified peptides or protein mixtures can be found already in course of the first experiment.

The real-time identification of proteins gives maximal analytical insight into a protein characterization problem during the analysis. This allows to rapidly identify modified peptides or protein mixtures. It guides the experiment to minimize the generation of redundant information.

Figure 1 Automatic setting of the parameters to acquire a tandem MS spectrum of the peptide with the m/z value 608.4. To acquire the spectrum only the "Frag" button has to be selected. The collision energy is calculated according to the m/z value and varied over the scanned region of the fragment spectrum. Small fragments are generated under high collision energy settings whereas a smaller collision energy is chosen for larger fragments.

INVESTIGATIONS OF HIGH ORDER PROTEIN STRUCTURE USING BIOREACTIVE PROBE TIPS AND QUANTITATIVE MALDI

J. Kathleen Lewis, Jennifer R. Krone, David Dogruel, Peter Williams, Randall W. Nelson
 Department of Chemistry and Biochemistry
 Arizona State University
 Tempe AZ, 85287-1604

The combination of proteolytic digestion with matrix-assisted laser desorption/ionization (MALDI) time-of-flight mass spectrometry has become a valuable tool in the mapping and partial amino acid sequence determination of proteins. New applications of the enzyme digestion/MALDI approach go beyond primary structure (i.e., sequence) elucidation allowing the investigation of higher order structure (tertiary and quaternary) through "fingerprint" recognition. Typically, these analyses are performed in manners which allow high speed and sensitivity while maintaining and lowest degree of ambiguity. We have found enzymatically-derivatized, or *bioactive*, mass spectrometer probe tips ideally suited to such purposes.

The tryptic digestion of horse heart myoglobin (MW = 16,951.4 Da) is one such example. Shown in Fig 1 are the MALDI spectra produced from the tryptic digestion (using trypsin-derivatized gold-coated mass spectrometer probe tips) of the myoglobin in the presence of the denaturant N-octyl pyranoglucoiside (NOG). Three different concentrations of the denaturant were used, 1, 10, and 100 mM. Few tryptic fragments are observed at the lower denaturant concentration (< 1 mM), however, once the concentration of the NOG is increased into the 10 mM range a significant number of cleavage fragments are observed, as well as a noticeable decrease in the parent ion signal (relative to prevalent digest fragments). Further increase in the NOG concentration yields even more complete digestion (as indicated by the absence of the parent), and the production of nominally lower (on average) molecular weight fragments. The observed progression is consistent with the unfolding of the myoglobin under the stronger denaturing conditions allowing access to sites normally shielded by the tertiary structure of the molecule.

Fig. 2 shows the progression of the digestion as a function of time while keeping the myoglobin in the unfolded state by maintaining the concentration of the NOG at 100 mM. As expected, the parent ion signal is observed to decrease with the progression of the digestion. A semi-quantitative evaluation of the time-course allows the formation digestion fragments to be tracked as a function of their precursor. The analysis can be made fully quantitative by the incorporation of an internal reference species (at a constant amount) into the spectra for signal normalization. Such methods have been used to track dynamically, the progression of the digestion of the regulatory protein calmodulin in the presence and absence of its allosteric effector (Ca^{2+}). Results indicate qualitatively different digestion paths; a result of two distinctly different protein conformations.

Figure 1. Au/trypsin digestion (15 minutes, 60 °C, pH 8.0) of equine myoglobin at different concentrations of the denaturant, n-octyl pyranoglucoiside (NOG)

Figure 2. Au/trypsin digestions of equine myoglobin (60 °C, pH 8.0) in the presence of 100 mM n-octyl pyranoglucoiside (NOG) as a function of increasing time.

Characterization of Synthetic Peptides using MALDI and Electrospray Mass Spectrometry

James A. Carroll, Janet M. Brostowin, and Ronald C. Beavis
The Skirball Institute of Biomolecular Medicine
New York University Medical Center
New York, NY 10016

Solid phase peptide synthesis often generates a mixture of species which must be characterized using analytical methods. Besides the target peptide, the crude mixture may contain partially protected peptides, peptides with adducts of alkylation scavengers used during deprotection, truncated sequences due to inefficient coupling, and combinations of these possibilities. If the peptide is not of sufficient purity, further deprotection or resynthesis may be required.

A variety of peptides synthesized using Fmoc chemistry on a peptide synthesizer were analyzed using HPLC with UV detection, electrospray ionization (ESI) mass spectrometry (LC/MS and direct infusion), and matrix-assisted laser desorption/ionization (MALDI) mass spectrometry. The relative abundances of the peptide mixtures analyzed using these techniques were compared, and factors such as the nature of the protecting group, the relative amount of impurity, and the overall concentration of the sample were investigated for their effect on the analyses.

Peptides containing a single t-butyl protecting group showed widely varying results between the three techniques, with no consistent pattern in the observed relative intensities of the impurity. For triphenylmethyl-protected and Pmc-protected peptides, however, there appears to be some discrimination in the techniques based on the presence of these groups. Peptides protected with triphenylmethyl generally give poor results upon analysis by MALDI MS. The relative abundance of the triphenylmethyl protected peptides are greatly underestimated compared to UV or ESI MS analysis. This can be explained by the hydrophobicity of the protecting group, which may have deleterious effects on important parameters which effect ionization such as solubility and inclusion of peptide molecules into the matrix crystals. Another example of the effect of the protecting group on the analysis of the peptide mixture is illustrated in figure 1. In this case, a mixture of peptide and Pmc-protected peptide was analyzed using these techniques. The MALDI MS and UV results compare well, but the ESI MS spectrum shows a considerably lower abundance of the impurity. This may be explained by the presence of the Pmc group, which protects arginine residues during synthesis. The presence of a Pmc group on the arginine residue may significantly affect the formation of doubly charged ions (which were used for this example) during the electrospray ionization process.

The effect of sample concentration was investigated using serial dilutions of a single peptide mixture. The results indicate that both of the mass spectrometric techniques tend to overestimate the relative abundance of the protected peptide at higher total concentrations, while UV detection tends to give a more stable result. Overall, HPLC with simultaneous UV and ESI MS detection appears to be the most reliable method for the analysis of synthetic peptides.

Figure 1. Analysis of an incompletely deprotected peptide using MALDI MS, ESI MS, and HPLC. ESI MS underestimates the amount of impurity relative to the other methods.

The Development of ESI-TOF and its Comparison with MALDI-TOF for the Characterization of Peptides

Marvin L. Vestal, Anatoli Verentchikov, Frank Hsieh, Steve Gabeler, Joe Zhou, Edward Takach, and Steve Martin

PerSeptive BioSystems Inc., 500 Old Connecticut Path, Framingham, MA 01701

Both ESI and MALDI are used extensively for determination of molecular weight and partial sequence of peptides in protein digests. TOF has been the analyzer of choice for MALDI, but up to now most of the ESI work has employed either single or triple quadrupole analyzers. The recent development of high-performance TOF analyzers with delayed extraction (DE) has substantially improved the quality of the data obtained with MALDI. We have recently developed a new ESI-TOF system with performance characteristics similar to those obtained with MALDI, but using a number of different components. Both employ single-stage reflectors and dual channel plate detectors, but the ESI-TOF uses a TDC with 2.5 nsec bins and ion counting techniques while the MALDI system is based on a transient digitizer with 2 nsec bins. The ESI system uses orthogonal injection with collisional relaxation in an RF quadrupole and the MALDI is coaxial. In both cases the ions are introduced initially into a field-free region and pulsed out to enhance performance. The ESI-TOF system is a small benchtop unit with an effective ion path of 1.5 m, an overall length of about 0.7 m, and it was operated at 3 kV ion acceleration for the work described. The MALDI-TOF system used for comparison is mounted in a 2 m long console and has an effective ion path of 3 m. It was operated at 20 kV ion acceleration, and under these conditions the two instruments give comparable total flight times for specific ions. For peptides in the mass range 500-5000 both instruments routinely provide nearly baseline resolution of all isotopes independent of charge state.

The ESI-TOF was interfaced to a high performance LC, equipped with multi-column switching capabilities, by using a pneumatically-assisted electrospray interface and a fraction was split off to a modified fraction collector where fractions were collected directly onto the MALDI sample plate at regular intervals. An example of results obtained with this system is shown in Figure 1. A solution-phase tryptic digest of reduced and alkylated BSA was separated on a 1 mm x 25 cm C-18 column with gradient elution at 50 μ L/min. In this case approximately 10% of the total flow was split to MALDI collection and fractions were collected at 10 sec intervals. The reconstructed TIC obtained from automated analysis of 90 such fractions collected during the indicated portion of the chromatogram is also shown. The intensities of the spectra were normalized by reference to background peaks present in the matrix preparation, and the masses were internally calibrated using these same reference peaks. The precise masses of the reference peaks were independently determined by calibration relative to known peptide standards. All of the MALDI data were obtained under computer control of the laser intensity and sample position without operator intervention. The deviations between measured masses and theoretical masses for all of the tryptic peptides identified in each measurement are summarized in the histograms attached to Figure 1. Similar results were obtained with unseparated protein digests, and with on-line reduction, alkylation, and digestion, followed by reversed phase separation and detection by both ESI-TOF and MALDI-TOF.

Both TOF instruments provide excellent resolution and mass accuracy. As indicated in Figure 2, the masses determined for at least 40% of the peptides identified as tryptic fragments were within 0.01 Da of the theoretical mass, and none were observed with errors larger than 0.03 Da. In analysis of complex

mixtures, such as the unseparated BSA digest, ESI-TOF showed rather less discrimination and better coverage, particularly in its ability to reliably detect smaller peptides. On the other hand, MALDI gave somewhat better sensitivity for the higher mass components when coupled with LC separation primarily because as much time as needed can be used in obtaining a spectrum, while in the on-line ESI the measurement time is limited to the width of the chromatographic peak. Ultimately, these results illustrate complementarity between the speed and convenience associated with direct on-line coupling with ESI versus the sensitivity and flexibility provided by off-line coupling to MALDI.

MALDI mass spectrometry of peptidoglycan oligomers after size exclusion chromatography and HPLC

¹Institute for Biochemistry and Molecular Biology, University of Vienna, A - 1030 Vienna, Austria

Peptidoglycan (PG) can be envisaged as a giant single macromolecule, representing an important constituent of pathogenic and apathogenic microorganisms. PG is a complex heteropolymer unique to bacterial cell walls that consists of a glycan backbone with peptide side chains linked via lactyl moiety to the carbohydrate unit. The peptides are cross-linking the glycan chains of various length. Often the peptide side chains are branched additionally. Numerous subtle variants in the chemical composition of PG isolated from quite different microorganisms have been determined [1]. The first molecular target of β -lactam antibiotics is a group of unique proteins, called penicillin binding-proteins, which are involved in several stages of PG biosynthesis. A complete understanding of the complicated chain of events is now accelerated by some recent progress in PG structural analysis of minute amounts based on positive and negative ion MALDI MS [2] and PSD [3]. The detailed knowledge on the structure of PG isolated from pathogenic bacteria (e. g., *Staphylococcus aureus* or *Salmonella typhimurium*) can give insight in the mechanisms involved in antibiotic resistance development. The strategies to elucidate the structure of small PG fragments (monomeric compounds with MWt. $\leq$ 1300 Da) are more or less well established if sufficient PG can be isolated [4]. Because of small, but for the understanding of the biosynthesis important variations of the relative distribution and/or structure of PG dimeric and oligomeric compounds it is desirable to analysis all PG fragments, which might be present in extremely small quantities. Our integrated mass spectrometric approach is based now on the separation of the muramidase-generated PG fragments by size exclusion chromatography (SEC) into monomeric, dimeric, trimeric and oligomeric compounds (Fig. 1), reduction of the carbohydrate moieties by sodium borhydride of these fractions, reverse phase HPLC purification and subsequent MALDI MS analysis. Molecular weight information was obtained for reduced PG oligomers up to 5000 Da in the subpicomole range (e. g., tetrameric compound see Fig. 2). Based on these values of the individual PG oligomeric compounds and on the detected amino acids as well as amino sugars in the total hydrolysate of the purified PG, the primary structures could be assigned. In case of doubtful or uncorrelated MALDI MS data, the individual PG fragment was analyzed

Figure 1. Size exclusion chromatogram of an unreduced muramidase-digested PG isolated from the cyanelles of *Cyanophora paradoxa*.

by positive ion PSD (Fig. 3) applying a curved field reflector. Intense fragmentation was observed for the precursor ion $[M + Na]^+$ and was helpful to elucidate at least parts of the primary structure.

TMPP- DERIVATIVES: A New Generation Of Charged Derivatives For Desorption/Ionization

Watson, J.T., Huang, Z.-H., Liao, P.-C., Wu, J., Roth, K.D.W., Lavine, G., Gage, D.A., Allison, J.
Departments of Biochemistry and Chemistry, Michigan State University, East Lansing, MI 48824

Having demonstrated the analytical advantage of triphenylphosphonium derivatives of peptides for amino acid sequencing and structural elucidation several years ago, we have now given considerable effort to the facile preparation of these kinds of charged derivatives at low levels. The tris-(trimethoxyphenyl) phosphonium-acetyl derivative at the N-terminus of peptides provides many of the analytical advantages of fragmentation during CAD MS/MS as we reported earlier for the TPP derivatives. The trimethoxy substitution of the phenyl ring substantially increases the basicity of the phosphine, which coupled with the highly reactive thio-ester linkage provides an efficient reagent with which to prepare charged derivatives at the low picomole level. Details on the synthesis and storage of the TMPP reagent together with the recipe for the preparation of the TMPP-Ac-derivatives of peptides can be found in these proceedings by Huang et al. (MPM)

It is possible to analyze the reaction mixture directly for the TMPP derivative of peptides because the reagent is used in only ten-fold excess, and the organic base used for catalysis does not interfere with subsequent analysis by MALDI. Thus, in most cases, the TMPP reagent allows a one-step reaction for preparation of picomole quantities of peptides permitting direct analysis with little or no clean up prior to analysis by mass spectrometry. Figure 1 shows the FAB-CAD-B/E-linked scan of VHLTPVEK as the α -N-TMPP-Ac-derivative prepared at the one nanomole level, of which 100 picomole were added to the FAB probe tip in thioglycerol: 2-hydroxyethyl disulfide (1:1) for analysis. The TMPP-Ac-derivative at the N-terminus reliably generates a series of a-type ions, which are readily detectable except for those corresponding to cleavage at residues of glycine or alanine (when these residues are present). Also note in Figure 1 that readily discernible d-type ions are present. In underivatized peptides with an arginine at the C-terminus, the CAD spectrum is frequently dominated by C-terminal fragment ions, however in cases where the TMPP-Ac-derivative is at the N-terminus, control of the fragmentation by arginine at the C-terminus is eclipsed by the effect of the TMPP-Ac-derivative in directing fragmentation for a complete series of a-type ions.

A peptide containing three lysines, INLKAALAKKIL, was treated to determine whether lysine would complicate the analysis. This peptide was converted completely to the N-terminal TMPP-Ac-derivative; no peak was observed (data not shown) for a doubly derivatized species, nor for residual underivatized peptide. Figure 2 shows the MALDI-PSD spectrum of the α -N-TMPP-Ac-derivative of INLKAALAKKIL. Again, the spectrum is dominated by N-terminal ions of which most are a-type ions. The peaks corresponding to a-type ions for the alanine residues are readily discernible, complementing the data obtainable by FAB-CAD. For more details on the fragmentation of the TMPP-Ac-derivatives, the reader is referred to Liao et al. (WPL) and Roth et al. (TPL) in these proceedings.

CHARACTERIZATION OF BOVINE ADRENAL MODULARY PEPTIDES BY USING ESI-MS AND LC/ESI-MS

CHHABIL DASS

THE UNIVERSITY OF MEMPHIS, DEPARTMENT OF CHEMISTRY, MEMPHIS, TN 38152, USA

INTRODUCTION: Bovine adrenal modulatory (BAM) peptides are high molecular weight (MW) endogenous peptides and are embedded in the C-terminal segment of proenkephalin A (ProEnk A), which is a 263 amino acid long large protein. They are biochemically synthesized by enzymatic processing of ProEnk A. Further enzymatic processing of BAM peptides by a trypsin-like enzyme produces two of the most important opioid peptides, methionine- (Met-Enk) and leucine enkephalins. Opioid peptides are known to play a critical role in a variety of physiological functions, including analgesia.

OBJECTIVE: The hypothalamo-pituitary-adrenal (HPA) axis is central to the maintenance of homeostasis and is a model neuroendocrine system, linking changes in central neuronal activity to alterations in target gland function. Several ProEnk A-derived peptides are present in adrenal medulla and are known to affect functioning of the HPA axis. Therefore, it is important to have a knowledge of the levels of ProEnk A peptides in adrenal medulla. It is an undenyng fact that this type of research is facilitated with the availability of analytical methods that are structure specific and can be used to analyze endogenous peptides from body tissues. The objective of the present study is to use a highly potent combination of reversed phase (RP) high-performance liquid chromatography (HPLC) and ESI-MS. A set of eight synthetic proenkephalin peptides, including metorphinamide, Met-Enk-RRVG, ProEnk A128-140, BAM-12P, BAM-18P, BAM-22P, Peptide E (BAM-25P), and Peptide B, was characterized by conventional ESI-MS and their mixture was separated by RP-HPLC using a narrow-bore column and characterized individually by ESI-MS.

EXPERIMENTAL: ESI mass spectra of ProEnk A peptides were acquired by using Fisons Platform II single quadrupole mass spectrometer. The quadrupole was scanned in the mass range of 150-1500 Da at a scan rate of 3.0 s per scan. The ESI solvent (50:50 mixture of 0.1% TFA:acetonitrile) was introduced at a flow rate of 10 µl/min with the help of a syringe pump. Chromatography separation used an HP 1050 equipment (Hewlett Packard) consisting of a quaternary pumping system and a diode array UV-visible detector (DAD). A Vydac C-18 201HS2 column (250 x 2.1 mm, 5 µm particle size) and gradient elution with a mixture of 0.1% aqueous TFA (A) and acetonitrile (B) was used to separate the peptide mixture. The eluents were monitored at 200 nm. For HPLC/ESI-MS analysis the outlet of the DAD was connected to a megaflo ESI probe. All peptides were purchased from Sigma Chemical Co and Peninsula Laboratories and used without further purification.

RESULTS AND DISCUSSION: ESI mass spectra-As expected, all of the peptides studied here produced multiply protonated molecular ions when subjected to positive ion ESI (see Table 1). As is evident from this set of data, a correlation exists between the number of basic sites in the peptide sequence and the number of protonated molecular ions. The multiprotonated ion series can be used to determine the MW of the peptide. As little as 40 femtomole of a peptide is enough to provide MW information.

LC/ESI-MS analysis: The set-up shown in Figure 1 was used in this study. No flow-splitter is used in this set-up. The flow rate of the mobile phase was 200 µl/min and the gradient used was 15-25% B in 0-5 min, 25-50% B in 5-18 min. The eluents were monitored both by UV absorption and the positive ion current. Figure 2 illustrates the total ion current and ion extracted chromatograms of individual components. These data were acquired from an aliquot of the mixture containing 27 to 110 pmole of individual peptides. It is obvious that much lower amounts of peptides than used here can be characterized with this technique. However, it was observed that sensitivity of the analysis largely depends upon the background ion current. Water clusters mainly contribute to the background. The composition and rate of flow of the mobile phase determine the extent of formation of water clusters, which can be reduced by (a) increasing the source temperature, (b) increasing the flow rate of drying gas, and (c) increasing the sampling cone voltage. In our set-up, the background water clusters were absent when the source temperature was increased to 150 °C, keeping the mobile phase flow rate at 200 µl/min and cone voltage at 30 V.

University of California at Davis, CA 95616

Matrix assisted laser desorption ionization (MALDI) of oligosaccharides performed in an external source Fourier transform mass spectrometer (FTMS) produced significant amounts of fragmentation in oligosaccharides. Several important correlations were found between the fragment ion yield and (1) the degree of branching and (2) the size of the alkali metal ion in branched oligosaccharides. An equation was developed to assign the degree of branching (BD) in an oligosaccharide. A plot of BD versus fragment ion abundance yielded a linear relationship showing that highly branched oligosaccharides fragment less than those that are more linear.

Several systematic studies were also performed with branched and linear oligosaccharides doped separately with alkali metal chloride salts. For each sugar we observed that lithium, the smallest alkali metal, produced the greatest amounts of fragments and that cesium, the largest alkali metal, produced the least (Table 1). Similar observations reported by Fura *et al.*¹ A further study of linear oligosaccharides ranging in size from the disaccharide maltose to the hexasaccharide maltohexaose doped with the alkali metal salts were also analyzed by MALDI/FTMS. The results show that a minimum number of saccharide monomers are necessary to stabilize the complex and produce a quasimolecular ion from the MALDI process. Disaccharides doped with Li⁺ and Na⁺ produced the respective quasimolecular ions, but not with K⁺, Rb⁺ and Cs⁺. At least a trisaccharide was needed to form potassiated parents in appreciable abundance's, a tetrasaccharide was needed with Rb⁺, and a pentasaccharide was needed to form a Cs⁺-carbohydrate complex (Table 2). The minimum size indicates that a specific number of interactions are necessary to stabilize MALDI produced metal coordinated carbohydrate complexes.

Molecular dynamics calculations reveal that Cs⁺ coordinates to five of the six glucose units in the linear maltohexaose, which mirrors the experimental results (Figure 1). For branched oligosaccharides the dynamics calculations showed that the complexes of Cs⁺-sugar had minimum internal energy when the cesium was coordinated to the most branched position in the oligosaccharide structure. Thus, maximizing the Cs⁺-sugar interactions which in turn stabilizes the complex. Similar calculations with Li⁺ and branched oligosaccharides reveal that the lithium coordinates to only two sugar residues along the glycosidic bond, previously predicted by semi-empirical calculation.² When the system was heated, to mimic MALDI or CID conditions, the Li⁺ became very labile moving along the carbohydrate. This behavior is evident in the large variety of fragment ions that are produced from the lithiated parent.

We conclude that a specific number of sugar residues are necessary to stabilize the coordinated metal complex, and that the number depends on the alkali metal. Fragmentation occurs probably by charge

remote mechanisms. The coordination of the sugar near the branch points stabilizes the complex so that increasing the branching produces less fragment ions.

Table 1

Percent Fragmentation as a Function of Coordinated Metal Ion

Sugar	Li ⁺	Na ⁺	K ⁺	Rb ⁺	Cs ⁺

Mechanisms In Thermal Ionization

J E Delmore, A D. Appelhans, T Huett and J E. Olson

Idaho National Engineering Laboratory
Box 1625, Idaho Falls, Idaho 83415-2208

Thermal (or surface) ionization has been recognized as a phenomenon since at least the 1920's, and by the late 1930's was being applied to mass spectrometry for the isotope ratio measurement of certain metals. Thermal ionization as applied to mass spectrometry had an important role in the development of nuclear technology, and after 1945 was developed into a powerful tool for many types of studies, primarily in the fields of geochemistry, nuclear technology and pollution monitoring. Thermal ionization can be divided into two broad categories; 1) Systems where neutral atoms and/or molecules strike a very hot filament which in turn produces ions. 2) Systems where a refractory inorganic complex is heated to a temperature sufficient to sublime (or evaporate if the deposit is molten) ions from the surface. Our studies have concentrated on the later area, and in particular with those systems where the material from which ions are to be produced are embedded in a matrix chosen to enhance ion emission. We call this matrix enhanced surface ionization (MESI).

We have developed three new tools to aid in the study of MESI. The first is the tube ion source, where the emitter is packed into a tube which is mounted to supporting pins via rhenium filaments. Current is passed through the rhenium filaments to heat the tube. The resistance of the tube is very low in comparison to the filament, hence there is almost no variation in voltage across the face of the emitter. The material that the tube is made of is chosen for compatibility with the emitter, and for these studies was either stainless steel or rhenium. The emitter was packed flush with the face of the tube, which was placed at the focal point of the lens. The second new tool is an ion source imaging instrument, which is able to image the ion emitting regions on the face of the tube source. This capability has been invaluable in defining whether the ions are emitted from interfacial regions or from the emitter itself (in all cases studied ions are emitted from the material itself). The absence of a voltage gradient across the face of the emitter was critical for maintaining high resolution. The third new tool is an ion/neutral mass spectrometer which is able to measure in sequence the ions, and then the neutrals coming from the surface of the emitter. This is a new capability in our lab, and so far has only been applied to zeolite emitters.

We have used these tools to study three general types of emitters to date. The first is the emitter class that is also the best understood, the alkali metal zeolites. The second is the emitter we have developed for our SIMS instruments, the perhenate anion emitter. The third is the broad subject of silica gel/molten glass ion emitters.

The alkali metal zeolite emitters have a massive and relatively refractory aluminosilicate anion matrix, which anchors the alkali metal cations. As this matrix is heated, the cations

desorb into the gas phase, leaving the anion matrix behind. There is no indication that the aluminosilicate matrix is decomposing or evaporating at the operating temperatures (~700°C). The only material vaporized from this matrix are the alkali metal cations and the desorbing neutral species such as water and carbon dioxide. No neutral species containing an alkali metal can be detected, hence, the alkali metal cations are desorbing directly from the solid state into the gas phase. A related material is silver zeolite, which starts out as an alkali metal zeolite, and is subsequently ion exchanged with silver. Analysis of this material with the ion/neutral mass spectrometer shows that the residual alkali metal has three orders of magnitude higher ion emission than silver, even though silver is present in much higher concentrations. Also, silver is desorbed both as neutrals and as ion.

The perhenate anion emitters were developed based on two observations. 1) Rare earth (+3) oxides provide a refractory matrix capable of emitting oxyanions with good sensitivity, including the perhenate anion. 2) Alkaline earth perhenates are stable up to 800-900°C, particularly when embedded in a +3 rare earth oxide matrix, and are capable of emitting perhenate anions (and other oxyanions) into the gas phase. We have not yet studied these materials on the ion/neutral mass spectrometer, but have done extensive testing of these emitters as a function of the rare earth element. The results of these studies clearly demonstrate that Europium and Ytterbium, the two rare earths with stable +2 chemistries, provide superior matrices for emitting perhenate anions. The criteria seems to be that the barium perhenate needs to be embedded in a +3 rare earth oxide matrix, but that the rare earth have an accessible +2 oxidation state. We have hypothesized that this type of rare earth system is capable of functioning as a mild oxidizing agent to maintain Re in the +7 oxidation state. These emitters work so well that they have been adapted for use as the primary ion gun for static SIMS analyses of insulators.

The silica gel/molten glass ion emitters have found wide use for the isotope ratio analysis of many different metallic and metalloid elements, but the mechanisms for ion emission have been poorly understood. Image analysis clearly demonstrates that ion emission is exclusively from the face of the molten glass, and not from interfacial regions as many people had presumed since the choice of metal for the support of these emitters had an important bearing on the ion emission properties. As an example, a molten glass emitter on rhenium metal produced 100 times the ion current as the same material on tantalum, and it was presumed that the metal provided the ion formation surface. Since the ions came from the molten glass surface, and not from the metal surface, there had to be another explanation. The answer was that the molten glass corrodes the metal substrate and poisons the glass emitter, and that Ta poisons the emission process much worse than Re. Areas of study likely to be productive in the near future include glass chemistry, including corrosion properties, and the oxidation state of the element to be ionized in the glass matrix. We also plan to study these systems on the ion/neutral mass spectrometer system in the near future.

**Ionization Mechanism and Theory of Thermal Ionization Sources,
On the Road to Higher Efficiency**

José A. Olivares, Yixiang Duan, and Ray E. Danen
Los Alamos National Laboratory, Los Alamos, NM 87545

Thermal ionization mass spectrometry is the most sensitive mass spectrometric technique used for high precision and accuracy absolute isotopic ratio determination and concentration measurements using isotope dilution. A number of mechanisms have been used to enhance thermal ionization performance, improve stability, or provide acceptable ionization levels for a variety of elements. Yet, the source has remained basically the same, i.e., ionization occurs from surface contact with a resistively heated filament. The basis for the mechanism of surface ionization has been well documented and is highly dependent on the work function of the filament surface, the filament temperature, and the first ionization energy of the element of interest. This is described by the popular Saha-Langmuir equation. Filament material composition and ionization enhancers, e.g., silica gel/boric acid, electroplating, and lanthanum hexaboride, are common agents used to change the surface work function and, therefore, the performance of the source. Although the electroplating technique and the "canoe" type filament do much to improve ionization efficiency by providing added surface-atom interaction, this critical interaction is still minimal in all of the traditional sources. In fact, once the analyte atom is in the gaseous state, ionization must occur instantaneously because in the vacuum of the mass spectrometer source the chance for a second interaction with the hot filament is minimal. It is this basic concept which lead to the successful development of high efficiency thermal ionization cavities by Beyer et al. [1] for isotope separator applications. In this particular application a factor of two in ionization efficiency may mean a difference in days to weeks for the collection of required amounts of a particular isotope. Or, as in the case of the production and detection of short-lived fission products in accelerators and nuclear reactors with on-line isotope separators, detection or no detection

During the past four years we have been developing a thermal ionization cavity for use on analytical mass spectrometers. The evolution of this source has taken different shapes to accommodate the mass spectrometer and the user while maintaining the basic concept of providing the most surface-atom interactions possible. Therefore, the sources maintain their characteristic high efficiency. The ion source used in this work originated from a design similar to Beryer's [1] and used in the isotope separator program at Los Alamos. This large, high power, ion source was redesigned for use on both the isotope separators and a small quadrupole mass spectrometer. Thus it was possible to test the stability and efficiency of this new ion source prior to further changes or application to the quadrupole mass spectrometer.

The original ion source was acceptable as far as stability and ionization efficiency. Yet, it was cumbersome to use since the mass spectrometer vacuum system had to be shutdown in order to change samples. A new design using a vacuum interlock and a sample insertion probe allows us to introduce the sample and be running within a few minutes with minimal perturbation to the ion source.

The ionization efficiency measured with this ion source on the quadrupole mass spectrometer is similar to that found on the isotope separator, Table I. When measuring ionization efficiency on

the quadrupole mass spectrometer the faraday cup is used and the quadrupole's resolution is reduced to allow all of the ions to pass through to the detector.

Table I Measured Ionization Efficiency of the Thermal Ionization Cavity

Element	Isotope Separator	Quadrupole MS
Europium	72 %	70 %
Lutetium	25 %	
Uranium	8 %	
Thorium	2 %	
Zirconium	2 %	

The enhanced ionization efficiency found in the thermal ionization cavity has been postulated by Kirchner [2] to be due to the large number of collisions with the hot cavity walls that vaporized atoms undergo prior to leaving the cavity. This is described as an enhancement factor above on the Saha-Langmuir equation:

$$\eta = \frac{\beta \omega \kappa}{1 - \beta(1 - \omega \kappa)}$$

where: $\beta = n^+/n^0$ from Saha-Langmuir
 ω is the probability of an ion leaving the cavity
 κ is the number of wall collisions
 $\omega \kappa$ is the enhancement factor

Table II. Ionization Efficiency with $\omega \kappa = 150$, and Typical Operation Temperatures

	Filament Material		Ni	Rh	Pd	Ta	W	Re	Pt
	Work Function (eV)		4.61	4.80	4.99	4.19	4.52	5.12	5.32

ENVIRONMENTAL AND NUCLEAR APPLICATIONS OF ISOTOPE RATIO MASS SPECTROMETRY

J.F. Wacker, O.T. Farmer, D.C. Gerlach, J.M. Kelley, D.W. Koppenaal, and M.R. Smith, Pacific Northwest National Laboratory, Richland, WA 99352, U.S.A.

Isotopic analysis by mass spectrometry is an essential tool for environmental monitoring of radionuclides released from nuclear material production facilities. Both thermal ionization mass spectrometry (TIMS) and inductively coupled plasma mass spectrometry (ICP/MS) have been used to assess both the inventory and migration of radionuclides in the environment, as well as for analyzing process waste. Instrumentation for trace level measurements includes ICP/MS (with laser ablation or with high efficiency nebulizers) and single and triple sector TIMS instruments. Research in several areas will be described, covering a span of applications from using isotopic measurements to benchmark reactor physics to the analysis of radionuclides in river samples.

The first area covers the analysis of impurity elements in graphite used as a moderator material in uranium-fueled reactors. Purified graphite used as a moderator contains impurity trace elements at concentrations in the ppm or less levels. Isotopic compositions of impurity elements are altered during progressive exposure to neutrons in the reactor, and these perturbations are detectable using TIMS. The isotopic variations are independent of the initial elemental concentrations of the impurities and their heterogeneous and small-scale distribution within the graphite. The measurement of these isotopic variations requires determination of the absolute isotopic abundance for a target element as the irradiation affects all isotopes simultaneously. Several elements, including Ti and Cr, possess adequate neutron cross sections and display significant isotopic changes during exposure. Sample preparation procedures, chemical separations, and mass spectrometric analytical methods for Ti, Ca, and Cr have been developed or modified from existing methods. Amounts of impurity elements required for analysis are typically 1 µg or less, depending on the neutron capture cross section and TIMS sensitivity. Thus, useful results can be obtained from total sample portions in the 1-gram range. Results from the TIMS analysis of Ti extracted from irradiated graphite samples were used in case studies to calculate estimates of cumulative neutron fluence. Cumulative neutron fluence may represent a life limiting consideration for graphite moderated reactors. This procedure has applications in validation studies, such as estimates of total energy produced over the lifetime of the reactor.

The second area covers the application of ICP/MS techniques for measuring isotopic and elemental abundances in Hanford nuclear waste samples. Compared to natural samples, the nuclear waste samples pose non-traditional ICP/MS interference problems due to altered isotopic abundances and radionuclide-derived isobaric interferences. A comprehensive ion chromatography (IC) with beta-counting (beta)

and ICP/MS detection approach has been developed to separate and detect radionuclides in a Hanford waste tank sample. The IC separation was performed using a multi-functional group (anion/cation) resin and eluents of oxalic acid, diglycolic acid, and hydrochloric acid. Radionuclides with half-lives less than 10 years were detected by a solid-state beta scintillation counter that was on-line with the IC separation. Mass spectrometric detection using ICP/MS provides the isotopic selectivity for discerning both stable isotopes and long-lived radioactive species. An effective separation of over 47 elements and 160 isotopes was obtained from a single elution scheme lasting 70 minutes. Automated IC-ICP/MS methods provide the potential for rapid isotopic and radionuclide analysis of complex radioactive waste samples, using minimal sample and reagent volume, thus reducing personal exposures to radiation. The IC-ICP/MS method has been used along with laser ablation ICP/MS (LA-ICP/MS) for direct solids analysis. The combination of LA-ICP/MS and IC-ICP/MS provide fast and reliable results to within a nominal precision of a few %, which is sufficient to fingerprint a material and determine if fission product material exists by comparison of relative ion intensities to fission yield curves.

The third area covers the measurement of very low levels of actinide elements in environmental samples. The sensitivity of isotope dilution TIMS analysis of plutonium and neptunium has been advanced by improvements in chemical separation and purification methods, leading to detection limits in the sub-femtogram range. Thus, quantification and characterization of isotopic abundances of Np and Pu (including minor isotopes) can be performed on one gram samples of soils and sediments. Applications for low level actinide analysis include the characterization of global fallout, monitoring the spread of environmental contamination from nuclear facilities, and the detection and tracking of actinides released into the Arctic ocean due to oceanic waste disposal. Analysis of air filter samples taken in 1956 [1], during a period when fallout was being produced, show Pu with $^{240}\text{Pu}/^{239}\text{Pu}$ in the range of 0.16 to 0.23, which extends both above and below of values for global fallout [2]. Recent measurements of suspended sediments (particulate material suspended in the water column) collected in 1995 from the Ob River in Russia [3] have shown $^{240}\text{Pu}/^{239}\text{Pu}$ in the range of 0.18 to 0.13. These results indicate the presence Pu and Np derived from both fallout and nuclear production facilities.

Thermal ionization has long been the method of choice for measuring isotope ratios when the best precision or the most sensitivity was wanted. Its most significant drawback is that, because an elementally pure sample must be loaded on the mass spectrometer filament, extensive sample preparation is required. It is sample preparation that more often than not dictated sample throughput and the cost of analysis. The possibility of better performance in this regard has always been attractive, but it is only recently that instrumentation became available that offered realistic hope of achieving substantial gains. This instrument, a VG Plasma 54, combines an inductively coupled plasma (ICP) ion source with a double focusing sector mass spectrometer equipped with a multicollector array. Multicollectors have long been used in thermal ionization and lead to improvement in precision of about a factor of five. Because an ICP is less stable than a thermal source, multicollectors are even more important. ICP has inherent advantages when compared to thermal sources. For example, many elements (e. g., Te) are readily analyzed with ICP and cannot be addressed thermally due to the combination of high volatility and high first ionization potential. Less time is required for an analysis, and it should not be necessary to go through the entire elemental separation process; these two together suggest that much greater throughput may be realized with the new instrument than was previously possible. Another advantage is that time-dependent fractionation, a constant problem in thermal ionization, does not occur. Walder, et al. (1,2) report precision of $\pm 0.01\%$ in many cases, sufficient for all but the most demanding isotope ratio problems. A thorough evaluation of the instrument is needed before definitive judgment can be made. Among the issues to be addressed are. What is the magnitude of isotopic bias and how stable is it? How reliable is external calibration? What sample size is optimum and what is the smallest amount necessary to provide a reliable analysis? What compromises in results ensue when the sample is not elementally pure? Which of several nebulization systems is best?

We have just started this work. Our initial efforts were directed toward integrating the Daly detector into the analytical process. This detector is located on the optical axis and may be used instead of the Faraday cup. It extends the dynamic range of the instrument down to the low ppm range and is necessary for the analysis of the minor isotopes of uranium. We used NIST U-010 as our working standard at a concentration of 5 weight ppm. Five blocks of 20 measurements each were used. Data were first collected with ^{234}U in the axial collector and then with ^{236}U . Each data set thus gave two values for $^{235}\text{U}/^{238}\text{U}$, one for each pocket-isotope configuration. Measured $^{235}\text{U}/^{238}\text{U}$ ratios were compared to the certified value and a bias correction per mass calculated on the basis of a power function. (3) The corrections necessary to apply to the $^{234}\text{U}/^{238}\text{U}$ were also calculated. These last two combined the contribution of mass bias and the calibration factor necessary to coordinate the Daly detector with the Faraday cups. The two mass bias values determined from the

two $^{235}\text{U}/^{238}\text{U}$ were statistically indistinguishable. The average was about 0.003/mass. The calibration factor between Daly and Faraday was about 1.03. The correction factors determined each day were then applied to two solutions of NIST U-010 that were 1 ppm U and 0.5 ppm U, respectively. These results are summarized in Table 1. As expected, precision is poorer for the less concentrated solution.

The results of this study indicate that daily calibration is necessary if the best accuracy is desired. Unlike thermal ionization, ionizing conditions in the ICP vary enough from day to day to preclude the use of long-term average bias corrections. It was also obvious that we were far from the statistical limits imposed by counting statistics; precision when 100 ratios were taken was no better than when 20 were. As shown in Table 1, results for the two minor isotopes (234 and 236) are quite good, suggesting that calibration between Daly and Faraday will be reliable.

Our next series of experiments will be to compare three nebulization systems: the conventional Meinhardt system; a CETAC MCN-100 microconcentric nebulizer; and a CETAC 6000AT* ultrasonic nebulizer. Uranium at various concentrations will be measured, and the effect of contaminants will be explored.

Glow Discharge Ion Trap Mass Spectrometry- A Look at Elemental Analysis and Isotope Ratios

Ritchie C. Eanes*, Douglas C. Duckworth*, R. Kenneth Marcus*

*Department of Chemistry, H.L. Hunter Chemistry Laboratory, Clemson University, Clemson, SC 29634-1905

*Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

A useful area of study for the ion trap is elemental analysis, especially since the advent of ion isolation techniques which effectively increase the dynamic range of the trap and hence the sensitivity of measurement due to decreased space charging effects. Along with this area of study is the importance of isotope ratio measurements. Isotope ratios are an important part of mass spectrometric analysis, providing useful qualitative data related to elemental identity as well as quantitative information of a gas phase chemical system. The study of how elemental isotope ratios are affected by isolation and ejection techniques is an important topic for ion trap usage.

Glow discharge mass spectrometry (GDMS) has been used for the direct elemental analysis of solids. The GDMS method is based on cathodic sputtering of the sample (SRM 1104 Free-Cutting Brass for these studies), with the liberated atoms subsequently being ionized through electron impact and Penning collisions in the plasma. In a collaborative effort between ORNL and Clemson University, studies have been initiated to examine the precision in measurement of isotope ratios of ions generated from a glow discharge interfaced via a gated lens assembly to a Teledyne 3DQ ion trap mass spectrometer.

The choice of a method for data handling with this system was a primary concern. Data was imported from the Teledyne Sequel Data System (as centroid and profile spectra) into spreadsheet form in Microsoft Excel and spectra evaluated by peak height and peak area. Experiments were run to examine the number of averaged microscans which should be acquired to achieve the best precision for subsequent experiments. Fig. 1 shows data (analyzed by peak area) for the $\text{Sn}^{120}/\text{Sn}^{118}$ isotope ratio (trapped at an "ideal" q_z value of 0.76 for Sn^{120}) as a function of the number of microscans averaged to give a spectrum. Each data point represents the %RSD for 5 consecutively acquired spectra. From this and similar experiments with $\text{Pb}^{208}/\text{Pb}^{206}$, 50 averaged microscans appear to be sufficient with a lower plateau of < 5% RSD for both $\text{Sn}^{120}/\text{Sn}^{118}$ and $\text{Pb}^{208}/\text{Pb}^{206}$.

Another area of interest to these studies was the effect of space charging on isotope ratio measurements. Fig. 2 shows the %RSD of ($\text{Cu}^{63}/\text{Cu}^{65}$) as a function of ion accumulation (injection time) at "ideal" q_z values of 0.997 and 0.633 for ^{40}Ar and

^{63}Cu , respectively (note the shift to the right of the Mathieu stability q_z value for ^{40}Ar). With increased injection times, there are increased levels of ions trapped which varies the degree of space charging. These preliminary data suggest that the space charging of copper and argon does not degrade the $\text{Cu}^{65}/\text{Cu}^{63}$ isotope ratio measurements in this experiment up to an injection time of 90 microseconds.

Further experiments were attempted at various combinations of helium pressure, q_z value during ion accumulation and ion injection times. Data acquired during study of the $\text{Pb}^{208}/\text{Pb}^{206}$ isotope ratio (at q_z values of 0.57 and 0.65) at various helium pressures and ion accumulation periods became questionable after examination of spectra revealed a mass shifting effect from spectrum to spectrum. It became difficult to analyze the data due to this peak shifting which changed the channel(s) over which a peak height (or peak area) could be taken. These complications seemed to coincide with an observed overheating of the amplifiers which drive the rf signal to the center electrode of the trap after experiments were run for several hours at high rf (1150 V_{pp} and higher) injection trapping potentials.

Future studies should focus on instrument stability and this effect of mass shifting after long run periods. Also, ways to improve data analysis of peak heights and peak areas need to be pursued.

Performance Test of a Moving Wire Interface for Isotope-Ratio-Monitoring LCMS

W.A. Brand, P. Dobberstein, R. Pesch and E. Schroeder
Finnigan MAT GmbH, D-28197 Bremen, Germany

A Liquid Chromatography-Combustion (LC-C) interface, based on a moving wire technique, has been built. The LC effluent is deposited onto a transport wire, which carries the sample through solvent evaporation and combustion ovens. CO₂ from the combustion step is analyzed in an isotope ratio mass spectrometer delta S. First results obtained with our breadboard design have already been reported [1]. For flow injections of sucrose a yield of 20% was reached, taking into account the splits of the liquid flow in front of the interface and of the He flow, which carries the CO₂ into the ion source. Precision, however, was only 5‰ for delta 13C vs PDB using water for the liquid carrier.

Fig.1

peak #	sample	$\delta^{13}\text{C}_{\text{PDB}}$ bulk comb.	$\delta^{13}\text{C}_{\text{PDB}}$ this exp.	difference
1	calib. gas	—	-38.4 ‰	—
2*	—	—	-38.3 ‰	(reference)
3	tartaric acid	-20.4 ‰	-19.7 ‰	+0.7 ‰
4	malic acid	-22.1 ‰	-23.0 ‰	-0.9 ‰
5	ketoglutaric acid	-24.4 ‰	-21.9 ‰	+2.5 ‰
6	citric acid	-12.5 ‰	-9.4 ‰	+3.1 ‰
—	fumaric acid	-26.3 ‰	not detected	—
7*	calib. gas	—	-38.3 ‰	(reference)

Table 1

The performance of the interface could be improved. We are now reaching yields between 80 and 100%, which means that none of the sample deposited on the wire is lost in the device, if the open split (10:1) in front of the ion source is taken into account. Accuracy and precision for delta 13C vs PDB, achieved with loop injections of sucrose and glucose into a liquid flow of methanol/water (80/20), are < 1‰. This performance is sufficient for studies at natural isotope ratios.

For 13C tracer applications we find a detection limit of 200 pg carbon label, injected into the 1 ml/min liquid flow in front of the eluent splitter preceding the coating assembly of the moving wire interface [2].

Testing the interface in combination with LC separation was the next step. In the investigation of organic acids from fruit juices for quality and authenticity control by IRMS typically preparative reversed-phase chromatography is applied [3]. We simulated this analysis step on an analytical microcolumn (MERCK Supersphere RP-18, 2 x 119 mm, 2 columns in series) using the same solvent system as in the preparative separation (0.02M H₃PO₄, isocratic). A cryotrap, operated with dry ice (-79 °C) was situated in the transfer line between the combustion oven and the mass spectrometer.

We used 5 organic acids (purchased from Sigma) in this analysis. Their ¹³C/¹²C isotope ratios were determined by bulk combustion in the elemental analyzer independently from the analysis with LC combustion (results are displayed in the middle column on table 1). In the LC chromatogram, detected with the Moving Wire interface (Fig. 2) one of the acids (fumaric acid) was missing. However, fumaric acid could be detected in separate runs by loop injections (no column) of the same sample. Delta values determined in this experiment (Table 1) differ between -0.9 and +3.1 ‰ from the values from bulk combustion. These values are less accurate than the values obtained by loop injection (no LC separation) possibly due to incomplete separation.

A NOVEL APPROACH FOR STUDYING CALCIUM FLUXES AT SUBCELLULAR SCALE: SIMS IMAGING OF STABLE ISOTOPES

Subhash Chandra

Department of Chemistry, Baker Laboratory, Cornell University, Ithaca, N.Y. 14853.

Calcium has been implicated to be a critical element in many biological events such as fertilization, mitosis, muscle contraction and allergic response. Fluxes of calcium play regulatory role and have been termed as "second messengers" in intracellular signal transduction. Consequently, their measurement in single cells is an area of active research in cell biology. Ion microscopy, based on secondary ion mass spectrometry (SIMS), provides a powerful technology for the study of ion fluxes as it produces visual images of isotopic gradients in relation to cell morphology at subcellular scale. The ion microscope is an imaging mass spectrometer capable of detecting any element (isotope) from H to U with sensitivities in the ppm to ppb range. We have employed a CAMECA IMS-3f dynamic SIMS instrument that is capable of a spatial resolution of 0.5 μm . The optics of this instrument are such that there is a one-to-one correspondence between the relative position of atoms in the sample and the final position of ions as they strike the detector. The ion images represent the surface chemistry of the sample. Since the technique distinguishes between the isotopes on the basis of their mass-to-charge (m/z) ratio and the analysis is made by continuously eroding (sputtering) the cell surface, it is possible to image, sequentially, intracellular distributions of several different isotopes from the same cell. An added advantage of isotopic detection is that one can use stable isotopes as tracers for ion transport. We have made use of the stable isotope of calcium, ^{44}Ca , for independently imaging the influx of calcium at mass 44 and endogenous calcium at mass 40 (^{40}Ca) from the same cell. The imaging of stable isotopes with SIMS has introduced a novel approach for measuring the transport of calcium at subcellular resolution in resting and stimulated cells.

We have developed strict cryogenic sample preparations for immobilizing highly diffusible calcium ions in native intracellular sites for SIMS analysis (1,2). We have also correlated laser scanning confocal microscopy, secondary electron microscopy and ion microscopy on the same cell for microfeature recognition of calcium gradients in single cells. We have evaluated SIMS matrix effects (3) and developed quantitative procedures (4) for pixel-by-pixel quantification of SIMS isotope images. These methodological developments have allowed physiological studies of calcium transport in both *in vitro* and fully polarized animal model systems with SIMS.

By using ^{44}Ca (98.78 % enrichment) in the nutrient medium, we have studied its exchange with cellular endogenous ^{40}Ca , by imaging both isotopes of calcium with SIMS from the same cell. This way we have studied the kinetics of calcium-to-calcium exchange and the exchangeable pools of calcium stored within subcellular compartments such as the nucleus, Golgi apparatus and cytoplasm (5). Golgi apparatus was identified as a calcium store by correlating laser scanning confocal microscopy and ion microscopy on the same cell (6). Recently, we have shown that Golgi apparatus is involved in intracellular regulation of calcium as it responds to hormonal and antigen stimulation (7, 8).

Direct imaging of $^{44}\text{Ca}^{2+}$ influx with ion microscopy revealed that regulation of calcium influx in cells undergoing mitosis is remarkably different from interphase cells. Mitotic

metaphase and anaphase cells exhibited significantly reduced levels of calcium influx as compared to the neighboring interphase cells. The prophase stage of mitosis did not show this pattern.

By directly injecting $^{44}\text{Ca}^{2+}$ in the intestinal lumen of chickens we have been able to image the transport of ^{44}Ca in the intestinal tissue with SIMS and to compare this transport between vitamin D-deficient and control chickens. In vitamin D-deficient chickens the main barrier to calcium transport was the brush border region (9).

SIMS methodologies developed for stable isotopes of calcium can be easily extended to other elements. Recently, we have also been successful in using stable isotopes of magnesium for magnesium transport studies. This development is particularly important since the short half-life of the radioactive magnesium isotope renders it impractical for kinetic studies. We are also exploring the possibility of imaging isotopically tagged (^2H , ^{15}N , ^{13}C , etc.) molecules with ion microscopy. Preliminary observations with a ^{13}C , ^{15}N labeled amino acid, L-arginine, indicate that its incorporation in intracellular sites may be cell cycle dependent (10).

HIGH-PRECISION D/H MEASUREMENT FROM ORGANIC MIXTURES BY CONTINUOUS-FLOW ISOTOPE RATIO MASS SPECTROMETRY USING A PALLADIUM FILTER

Herbert J. Tobias and J. Thomas Brenna

Division of Nutritional Sciences, Cornell University, Ithaca NY 14850

The measurement of D/H isotope ratios from organic molecules is usually performed by total conversion to hydrogen gas by the combustion of the sample to CO₂ and H₂O using cupric oxide, cryogenic separation of CO₂ from the water, and reduction of the water using uranium or zinc metal. Subsequent isotopic analysis is done using a gas-isotope ratio mass spectrometer (GIRMS). These offline procedures are very laborious and time consuming, often require large sample quantities for precise analysis, and difficulty working with water vapor results in problems of isotopic fractionation and sample memory effects. Here, online continuous-flow high-precision determination of D/H ratios from an organic mixture is described using gas chromatography coupled to a Pd filter system¹ (PFS) as an interface for IRMS. A GC, and combustion and reduction furnaces are connected to an IRMS by a Pd filter. This interface is evaluated using benzene as an internal standard in a mixture of ethyl benzene and cyclohexanone in hexane with analyte measured at quantities of < 3 ng (<300 pg H).

When analyzing complex mixtures of organics, long capillary columns are often required, which result in lower flow rates and carrier pressures at the Pd filter. Comparing the same sample mixture analyzed via an FID to the online PFS, we observe that the peaks are substantially sharper for the PFS. This effect, shown in figure 1, appears to be due to the insensitivity of the Pd filter at the lower analyte pressure where peaks are broad. A

Figure 1: A-FID trace, B-PFS without pressure makeup, C-PFS with pressure makeup.

was constructed and inserted between the water trap and the Pd filter to increase the pressure at which the carrier and analyte impinge upon the palladium surface. Figure 1 also shows that this addition produces peak shapes that more closely resemble those seen in the FID trace with greater peak broadening expected for a system with more plumbing.

A calibration curve is constructed using four benzene samples over a range of -48 to 372‰ (δD_{SMOW}), resulting in an average benzene D/H precision of SD < 5‰ (δD_{SMOW}) and deviations of <4‰ from the calibration curve. Ethyl benzene and cyclohexanone of a single D-enrichment are analyzed as unknowns in three sample mixtures with varying D-enriched benzene and result in precisions of SD < 5‰. In figure 2, the question of memory effects was addressed by comparing the average value for each analyte in a specific sample mix versus the enrichment of the benzene standard within that mixture. No apparent memory is observed between peaks of differently enriched analytes within the same chromatogram. Due to a non-linear effect for hydrogen over a varying signal range, mostly due to an H₃⁺ contribution, measured hydrogen isotope ratios depend highly on the partial pressure of hydrogen in the ion source and present an accuracy problem with chromatographic analysis.

However, this effect can be characterized using a second order relationship and all results are corrected using the internal peakwise correction algorithm, described previously².

A small dependence of isotope ratio on palladium membrane temperature is demonstrated over a

range of 4°C; therefore, with tighter control of palladium temperature, precision can probably be improved. The data indicate that this system is useful for rapid continuous-flow IRMS analysis of D/H ratios from organics in complex mixtures characteristic of geological and biological samples.

Figure 2: Measured ratio of analytes vs the isotope ratio of internal standard benzene in the sample mixture.

Hair analysis for drugs of abuse is based on the well-recognized fact that drugs circulating in the blood stream become permanently entrapped in the keratin matrix of the hair shaft. As the hair grows at an approximate rate of 1.3 centimeters per month, it serves as a recorder of the time frame of drug use. Drug consumption during the most recent 90 days is recorded in approximately the first four centimeters of hair growth. This extended surveillance over a three-month period, which is routinely used in employment testing, has many advantages over the very small time window of approximately 3 days after consumption provided for most drugs by urine analysis. The record of drug use is retained in hair for long periods of time, and in the case of morphine and cocaine, this has been shown to cover many centuries. Detection and confirmation of the five major drugs of abuse and their various metabolites (e.g., marijuana, cocaine, opiates, amphetamines and PCP) involves the dissolution or extraction of the hair sample (usually 10-20 mg) followed by an initial screening by radioimmunoassay (RIA) and structural confirmation of presumptive positives by gas chromatography/mass spectrometry (GC/MS). The promise of this new technology lies in the opportunities for forensic scientists, physicians and employers to develop alternate strategies for the investigation of drug use. The impressive volume of data on hair analysis for drugs of abuse has clearly demonstrated that this technology is generally recognized as scientifically sound by the forensically relevant community of hair analysis practitioners.

ADVANTAGES OVER URINE

Hair sampling possesses several unique advantages over traditional urine sampling. The primary advantage is the chronological retrospective identification of drugs over the 90 day window via hair versus the short window of 48 hours via urine immediately following ingestion. However, the complementary aspect of both tests should not be overlooked. In the case of monitoring for cause after an accident, urine testing provides effective surveillance since hair at the point of ingestion would take 4-5 days to emerge from the scalp surface for subsequent sampling. Comparison of data provided by urine versus hair testing for drugs of abuse has concluded that such tests often provide complimentary features based on their windows of detection.

ROUTINE PRODUCTION ANALYSIS OF CARBOXY-THC VIA NICI-GC/MS/MS

By far the most difficult analytical issue in testing for the various groups of drugs of abuse is the detection of marijuana. For sound scientific reasons to avoid passive contamination issues, the moiety of choice for detection in hair is the primary metabolite of tetrahydrocannabinol (THC), 11-nor-carboxy-delta9-tetrahydrocannabinol (cTHC). While samples are screened by radioimmunoassay to detect positives, the structural confirmation step involves derivatization of cTHC to a volatile derivative containing sufficient fluorines to permit low level detection via negative ion chemical ionization. The analytical approach in this laboratory permits detection to the femtogram level with concurrent reduction in the sample matrix background contribution. However, the appearance of base peak corresponding to the molecular anion after loss of HF at m/z 670 and a major fragment ion at m/z 492 are insufficient evidence to provide unambiguous proof of presence. Therefore, the power of tandem mass spectrometry has been employed to provide characteristic daughter or product ions to satisfy the criteria for structural identification. In addition, the use of a deuterated (d3) internal standard of cTHC provides quantification of trace levels via accepted isotope dilution analysis.

The experimental protocol chosen to perform routine detection of cTHC in hair digest via GC/MS/MS involved selected reaction monitoring (SRM) using the two parent ions (m/z 670 and 673) belonging to CTHC and its d3 analog. The corresponding daughter ions produced in Q2 by collision processes, m/z 492 and 344 for CTHC and m/z 495 and 347 for the d3-analog, were recorded for structural confirmation concurrent with quantification via isotope dilution.

CONCLUSIONS

The analysis of trace levels of drugs of abuse in hair has rapidly become the preferred method by many corporations to provide data on drug use of pre-employment candidates stretching over the past 90 days rather than the 3-4 day time window provided by urine analysis. Clearly the emphasis placed on forensic toxicology and trace analysis has stimulated technological advancements to the present day accelerated pace. History has clearly demonstrated that it has been the development of innovative technologies for drug analysis by analytical chemists that has stimulated the development of new forensic approaches for the detection of drug users. This relationship between the new and traditional approaches should not be viewed as one of competition between blood, urine and hair analysis, but rather as one where the different techniques are in synergistic interaction in solving the unique forensic challenges associated with the identification of drug use. In this respect, the particular value of hair analysis lies in the ability to determine long-term usage of drugs of abuse rather than the short term elimination provided by blood and urine.

The greatest challenge in the area of hair analysis has been the development of ultrasensitive mass spectrometry technologies to provide reliable confirmation of structure. The case histories described in this review stand as testimony to the evolution of criteria for confirmation of presence which are generally recognized as scientifically sound. While the variation in application of MS methods is large, the underlying theory that at least three structurally significant ions are necessary for confirmation has been experimentally established. With the increasing practice of using soft ionization methods, the universal problem of meeting these established criteria has been overcome by MS/MS using a combination of parent and daughter ions. In some instances two ions have been employed as definitive proof of presence and then the supporting evidence of GC retention time and analytical extraction have been considered important. Also the ability of GC/MS to concurrently detect metabolites as well as the parent drug is an added benefit not available from RIA methods. In most quantification assays, the employment of one ion representing the compound of interest has been acceptable provided confirmation has been carried out *a priori*. The linearity of detection of a mass spectrometer has been demonstrated under most ionization modes by calibration plots covering at least two orders of magnitude. While the use of isotope dilution techniques has been used extensively using chemical ionization methods to avoid additional sample clean-up as well as to avoid potential interferences, its recent extrapolation to daughter ion chemistry has now extended the linearity concept to collisionally induced dissociation experiments. Moreover, the introduction into commerce of the low-cost ion trap mass spectrometers with sensitivity in the low picogram range might well bring this type of MS into more general applications to drugs of abuse testing in hair. In spite of the 15% coefficient of variation predicted for quantification of at the nanogram and low picogram level between laboratories, the precision and accuracy demonstrated by a single laboratory can be as low as 10%. The scientific excellence portrayed by members of this discipline in publication of results of reliable methods for analysis of drugs of abuse in hair stands as evidence that no mandated carved-in-stone criteria are necessary for confirmation. The good judgment of the MS expert, coupled with established quality assurance procedures, result in analytical practices which are considered scientifically sound by forensic science standards.

The Role of Mass Spectrometry in Drug Metabolism and Pharmacokinetics

Ian A. Blair

Departments of Pharmacology and Chemistry, and Center in Molecular Toxicology, Vanderbilt University, Nashville, TN 37232, USA

Mass spectrometry has become one of the most important analytical tools employed in the analysis of drugs and their metabolites. This can most likely be attributed to the availability of new instrumentation and ionization techniques that can be used to help solve difficult bioanalytical problems associated with this field. Perhaps the best illustration of this occurrence is the development of electrospray ionization (ESI) and related atmospheric pressure ionization (API) techniques such as ionspray (nebulizer assisted ESI) and atmospheric pressure chemical ionization (APCI; nebulization coupled with corona discharge) for use in drug disposition. Over the last five years, there has been an unprecedented explosion in the use of instrumentation dedicated to API/MS. API-based ionization techniques are gaining increasing importance in the analysis of drugs and their metabolites as compared to thermospray, which clearly was the predominant LC/MS technique throughout the 1980's. Numerous reports of API/MS studies concerning drugs and their metabolites have appeared in the literature over the last five years. In addition, it is clear that many studies have been conducted using proprietary compounds, and it will take several years for patent clearance to be obtained for the full release of all the findings to take place.

The use of stable isotope analogs has assumed increasing importance in drug disposition studies. The isotope cluster technique is particularly useful. This method allows for the recognition of metabolites in complex biological matrices such as urine and plasma. Numerous methods have been developed for the deconvolution of isotope clusters from stable isotope analogs so that mass spectral identification can be facilitated. In the field of pharmacokinetics, stable isotope analogs are used as internal standards for quantitative purposes, to determine bioequivalence and in chiral drug disposition. In studies regarding chiral drugs, the use of a pseudoracemate, where one enantiomer is labeled and the other is unlabeled, provides the basis for a robust method that can be used to determine pharmacokinetic parameters of individual enantiomers and their metabolites. An innovative approach to the use of stable isotopes was pioneered by Abramson and his co-workers who have introduced the chemical reaction interface (CRI) mass spectrometer for quantitative drug metabolism studies. This type of approach will ultimately provide an alternative to utilizing radioisotopes in drug disposition studies. There is a genuine need for this type of methodology in view of the increasing cost of disposal of radioactive waste, the cost of radiolabeled compounds, and the increasing reluctance to dose normal subjects with radiolabeled compounds.

Tandem MS (MS/MS) is particularly powerful for both quantitative and structural analyses. A major factor that has ensured the rapid acceptance of API-based methodology is the ability

to conduct collision-induced dissociation (CID) of molecular ions and MS/MS analysis. The resultant product ion spectra, constant neutral loss spectra or precursor ion spectra can be obtained with extremely high sensitivity. It is also possible in some instances to obtain significant structural information using API techniques without employing a tandem mass spectrometer by performing CID in the API source of a single-stage mass spectrometer (in-source collisions). Thus, even relatively simple single quadrupole instrumentation can often provide rich structural information.

The exquisite sensitivity of electron capture negative chemical ionization (ECNCI)/MS has facilitated quantitative determinations of drugs at femtomole and attomole concentrations. GC/ECNCI/MS has generally been the method of choice where pharmacokinetic determinations require a very high level of sensitivity. The method normally requires that analyte molecules are derivatized so that they can capture thermal electrons generated in the source of the mass spectrometer. Because it is relatively easy to prepare in high yield under very mild conditions, the pentafluorobenzyl (PFB) derivative has found the widest applicability. Dissociative electron capture provides an anion that contains the intact analyte molecule and virtually no fragmentation is observed. Therefore, assays using this technique have high specificity in addition to high sensitivity.

There is a substantial interest in the use of mass spectrometry for examining drug-induced lesions to DNA. LC/API/MS makes it possible to characterize DNA-adducts that are formed by activation of drugs to reactive electrophilic species. This methodology has also proved to be useful for characterizing the DNA-adducts that arise through endogenous pathways that involve reactive oxygen species. For example, the malondialdehyde adduct of 2'-deoxyguanosine has been identified in rat and human liver DNA. Quantitation of DNA-adducts in biological tissues can often be performed using LC/SRM/MS. However, it may be necessary to perform GC/ECNCI/MS analyses of appropriate PFB-derivatives when DNA-adducts are only present in trace amounts.

In summary, the power of MS/MS in combination with API makes it the method of choice for both structural and quantitative studies. In selected cases, when concentrations of the analyte are extremely low, it may be necessary to employ the high sensitivity of GC/ECNCI/MS. The development of quantitative methodology for the analysis of drugs and their metabolites is still heavily reliant on the availability of authentic standards. This can overcome the potential problem of analyzing individual metabolites that may have quite different ionization characteristics. However, when authentic standards are not available, CRIMS offers a potential alternative.

Liquid Chromatography Tandem Mass Spectrometry (LC/MS/MS) of Buprenorphine and norBuprenorphine in Human Plasma and Hair

John D. Laycock, Alan C. Spanbauer, Diana G. Wilkins, Dennis J. Crouch, Rodger L. Foltz, David E. Moody,

Center for Human Toxicology, University of Utah, Salt Lake City, UT 84112

Introduction

Buprenorphine (Bup) is a potent, synthetic opiate that is of interest in treating opiate dependence due to its k -antagonist and partial μ -agonist properties (Fig. 1). The long-lasting effect and the slow dissociation of buprenorphine from the receptors lead to particular interest in its pharmacokinetics. The low plasma concentrations of buprenorphine and its dealkylated metabolite, norbuprenorphine (norB), require a sensitive technique for measurement. Previous work in our group using gas chromatography positive chemical ionization mass spectrometry (GC/MS) established an LOQ of 1.0 ng/mL of buprenorphine extracted from 2 mL of plasma. A liquid chromatography tandem mass spectrometric (LC/MS/MS) method has been developed in order to avoid the derivatization step required for GC/MS and to bring the LOQ closer to the low end of the therapeutic concentration range for buprenorphine. Both plasma and hair validations for the measurement of Bup and norB are summarized in the presentation.

Experimental

One step liquid-liquid extractions of 1 mL of plasma and 20 mg of digested hair (pH adjusted to 9.5) are performed utilizing n-butyl chloride:acetonitrile (4:1 v/v). The reconstituted plasma extracts are separated isocratically on an Alltech C8 LC column (150 x 2.1 mm) with H₂O:MeOH:ACN (25:30:45 v/v) containing 0.1 % Formic acid. The method uses a Finnigan TSQ 7000 triple stage quadrupole mass spectrometer utilizing both the ESI and APCI LC/MS interfaces. The ESI spray voltage is 5 kV and the capillary temperature is 250 C. The APCI corona current is 5 uA the capillary/vaporizer temperatures are 175/500 C. Both Bup and norB are quantitated based on analyte area/buprenorphine d4 ratios (Fig 2).

Results and Conclusions

The calibration curves (Fig. 3) are linear from 0.1 to 10 ng/mL (plasma) and 0.01 to 50 ng/mg (hair) with correlation coefficients 1.000 and 0.998 respectively. The average extraction efficiency for all three controls is 76% and 79% for Bup and norB, respectively (Table 1). Five different plasma extracts were run as selectivity controls and no quantifiable peaks eluted in the Bup-d₄ retention window. The intra-run precision and accuracy plasma (ESI) data are summarized in Table 2. All of the Bup precision and accuracy data were well within acceptability criteria. The norB data was marginally acceptable above the 0.25 ng/mL QC. The hair validation summary (APCI) is presented in Table 3. The precision measurements are based on triplicate calibration points. All values are acceptable except for the mean of the 10 pg/mg calibrators.

Tandem Mass Spectrometry in Natural Products Discovery

Randall K. Julian, Jr.

Lilly Research Laboratories, Eli Lilly and Company

Despite the vast global genetic diversity, many organisms produce the same secondary metabolites. This is due in part to the relatively recent genetic divergence of microorganisms leading many bacteria, fungi and plants share key biosynthetic pathways via evolution. Common secondary metabolites can also arise from the direct sharing of genetic material between organisms.

The fact that single-cell and multi-cell organisms have only recently diverged has the positive effect of increasing the probability that a microorganism will produce a compound which binds specifically to human molecular targets. However, once an active secondary metabolite has been discovered, there is a significant chance of finding the same compound again especially within a taxonomic class. It is also likely that compounds which produce non-specific activity will be observed repeatedly if a large number of organisms in a producing class are tested.

For commercial drug discovery, it is important to establish the novelty of active compounds quickly. To aid in this process a combination of chromatography, spectroscopy and biological assays are used. The traditional method for identifying active compounds from a complex mixture involves collecting and testing HPLC fractions from the original sample. By collecting UV-visible and mass spectra during the separation, it is often possible to identify common metabolites from reference samples or the literature. Once a structure has been proposed, tandem mass spectrometry can then provide a final confirmation. HPLC fractions are collected, dried and reconstituted in solvent suitable for direct infusion into a tandem mass spectrometer equipped with an electrospray source.

Recently both triple quadrupole mass spectrometers as well as ion trap mass spectrometers have been used to provide MS/MS data for the confirmation of known structures from biological samples. In Figure 1, the UV-vis chromatogram is shown. Fractions were collected at 15 second intervals and the biological activity of each fraction was measured. The "biogram" is shown in Figure 2 where activity is plotted by retention time to establish the location of the active compound (here fractions 37 and 38 are active). The molecular weight from fraction 37 was 612 amu. A literature search of the molecular weight produced novobiocin as a candidate. In Figure 3 the MS/MS spectrum from well 37 is shown and confirms the structure assignment.

The ion trap mass spectrometer further extends the capability of tandem mass spectrometric comparison. Using a Finnigan LC/Q ion trap mass spectrometer the MS/MS and MSⁿ spectra of novobiocin reveal an extended collection of spectra for comparison.

This talk includes data from the work of John Mynderse, John Richardson, Larry Sachs, and Dale Duckworth. Their effort is greatly appreciated.

New Automated Data Acquisition and Processing Tools for Pharmaceutical Research Utilizing API/MS/MS

Bori Shushan, Tom Covey, Mark Allen, Joe Anacleto, Ron Bonner, Yves LeBlanc, PE SCIEX, 71 Four Valley Dr., Concord, Ontario, Canada L4K 4V8

This paper discusses pharmaceutical biotransformation studies featuring API/MS/MS techniques combined with novel data acquisition and processing employing AppleScript and a Macintosh-based data system. The instrument used in the present work was an API 300 LC/MS/MS (PE SCIEX, Foster City, CA). The first example is a script which, based upon the user input of the substrate molecular ion mass (in this case m/z 346.2 of Omeprazole), produces appropriately labelled RIC's for all user-specified metabolites in LC/MS data. The TIC for the LC/MS of rat metabolites extracted from urine is shown in Figure 1.

Figure 1. LC/MS of Omeprazole metabolites in urine after administration to rat.

Figure 2. LC/MS RIC traces for Omeprazole metabolites from rat urine automatically created using an AppleScript in MultiView.

isotopically labelled forms of Omeprazole permitting the recognition of drug and metabolites by observation of the unique and artificial isotopic signature. We use the Cluster Filter algorithm in MultiView to scrutinize the whole LC/MS run on a scan-by-scan basis eliminating signals which do not exhibit this unique isotopic pattern. To illustrate how such an algorithm simplifies LC/MS data, the complete metabolic profile of Omeprazole in the rat was analyzed after administration of a 50:50 mixture of native and ^{34}S versions of the drug. Signals due to endogenous compounds do not feature the characteristic isotopic pattern and are eliminated from the LC/MS data set (see the sum of all IonSpray mass spectra from before and after 'cluster filter' analysis in Figure 3). Omeprazole metabolites were thus accentuated and

In the present example the RIC's of phase 2 metabolites were automatically created and appropriately labelled with the metabolite name and printed, all under AppleScript control (see Figure 2). An unlimited number of metabolites can be specified. The mass, retention times and intensities can be automatically captured by the script and the information used to program subsequent LC/MS and/or LC/MS/MS experiments. The next example employs stable

Figure 3. Summed spectra from the LC/MS of Omeprazole metabolites which contain a mixture of ^{34}S and native S before and after cluster filter analysis.

lites are observed in the LC/MS/MS data (see Figure 5). The LC/MS data were far more complex exhibiting signals due to a matrix of 40 or 50 endogenous components. The retention time data of the PI and NL scans can then be used to automatically set up subsequent LC/MS/MS experiments.

Figure 5. LC/MS vs. LC/MS/MS (Precursor ion scan) for Bosentan metabolites. The mass spectra are comprised of summed scans from the retention time regions shaded.

identified including mono-to-tetra-hydroxylated, glucuronidated and sulfated species. Another means of increasing specificity in biotransformation studies is by LC/MS/MS. By employing precursor ion (PI) and neutral loss (NL) scans it is possible to highlight only those compounds structurally related to the substrate drug. The example of Bosentan is employed to illustrate the principle by comparison of LC/MS and LC/MS/MS data from bile after administration of the drug to dog. The MS/MS spectrum of Bosentan is shown in Figure 4 where this compound fragments to form characteristic product ions at m/z 280 and 202. The MS/MS specificity of the NL and PI scans is such that only the Bosentan signals for the parent drug and the desmethyl and hydroxylated metabo-

Figure 4. MS/MS spectrum of Bosentan.

Conclusions:

Automated biotransformation analysis of LC/MS data is provided by AppleScript in MultiView; Stable isotopic labelling facilitates biotransformation studies through the use of isotopic pattern recognition algorithms in MultiView; LC/MS/MS precursor ion and neutral loss scans provide chemical compound class specificity and simplify biotransformation studies.

Rapid *In vivo* Pharmacokinetic Screening of Drug Discovery Mixtures Using APCI LC/MS

K.A. Halm, K.K. Adkison, J. Berman, J.E. Shaffer, Q.W. Tong, F.W. Lee and S.E. Unger, Glaxo Wellcome, Five Moore Drive, Research Triangle Park, North Carolina 27709

INTRODUCTION

In pharmaceutical research, large numbers of lead compounds are identified from *in vitro* screens. Traditional methods for *in vivo* pharmacokinetic characterization of large numbers of active compounds can be a bottleneck in selection of an optimal compound for progression to development. We have increased *in vivo* screening throughput an order of magnitude by dosing mixtures of lead compounds (N-in-One) to a single animal and using Atmospheric Pressure Chemical Ionization LC/MS for quantitation on a Finnigan TSQ-700 mass spectrometer. This strategy was applied in the context of our Alpha1 receptor antagonist program. The inherent detection sensitivity and selectivity of mass spectrometry afforded rapid analytical method development and application for screening nearly 150 compounds *in vivo*.

ANALYTICAL METHODS

The N-in-One dosing strategy was initially validated by examining a mixture of five Alpha1 receptor antagonists administered intravenously in the dog. Multiple reaction monitoring (MRM) was used to increase selectivity from the biological matrix. Plasma samples were prepared by protein precipitation with addition of an internal standard. The LC/MS/MS method was developed on a 4.6x50 mm BDS Hypersil C18 (3 micron) column with isocratic mobile phase conditions. Flow switching with a 6-port Valco switching valve was used to minimize contamination of the APCI source from the plasma extracts. Plasma concentrations were calculated using peak area ratios with 1/x weighted linear regression over a range of 5 - 2500 ng/mL. Linearity, accuracy and precision of the composite calibration standards were acceptable. Pharmacokinetic parameters (half-life, clearance, volume of distribution) compared favorably between the 5-in-One dosing study (LC/MS/MS) and the individual compound studies (HPLC/fluorescence). The correlation of half-lives yielded an R^2 of 0.9021.

Concentration-Time Profiles of Five Alpha1 Receptor Antagonists Following Concomitant Intravenous Dosing in the Dog (0.25mg/kg)

Pharmacokinetic Parameters of Five Alpha1 Receptor Antagonists Following Concomitant (0.25mg/kg) and Individual Intravenous Dosing (1mg/kg) in the Dog

Compound	Clearance (mL/min/kg)		Volume (mL/kg)		Half-life (h)	
	5-in-One	Individual	5-in-One	Individual	5-in-One	Individual
GW4470	5.9	5.0	473	382	1.5	1.4
GW0016	17.3	28.9	2757	3464	2.4	2.1
GW7841	18.7	10.3	2833	600	2.9	2.6
GW3561	11.2	11.6	2857	2907	3.0	3.4
GW1818	0.9	0.9	330	243	4.9	4.2

The LC/MS methodology was subsequently extended for the determination of mixtures ranging from 10 to 22 compounds in later studies using HPLC separation on longer BDS Hypersil C18 columns and selected ion monitoring (SIM). The combination of the longer HPLC column and the APCI interface afforded specificity. Analytically, compounds were grouped based on chromatographic and mass spectral requirements, such as chromatographic resolution of structural isomers. The applicability of LC/MS for the quantitative analysis of Alpha1 receptor antagonist mixtures for pharmacokinetic screening was demonstrated.

Rapid Screening Procedures for Metabolic Stability and Biotransformation

Richard C. King, Carmen Fernandez-Metzler, Thomas A. Baillie
Merck Research Laboratories, West Point, PA

Kevin G. Owens
Chemistry Department, Drexel University, Philadelphia, PA

The accelerated pace of contemporary drug discovery and development in the pharmaceutical industry has generated increasing demand for early information on the metabolic fate of candidate drugs in order to guide the selection of new compounds for clinical evaluation. In response to these demands, we have evaluated the use of LC-MS/MS technology, together with correlation analysis techniques, for the rapid screening of complex biological mixtures for the presence of drug-related materials, and have embarked on the development of novel computer-based approaches whereby such screening procedures can be automated. The goals of this work were (a) to rapidly identify drug metabolites (derived either from a single substrate or a mixture of substrates) formed *in vitro* or *in vivo*, and (b) to provide a semi-quantitative indication of the relative metabolic stability of a series of compounds of interest.

The approach we have developed relies on the use of generic chromatographic and mass spectrometric methods for the LC-MS analysis of mixtures of drug metabolites (1), and on correlation analysis of the MS/MS spectra in order to distinguish drug-related components from endogenous materials. A cross-correlation procedure also is used to identify the relationship between each parent drug in the substrate mixture and its metabolites (2). The relative metabolic stability of the substrates is determined by measuring the disappearance of the substrate in the experimental system relative to that in a control system. Analysis for both metabolic stability and biotransformation are performed using aliquots of the same sample. In this way, the relative metabolic stability and the metabolites of a mixture of several drugs may be analyzed in the time it normally would take to analyze the products from a single substrate.

Table 1 shows the results from the cross-correlation analysis of a representative mixture of five substrates incubated with human liver microsomes and analyzed by LC-MS/MS on a PE-Sciex API III instrument. The values in the table come from the correlation analysis and they relate the degree of overlap between the product ion spectrum of the substrate and the product ion spectrum of the suspected metabolite. The higher this value, the more similar are the two spectra in terms of both *m/z* and the corresponding intensities. This value then is used as a measure of similarity between the structures of the substrate and each suspected metabolite. Table 2 summarizes the proposed assignment of each metabolite to its respective substrate, based on the mixture of substrates and using the automated correlation analysis, while Table 3 indicates the assignments made manually from the analysis of incubations containing single substrates. In this example, the automated method correctly assigned all fifteen metabolites to the correct substrate.

One limitation of studying the metabolism of mixtures of substrates is seen

with this data set. Common metabolite structures that arise from different substrates can not be clearly distinguished. The metabolite with an MH^+ at *m/z* 290 is common to substrate D(589) and substrate B(553). The correlation procedure only identifies the single most similar structural pair and does not indicate that the metabolite with *m/z* 290 is common to both substrates.

From the same sample analyzed above for metabolic pathways, the relative metabolic stability also is measured. The areas measured by monitoring a single precursor ion / product ion transition from an LC-MS/MS experiment are used to assess the amount of substrate in both the experiment and the control. The metabolic stability of each substrate then is calculated as a fraction of substrate remaining at the end of the incubation relative to the control (boiled microsomal preparation).

The use of these automated procedures has proven to be of value in that important metabolism data can be generated quickly on relatively large numbers of compounds. The ability to analyze mixtures of substrates for relative metabolic stability and biotransformation pathways will enhance the role of drug metabolism in the discovery and development of new drugs.

ESI/MS Studies of Metabolic Enzymes: Elucidation of Mechanism and Design of Enzyme Inactivators

A. Daniel Jones, Babak Borhan, Jiang Zheng, Alyson E. Mitchell
Franck Pinot, David F. Grant, Mark J. Kurth, Bruce D. Hammock
University of California-Davis, Davis, CA 95616 USA

Phase II metabolic enzymes catalyze detoxification of electrophilic xenobiotic chemicals through conjugation reactions and hydrolysis. Since byproducts of these enzymatic reactions are usually less toxic than their precursors, these enzymes play important roles in protecting organisms from toxins. However, there are growing numbers of examples where Phase II enzymes exert detrimental health effects such as facilitating the breakdown of chemotherapeutic agents. We hope to determine the role of these enzymes in various disease states through design and use of specific enzyme inhibitors.

I. Catalytic Mechanism of Soluble Epoxide Hydrolase (sEH)

sEH is a 63 kDa enzyme that catalyzes hydrolysis of epoxides to form vicinal diols. Early views suggested the enzyme acted through enzyme-mediated activation of a water molecule which reacted with epoxides via direct addition (Mechanism 1), but recent work postulated formation of an acyl-enzyme intermediate (Mechanism 2) involving the conserved residue Asp-333. GC/MS studies of incorporation of ^{18}O from H_2^{18}O into diol products indicated a kinetic lag in label incorporation at low turnover.

sEH Mechanism 1

sEH Mechanism 2

Proposed Mechanism 2 predicts specific incorporation of ^{18}O label into the carboxylic acid side chain of Asp-333. To test this hypothesis, sEH was incubated with *trans*-1,3-diphenylpropene oxide in H_2^{18}O (50 theoretical turnovers), protein was precipitated with TCA and digested with trypsin. Controls were treated in the same way except in unlabeled water. Digestion products were isolated using a microbore C-18 column and electrospray mass spectra were generated on a VG Quattro-BQ mass spectrometer. Molecular masses of numerous late-eluting tryptic peptides were determined using the algorithm MaxEnt. Tryptic fragments containing Asp-333 (T26) increased in mass by an average of 3.5 Da.

Fragment	Theor. (Da)	H_2^{16}O (Da)	H_2^{18}O (Da)	ΔM (Da)
T21	2992.3	2992.5	2992.2	-0.3
T26	3218.8	3218.3	3221.8	+3.5
T25+T26	4183.0	4182.5	4185.7	+3.2
T25+T26+T27	4438.3	4438.2	4441.7	+3.5
T16	4777.6	4775.3	4775.2	-0.1
T24+T25+T26	6483.6	6483.4	6487.2	+3.8
T24+T25+T26+T27	6738.9	6738.4	6742.6	+4.2

II. Development of Isozyme-Selective Inactivators of Glutathione S-Transferases

Glutathione S-transferases (GSTs) catalyze addition of glutathione ($\gamma\text{-Glu-Cys-Gly}$) to various electrophilic compounds. Numerous GSTs are expressed in all eukaryotes including multiple isozymes within given classes. Expression of individual GST isozymes is tissue, gender, and environment-dependent. Increased expression of the π -class isozyme of GST in tumor cells reduces the effectiveness of anti-cancer drugs, and cancer treatment provides a good reason for development of potent and specific inhibitors of GST- π . Selectivity of irreversible enzyme inactivation can be obtained when an inhibitor is converted to an active form in the enzyme active site by taking advantage of active site chemical reactivity. GST isozymes of the π -class have a conserved acidic cysteine residue usually found as Cys-47. Several haloenol lactone inhibitors were designed such that an active site nucleophile would add to the lactone ring and expose an α -bromoketone group capable of alkylating a side chain near the active site (Mechanism 3).

Mechanism 3

Incubation of GST isozymes purified from mouse liver with the haloenol lactone gave selective and irreversible inactivation of GST- π , with near complete inactivation in ~ 10 minutes using a 10:1 molar ratio of lactone:enzyme. Electrospray ionization mass spectra of the incubation products showed an increase of molecular mass of ~ 230 Da (23708 Da) relative to control GST- π (23478 Da). This increase corresponds to formation of the anticipated adduct followed by hydrolysis of the initial attachment, perhaps during dialysis to remove buffers. ESI mass spectra of products of tryptic digestion of the covalent adduct demonstrated the remaining attachment to be at Cys-47.

Covalent Sequestration of Mechlorethamine by Metallothionein

Miquel Antoine, Daniele Fabris, Mark Han, Catherine Fenselau Structural Biochemistry Center, University of Maryland Baltimore County

Overexpression of metallothionein (MT) in cells exposed to electrophilic compounds has generated interest as to its role in resistance acquired by tumor cells to therapeutic agents. Elevated intracellular levels of MT have been found in tumors of cancer patients who have developed cross reactive resistance to alkylating agents (1). Due to its high cysteine content and overexpression in cancerous cells, MT is able to compete with intracellular DNA for alkylation by chemotherapeutic drugs.

In the present study, we investigate the hypothesis that MT covalently sequesters the nitrogen mustard mechlorethamine, *in vitro*. Equimolar amounts of MT and mechlorethamine are incubated for various times at pH7.4, *in vitro*. The courses of the reactions are monitored by HPLC, MALDI, and ESI MS. MALDI and ESI MS data reveal modified protein adducts corresponding to mono- and disubstituted MT/mechlorethamine (MT/MCE) species as evidenced in Table 1.

Table 1. Product identification of MT/MCE reaction

MT/MCE adduct	MALDI	ESI	Calc. MW
1 MCE bound to 1 site	6245.6	6244.4	6244.9
1 MCE bound to 2 sites	6210.4	6208.7	6208.4
2 MCEs bound to 4 sites	6290.0	6291.4	6291.5

MALDI and ESI data give very consistent results and detail the complexity of the reaction. To get more information on the reaction kinetics, on-line reaction monitoring using ESI MS was conducted. Covalent alkylation of metallothionein occurs within the first three minutes of incubation and formation of the crosslinked MT/MCE adduct (one drug complexed to two residues on MT) is detectable after 3 minutes. In addition, this MT/MCE crosslinked adduct is the major product formed over a 30 minute time period.

To characterize sites of covalent alkylation, the MT/MCE adducts were digested with trypsin and mapped using FAB and MALDI MS. Two tryptic fragments corresponding to MT/MCE alkylated species were isolated having molecular weights of 1449.4 Da and 1908.4 Da, corresponding to a metallothionein fragment with one mechlorethamine molecule complexed to two residues. More specifically, one mechlorethamine molecule is complexed to two cysteine residues on two separate MT peptide fragments. Figure 1 displays the CID MS spectrum of both MT/MCE adducts. Interpretation of the spectra indicates alkylation occurring at Cys-48 which is consistent with results obtained from alkylation studies of chlorambucil and melphalan, two nitrogen mustards that are also utilized in chemotherapeutic regimens (2,3). The second site of alkylation has not been determined yet. Macromolecular mechanics calculations using Quanta Charm also provide evidence for selective binding, consistent with the selective alkylation observed. Overall this work provide evidence that covalent sequestration by MT is a new mechanism for acquired drug resistance to anticancer agents.

Figure 1. (Top) CID MS spectrum of m/z 1449.4 MT/MCE adduct, (Bottom) CID MS spectrum of m/z 1908.2 MT/MCE adduct.

COVALENT BINDING OF REACTIVE EICOSANOID INTERMEDIATES WITH TARGET PROTEINS

Russell J Waugh, Keith L Clay and Robert C Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street, Denver, CO

INTRODUCTION

Prostaglandin biosynthesis involves the transformation of arachidonic acid by PGH synthase into the reactive cyclic endoperoxide prostaglandin H_2 (PGH_2). PGH_2 has a very short half life (2-3 mins), and is further transformed by a number of synthases and isomerases into a diverse number of biologically active molecules. The chemical reactivity of PGH_2 causes it to rapidly decompose to a variety of products in the absence of enzymes as well. Evidence in the literature suggests covalent binding of PGH_2 to target proteins such as human serum albumin and PGH synthase(1,2). We have investigated the reaction of PGH_2 with human serum albumin (HSA).

RESULTS

3H -labelled PGH was synthesised from [3H] arachidonic acid and purified PGH synthase. This product was reacted with an equimolar quantity (16 nmoles) of HSA for 60 minutes at room temperature. The protein solution was extracted three times with ethyl acetate and the extracted protein reduced and alkylated prior to C3-reverse phase HPLC (figure 1). The radiolabelled protein was subjected to site specific enzymatic digestion with Lys C, Glu C and trypsin. The LC/MS tryptic map is shown in figure 2. The major radiolabelled peak eluting at 65 mins (figure 2) was shown by negative ion multiple reaction monitoring LC/MS/MS experiments to be PGE_2 (figure 3) and not a peptide adduct.

In these experiments we have shown PGH_2 binds to human serum albumin. This binding is sufficiently tight to retain the adduct even after extraction, reduction and alkylation, as well as purification under HPLC conditions. The question remains as to whether this major adduct is covalently bound to HSA as the products obtained following enzymic proteolysis are PGE_2 and PGD_2 .

The Analysis of the Urinary Mercapturate of Vinyl Chloride Using Isotope-Dilution High-Performance Liquid Chromatography Tandem Mass Spectrometry

Dana B. Shealy, and David L. Ashley

Division of Environmental Health Laboratory Science, National Center of Environmental Health, Centers for Disease Control and Prevention, Atlanta, GA 30341

Vinyl chloride is the primary ingredient for the production of polymeric (PVC) tubing used for cables and pipes. Because of its hepatotoxic and carcinogenic effects, industrial exposure to vinyl chloride is often monitored by measuring the internal dose of the toxicant, a technique commonly known as biological monitoring. Due to the highly reactive nature of vinyl chloride, the internal dose cannot be reliably measured in the blood, therefore, urinary metabolite measurements are usually made.

Previously, vinyl chloride exposure has been estimated by measuring urinary thiodiglycolic acid (TDA) levels. However, thiodiglycolic acid is a non-specific urinary metabolite that has also been observed in premature neonates with no attributable exposure. Another urinary metabolite of vinyl chloride is S-2-hydroxyethyl-N-acetyl-L-cysteine (HAC) which is derived via glutathione-mediated detoxification of the reactive metabolite, vinyl chloride epoxide. As with TDA, HAC is also a metabolite of ethylene oxide and other halogenated vinyl or vinylidene compounds. However, measurable HAC levels have never been reported in non-exposed individuals; therefore, HAC may be a more reliable indicator of vinyl chloride exposure than TDA.

We have developed a high throughput method for the quantification of HAC (M.W. 207 amu) using isotope-dilution high-performance liquid chromatography-tandem mass spectrometry (ID-HPLC-MS/MS) with atmospheric pressure chemical ionization. Urine samples are enriched with a deuterated HAC (M.W. 211 amu) and are prepared using a simple solid-phase extraction scheme. The enriched urine is diluted 1:1 with water and applied to a preconditioned mixed phase (C₁₈/SAX) solid-phase extraction cartridge. The cartridge is washed with water and a dilute acid, then eluted with 0.5 mL (NH₄)₂SO₄ : CH₃OH (4:1). Approximately 75% of HAC/d₄-HAC is recovered from the cartridge. One fifth of the eluate is analyzed using a Hewlett Packard 1090L HPLC coupled with a Finnigan 700 triple quadrupole mass spectrometer. A total of four parent-to-product ion transformations are monitored (Figure 1). The limit of detection (LOD) is approximately 2 ng on-column which can be translated into about 1.5 parts-per-billion (ppb) in a 10 mL urine sample. However because most interferents have been removed during the urine extraction process rendering the extract relatively "clean" (Figure 2), the method LOD can be lowered by increasing the urine sample volume. The total analysis time per sample including all sample manipulation is less than fifteen minutes.

Additional mercapturates derived from other reactive volatile organic compounds such as 1,3-butadiene and styrene will eventually be incorporated into this method.

Figure 1 MS/MS transformations monitored for native HAC (A) and d₄-HAC (B)

Health Science Research Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6378 USA

Up to now, gel electrophoresis is still the only method used for routine DNA sequencing. With gel electrophoresis approach, DNA ladders have to be produced either by Sanger's enzymatic method or by Maxam-Gilbert's chemical degradation method. Either radioactive labels such as ^{32}P or ^{35}S or chemical labels such as fluorescent dyes are currently used for detection of DNA. Since gel electrophoresis is a time consuming and labor extensive method, laser desorption mass spectrometry has been considered as a possible alternative method for DNA sequencing during the past few years. Mass spectrometry can be useful in DNA sequencing effort in three different ways. They are (1) use of mass spectrometry just to detect DNA (both DNA ladders preparation and running a gel is still needed); (2) use of mass spectrometer analysis for both separation and detection of DNA (gel electrophoresis is not needed, but preparation of DNA ladder products is still needed) Most researchers trying to use mass spectrometer to do DNA sequencing takes this approach; and (3) use of laser desorption mass spectrometry to achieve DNA ladder preparation, separation and detection of different sizes of DNA. With this approach, neither DNA ladder preparation nor gel electrophoresis is needed. The time needed for sequencing can be reduced to minimum.

Since the glycosidic bond in DNA is quite fragile, it is not easy to keep intact DNA during the laser ablation process. Thus, one approach for DNA sequencing is just to use MS to detect DNA. With this approach a stable isotope such as Sn is tagged to DNA ladders¹. After gel electrophoresis of DNA, DNA ladders with metal atom tagging on films are placed inside of a mass spectrometer for analysis. A higher energy laser beam or an ion beam is used to ablate DNA samples on films such that some of these tagged metal atom are released. A second laser beam can be used to achieve resonance excitation and ionization of metal atoms. Since the detection sensitivity of resonance ionization processes can reach single atom detection level, the detection sensitivity can be better than radioactive tagging method. A laser beam or an ion beam can be focused down to 1 μm . Thus the resolution can also be better than conventional gel sequencing. However, tagging the DNA and running gel are still the limiting step to speed up sequencing with this approach. Recently, molecules tagging have been suggested with multiplexing approach which can save significant sequencing time if it succeeds.

Since the discovery of matrix-assisted laser desorption/ionization (MALDI) by Hillenkamp and his co-workers, many groups have tried to use MALDI for DNA sequencing. With this approach, different sizes of DNA segments are separated in the vacuum chamber of a mass spectrometer instead of gel medium in gel electrophoresis. The time needed for DNA separation is only a few hundred microseconds compared to hours in gel sequencing method. With the use of newly discovered matrices for DNA and better instrumentation design, DNA segments with the size of 500 nucleotides have been detected. Recent improvement of mass resolution for small DNA segments by delayed pulsed ion extraction has made this approach feasible to sequence small DNA segments^{2,3}. However, the sensitivity still needs improvement to use standard Sanger's method to prepare DNA ladders. In order to sequence longer DNA segments (longer

than 100 nucleotides), fundamental understanding of poor mass resolution of long DNA segments is in critical need. Post-ionization after DNA desorption has also been pursued by several groups since it is very possible that much more neutral DNA produce than DNA ions during the laser ablation process. However, the progress is very limited due to the difficulty of photoionization of large DNA molecules.

If a laser pulse or an ion beam for DNA desorption can also achieve DNA ladders production and ionization, the overall sequencing time can be truly reduced to be less than one second per sample. Recently, McLafferty and his colleagues⁴ using high resolution FTMS and electrospray ionization to achieve sequencing of short DNA segments. However, the mass spectra obtained were very complex, only mass spectrometers with ultra-high resolution can be used for the sequencing. Hillenkamp and his co-workers⁵ applied infrared MALDI for direct sequencing, they obtained structure information of a ss-DNA with 21 nucleotides by careful analysis of the pattern of both primary and secondary DNA fragmentation ions. In order to make direct sequencing for routine use, we consider the following three requirements need to be met. They are (1) selective bond cleavage to simplify the mass spectra, (2) no ions from secondary fragmentation and (3) nearly equal probability to cleave bondings between bases. We found with careful selection of matrices, a ultraviolet laser beam for MALDI can possibly be used for direct DNA sequencing of longer oligonucleotides. Due to the 1% abundance of ^{13}C isotope, the maximum size of DNA can be sequenced by this approach is limited to about a 90 nucleotide DNA.

During the past two years, both MALDI sequencing for DNA ladders and direct sequencing have been clearly demonstrated for short DNA segments. It indicates mass spectrometry DNA sequencing has become a reality. In order to have mass spectrometry DNA sequencing to replace conventional gel sequencing method to become the major tool for Human Genome Sequencing, the following barriers still need to be overcome. They are (1) capability to sequencing DNA segments longer than 500 nucleotides (2) improving detection sensitivity to be suitable for small quantity of DNA samples (3) Automation for sample preparation and data analysis. With the rapid progress during the past 5 years, it should be very possible to achieve fast DNA sequencing in the near future.

DNA Analysis for Rapid Genetic Screening with Matrix-Assisted Laser Desorption/Ionization TOF Mass Spectrometry

Yan-Hui Liu, Jannavi Srinivasan, Jian Bai, Yongdong Zhu, Xiaoli Liang, and David M. Lubman
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109

INTRODUCTION Since the introduction of MALDI MS, efforts to adopt this method for DNA analysis have resulted in rapid advances in this field. Among these advances, the application of MALDI MS in the analysis of real biological samples for DNA mapping and screening may ultimately result in a rapid, accurate, and cost-effective genetic screening technique. The approach of employing MALDI TOF MS for detection of human genetic mutations/polymorphisms based on PCR amplification of DNA from various sources is demonstrated in this work. The application of a nitrocellulose (NC) film substrate for on-probe purification of DNA samples and a postacceleration detection scheme are found essential for the analysis of PCR products and the restriction fragments from biological procedures. Subpicomole sensitivity has been achieved for MALDI MS of model genes such as Tay-Sachs disease (1) and Histo-blood group

EXPERIMENTAL The preparation of NC film substrate and MALDI samples has been described previously (2, 3). DNA extracted from buccal cells from voluntary individuals or obtained commercially which carry mutations on either intron 12 or exon 11 genes of Tay-Sachs disease have served as templates for PCR amplifications. The mutated DNA samples are employed as controlled genes in this study and are used without further purification. A linear TOF with postacceleration and a 355 nm Nd:YAG laser were used for MALDI MS.

RESULTS Previous work has shown that a thin film of NC can effectively adsorb the cationic species and buffers in DNA biological samples to its hydrophobic and negatively charged surface, hence exclude/reduce their interference during the MALDI process. The hydrophobic surface of a NC film also enables LD of DNA from a smaller sample spot where higher sample concentration is obtained. Equally important in DNA screening with MALDI TOF MS is the application of postacceleration before ion detection, which can effectively increase detection sensitivity of heavy ions as well as reduce fragmentation of DNA molecules. In this study, the clinical application of MALDI TOF MS for Tay-Sachs disease diagnosis and blood typing are demonstrated by the analysis of PCR products of both normal and disease genes and/or their restriction enzyme digests. Mass spectra showing the patterns of PCR and/or restriction fragments similar to gel electrophoresis were analyzed to determine the DNA mutation. Accurate diagnosis is based on the external mass calibration with MALDI MS analysis of the *Msp* I digests of pBR 322 (mixture of 26 fragments from 9 to 622 bp) from a NC film substrate.

MALDI MS of intron 12 gene of Tay-Sachs disease Figure 1 shows the mass spectra of PCR of intron 12 gene and its *Dde* I digestion product. The digestion fragment of 100 bp indicates that the individual tested is from an unmutated population.

MALDI MS of exon 11 gene of Tay-Sachs disease MALDI mass spectra of a diseased individual with mutation on both alleles involving a four base pair insertion on exon 11 gene is shown in Figure 2(a). The 195 bp PCR product shown in Figure 2(b) is from a healthy individual with both alleles unmutated.

Typing of ABO blood groups by PCR with MALDI MS Blood typing is accomplished by MALDI MS analysis of PCR of a 258 allelic difference of Histo-blood group and its *Bst*E II digests. The result shows that the individual tested has blood type O.

CONCLUSION The results presented herein further demonstrate the feasibility of the MALDI TOF MS methodology with the application of an active substrate in clinical applications for genetic screening of DNA mutations/polymorphisms. Compared with gel electrophoresis, this method provides much improved mass determination accuracy (< 0.1%) and speed of analysis

Characterization of Oligonucleotide Strands by Enzymatic Digestion and MALDI-TOF

Catherine M. Bentzley, Murray V. Johnston
Department of Chemistry
University of Delaware
Newark, DE 19716

Barbara S. Larsen, Steven Gutteridge
The DuPont Company
Science & Engineering Labs
P O Box 80228, Wilmington, DE 19880

An enzymatic method was developed for ladder sequencing oligonucleotide strands using the exonuclease calf spleen phosphodiesterase. The diesterase enzyme cleaves individual nucleotides from the 5' end of the strand. The oligonucleotide unit that is lost consists of a phosphate group, a deoxyribose moiety and a base- adenine (A), guanine(G), thymine(T) or cytosine(C). The oligonucleotide products of the digestion are observed as peaks in the MALDI spectra which differ in mass by the successive loss of individual nucleotide units. We have used this method to sequence oligonucleotide strands up to 24 base units.¹

The sensitivity of calf spleen phosphodiesterase to a particular base has been investigated (Figures 1 and 2). For example, if the terminal unit that is being digested contains thymine the digestion rate appears to be slow. If the terminal unit contains adenine then the digestion appears to be fast. This is illustrated in Figure 1. These spectra represent the digestion of two separate 7mers which are identical sequences except for one base unit. In each case, the digestion was stopped after 3 minutes. In Figure 1a, the peak at m/z 1486 represents an oligonucleotide strand with a T terminal end that is in the process of being digested. This peak is relatively intense suggesting that the digestion rate is slow. Figure 1b represents the same strand except that T is now replaced with A. The peak at m/z 1495 in Figure 1b is not as intense as the corresponding peak at m/z 1486 in Figure 1a. This suggests that the enzyme will digest an adenine unit more quickly than a thymine unit.

Figures 2a and b compare the digestion rates of two other bases- G versus A. In each case very little signal intensity is observed in the m/z 1480 region. Apparently, the enzyme has quickly digested through these bases (A, G). Other oligonucleotide strands were synthesized, digested and their spectra analyzed under the same conditions. It was found that the signal intensities of the product oligonucleotide strands depended upon the terminal base unit in the following way $C > T > G, A$. This order also represents the relative amount of time required by the enzyme to digest through a particular terminal base unit. These results are consistent with previous studies of calf spleen phosphodiesterase.²

To ensure that the signal intensities were due to relative digestion rates and not to different ionization efficiencies, equimolar amounts of the following oligonucleotides were analyzed as a single mixture. 5' CCT AA 3', 5' TCT AA 3', 5' ACT AA 3' and 5' GCT AA 3'. The strands with T, G and A terminal units had similar signal intensities while the strand containing the C terminal was half as intense. Since the apparent ionization efficiencies of C, T, G and A terminal strands are comparable, the relative signal intensities in Figures 1 and 2 do indeed reflect differences in the digestion rate.

FRAGMENTATION IN THE MALDI-TOF ANALYSIS OF NUCLEIC ACIDS

Lloyd M. Smith, Christine Nelson, Wei Tang and Lin Zhu

Department of Chemistry
University of Wisconsin-Madison
Madison, Wisconsin 53706-1396

The heart of DNA sequence analysis is the separation and detection of DNA fragments by size. Although this is typically accomplished by electrophoresis, substantial interest has developed in the possibility of replacing electrophoretic analysis with mass spectrometric analysis, and in particular, in using the technique of Matrix-Assisted Laser Desorption/Ionization (MALDI) for this purpose. Although substantial progress toward this goal has been made over the past several years, limitations in mass range, sensitivity, and resolution remain substantial. At the present time analysis of mixtures of single-stranded DNAs continues to be limited to components 40-50 bases in length, with severe decreases in signal intensities and resolution evident for the longer fragments. Possible reasons for this behavior are of two general types: a) those concerning interactions between the analyte and the crystalline condensed phase prior to the MALDI desorption events, and b) those concerning reactions occurring in the gas phase during and subsequent to the MALDI desorption events. In particular, fragmentation of DNA analytes in the gas phase appears to constitute an important process limiting the analysis of longer DNA molecules by MALDI. It has been shown that fragmentation of the DNA is both strongly matrix dependent (for example, 3-HPA causes much less fragmentation than 2,5 DHBA) and strongly sequence dependent (thymidine is much less susceptible to fragmentation than the other three nucleosides).

Studies by ourselves and others of DNA fragmentation in MALDI have led to a proposed pathway for nucleic acid fragmentation. In this pathway the initiating step in fragmentation is nucleobase protonation, followed by base loss and backbone cleavage (1). This pathway suggests two approaches to increasing the resistance of the DNA to fragmentation by chemical modification: a) by modification of the nucleobase to reduce its propensity to protonation (2), or b) by modification of the deoxyribose ring to stabilize the N-glycosidic bond. The potential of this latter approach is supported by studies of RNA stability in MALDI, in which it has been shown that the presence of the 2'-OH group in RNA provides substantially increased stability (3,4). This stabilization is likely to be due to the well-known inductive effect of the 2' OH group in RNA in destabilizing carbonium ion formation at the 1' carbon (5,6). Regrettably, the general susceptibility of RNA to hydrolytic and enzymatic degradation render it less than ideal as a general sequencing substrate.

In this paper we describe the results of recent studies in our group in which the effect of substituents at the 2' position upon nucleic acid stability is explored. It is shown that arabinose nucleosides, in which a 2' hydroxyl group is present trans to the 3' hydroxyl, exhibit similarly increased stability in MALDI to that shown by RNA. This increased stability significantly increases the accessible mass range. Also explored is the effect of a 2' fluoro substituent, which would be expected to exert an even more powerful inductive effect than the hydroxyl group and hence provide greater stabilization of the DNA. As no 2' fluoro DNA phosphoramidites are commercially available, this idea was explored using enzymatic incorporation with terminal deoxynucleotidyl transferase of a 2' fluoro deoxycytidine nucleoside triphosphate

available commercially. These modified nucleosides show dramatically increased stability compared to unmodified DNA, and hence appear to constitute an interesting avenue to pursue for the development of MALDI-based DNA sequencing. To this end we are presently exploring the ability of a variety of DNA polymerases to incorporate 2' fluoro nucleoside triphosphates in enzymatic extension reactions. This chemistry, once developed, should permit a substantial extension of accessible mass range in MALDI-based DNA sequencing applications.

DNA-Cycle-Sanger-sequencing by MALDI-TOF-MS with nucleotides modified for enhanced ion stability

E. Nordhoff, F. Kirpekar, S. Hahner¹, K. Kristiansen, P. Roepstorff, F. Hillenkamp¹

Department of Molecular Biology, University of Odense, Denmark, and ¹Institute for Medical Physics and Biophysics, University of Münster, Germany

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) has been proposed as a fast method for the analysis of DNA-sequencing ladders. Today, the success of this method is mainly limited by the accessible mass range up to where oligodeoxynucleotides differing by one nucleotide can be sufficiently resolved, by a lack of ca 1-2 orders of magnitude in sensitivity, and by the need for careful sample purification (metal cations, reaction buffer, detergent, dNTP) prior MALDI-MS.

Ion fragmentation is one reason for the first limitation and base loss is the key fragmentation reaction. In terms of stability upon MALDI, the N-glycosidic bond shows a remarkable dependency on the identity of the nucleobase, i.e., thymidine exhibits a considerably lower tendency for base loss than the other deoxyribonucleotides¹. It has been shown that the stability of oligodeoxynucleotide ions can be increased when derivatives of the nucleobases replace their natural analogues^{2,3}. A second important criterion for the choice of modification is compatibility with the Sanger sequencing reaction, i.e., proper incorporation of the corresponding deoxyribonucleotide (dNTP as precursors) during the sequencing reaction and minimal nonspecific premature termination, e.g., caused by secondary-structure problems. 7-deaza-dATP and -dGTP have been shown to fulfill both criteria^{2,4}. In addition to the dNTPs also the primer has to be taken into consideration, since the sequence of the latter becomes part of the sequencing reaction products.

Cycle-sequencing possible by the use of a thermostable DNA-Polymerase (Thermosequenase, Amersham, UK) enables linear amplification of the reaction products and, thereby, offers a promising improvement for the sensitivity problem. The need for sample purification has been addressed by the development of a miniaturized device for reverse-phase liquid chromatography. Poros RP 50 2 (PerSeptive Biosystems) is used as stationary phase filled in the extended tubing of a GELoader tip (Eppendorf) to a column volume of ca 1-1.5 µl. A 200 µl tip serves as sample load chamber and adapter for an additional liquid reservoir containing buffer A (5 % MeCN, 10 mM TEAA, pH 7.0, 400-600 µl). The latter hardware is separated from the column by a 2-way stopcock and on the other end connected with an argon bottle via a needle valve allowing fine regulation of the liquid flow for sample load, washing (0.2-0.5 bar argon), and elution (ca. 0.1 bar argon). After washing the sequencing products are eluted with 2 µl buffer B (20 % MeCN, 10 mM TEAA, pH 7.0) directly onto the sample support for MALDI-MS. The main advantages of this purification technique are: speed, simple and cheap hardware, no memory effects (disposable column and load chamber), high recovery, no glass and metal ware (Na⁺, K⁺), parallel processing possible (4 columns in parallel were used for these studies).

Combining all named approaches with DE-MALDI-LTOF-MS (Voyager Elite-MS, PerSeptive Biosystems Inc.) using 3-hydroxypicolinic acid as the matrix we have been able to sequence a DNA 78-mer template up to nt 77 starting with 4 pmol template material (see Fig. 1). We are now extending these studies to plasmid- and PCR-template material.

Fig. 1: DNA-cycle-Sanger sequencing of a DNA 78 nt template by DE-MALDI-LTOF-MS with 7-deaza-A/G for enhanced ion stability. Primer: 5'-A^{*}T A^{*}T A^{*}T A^{*}TTT A^{*}TTTT A^{*}TTT-3' (A^{*} = 7-deaza-A), number of cycles: 30, total amount of template used: 4 pmol. To increase the detection efficiency data acquisition was performed in two steps: detector bias gating set (a) at 5,600 Da (left window), (b) at 12,700 Da (right window). Matrix: 3-hydroxypicolinic acid / diammonium citrate; laser wavelength: 337 nm, scans averaged: 100-150.

Fragmentation of DNA and RNA in MALDI

Chau-Wen Chou and Peter Williams

Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1604

Introduction:

The low intensities of intact DNA signals produced by MALDI have it difficult to develop a fast mass spectrometric readout of DNA sequencing mixtures by MALDI TOFMS. A major problem appears to be that DNA fragments during desorption/ionization. Previously, Schneider and Chait¹, Stemmler and Buchanan² etc. had noticed that the severeness of fragmentation of DNA depends both on the matrices used and the nucleobase composition of the DNA. Later, Nordhoff et al.³ proposed a mechanism which suggested that the depurination of nucleobases initiates the cleavage of phosphodiester bonds at the 3'- and 5'- carbons of the sugar ring. RNA has more stable N-glycosidic bonds. Therefore, comparison of fragmentation in RNA and DNA might allow us to understand what factors might control fragmentation.

Experiments:

It has been reported that 2,5-dihydroxybenzoic acid (2,5-DHBA) gives intense prompt DNA fragment ions, while 3-hydroxypicolinic acid (3-HPA) provides the least amount of prompt fragment ions. We also tested sinapinic and anthranilic acids (SA, AA) with the above matrices. The RNA 8-mer (GACUUGAC) was purchased from Cruachem. The ASU Nucleic Acid Resource synthesized all the DNA samples (7mer, GACTGAC and 8mer, GACTGACT). All the spectra were obtained with 1 pmole oligo loaded, at 20 kV (+ or -) accelerating voltage and a laser wavelength of 355 nm.

Results and discussion

In the study of DNA fragmentation:

The most significant type of fragmentation is the base loss (G, A, or C but not T). The dominant fragment ions which form with the breakage of the phosphodiester bond at the 3'-C of the sugar are the w-series which retains the charge at the moiety of 3'-end. The other fragment types consistently observed are the a- and d-types which retain charge at the 5'-moiety of the fragment after the rupture of the backbone at the 3'-C and 5'-C of sugar, respectively. Occasionally, additional base loss occurs accompanying the w- and a-series ions (figure 1).

We also noticed that the positive ion and negative ion spectra look similar except that the loss of bases was observed much more strongly in the positive ion spectra. This indicates that the charge is not a factor in the fragmentation.

In the study of RNA fragmentation:

It has been known for some time that large RNA analytes produce mass spectra more readily than DNA. However, we observed fragmentation in the RNA spectra similar to that of DNA (w-, a- and d-fragment ions) except that base loss was not observed. Unlike DNA, these fragment ions are never seen with additional base loss. This implies that another fragmentation path might exist besides the path induced by depurination, or simply that RNA just fragments differently to DNA.

The major difference between DNA and RNA mass spectra is that the intact RNA molecular

ions are generated in higher yield than intact DNA ions of comparable size. The spectrum shown, with equimolar amounts of RNA and DNA shows that the intact RNA molecular ions are produced with $\sim 10 \times$ efficiency of DNA (figure 2). Assuming that comparable amounts of RNA and DNA were ablated by each laser pulse, this result might mean that more RNA is ablated intact, more is ionized or more survives without fragmentation. The mass spectra of Fig. 2 show no evidence for slow fragmentation (which would produce tailing to shorter flight times), while the relative abundance of prompt fragments from RNA is greater than from DNA as 3HPA as the matrix. One possible difference between the two species might be conformation. A molecule folded into a compact structure can be ablated in a single laser pulse at relatively low power. Conversely a string-like structure extended away from the surface might not be ablated in a single laser pulse but could be progressively damaged if it experiences several laser pulses on the same site.

DNA Analysis Using Time-Lag Focusing MALDI TOFMS

Yueqin Dai, Randy M. Whittal, and Liang Li*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

Matrix-assisted laser desorption/ionization (MALDI) time-of-flight mass spectrometry (TOFMS) has the potential to become a very powerful tool for DNA structural confirmation and DNA sequencing. Since the introduction of MALDI in 1988, a number of research groups have demonstrated the utility of the technique for detecting oligonucleotides and DNA samples with varying degrees of success. At present, one major limitation in using TOFMS for mass analysis of DNA fragments by MALDI is related to poor mass resolution and mass measurement accuracy.

Much improved mass resolution has recently been demonstrated for MALDI TOFMS¹⁻⁴ using the time-lag focusing (TLF) technique pioneered by Wiley and McLaren.⁵ High mass measurement accuracy has also been demonstrated using both internal and external calibration for peptides¹, proteins¹, oligosaccharides⁶, and industrial polymers.^{7,8} For the analysis of DNA fragments, Reilly and coworkers reported the observation of improved mass resolution over conventional DC extraction in their pulsed extraction instrument.⁹ Mass resolution over 1000 and good mass measurement accuracy have been demonstrated by Juhasz et al for several DNA fragments up to a 31-mer.¹⁰

In this work, we report our studies of the analysis of oligonucleotides based on a time-lag focusing MALDI time-of-flight mass spectrometer.¹ For sample preparation, the matrix 3-hydroxypicolinic acid (3HPA)¹¹ was saturated in 33% CH₃CN / H₂O with the aid of vortex mixing, centrifuged and the supernatant solution was transferred to another vial containing regenerated H⁺ activated ion-exchange beads. Preparation of the ion-exchange beads was as follows. Dowex 50W-X8, 20-50 mesh beads were regenerated in a glass column by rinsing with 50 mL ultra pure water, 50 mL 3M HCl, followed by rinsing with ultra pure water until neutral pH was reached.¹² A few beads were added to the 3HPA solution. To prepare the ammonium form of the ion-exchange beads, the regenerated H⁺ form beads were placed in a column and washed with 50 mL of 3M NH₄Cl and then rinsed until neutral pH was achieved. DNA was prepared by dissolution in pure water with the addition of NH₄⁺ activated ion exchange beads.

The crushed crystal method, as described by Xiang and Beavis, was used to prepare the sample on the probe tip.¹³ In brief, 1 µl of 3HPA solution was loaded on the probe tip and allowed to dry, the crystals were crushed, and then 0.7 to 1 µl of the second layer solution was applied on the top of the first layer. To prepare the second layer solution, 1 µl of ion exchanged DNA solution, 0.75 µl 0.3M diammonium citrate and 3.25 µl ion exchanged matrix solution were mixed. As the second layer was drying the solution was stirred on the probe tip using a micro pipette tip until small crystals formed.¹⁴

Using this TLF instrument, mass resolution in the range of 1170 to 1300 fwhm for analysis of DNA up to a 40-mer is observed using a 1-meter, linear time-of-flight instrument with a total sample loading of less than 10 pmol. As an example, Figure 1 shows the MALDI mass spectrum of a DNA 40-mer obtained by using TLF TOFMS with positive ion detection. In this presentation, the effects of sample preparation, type of calibrant and matrix used on the accuracy of mass measurement based on external calibration are also discussed. It is shown that mass measurement error less than 100 ppm with reproducibility better than ± 60 ppm can be obtained with either proteins or DNA fragments as external calibrants. Accurate mass measurement for a mixture of DNA fragments is also illustrated. It is also found that detection sensitivity is mass dependent. Typical sample loading is in the range of 250 fmol to several pmol.

The future work will include the development of matrix and sample preparation methods for high mass DNA analysis with improved performance. In addition, we plan to apply the Micro-Spot MALDI Technology¹⁵ to DNA for improving detection sensitivity.

Matrix Assisted Laser Desorption Time-of-flight Mass Spectrometry (MALDI-TOF) is a powerful tool for structural and chemical compositional analysis of short fragments of DNA, RNA, and synthetic oligonucleotides. Delayed Extraction (DE) MALDI has significantly changed the situation in nucleic acid applications, since it provides significantly higher resolution and sensitivity, particularly for longer lengths of nucleic acid. DE MALDI can resolve oligonucleotide synthetic problems by providing chemical information (e.g. the nature of N-1 failure product, degree of oxidation of phosphorothioates) that is difficult to obtain any other way. As an example, RNA transcription products of size >60 bases can be analyzed by DE MALDI with resolution > 2000 m/Δm.

We describe an exonuclease sequencing method for oligonucleotides, based on the partial digestion in the 3' → 5' and 5' → 3' directions, by different enzymes. With DE-MALDI, this method is demonstrated suitable for sequencing a 51-mer DNA. Some of the problems which were solved to make this technique simple enough for routine use included modification of the reaction conditions to match the specific requirements of the exonucleases, sample purification, and optimization of the enzyme concentration. Our results show that snake venom phosphodiesterase tolerates 2' sugar modifications.

The use of DE MALDI has also been extended past analysis of oligonucleotides towards identification of base sequences differences in various forms of genetic analysis, such as Sanger sequencing and allelic identification by ligase chain reaction. In the case of ligase chain reaction, DE MALDI enables not just the detection of 40 base pair ligase chain reaction products but the identification of allelic differences based solely upon the differences in masses conferred by these allelic differences. The greatly enhanced mass resolution and sensitivity of DE MALDI may provide a robust alternative to conventional means of analysis such as electrophoresis for high volume quality control of synthetic oligonucleotides and genetic analysis.

DETAILED CHARACTERIZATION OF ANTISENSE DNA OLIGONUCLEOTIDES; T. Keough, J.D. Shaffer and M.P. Lacey, The Procter and Gamble Co., Miami Valley Laboratories, P.O. Box 538707, Cincinnati, OH 45253-8707; T.A. Riley, W.B. Marvin, M.A. Scuria, J.A. Hasselfield and E.P. Hesselberth, JBL Scientific, Inc., 277 Granada Drive, San Luis Obispo, CA 93401-5809.

A time-of-flight matrix-assisted laser desorption ionization (MALDI) mass spectrometry method has been developed for verification of the structure of novel oligonucleotides having alternating methylphosphonate/phosphodiester (MP/PDE) internucleotide linkages. Failure synthesis analysis (1) provides easy confirmation of oligonucleotide length, partial base composition and partial sequence information from the 5'-end of the molecule. The remaining base composition and sequence information are obtained by MALDI analyses of degradation products, formed by various enzymatic and chemical means. Molecular mass measurements, which reflect subtle changes in structure, also allow verification that the bases, sugar moieties and internucleotide linkages have not been affected by the enzymatic and chemical procedures used for sequencing. This general approach should be adaptable to other classes of antisense oligonucleotides, as already demonstrated with methylphosphonates (1). In fact, failure or termination synthesis should prove generally useful for the characterization of biomolecules synthesized in a stepwise fashion on solid supports. We recently employed intentional termination synthesis for the rapid identification of biologically active peptides isolated from support-bound combinatorial libraries (2).

MALDI Mass Spectra - Positive ion MALDI mass spectra (ferulic acid matrix) were obtained from about 5 pmols of both a crude and a purified 12-mer d(CA-TC-TT-CC-TC-GT), where the - indicates PDE linkages and the alternating linkages are MPs. The spectrum of the purified material is dominated by an intense protonated molecule (MH^+) having a measured chemically averaged molecular mass (3536.3 Da) that agrees within 0.02% of the actual value. The MALDI spectrum obtained from direct analysis of the crude synthetic products also showed failure synthesis ions weighing approximately 2936.1, 2344.5, 1738.9 and 1162.6. These ions differ in mass by successive methylphosphonate dinucleotides as a result of the synthetic procedure. The reading direction is from the 5'- to the 3'-end of the molecule when reading from high to low mass.

Length - Electrospray and MALDI mass spectrometry offer, in principle, simple means to unambiguously establish the length of synthetic oligonucleotides. However, direct determination of length is not always possible for oligomers longer than 7-mers because the oligomer molecular mass distributions overlap. The observed molecular mass of the 12-mer falls within the range theoretically allowed for either 11- or 12-mers. Fortunately, MALDI mass spectrometry of crude synthetic mixtures, which contain failure synthesis products, provides a simple means to resolve this ambiguity. The two lowest-mass failure synthesis products are shorter than 8-mers, and their lengths can be unambiguously confirmed even with low-resolution mass measurements. The lowest-mass failure synthesis ion has an observed mass that falls within the range allowed for tetranucleotides, and well outside of the mass ranges allowed for either trinucleotides or pentanucleotides. The next lowest failure synthesis ion has an observed mass that falls within the range allowed for hexanucleotides. It is possible to verify the length of the final product by simply counting up by twos from the tetranucleotide. This trivial procedure verifies that the full-length product is a 12-mer, and it excludes all 11-mers, in agreement with the synthetic procedure.

Base Composition - Partial base composition of the full-length material can be verified by measuring the mass differences between adjacent members of the failure synthesis family, and by comparing those results to the values calculated for all of the methylphosphonate dinucleotide 3'-monophosphates ($-H_2O$). The measured mass differences of 600.2, 591.6, 605.6 and 576.3 Da establish the composition of the four dinucleotides from the 5'-end of the molecule as (AC), (CT), TT and CC, where the parentheses indicate that only the composition, not the sequence, is determined by this procedure. The base composition of the last two dinucleotides at the 3'-end of the molecule cannot be directly determined from this spectrum because a key low-mass failure synthesis ion was not detected. However, the composition of the last four nucleotides near the 3'-end can be established, even with low-resolution mass measurements, because the minimum mass difference between all of the 34 tetranucleotide base compositions is 1 Da. Both electrospray and MALDI (with an internal standard) showed that the tetranucleotide had a refined nominal

mass of 1161.9 Da, and that its base composition was CT₂G. The complete base composition of the molecule is then verified as CT₂G + CC + TT + (CT) + (AC) = C₅T₅A₂G, in agreement with the synthetic procedure. Failure synthesis analysis allowed easy confirmation of the complete base composition of the 12-mer and exclusion of the other 454 theoretically allowed 12-mer compositions.

Sequence - Four of the six MP dinucleotides comprising the 12-mer were established by failure synthesis analysis. The remaining two dinucleotides at the 3'-end were established by MALDI analysis of the products formed by snake venom phosphodiesterase (SVP) digestion, an enzyme having both 3' exonuclease and endonuclease activity. The results established (TC)-(GT) 3' as the final dinucleotides, in agreement with the base composition data. The complete set of MP dinucleotides comprising the 12-mer are given in (a), and only 16 sequences are consistent with that structure.

Verification of the single unique sequence for the 12-mer required generation of an "overlapping" PDE dinucleotide sequence that is summarized in b. This overlapping sequence was generated by MALDI analyses of the products formed by partial base-hydrolysis of the full-length 12-mer and selected nuclease digestion products. This approach relies on the fact that the MP internucleotide linkages can be selectively hydrolyzed in the presence of the PDE linkages. Base-hydrolysis of the full-length 12-mer established nucleotides (9-4) as (CT)-(TC)-(CT), where the 5'-end is nucleotide 12 and the 3'-end is nucleotide 1. Unfortunately, the dinucleotide sequences at both ends of the molecule could not be confirmed directly from this digest because of the low mass resolution of the linear TOF used in these experiments. A more modern instrument, equipped with delayed extraction, would presumably allow completion of the overlapping sequence from this single hydrolysis experiment. We confirmed the sequences at both ends of the 12-mer by base-hydrolysis/MALDI of (12-5) and (p6-1), which were generated by nuclease digestion and purified by HPLC. Only 32 sequences are consistent with b.

Derivation of the unique sequence for the 12-mer is possible by comparing structures a and b. The 5'-nucleotide was established as C by base-hydrolysis of (12-5), b. The dinucleotide (12-11) is (CA) according to a. Since 12 is C, 11 must be A. The PDE dinucleotide (11-10) is (A-T) according to b. Since 11 is A, 10 must be T. The MP dinucleotide (10-9) is (TC) according to a. Since 10 is T, 9 must be C. This process is carried out to completion, confirming the one unique sequence for the 12-mer (CA-TC-TT-CC-TC-GT) and excluding the more than 16,000,000 other sequences that are at least theoretically allowed for oligonucleotides of this length.

Sugar Moieties and Internucleotide Linkages - Subtle chemical modifications to either the bases or sugars would, in general, be reflected by changes in the molecular masses of the full-length oligonucleotide, the failure synthesis products or the various digestion products. However, all of the measured masses agreed with expected values with an rms error of ≤ 0.9 Da. These results indicate that no modifications occurred to the bases or sugars during the various digestion and analysis procedures. Furthermore, the alternating MP/PDE internucleotide linkage pattern was confirmed chemically because the PDE linkages are labile to nucleases and stable to base, while the MP linkages are labile to base and stable toward nucleases. The 12-mer was exposed to nucleases and base during the sequencing part of the study, and all of the digestion patterns were consistent with the alternating MP/PDE structure.

Conclusions - A MALDI method has been developed for detailed characterization of novel antisense DNA oligonucleotides. The method, which has been successfully applied to molecules as large as 18-mers, allows verification of length, base composition, complete nucleotide sequence and the internucleotide linkage pattern. No undesired chemical modification to either the sugars or the bases have been observed.

Solid-Phase DNA Sequencing Detected by Matrix-Assisted Laser Desorption/Ionization Reflectron Time-of-Flight Mass Spectrometry

Kai Tang¹, Dong-Jing Fu¹, Charles R. Cantor³, Robert J. Cotter⁴ and Hubert Köster²

¹Sequenom Inc., 101 Arch Street, Boston, MA 02110; ²University of Hamburg, Department of Biochemistry and Molecular Biology, Martin-Luther-King Platz 6, 20146 Hamburg, Germany; ³Boston University, Center for Advanced Biotechnology, 36 Cummington Street, Boston, MA 02215; and ⁴Johns Hopkins University School of Medicine, Department of Pharmacology, 725 N. Wolfe Street, Baltimore, MD 21205

Solid-phase DNA sequencing method has been shown to be an effective way for easy purification of the sequencing reactions. High affinity and stability of biotin-streptavidin chemistry permit the immobilization and sequencing of DNA fragments and provide easy removal of contaminating species such as enzyme, buffer salts, unincorporated dNTPs and ddNTPs. It has been demonstrated recently that the immobilized duplex DNAs are compatible for MALDI-MS analysis (1). The biotinylated strand remains bounded to the streptavidin coated magnetic beads and only the annealed complementary strand appears in mass spectra. The discovery enables us to propose new robust sequencing strategies that combine solid-phase sequencing and MALDI-TOFMS detection.

In our first approach, DNA templates were immobilized on the beads. Sequencing ladders generated by primer extension were desorbed and detected directly by MALDI-TOFMS. The approach gave the best results so far with resolution high enough to read DNA sequences up to the 70-mer mass range (Fig. 1). The power of mass spectrometry was demonstrated not only by its high speed, but also by its ability to identify ambiguous sequences, such as full-stop reactions due to secondary structure of the template (Fig. 2). Such identification which relies on the knowledge of mass values of sequencing ladders, is not possible using any current techniques based on gel electrophoresis.

Our second approach employs the strategy developed by us recently, which uses immobilized duplex DNA probes with single-stranded 5-base overhang to capture DNA templates of interest (2). Subsequently, conventional solid-state sequencing can be performed using one strand of the duplex probe as primer (3). The advantage of this approach is that only five bases of known terminal sequence are required for priming. Therefore, appropriate restriction enzymes can be chosen to digest genomic DNA and generate known terminal sequences for capturing by corresponding duplex probes. Multiple Sanger reactions can be performed simultaneously on each of the captured DNA fragments. Using MALDI mass spectrometry to analyze the sequencing ladders directly from the streptavidin coated magnetic beads (Fig. 3) further increases sequencing speed.

ENERGY-RESOLVED CID THRESHOLD STUDIES OF METAL-POLYETHER COMPLEXES

Lee Sunderlin, Khanh Do, and Tim Klein
Department of Chemistry
Northern Illinois University
DeKalb IL 60115

While the gas-phase reactions of alkali metal cations have been studied in some detail, little of the analogous chemistry of the alkaline earth cations has been investigated. We have begun to measure the energetics of M^+ -polyether and XM^+ -polyether systems, where M is an alkaline earth metal and X is a halogen. Metal-ether bond strengths are measured using energy-resolved collision-induced dissociation, where the threshold for decomposition is taken to be the bond strength. These large ions are subject to substantial reactant internal energy effects and kinetic shifts (lifetime effects). The data is fit with the CRUNCH program, which includes these effects. The instrument used is a new machine of flowing afterglow-QoQ design, where the QoQ is a tandem mass spectrometer with an octopole ion guide between two resolving quadrupoles.

In this talk, we will concentrate on the bond strengths from metals to dimethoxyether (DME), $CH_3OCH_2CH_2OCH_3$. The data indicate three trends in the metal-ether bond strengths:

The larger the ion, the weaker the M^+ -ether bond.

The first DME is bound more strongly than the second.

Addition of a halogen to the metal results in stronger M^+ -ether bond.

Work in progress will extend these studies to other ethers and the rest of the alkaline earth metals.

Acknowledgements. We are particularly grateful to the ASMS for a 1995 Research Award that is supporting this project. The NIU College of Liberal Arts and Sciences and Graduate School, and the Petroleum Research Fund (ACS), have also supported related work. We also thank Prof. P. B. Armentrout for a copy of the CRUNCH program, as well as helpful discussions.

Guided Ion Beam Studies of the Binding Energies for Alkali Metal Ion Crown Ether Complexes

P. B. Armentrout, Michelle B. More,
Chemistry Department, University of Utah, Salt Lake City, UT 84112
and Douglas Ray,
Environmental Molecular Sciences Laboratory,
Pacific Northwest National Laboratories, Richland, WA 99352

Threshold collision-induced dissociation (CID) of several alkali metal ion - ether complexes are studied using a guided ion beam mass spectrometer (GIBMS). The ethers studied include dimethyl ether (DME), $O(CH_3)_2$; dimethoxyethane (DXE), $CH_3OCH_2CH_2OCH_3$; 12-crown-4 (12c4), $c-(OC_2H_4)_4$. The GIBMS utilizes a BOQ geometry with a central rf-only octopole region passing through a gas cell filled with the Xe collision gas. For all complexes, the primary and lowest energy dissociation channel observed is endothermic loss of one ligand molecule. The threshold regions of the cross sections are analyzed to yield 0 K bond dissociation energies for the metal ion - ether interactions. This analysis includes the effects of multiple ion-molecule collisions, the internal and kinetic energy distributions of the reactants, and unimolecular decay rates. A careful assessment of the lifetime effects, which are particularly large in the crown systems, has been performed in these studies. Our most reliable results for lithium,^{1,2} sodium,³ and potassium³ with 1 - 4 DME ligands, 1 and 2 DXE ligands, and the 12c4 ligand are given in Table 1. In all cases, the bond dissociation energies determined experimentally are in reasonable agreement with the results of recent theoretical *ab initio* calculations,^{1,2,4} as shown in Figure 1

Table 1 Bond Dissociation Enthalpies at 298 K in kJ/mol^a

Complex	M = Li	Na	K
M ⁺ -DME	166(10)	93(5)	71(5)
(DME)M ⁺ -DME	119(6)	78(7)	63(6)
(DME) ₂ M ⁺ -DME	87(7)	67(6)	57(7)
(DME) ₃ M ⁺ -DME	66(10)	52(10)	46(7)
M ⁺ -DXE	245(18)	152(7)	118(5)
(DXE)M ⁺ -DXE	138(12)	113(14)	87(9)
M ⁺ -(12c4)	376(51)	231(23)	163(15)

^aUncertainties in parentheses.

Figure 2 shows the trends in these values for complexes having the same number of oxygen atoms, e.g. M⁺(DME)₄ vs M⁺(DXE)₂ vs M⁺(12c4). It can be seen that the trends in the bond energies for different metals parallel one another. The binding energies for Li⁺ are greater than for Na⁺ which are greater than those for K⁺. This is simply due to the different covalent radii of the metal ions and the consequent difference in electrostatic attraction with bond length. A more subtle effect is the relative bond energies for the sum of D(M⁺-DME) + D[(DME)M⁺-DME] vs D(M⁺-DXE) and the sum of the four M⁺-DME bond energies with the sum of the two M⁺-DXE bond energies and the M⁺-(12c4) bond energy. It can be seen that for all three metal ions, the DME complexes have higher bond energies than the polydentate ligands.

Figure 1 Theoretical vs experimental bond energies for ether complexes with Li⁺, Na⁺, and K⁺.

Figure 2. Bond energies for complexes of DME, DXE, and 12c4 with Li⁺, Na⁺, and K⁺ as a function of the number of oxygen atoms in each complex

This is because the DME ligands are free to orient their dipoles and change the metal-oxygen bond distance to optimize the interaction with the metal ion. In contrast, the DXE and crown ligands are constrained in these motions by the C-C backbones.

Further work includes examination of the same set of ligand complexes with Rb⁺ and Cs⁺ and extensions to larger crowns and the glymes.

Formation and Binding Energies of Metal-Ion/Coronene Complexes and Sandwiches

Robert C. Dunbar and Boguslav P. Pozniak

Chemistry Department, Case Western Reserve University
Cleveland, OH 44106

Introduction. The binding of metal ions to planar π systems has interest for the understanding of a variety of host-guest interacting systems. Our group has been interested in characterizing and comparing the binding behavior of a large variety of monocations with the two isomeric ligands coronene and tribenzocyclyne, TBC.

We have developed a considerable amount of understanding of the binding of metal ions to TBC,¹ and the present study of binding to coronene aims to look at similarities and differences. Most prominently, TBC has a large central cavity into which small ions are believed to insert at least partially, whereas coronene presents a more impenetrable surface

Radiative association kinetics provide a convenient approach to characterizing the binding, since relations between association rates and binding energies are being used with increasing confidence. Although this approach is somewhat uncertain for determining precise absolute binding energies for large complexes like these, it is expected to be a reliable way to look at small differences in binding energies, as between different metal ions binding to the same ligand.

Experimental. Experiments were done in the FT-ICR spectrometer, using a 1.4 T iron magnet, and a 1-inch cubical ICR cell, controlled by an IonSpec data system. Metal ions were made by laser desorption/ionization, usually from the bare metal surface, or from a crystalline salt of the desired metal. Coronene was evaporated from the solid on a heated probe. Pressure was a few times 10^{-8} Torr. Chamber temperature was 85° C. Absolute pressure was not measured directly, but all reactions were compared with the Al^{+} + coronene reaction, which was assigned a rate constant of 11×10^{-10} cc molec $^{-1}$ s $^{-1}$ and used as an internal standard to measure neutral pressure. The reaction scheme shown below was followed in time using standard FT-ICR methods.

Results. Rate constants were measured for the first association, k_1 , the sandwich formation reaction, k_2 and the charge transfer reaction, k_{ct} . The association rate constants are graphed below for the 22 metals which showed reactivity. The alkali ions Na, K, Rb and Cs underwent no measurable reactions.

Conclusions.

M⁺ + Coronene: Association with M⁺ is fast for all metals; *except* it is slow for alkalis, and is suppressed by very exothermic charge transfer. Bond strengths estimated from the “standard hydrocarbon” model are around 1.3 eV, *except* the alkalis < 1.0 eV.

Sandwich Formation. Sandwich formation is fast *except* for Mg, Al, Si, In, Pb and Bi. Sandwiches are bound by about 1.5 eV.

Charge Transfer: Charge transfer is fast when available. Association competes well with exothermic charge transfer if the energy release is not more than about 1 eV.

Comparison of Coronene with TBC: The binding energies are comparable. Binding of the alkalis is much worse for coronene than for TBC. With coronene, the reactions with Ni and Cu are not suppressed by a "cavity effect."

MALDI Analysis of Crown Ether Interactions with Cations

Tammy T. Fang and Bert C. Lynn, Jr. Department of Chemistry, Mississippi State University, Mississippi State, MS 39762

Recently considerable effort has been devoted to the study of noncovalent complexation of biomolecules using matrix assisted laser desorption/ionization (MALDI) techniques. Different parameters involved in the MALDI process, such as wavelength, laser irradiance, sample preparation, type of matrix and matrix pH have different effects when applied to studies of noncovalent interactions. Since the utility of MALDI for the study of noncovalent interactions has been limited to biological systems, we were interested in evaluating other model systems. The noncovalent interactions of a series of crown ethers and alkali metal (K^+ , Rb^+ , Cs^+) and ammonium cations were investigated. The crown ethers were 15-crown-5, 18-crown-6, dicyclohexano-18-crown-6 and dibenzo-18-crown-6. Also studied were the noncovalent interactions of calcium cation with a series of *bibracchial* lariat crown ethers: diaza-18-crown-6- $(CH_3)_2$, diaza-18-crown-6- $(CH_2CH_2OH)_2$, diaza-18-crown-6- $(CH_2CH_2OCH_3)_2$, diaza-18-crown-6- $(CH_2CH_2CH_2CH_3)_2$, diaza-18-crown-6- $(C_6H_5)_2$, diaza-18-crown-6- $(gly-ala-OCH_2CH_3)_2$, and diaza-18-crown-6- $(gly-leu-OCH_3)_2$. The nature of these interactions were evaluated based on, ligand, cation, solvent, and counter ion effect. The experiments were carried out on a lab-constructed MALDI/TOF mass spectrometer with 2-(4-hydroxyphenylazo)benzoic acid (HABA) and α -cyano-4-hydroxycinnamic acid (α CHCA) as matrices.

The experimental results indicated that the utility of MALDI for detecting the noncovalent complexes seemed limited by matrix/analyte co-crystallization requirements. Gas phase cationization and complexation were competing processes when alkali metal ions were used as the guests for the crown ethers (Figure 1). The resulting gas-phase selectivity indicated that crown ethers prefer a slightly smaller cation because of the increased electrostatic interactions within the cavity for a given conformation of the crown ether. In contrast, the MALDI analysis of *bibracchial* lariat ethers and $CaCl_2$ demonstrated specific noncovalent interactions. In such a case, cationization could be differentiated from complexation. Only $CaCl^+$ complexes with *bibracchial* lariat ethers having two dipeptide sidearms were observed. The amide groups exhibit a resonance structure, which, in turn results in partially charged donors which favors cation complexation. The stability of a complex also plays an important role in the gas phase complexation. In addition, the peaks of the fragments of $CaCl^+$ complexes of *bibracchial* lariat ethers having two dipeptide sidearms were observed due to the loss of parts of the amino acid side chain (Figure 2). The fragmentation can be rationalized by a photochemical ionization model, which involves an initial photoionization step followed by ion-molecule reactions to yield the product ions. Ionization of the analyte was actively promoted by the $CaCl^+$ adduct ions. Since complexation occurs in the dense plume via a biomolecular reaction between the matrix and analyte molecules, excess energy transferred to the complex ions can induce fragments. $CaCl^+$ behaved differently from alkali metal ions, such as K^+ . When the same *bibracchial* crown ether was analyzed in the presence of KCl, abundant $[M+K]^+$ ions were observed with no accompanying fragmentation. The abundant alkali metal adduct ions were formed due to relatively large

interaction cross section for nonspecific gas phase cationization. Gas-phase capture of cations by the analyte model can explain the formation of alkali metal ion adducts. The expansion conditions provide the necessary collision frequency and relative energy distributions of the analyte and cations to ensure the reaction of the analyte and cation within the expanding plume.

MULTIPLE BINDING INTERACTIONS IN GAS-PHASE COMPLEXES

Jennifer Brodbelt, Department of Chemistry, University of Texas, Austin, TX 78712

Molecules that have an array of identical binding sites, such as crown ethers and polydentate pyridine ligands, prove to be intriguing candidates for reactions with metal ions because multi-site coordination should be promoted. In fact, this type of process has been extensively studied in terms of molecular recognition and chelation. The electronic nature and size of the metal ion and number of coordination sites and flexibility of the ligand clearly play an important role in influencing the binding energies and structures of the resulting complexes in the gas phase. In this work, we evaluate the formation of various types of metal complexes by ion-molecule association reactions between organic polydentate ligands and laser-desorbed transition metal ions. Ligand exchange and collisionally activated dissociation methods in a quadrupole ion trap are used to investigate the nature of the binding interactions and the relative binding affinities of the various ligands. We focus primarily on two types of complexes: ones involving two polyether molecules and a metal ion, and mixed complexes that incorporate a polyether and a heteroaromatic ligand bound to a transition metal ion.

Polyether Dimer/Metal Complexes

To explore the influence of ligand flexibility and cooperativity on the dissociation of the metal complexes, glyme and crown ether dimer complexes were formed by ion-molecule reactions between selected metal ion and two glymes or crown ethers to produce dimer complexes. These complexes incorporate between four and ten oxygen atoms, some or all of which may be coordinated to the metal ion. These dimer complexes have two independent ligands and multiple coordinating sites, so they serve as systems to allow further comparison of flexibility and cooperative coordination of the ligands. The CAD results are summarized in Table 1. For example, the (2 x diglyme + Co⁺) complex dissociates predominantly by elimination of one entire diglyme unit, whereas the (2 x glyme + Co⁺) complex dissociates predominantly by loss of one CH₃ unit. As elucidated previously, the products formed via radical losses are the most energetically favorable ones and incorporate one covalent bond between a polyether unit and the metal ion. These striking differences support a mechanism in which the number of oxygen atoms coordinated to the metal ion greatly alter the dissociation behavior of the complex. The complexation of two independent polyether units permits more favorable coordination of the metal ion and contributes more conformational flexibility during the dissociation processes.

Mixed Heteroaromatic/Polyether Metal Complexes

The complexation of the glymes and crown ethers with 2,2'-dipyridine, 4,4'-dipyridine, 1,10-phenanthroline, and 2,2',6',2''-terpyridine ligands was evaluated because the mixed complexes involve contrasting types of coordination interactions with different binding strengths. In general, the heteroaromatic ligands bind the metal ions more strongly than do the polyethers, but there are some interesting trends observed from ligand-switching experiments and from CAD experiments. For example, the (1,10-phenanthroline + Co⁺) complex readily adds a second phenanthroline unit or a 15-crown-5 unit with nearly equal efficiencies, but the (2 x 1,10-phenanthroline + Co⁺) dimer does not exchange one of its ligands for a 15-crown-5 unit. This latter result suggests that the phenanthroline ligand is more strongly bound to the Co⁺ ion than a 15-crown-5 molecule. In contrast, CAD of the mixed dimer (1,10-phenanthroline + Co⁺ + 15-crown-5) dissociates predominantly by elimination of the phenanthroline unit (> 90%). Thus, the loss of the phenanthroline unit is the kinetically favored process, but not the thermodynamically favored one.

When the (2 x 4,4'-pyridine + Co⁺) complex interacts with 15-crown-5, both pyridine ligands are rapidly pulled off the metal ion and a stable (15-crown-5 + Co⁺) complex is formed (Figure 1). The intermediate complex, (pyridine + Co⁺ + 15-crown-5) is never observed. When a smaller, less flexible crown ether such as 12-crown-4 is used in the ligand switching reactions, then the mixed complex, (4,4'-pyridine + Co⁺ + 12-crown-4), is observed, but (12-crown-4 + Co⁺) is not generated. The 12-crown-4 molecule is not flexible enough to adopt a conformation that allows it to fully coordinate the Co⁺ ion. The acyclic analog of 12-crown-4, triethylene glycol dimethyl ether (triglyme), behaves like 15-crown-5 because it rapidly strips both bipyridine ligands off of the Co⁺ ion to form (triglyme + Co⁺). This results highlights the importance of the flexibility of the polyether ligand in defining its coordination strength.

Conclusions: Mixed pyridine/polyether complexes provide insight into the factors that influence chelation of metal ions. Large, flexible polyethers with multiple coordination sites can not form stable dimer complexes, but they can strip off two or three pyridine ligands around a metal ion.

HOST-GUEST INTERACTIONS BETWEEN CAVITANDS OR CALIXARENES AND TARGET ORGANIC MOLECULES OR IONS

Marco Vincenti*, Dip. Chimica Analitica, Università di Torino, Via Giuria 5, 10141 Torino, Italy
 Enrico Dalcaneale, Dip. Chimica Organica e Industriale, Università di Parma, 43100 Parma, Italy

Mass spectrometry has been applied to the study of host-guest chemistry either in the analysis of products formed in the condensed phase or to make the interactions occur in the gas phase, in the absence of solvent effects. Both types of applications have been reviewed recently [1]. Since 1990, we have been studying the host-guest interactions occurring in the gas-phase between large concave molecules, such as cavitands or calixarenes, and neutral organic molecules (aromatic hydrocarbons, aliphatic alcohols, amines, esters). The interaction processes were established at room temperature either in the ion-source of a conventional mass spectrometer, run under CI conditions, or in the collision cell of a tandem mass spectrometer. The products formed were observed as both positive and negative ions, and the detection of complexes in both polarities was taken as an evidence that the charge was delocalized on the large structure of the host, while the guest did not compete for it. The interaction energy involved in the complexation of a neutral guest is generally quite low and, in fact, the formation of complexes was observed quite rarely under such conditions. However, the complexation of neutral guests becomes highly specific and strong, whenever the host has a rigid cavity of adequate dimension and geometry, and specific groups directed toward the inside of the cavity. This is the case for structures such as, for example, cavitand **1** and calixarene **2**, which underwent quite selective complexation with, respectively, aromatic hydrocarbons and aliphatic ketones and esters. The selectivity toward different guests could be quantified (and their relative thermodynamic complexation constants determined) by mixing the vapors of two or more guests in known relative abundance and measuring the products formed. Despite the apparent simplicity of the experiment, the mechanism for the complexation remains rather elusive. A mechanism involving the interaction of charged host and neutral guest was proved when the relative abundance of the products turned out different in the positive and negative ion mode. No clear evidence of the mechanism was obtained in the cases when the mass spectra looked very similar for the two polarities. This seems consistent with the hypothesis that the host reacts with similar kinetics whatever its charge is, positive, negative or neutral, the latter being favored by probabilistic factors. FAB mass spectra of host-guest complexes should, in theory, reflect the product distribution existing in the matrix, although Shinkai observed remarkable differences between solution data and the FAB results in the complexation of quaternary ammonium ions by some calixarenes [2]. These differences are likely

to be especially large when the binding energy for host-guest complexes is small. Some contribution from processes occurring in the seldge is possibly reflected in FAB results, even if direct desorption of preformed ions is the mechanism generally accepted.

In order to investigate these aspects further, a FAB/MS study was undertaken on the host-guest chemistry of a series of cavitands, built by bridging a calixarene moiety with four arylphosphate groups (see compound **3**). It should be noted that, for each phosphate group, the P=O bond can be either directed toward the inside of the cavity or toward the outside, leading to six possible diastereoisomers which, obviously, can not interconvert into one another. These diastereoisomers have been synthesized, isolated and characterized. In solution, the isomers showed dramatically decreasing binding abilities, going from the isomers having at least three converging P=O bonds to the ones with one or no converging P=O bond. FAB mass spectra obtained by mixing each isomer with an excess of one or more different alkylammonium ions (or arylammonium) in 3-nitrobenzyl alcohol (used as the FAB matrix) showed the same trend ($b > c > d > e$).

3 = 5b : iiio C_s

From the relative abundance of the MS peaks corresponding to the complexes with two different guests, the relative complexation constants were obtained, giving the following scale of decreasing stability: methylammonium > dimethylammonium > ethanolanionium > benzylammonium > p-toluidinium > o-toluidinium $\equiv$ trimethylammonium. An attempt was made to determine the absolute complexation constants, despite the limits intrinsic to the FAB method, by varying the "pH" of the solution, and consequently the protonation and complexation equilibria. The results turned out substantially unchanged by the addition of strong acids. This means that either the molar fraction of the protonated host is close to one or close to zero. In favor of the first hypothesis is the relatively high dielectric and autoprotolysis constants for the matrix and its acidic character. On the other side, the proton affinity of **3** in the gas phase was tested by the "kinetic method". The proton-bound dimers formed by **3** (or triphenylphosphate) and various amines, were collisionally dissociated and the products determined by the second mass analyzer of a MS/MS system. Triphenylphosphate turned out more basic than anilines and less basic than pyridines, while **3** apparently showed even higher proton affinity than alkylamines, provided that the kinetic method is applicable to this case. It is concluded that in host-guest complexes formed by cavitand **3** and alkylammonium ions, strong and multiple hydrogen bonds are formed, where **3** favorably competes with the corresponding amine for the partial proton-charge transfer.

**Progress in Gas-Phase Molecular Recognition:
Salts of Alkaline Earths and Allosteric Effects**

*R. Marshall Pope, Nanzhu Shen, Jeremy Nicoll, Chadin Desjupa, Spencer Carter and David Dearden
Department of Chemistry and Biochemistry, Brigham Young Univ., Provo, UT

Several distributions of small polynuclear ions of general form $[nM + mA + pS]q+$ (where M represents an alkaline earth cation (Mg, Ca, Sr or Ba), $n = 2 - 10$, A represents either a halide, acetate or nitrate counter-ion originating in the divalent salt and S represents an acetic acid or methanol adduct) are detected by FTICR when water / methanol solutions of alkaline earth salts are electrosprayed. Clusters with a net charge of +2 were detected in solutions of barium chloride, barium bromide and calcium acetate but other solutions have only produced the +1 charge state ions. In addition, aqueous mixtures of two group II salts produce mixed metal cluster ions with a range of stoichiometric proportions that varies from 1:1 to 1:7. For example, the largest cluster ion derived from 6.3 mM solutions of calcium acetate acidified with 2.5% acetic acid have $n = 10$, $m = 18$, $p = 5$ and $q = 2$. A mixture of calcium and magnesium acetate in the same electrospray matrix, shown in Figure 1, produces binary clusters with 4:0, 3:1, 2:2, 1:3 and 0:4 ratios of magnesium to calcium.

It is important to note that the distribution of *mixed* clusters is dependent upon the procedure used to prepare the solutions. Stock solutions may be prepared up to two weeks in advanced at .125 M concentration in 1:1 methanol : water solvent. Just prior to spraying, these solutions are diluted to 6 mM total concentration and, for acetate counter-ion, 1% acetic acid is added. If the solutions are mixed at stock concentration, the distributions of *mixed* clusters reflect a "homogeneous" partitioning. If solutions are diluted prior to mixing, one stoichiometry of mixed cluster usually dominates the distribution. This observation when combined with results of preliminary light scattering experiments, slow solution equilibria, and the fact that signal is only observed when the glassware has been "etched" prior to use suggest that these clusters may originate from colloids

Selected alkaline earth clusters may be isolated in the 4.7 Tesla field of a FTICR by radio frequency ejections. These clusters are found to react in a low-pressure background of crown ethers (12-crown-4, 15-crown-5 or 18-crown-6) by both adduction of the crown ether and transfer of an alkaline earth salt. The slow decomposition of metastable crown-cluster adducts also produces the latter ion-transfer product. As a specific instance, we note that 12-crown-4 reacts with $CaSrI_3 \cdot 2MeOH+$ to produce the CaI -12-crown-4+ ion at approximately four times the rate of the analogous strontium-iodide ion. However, if iodide is replaced with acetate, the rates are indistinguishable. Interpretation of relative rates is complicated by the fact that the experiment is run in the presence of methanol adducts in the first case and acetic acid adducts in the latter. However CID in the first skimmer region of the electrospray interface can remove these adducts.

We also present preliminary work designed to detect allosteric effects in reversible binding. The molecule shown in Figure 2 is a cisplatin analog consisting of a crown ring segment fused to a bipyridine chelate. In this structure, the conformation of the crown cavity affects the torsional angle between the two 2, 2' nitrogen donor atoms. This conformation is affected, in turn, by the degree to which the two oxygen donors separated from the bipy by one methylene unit participate in alkali metal coordination. We hope to detect the effect that such pre-organization has on metal transfer rates when an electrosprayed cocktail of the alkali metal adducts of this molecule (with and without $PtCl_2$) are trapped in the presence of a crown ether. Thus far, 12-crown-4 has shown high selectivity for the lithium adduct, reacting ~10 times faster with this than with the cesium adduct. Other rates vary smoothly with the size of the alkali metal. The relative rates of metal transfer to 18-crown-6, follow the same trend, but vary by only 15%.

DEPENDENCE OF THE Na⁺ AND Cu⁺ AFFINITIES OF SIMPLE BIOMOLECULES ON SEQUENCE AND STEREOCHEMISTRY

Chrys Wesdemiotis, Blas A. Cerda, and Wei Deng

Chemistry Department, The University of Akron, Akron, OH 44325

Metal ions play an important role in many biological processes. In vivo, they are stored and transported by biomolecules that selectively recognize and bind them. Knowledge of the intrinsic bond strengths between a specific metal ion and the different types of functional groups present in biomolecules is, therefore, of fundamental interest. In this study, the binding of simple linear and cyclic peptides to Na⁺ and Cu⁺ (i.e. of a main group and a transition metal ion, respectively) is probed by Cooks's kinetic method.¹ The peptides chosen bear no heteroatom(s) in their side chains, to allow for the assessment of the properties of the backbone substituents, viz. of the amino, carboxylic, and amide groups. Additionally, this investigation interrogates stereochemistry effects by determining the Na⁺ affinity order of monosaccharides.

For the peptides investigated, absolute Na⁺ affinities were measured using glycine, alanine, and valine as reference bases.² We employed a modified version of the kinetic method to account for entropy effects, which are unavoidable when molecules with different functional groups are compared.^{3,4} The sodium affinities derived increase in the order (ΔH°_{Na} in kJ mol⁻¹): cyclo-GG (132) < cyclo-GA (135) < cyclo-AA (137) < G (159) < A (165) < GG (198) < AG (200) < GA (202) < AA (206) < GGG (233) < AGG (253) < GAG (255) < GGA (260) < AAG (281) < AGA (284) < GAA (309) < AAA (326). Cyclic peptides, which contain no free termini, show the lowest affinities. On the other hand, linear dipeptides bind stronger than amino acids and ΔH°_{Na} becomes significantly larger from di- to tri-peptides, most likely due to a better complexation of the metal ion. Notice that Na⁺ recognizes the sequence of isomeric peptides and forms a stronger bond as alanine(s), which is a better ligand than glycine(s), moves towards the C-terminus. These trends are consistent with Na⁺, a hard Lewis acid, attaching close to the C-terminus, where more hard basic sites are present.

With Cu⁺, only relative affinities were determined because of the absence of suitable reference bases. The resulting ladder is: G < A < cyclo-GG < cyclo-AA < GG < GA < AG < AA < GGG < GGA < GAG < AGG < GAA < AGA < AAG < AAA. The ΔH°_{Cu} and ΔH°_{Na} rankings of specific peptides differ substantially (e.g., see Figure). It is noteworthy that Cu⁺ binds progressively stronger as alanine(s) move towards the N-terminus. Hence, Cu⁺, a softer Lewis acid than Na⁺, complexes close to the N-terminus, where more soft basic sites are available.

Finally, the effect of stereochemistry was interrogated by acquiring the relative sodium affinities of pentoses and hexoses. ΔH°_{Na} becomes larger in the order deoxyribose < arabinose < ribose < glucose < sorbose < tagatose < fructose = mannose < psicose. The rankings obtained point out that the number of hydroxyl groups and the stereochemistry of the sugar molecule markedly affect the Na⁺ binding. The Na⁺ - saccharide affinity increases with the number of O-coordination sites available, which in turn is influenced by the size of the saccharide (pentose vs. hexose) as well as the exact arrangement of the OH-substituents. It is worth mentioning that enantiomers (viz., glucose vs. mannose, sorbose vs. tagatose, and fructose vs. psicose) can readily be distinguished based on their ΔH°_{Na} values.

Figure. Metastable ion spectra of M⁺-bound dimers of GG with either GA or AG. The relative abundances show that $\Delta H^\circ_{Na}(GA) > \Delta H^\circ_{Na}(AG)$ but $\Delta H^\circ_{Cu}(GA) < \Delta H^\circ_{Cu}(AG)$.

(*Present Address: Department of Chemistry, Washington University, St. Louis)

Inclusion complexes of cyclodextrins (CDs) are formed by the entrapment of guest species into the hydrophobic cavity of the cyclic oligosaccharide. Large molecules such as peptides and proteins cannot be fully entrapped. Appropriate complex-forming side-chains can, however, bind cyclodextrins, resulting in modified solubility, stability and/or membrane transport properties.¹ The lack of adequate techniques has hindered the proper characterization of peptide - CD interactions, because of the complexity of their association involving multiple binding sites for CDs. The lack of adequate techniques has hindered the proper characterization of peptide - cyclodextrin interactions, because of the complexity of their association involving multiple binding sites for CDs. Electrospray ionization (ESI) has been used to study noncovalent complexes involving CDs, and amino acid - CD complexes formed in solution have also been characterized by ESI mass spectrometry.² Complexes with various stoichiometry have been detected.³ The preferential formation of CD- aromatic over CD- aliphatic amino acid complexes was confirmed by the experiments, and their relative gas-phase stabilities were determined by collisionally-induced dissociation (CID).² However, a recent study suggested that certain β -CD-amino acid and β -CD-peptide complexes might not be true inclusion complexes, but electrostatic adducts.⁴

Our present study has been focused on determining gas-phase stability of CD-peptide complexes by using CID. ESI - quadrupole mass spectrometry was done by using a Vestec 200 ES instrument (PerSeptive Biosystems/Vestec, Houston, TX), as described in Ref. 2. Ionization was achieved by applying a potential of 2.5-2.7 kV to a flat tipped (120 μ m ID) stainless steel needle. The sample (acidified aqueous/methanolic) solution was delivered to the needle by a syringe pump at 2-5 μ L/min flow rate. A flat stainless steel plate with a 0.4-mm orifice functioned as the counterelectrode (nozzle). The source block was heated to 250 $^{\circ}$ C to reach 55-60 $^{\circ}$ C in the spray chamber. The collimator was held at 10 V, and the repeller potential was maintained at 12-15 V under normal operating conditions, and increased up to 200 V for CID. ESI experiments were also performed on a 4.7-tesla FTICR mass spectrometer (Bruker Instruments, Inc., Billerica, MA). Ions were produced via an electrospray source equipped with a hexapole ion guide/trap and heated capillary (Analytica of Branford, Branford, CT). ESI was achieved at a flow rate of 2 μ L/min with a needle voltage of 3 kV. The capillary was held at ground potential while the temperature was maintained at 100 $^{\circ}$ C. Sample concentrations were ca. 1×10^{-6} M in 50/50 (v/v) methanol/water for the CDs and ca. 5×10^{-5} M in 45/45/10 (v/v/v) methanol/water/acetic acid for the amino acids and peptides. On-resonance CID was accomplished by argon as a collision gas at a cell pressure of 1×10^{-7} torr.

Our CID experiments involving the FTICR instrument and using the α -CD complex of protonated valine (m/z 1090.4) and tryptophan (m/z 1177.4) as models have revealed unequivocally that there was, as a principal reaction beside the direct dissociation of the host-

guest complex, a charge (proton) transfer from the protonated guest molecule to the CD host (yielding m/z 973). The proton transfer was followed by losses of $[C_6H_{10}O_5]_n$ from the protonated α -CD (m/z 811, 649, 487, 325 and 163). In-source CID experiments involving β -CD- and heptakis(2,6-di-O-methyl)- β -CD-complexes of peptides such as Leu-enkephalin (Tyr-Gly-Gly-Phe-Leu) and Ala-Leu-Gly also showed this process to occur. As a consequence, direct measurements of binding energies between the cyclic oligosaccharide host and the protonated peptide guest based on the laboratory frame of kinetic energies were impossible. However, in-source CID has been shown to produce numerous sequence ions from peptides. For inclusion complexes that were expected to form involving side-chains of aromatic amino acid residues (e.g., in Leu-enkephalin), a shift in the appearance of peptide sequence ions as a function of the collision energy was observed, when data were expressed in the center-of-mass frame of reference,² and by taking the CID of the uncomplexed peptide as a reference (Fig. 1). There was no such shift for the complex of peptides that were presumed to bind weakly to CDs ("adduct"). Therefore the difference in appearance energies of the sequence ions between the CD-complexed and uncomplexed peptide may be in apparent correlation with the energy required to dissociate the host from the guest.

Figure 1. In-source CID of CD-complexed and uncomplexed Leu-enkephalin (YGGFL). DM- β -CD: heptakis(2,6-O-dimethyl)- β -cyclodextrin.

Structural Factors that Govern the Strength of Non-Covalent Bonding Interactions in Gas-Phase

Peptide-Cyclodextrin complexes

Sharron G. Penn, Fei He, M. Kirk Green and Carlito B. Lebrilla. Department of Chemistry, University of California, Davis, CA 95616

Recently, several reports of cyclodextrin complexes formed with electrospray ionization (ESI) mass spectrometry (MS) have appeared in the literature, along with debate as to whether their gas-phase and solution phase structures are related^{1,2,3}. Observation of intensities at m/z corresponding to the complex is not sufficient evidence that solution-phase structure is maintained in the gas-phase.

Using an external source Fourier transform mass spectrometer (FTMS) equipped with an ESI source, we have used collision induced dissociation (CID) and heated capillary dissociation (HCD) to determine the relative binding affinities of bradykinin (BK, Arg-Pro-Gly-Phe-Ser-Pro-Phe-Arg) and three of its analogs to heptakis (tri-O-methyl)- β -cyclodextrin (CD). The analogs were chosen to investigate the relationship between charge and inclusion sites.

HCD is a technique under development in our laboratory that uses the heated desolvation capillary of the ESI source at various temperatures to probe the strength of non-covalent interactions. In these studies, the temperature at which the complex of interest disappears relative to the complex of $[BK+CD+2H]^{2+}$ is monitored. The temperature of dissociation (T_d) is determined as shown in Figure (1). The use of CID to determine dissociation thresholds is well known. We determine the CID amplitude at which the complex is dissociated, and the threshold is determined as shown in Figure (2).

The results are summarized in the Table. The order of binding strength from CID and HCD results agree. The gas-phase complexes may exist in a number of differing structures, which we call isoplexes. As CID monitors only the most weakly bound isoplex, and HCD monitors only the most strongly bound isoplex, we propose that only a small number of isoplexes exist.

The results also provide strong evidence that there is a relationship between the charge site and the inclusion site consistent with the formation of an inclusion complex. In solution, the phenyl group is likely included into the cavity, and the arginine group interacts with the cyclodextrin rim. But, the forces keeping the complex together in the solution-phase will not have same effect in gas-phase. The results suggest that Phe is destabilizing in the gas-phase, since G^5G^8BK is a stronger complex than BK.

In conclusion, gas phase structures are not limited to ion-dipole interactions, the relationship between charge and inclusion site is important, inclusion complexes are destabilizing in the gas-phase and HCD and CID provide important supporting information.

Figure (1) shows the HCD threshold for $[dR^9BK + CD + 2H]^{2+}$ monitored relative to $[BK + CD + 2H]^{2+}$.

Figure (2) shows the CID threshold for $[BK + CD + H]^{2+}$

Table : CID and HCD results

Peptide	Excite amplitude (V_{b-p})	E_{LAB} (eV)	E_{COM} (eV)	T_d
G^5G^8BK	11.0	128	1.53	>330 °C
dR^1BK	11.0	127	1.50	>330 °C
BK	10.5	108	1.20	300 °C
dR^9BK	9.0	85	1.00	270 °C

THE SKIMMER IN DIRECT SAMPLING MASS SPECTROMETRY

David R. Miller
Dept. A.M.E.S., U.C. San Diego
La Jolla Calif., 92093-0411

Fig. 1 shows the basic elements utilized by many DSMS researchers. This talk will review the background for selected design considerations for the DSMS, especially the free jet-skimmer interaction. A nozzle (N) terminates a probe, which may be an aperture, tube, or skimmer-like diverging nozzle. The flow exits the nozzle as a free jet supersonic expansion, from which a centerline molecular beam is sampled with a skimmer (SK). The beam is then mechanically chopped (C) and passes through a collimating aperture (A) into the mass spectrometer detector (D). Since in DSMS the source conditions are usually given, the important design variables are the nozzle and skimmer geometry's, the nozzle-to-skimmer distance, and the type of pumps used which determines the important background pressure P_b . The rest of the geometry is usually determined by physical constraints such as pump and detector geometry's. The overall source-to-detector distance is kept to a minimum whenever possible since overall signal scales as the solid angle from the source to the active detection region. Fig. 2 shows the continuum free jet terminated along the centerline by a strong shock wave called the Mach disk. It is well understood that the skimmer must be placed upstream of this shock wave. The problems with placing the skimmer into such a supersonic flow field are well understood and there are reasonably good guidelines on designing the skimmer angle and position to maximize beam intensity. This talk will review the development of our understanding of such skimmer interaction and the guidelines for proper design.

Figure 1

As the gas expands in the free jet the number density and temperature fall rapidly. Under the conditions of many DSMS researchers the collision frequency falls below that required to maintain continuum flow and the quiting surface model of the free jet shown in fig. 3 becomes appropriate. Rather than shock-like structures about the skimmer we now envision the interaction as scattering of gases from background gases and, especially, from those molecules which leave the quiting surface in free molecular flight and then scatter back into the free jet from the skimmer surfaces. Characterization of this regime will also be presented. Usually the type of pump being used, e.g. a mechanical roots or a diffusion pump, determines which regime, near continuum or near free molecular flow, the skimmer operates in and therefore how we deal with the design.

In order to keep the nozzle probe orifice removed from the chamber walls and/or to minimize the flow disturbance, DSMS researchers often use the skimmer-like diverging nozzle, rather than a simple orifice, to probe a flow. In this geometry there are important differences in the gas expansion characteristics due to

THE FREE JET EXPANSION

Figure 2

the diverging nozzle walls. This geometry can cause significant differences from well established free jet behavior because of strong viscous boundary layer effects along the diverging nozzle walls and the slower rate of expansion within the nozzle; The latter effect can drastically effect relaxation, clustering, and chemical rates. In other cases, the DSMS sampling may be through a capillary tube. Examples of such nozzle geometry effects will also be presented.

The literature on free jets and skimmer interaction has grown since the early 1960's. Many of the original results, from a large number of laboratories, have been archived in the International Symposia on Rarefied Gas Dynamics (RGD). While it is impossible to cite all of the important references, a few selected ones for specified subjects are presented below; these are reasonable entries to the field.

SAMPLING METHODS FOR SUPERSONIC MOLECULAR BEAM - MASS SPECTROMETRY

Aviv Amirav* and Shai Dagan, School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel

Phone: 972-3-6408253, Fax: 972-3-6424048, E-mail: amirav@post.tau.ac.il

Supersonic molecular beams (SMB) are characterized by several features of importance to mass spectrometry including: 1) Extreme intramolecular vibrational supercooling; 2) Unidirectional molecular motion with hyperthermal kinetic energies up to 30 eV; 3) Effective jet separation; 4) High flow (100-500 ml/min) atmospheric pressure sample inlet capability. We have explored the implications of these features in order to study and develop new MS sampling methods with unique advantages as follows:

1. A conventional GC injector combined with a short, high flow rate, capillary column was modified into a unique direct sampling introduction (DSI) device. This GC based DSI is characterized by very fast sample introduction and very short switching time back to GC-MS operation. It can also accept very dirty samples including sludge, urine, blood, etc. in a disposable vial for GC injection, without deterioration of the GC column and injector liner cleanliness.

2. Fast, very fast and ultra fast GC-MS is achieved with SMB-MS. The fast GC-MS in SMB is uniquely characterized by improved sensitivity, lower detected concentration, increased level of mass spectral information, unique selective hyperthermal surface ionization and a broader range of thermally labile compounds amenable for analysis.

3. Laser desorption injection followed by ultra fast GC-MS in SMB (1-10 seconds) was developed and studied. Laser desorption injection provides an advanced tool for the sampling of very complex matrices with minimal or no sample preparation.

Several examples will be shown including fast GC-MS of underivatized steroids, drug screening in urine by direct urine injection without extraction and laser desorption analysis in untreated blood.

Fig. 1. Drug analysis in untreated urine. 2 µL urine was loaded into a disposable vial and introduced with the DSI into the GC injector, followed by fast GC-MS using hyperthermal surface ionization.

Direct Sampling Tandem Mass Spectrometry of Premixed Flames

Helge Egsgaard and Elfinn Larsen
Environmental Research and Technology Department,
Risø National Laboratory, DK-4000 Roskilde, Denmark

The goal of modern combustion chemistry is to combine results obtained by theory and experiments at both the elementary and global levels. Due to the complexity of flames, such an integrated approach is in fact essential. A flame may be regarded as a weak plasma as a result of highly energetic reactions, e.g. between the CH radical and atomic oxygen. This reaction leads to a highly excited formyl radical and subsequently, by expulsion of an electron, to the formyl cation. Proton transfer from the latter to other flame constituents gives rise to a large number of ions within the flame. Thus, very basic reactions within the flame provide the basis for using the flame itself as the source of ions reflecting the distribution of neutral intermediates.

The novel Risø flame-ion tandem mass spectrometer includes a high-temperature supersonic molecular beam sampling system, which opens up the possibility for combining studies on both the global and elementary levels of combustion chemistry [1]. Thus, the MS/MS studies, including ion/molecule reactions, are based on experiments involving the molecular species actually present in the flame. In general, the investigations address two different questions: I) the identity of the ion and, hence, the structure of the neutral counterpart and II) the significance of chemi-ions to combustion processes.

Structure Elucidation: The application of collision activation mass spectrometry enables in a number of cases identification of the ion in question. However, more intriguing cases do easily arise such as the $C_2H_3O^+/C_2H_3S^+$ chemi-ions, which obviously are related to protonation of ketene and thioketene, respectively. In this case the diagnostic fragmentation processes are highly energy demanding and thus, not easily accessible with low-energy collisions. The analysis may in such cases benefit greatly by the use of ion/molecule reactions. Thus, the use of a polar [4+2] Diels-Alder cycloaddition with isoprene as well as a formal oxirane addition with 1,3-dioxolanes were found to be particularly valuable in distinguishing acylium ions, that is the acetyl and thioacetyl cations, from the heteroatom protonated species, respectively [2,3].

On the possible catalytic role of chemi-ions: The stationary concentration of ions and radicals as well as their reactions rates are comparable in flames. However, only one carbon atom out of one million ends up in an ionized species. Thus, the chemical significance of chemi-ions has to be sought for in their possible catalytic properties. The ionic mechanism for soot formation remains unique in the sense that ionic reactants seem to play a dominant role in a common combustion process. The ionic mechanism is initiated by the propargylic cation, which rapidly grows by the addition of alkynes. Such reactions have very recently been studied in detail using chemi-ions isolated from premixed flames and conceivable reactants [4,5]. In addition, the investigations strongly support the partial equilibrium between polyynic ions and simple alkynes in flames [5].

Specific Applications - New and Alternative Fuels: At present, the reformulation of fuel is a high priority area. Dimethyl ether (DME) has very recently been announced as an excellent diesel substitute [6]. The apparent non-sooting properties of DME [6] is strongly supported by investigations of premixed DME flames, which show that the intermediates related to ionic mechanism for soot formation are of vanishingly low intensity (cf. Fig. 1). The CH yield, as monitored by flame ionization detection, is reduced to approximately one C-equivalent. So-called prompt NO_x arises predominantly by the reaction of CH radicals with molecular nitrogen. Thus, the total ionization indicates that prompt NO_x is suppressed in DME flames, hence, in part explaining the low NO_x emissions from DME-fuelled engines [6]. Finally, the relatively high concentration of formaldehyde in DME flames ($MH^+ = m/z$ 31, cf. Fig. 1b) indicates that the thermally induced homolytic cleavage of the methoxymethyl radical plays a central role in the combustion of DME [7].

Figure 1. Positive ions sampled from the reaction zone of a) a premixed methane/oxygen flame and b) a premixed DME/oxygen flame. Ions which relate to the ionic model for soot formation are indicated in Fig. 1a).

In sum, it can be concluded that intermediates in combustion processes can advantageously be studied using chemi-ions. In particular, direct sampling tandem mass spectrometry constitutes a powerful strategy for investigations of new and alternative fuels.

DESIGN AND CONSTRUCTION OF AN ION TRAP MASS SPECTROMETER SYSTEM FOR ON-LINE GAS EMISSION ANALYSIS

Joe C. Scoggin and Bert C. Lynn, Jr.
Department of Chemistry
Mississippi State University
Mississippi State, MS 39762

Government regulations for gaseous emissions are increasingly more stringent creating a need for on-line technologies capable of monitoring effluent streams. Such systems should be robust, yet capable of sensitive analytical determinations. On-line monitoring systems should also provide continuous, nondiscriminatory sampling and effective elimination of background matrix effects. We have assembled a prototype instrument which meets the requirements of a continuous emission monitor. The following characteristics were incorporated into our instrumental design: a continuous molecular beam, photoionization, and a quadrupole ion trap (with MS/MS capability) orthogonal to the molecular beam.

A continuous molecular beam was constructed by using a capillary inlet tube and a skimmer cone mounted in a differentially pumped interface. The interface was constructed from a stainless steel tee (1.25 inches o.d.) with two KF (NW 40) flanges attached to two arms of the tee. A 1/16" o.d. stainless steel capillary (0.5 mm i.d.) inserted through a blank KF (NW 40) flange, sealed with a Kel-F hand tighten fitting, was used for sample introduction. The interface was evacuated to a pressure of 9.0×10^{-1} torr by a 920 L/min roughing pump. The vacuum side of the capillary was located approximately 3 mm from the 0.5 mm skimmer orifice. An o-ring compression fitting was used to connect the interface via an 8 inch CF flange to the high vacuum region. The main vacuum chamber was constructed from a six way cross evacuated by a 300 L/sec Varian turbomolecular pump. The pressure in this region was 2×10^{-5} torr.

Compounds seeded in the molecular beam were ionized using the fourth harmonic of a Continuum Minilite Nd:YAG laser (2 mJ) by a resonant two photon ionization process R2PI (two 266 nm photons ~ 9.4 eV). The laser beam was focused to ca. 0.5 mm by a 30 cm focal length quartz lens at the point of intersection with the molecular beam. The R2PI process allows for a greater degree of ionization specificity, virtually eliminating ions from background gases.

Components in the molecular beam upon ionization retain a mass independent velocity which must be compensated for when the ions are turned orthogonally. An electrostatic lens stack was designed to accomplish this task using the Simion 6.0 modeling program¹. The lens stack was constructed from stainless steel components separated by ruby balls. The lens components include a repeller plate, a grounded grid to define the ionization region, an ion deflector lens and a three element einzel lens.² Simion simulations of this lens stack demonstrated that ions with mass to charge ratios ranging from 100 to 500 daltons and energies ranging from 0.12 to 0.67 eV could be focused into the ion trap end cap when appropriate voltages were applied.

The quadrupole ion trap was chosen as a mass analyzer in this application for a variety of reasons, such as size and sensitivity. The duty cycle of the ion trap can be coupled to the pulsed ionization event to produce an efficient mass analysis. The use of MS/MS techniques can further reduce interferences thus enhancing specificity and increasing the signal to noise ratio.

The molecular beam, photoionization, and lens stack were evaluated in a series of experiments in which the ion was replaced with a cylindrical flight tube (producing a field free region) of approximately the same dimensions as the ion trap. Samples were introduced through a 0.32 mm fused silica capillary. Signals from the electron multiplier were amplified and transferred to a Lecroy digital storage oscilloscope (DSO). Spectra were obtained for a series of compounds including toluene, naphthalene, anthracene, and chlorobenzene which all have ionization potentials less than 9.4 eV. Several polychlorinated compounds with ionization potentials less than 9.4 eV were also evaluated, however no signals were detected. The chlorine substituent effect³ was responsible for the lack of ionization. As the number of chlorine substituents increase, the energy of the first excited state decreases, thus no state is available for the first photon in the two photon process. The ionization of polychlorinated compounds is therefore limited using R2PI.

Future research efforts include investigation of alternative ionization methods such as nonresonant ionization, two color resonance enhanced multiphoton ionization (REMPI), or a tunable electron gun for electron impact ionization. Improving the trapping of externally produced ions using Rf ramping experiments. Interfacing the Varian Saturn 3 control unit to the system for instrumental control and data acquisition.

Simion simulation of the lens stack.

EVALUATION OF DIRECT SAMPLING ION TRAP MASS SPECTROMETRY FOR IN-FIELD ANALYSIS OF VOCs IN AIR, WATER, AND SOIL.

Marcus B. Wise and Cyril V. Thompson, Chemical and Analytical Sciences Division
Oak Ridge National Laboratory, PO Box 2008, MS-6120 Oak Ridge, TN 3783-6120

Richard Yelton, Teledyne Electronic Technologies, Mountain View, California

A Teledyne ion trap has been modified for transportable in-field operation and equipped with a modular direct sampling inlet system for rapid analysis of environmental samples. No GC is used with this instrument. Instead, a variety of direct inlet systems permit the real-time or near real-time analysis of VOCs and targeted SVOCs in air, water, and soil. This instrument has been used extensively during the last year for a number of real-world applications and has also been evaluated as part of demonstrations which were overseen by the Consortium for Site Characterization.

For most applications, the instrument is operated from the back of a mini-van using either battery power, a gasoline generator, or line power if available at the site. Samples which have been tested include soil-gas, soil core samples, and groundwater. Analytes have included a wide range of volatile organics such as chlorinated industrial solvents, gasoline, jet fuel, and freons. Concentrations of analytes in the real-world samples have ranged from less than 1 ppb to several hundred ppm. Little or no sample preparation or preconcentration was required to achieve low ppb detection limits.

For soil-gas analysis, the instrument was used in conjunction with a real-time air monitoring inlet and Tedlar bags containing the samples were connected directly to the inlet for analysis. Both electron ionization and chemical ionization spectra were collected for each sample using an alternating EI/CI scan function. Water samples and soil core samples were analyzed by direct purge of 40 mL VOA vials containing the sample or a slurry of the sample. Alternating electron ionization and chemical ionization spectra were also collected for each of these samples. The electron ionization spectra provided the ability to identify and quantitate chlorinated solvents while the chemical ionization provided the ability to identify and quantitate BTEX and other alkyl aromatics. In addition, MS/MS spectra were obtained for some of the samples which contained xylene and ethyl benzene in order to differentiate between these two compounds.

Although this is a direct sampling technique and does not use GC to separate the analytes in a sample, we have repeatedly demonstrated the ability to produce high quality quantitative information for targeted analytes in many real-world environmental samples. High throughput and fieldability of the instrument make this a powerful tool for expedited site characterization or for periodic monitoring of large numbers of compliance monitoring wells. Data in many instances is comparable to standard GC/MS methods and the cost per sample is considerably less than half the cost of conventional laboratory analysis.

We are evaluating a number of approaches to the direct analysis of environmental samples using laser desorption ion trap mass spectrometry as the primary tool. The simplest approach, although not necessarily the best, is the direct interrogation of the sample with a pulsed laser. Using this method, we have demonstrated the direct detection of metals in SRM soil samples, and the detection of semi-volatile compounds such as polynuclear aromatic hydrocarbons and organophosphates spiked into a soil matrix. However, solid-phase microextraction of analytes from complex matrices using fused silica fibers or other selective sorbents such as zeolites has many advantages over both traditional chemical sample preparation techniques and direct desorption of the analyte from its native matrix. Microextraction requires small sample sizes, little sample preparation (providing rapid sample throughput), and greatly reduces the amount of chemical waste generated in sample preparation. Additionally, the small amount of preconcentration increases the amount of analyte available for desorption as well as reducing the chemical background in the mass spectrum. Increased sample adsorption and selectivity can be achieved by chemically modifying the surface of the fiber. These advantages make selective sorbents (e.g., fused silica fibers) attractive for direct sampling and detection experiments using laser desorption ion trap mass spectrometry.

In addition to chemically modified fused silica fibers, we have also evaluated traditional carbon-based sorbents, sol-gels, and zeolites as sampling matrices and supports. Fused silica microfibers can be coated with a sol-gel, which in turn can be chemically modified. This enhances both selectivity and sample adsorption, and hence sensitivity, by significantly increasing surface area. Zeolites are particularly well-suited as sampling matrices. By selecting zeolites with appropriate pore sizes, discrimination can be built into the sampling process. For example, tributyl phosphate can be trapped within the cavity of mordenite, but is not captured by the zeolite ZSM-5. A drawback to using zeolites as sampling matrices is their catalytic activity. Solid-state NMR experiments have shown that acetone, entrapped in mordenite, undergoes extensive decomposition. This catalytic activity can be quenched to a large extent by exchanging sodium counter-ions in the zeolite with silver. An added advantage here is that the silver, when ionized through resonant laser ablation, can serve as the cationizing reagent for the trapped organic molecule. For example, we have used a novel silver derivatized zeolite, in which the silver serves to both quench the catalytic activity of the zeolite and to provide a source of metal cationization reagent ions. This has been demonstrated with tributyl phosphate, a notoriously difficult compound to analyze by mass spectrometry. Structural information can be provided by MS/MS (upper figure). The technique of resonant laser ablation (RLA) also abets this

process. RLA provides a means to selectively ionized ablated metal samples from a complex substrate. The calibration curve for the detection of lead in soil is shown in the lower figure. Here the laser was tuned to 450.3 nm with a pulse energy of 84 μ J per pulse. Even with this difficult matrix, a linear calibration curve is obtained over nearly 6 orders-of-magnitude concentration. Absolute detection limits of attogram amounts of metals has been demonstrated with this technique.

In conclusion, the combination of laser sampling and ion trap mass spectrometry is very well-suited to the direct analysis of a wide variety of analytes in a vast array of matrices. Laser interrogation provides a nearly universal ionization tool while ion trap mass spectrometry allows ion/molecule chemistry to be exploited for ionization and fragmentation, and it brings high sensitivity detection. Further improvements to this general strategy are provided by selective sampling matrices such as silica fibers, sol-gels, and zeolites. The specificity of zeolites can be tailored by selection of cavity size and chemical modification. The technique of resonant laser ablation provides a selective and efficient means of creating metal ions and, because of the selectivity in ionization, alleviates space-charging of the ion trap.

PYROLYSIS-QUADRUPOLE ION TRAP MASS SPECTROMETRY OF PATHOGENIC BACTERIA

Franco Basile, Michael B. Beverly, Ted L. Hadfield¹, and Kent J. Voorhees^{*}
Colorado School of Mines, Golden, Colorado 80401
¹Armed Forces Institute of Pathology, Washington, D.C.

The need for an automated, real time detection of bacteria in the environment led to the development of the Chemical and Biological Mass Spectrometer, CBMS. The CBMS consists of a non-linear quadrupole ion trap mass spectrometer and an infrared pyrolyzer. The pyrolyzates are introduced into the ion trap via a silicon membrane interface (Figure 1). The ion trap uses a non-linear ejection mode which results in an increased resolution at a faster scan rate while using air as the buffer gas. An ion cloud cooling period (20 ms) before scan is also employed to increase resolution without the use of higher buffer gas pressures (collisional cooling)¹.

Detection of whole-cell bacteria with the CBMS was achieved by obtaining their fatty acid methyl esters (FAMES) profiles. Fatty acid methylation was achieved *in situ* during the pyrolysis step with tetramethylammonium hydroxide (TMAH). Because of the ion cooling period before scanning, FAMES undergo self-chemical ionization² after electron ionization (70 eV). Figure 2 shows the FAME mass spectra obtained from the pyrolytic *in situ* methylation of four pathogens, *Bacillus anthracis*, *Brucella neotomae*, *Francisella tularensis*, and *Yersinia pestis*, with TMAH. The FAME [M + H]⁺ ions observed are C16:1 ME (m/z 269), C16:0 ME (m/z 271), cyclopropylC17:0 ME (m/z 283), C18:1 ME (m/z 297), and cyC19:0 ME (m/z 311). The discrepancy between profiles obtained with a direct inlet, Curie-point pyrolyzer-quadrupole MS system³ and those obtained in this study is attributed to the higher volatility of saturated FAMES over that of unsaturated FAMES. This is confirmed by the higher ion abundances obtained for saturated FAMES if a higher transfer line flow (> 1.5 mL/min) is established prior to pyrolysis. This prevents sample losses through upward convection or "chimney effect" during the pyrolysis step. Spore detection is also accomplished with this approach. Figure 3 shows the pyrolytic *in situ* methylation of dipicolinic acid, the major component in spores, in whole cells of *Bacillus anthracis*-spores.

It is feasible to obtain FAME profiles and detect other biomarkers with the CBMS under 10 minutes total analysis time with the *in situ* methylation protocol. Further optimization of instrumental and sampling parameters should follow in order to increase the specificity of the measurement, lowering biomarker detection limits, and hence, bacteria detection limits.

Atmospheric Pressure Ionization Flow Injection Analysis by Orthogonal Time-of-Flight Mass Spectrometry.

B. A. Andrien, T. Dresch, P. J. Haren, and C. M. Whitehouse.

Analytica of Branford Inc., 29 Business Park Dr., Branford, CT 06405.

An Atmospheric Pressure Ionization (API) source equipped with an Atmospheric Pressure Chemical Ionization (APCI) probe has been evaluated by Flow Injection Analysis (FIA) using an Orthogonal Time-Of-Flight (OTOF) Mass Spectrometers (MS). Reserpine was the sample injected and scan data was acquired from mass 250-1200 AMU. The 609 AMU Reserpine peak was extracted and its peak area and peak height are plotted in the five figures, where the peak height is the signal to noise of the peak maximum. The five different figures show the effects of sample concentration, mobile phase flowrate and sample injection loop volume.

The first figure shows concentration data taken at 1mL/min with a 5 μ L injection volume. This data has been analyzed and found to be linear in peak height and peak area as a function of total mass injected and sample concentration with linear correlation coefficients ($r>0.99$).

The second figure shows flowrate data taken with a 5 μ L injection volume and a sample concentration of 5ng/ μ L. Flowrates from 100 μ L/min to 2ml/min have been obtained and show a decrease in peak area with increasing flowrate, whereas the peak height initially increases with flowrate due to increasing the amount of sample per time into the probe to the point at which the injection volume starts to pass through the probe faster than the MS sampling rate at which point the signal decreases. These results seem ambiguous but will become clear with next three figures.

The third figure shows the effects of loop volume at a flowrate of 1mL/min and with a sample concentration of 5ng/ μ L. As expected the peak area is linear with loop volume and peak height increase with loop volume and then levels off at the direct infusion intensity.

The fourth figure shows data taken with constant total mass injected with different loop volumes and corresponding concentrations at 1mL/min. The peak height and peak area increases with increased concentration and corresponding decreasing loop volume. This shows that better sensitivity can be achieved with smaller loop volumes and higher concentrations. Also, note that concentration is linear with peak height and loop volume is linear with peak area if re-plotted with a linear scale. APCI-MS is a concentration detector, if it were a mass detector we would expect that the peak area would be constant for all these injections.

The fifth figure shows data taken with the loop volume to flowrate ratio held constant and with a total mass injected equal to 25ng. Thus, the same amount of sample pass through the probe in the same amount of time independent of flowrate. This shows for a fix scan speed that better sensitivity can be achieved with smaller loop volumes and higher concentration. Since sensitivity is define as the signal to noise ratio of the peak to peak intensity of the injection signal to the peak to peak intensity of the noise band.

Finally, for a given total mass and MS scan speed the best sensitivity that can be obtained is when the highest concentration and smallest loop size is used with the highest flowrate which does not compromise the sampling of the injection peak.

Two-Step Laser Mass Spectrometry for in-situ Chemical Analysis of Complex Mixtures

Renato Zenobi*, Qiao Zhan, and Olivier Haefliger

Laboratorium für Organische Chemie, ETH Zürich,
Universitätstr. 16, CH-8092 Zürich, Switzerland

Two-step laser mass spectrometry (L2MS) is used for the direct chemical analysis of selected compounds in complex mixtures. Virtually no sample preparation is necessary and analyses can be performed very rapidly. The L2MS method uses two laser pulses. First, an infrared laser pulse desorbs intact neutral molecules from the sample surface, even for nonvolatile or thermally labile substances. Second, a pulse from a tunable ultraviolet laser is used for resonant two-photon post-ionization of the desorbed species. This highly efficient postionization scheme exhibits soft ionization properties and spectral selectivity. Mass analysis is performed in a reflectron time-of-flight mass spectrometer. The mass spectra are dominated by intact parent ions of those mixture components that strongly absorb the selected UV laser wavelength.

Several new experimental options are now available to us for analyses of complex mixtures. They include (i) a continuously tunable (220 - 350 nm) optical parametric oscillator (OPO) laser for postionization, (ii) comparison with gas chromatography for quantitative measurements, using NIST standard reference materials, and (iii) spatially resolved laser desorption with about 1 μm depth resolution and a lateral resolution of 20-30 μm to less than 100 nm. The latter is below the optical diffraction limit and is possible with laser-heated tips for scanning near-field optical microscopy (SNOM). A coupling of SNOM desorption with mass spectrometric detection is planned.

New applications of L2MS include the direct chemical analysis of environmental samples such as aerosol particle surfaces and sewage sludge (Fig. 1), geochemical samples such as kerogen, and synthetic materials such as polymer additives (Fig. 2, 3). Figure 1 shows selective detection of small polycyclic aromatic hydrocarbons (PAHs) directly in a sample of lyophilized sewage sludge. Figure 2 shows the analysis of a polymer additive, and figure 3 the measurement of the depth profile of the same substance in a polyoxy methylene (POM) polymer formulation. The dimensions of the electron micrograph of the ablation crater are ca. 120 x 120 μm .

MBMS Study of A Premixed Fuel-Rich Ethylene Flame

Fei Luo and Lisa I. Yeh
Exxon Research and Engineering Company
Annandale, NJ 08801

The compositional analysis of flames is an important experimental approach for developing combustion chemical kinetics models. Among several techniques involved in flame analysis, molecular beam mass spectrometry (MBMS) remains an attractive and powerful option because of its ability to detect both stable and radical species. Recently, we constructed a new flame chamber coupled with MBMS sampling for characterization of 1-D premixed laminar flames¹, aimed at study of molecular weight growth reactions leading to soot precursors.

Here we report our new measurements on a premixed ethylene flame with an equivalence ratio of 1.63. The flame was stabilized on a water-cooled 2.5 inch diameter sintered bronze burner and was formed under the following conditions: 14% C₂H₄, 26% O₂, 60% Ar, pressure of 20 torr, and cold gas velocity of 104 cm/sec. Flame gases were sampled by expanding adiabatically into vacuum (1.6×10^{-4} torr) through a 80 μ m diameter orifice in a quartz cone having an angle of 40° near the tip and 90° at the base. The rapid decrease in temperature and gas density during the expansion quickly quenched the combustion reactions downstream of the orifice. A molecular beam was formed by extracting the center part of the expansion by a skimmer downstream of the quartz cone and then modulated by a tuning fork run at 400 Hz. It was subsequently detected by an electron-impact quadrupole mass spectrometer (Extrel C-50) and counted by a dual channel scalar. To minimize fragmentation interference the electron energies were kept at only 1-2 eV above ionization thresholds. Isotopic contributions from ¹³C were corrected by subtracting measured m-1 signal multiplied by natural abundance ratio. Oxygen atom was resolved from CH₄ by significantly increasing mass resolution. Species profiles were obtained by translating the burner vertically relative to the quartz cone. Major and some minor stable species were directly calibrated by mixtures of known composition. Quantification for radical and the other minor stable species were estimated by means of relative ionization cross section method². Temperature profile was also taken using a Ceramabond 569 coated Pt/Pt-13%Rh thermocouple.

Concentration profiles of 42 species are obtained, some of which are shown in Figure 1. While the profiles of primary radicals H, OH, and O extend well into the post flame zone, the hydrocarbon intermediates generally exhibit narrow bell shape profiles. The larger molecules in each C_i (i=1-6) group tend to reach their maxima earlier than smaller ones. Interestingly, it is observed that polyacetylenes are dominant molecular weight growth species, which indicates a strong need to develop kinetics of polyacetylene growth reactions and to determine their role in the early stage of soot formation. In addition, by doing rate analysis, the relative dominance of different reaction pathways for benzene formation, a widely-considered soot precursor, can be deduced.

Structure Determination in a Series of Substituted Silacyclobutane Ions Using Triple Quadrupole MS

Joseph A. Hankin† and Robert Damrauer‡

†National Jewish Center for Immunology and Respiratory Medicine, Denver, CO

‡University of Colorado at Denver, Denver, CO

Collision induced dissociation (CID) in a triple quadrupole mass detector has been used to determine structures of products in gas phase ion-molecule reactions.¹ The versatility of a flowing afterglow source in a tandem flowing afterglow selected ion flow tube instrument (FA-SIFT) has been demonstrated in studies where isotopically labeled ions or unusual ions can be selected uniquely for further study.^{2,3} Recently, a triple quadrupole mass detector has been added onto the FA-SIFT instrument in Boulder, CO, to create a tandem FA-SIFT-TQ instrument. Unusual ions formed in the source region can be selected uniquely out of a mixture of species, and studied by their reactivity and additionally by the CID behavior of the ion and reaction products.

Dimethylsilacyclobutane (DMSCB; cyclotrimethylenedimethylsilane) has been used in earlier gas-phase studies to form stable pentacoordinate silicon species in the gas phase.^{4,5} Recently, while repeating these earlier experiments to test out the capabilities of the new FA-SIFT-TQ instrument, a series of substituted sila-cyclobutane anions were inadvertently formed in the source region. The structure and relatedness of these three ions (**1**, **2**, and **3**) was confirmed by ion-molecule reactions, and CID of parent and product ions of the ion-molecule reactions. The entire stream of chemistry (unusual ion formation, ion selection, ion-molecule chemistry, and analysis of products by CID) demonstrates the utility of the FA-SIFT-TQ instrument.

Dimethylsilacyclobutane (DMSCB) can be deprotonated in the source of the FA-SIFT-TQ by reaction of amide ion with DMSCB. This M-1 ion undergoes CID in the triple quadrupole detector to lose a neutral fragment of ethylene. Reaction of **1** with CO₂ results in the formation of a product (**2**) which loses ethylene in similar fashion upon CID in the triple quadrupole. This ion could be produced directly in the source of the FA-SIFT-TQ (minor product) by reaction of hydroxide with DMSCB. Ion **2** formed in this fashion loses a neutral fragment of ethylene upon CID in the triple quad. Both **1** and **2** react with COS to produce the analogous sulfur-substituted silacyclobutane product (**3**). This product loses ethylene upon CID in the triple quadrupole. Ion **3** could be produced directly in the source by sequential reaction of amide with DMSCB

and CS₂. Ion **3** when formed in the source undergoes CID in like fashion to lose a neutral fragment of ethylene.

The preference for sulfur substitution in reactions with COS is similar to the reactions of other alpha-silyl anions. Substitution reactions are believed to take place via a four membered intermediate complex where exchange takes place, and a stable neutral species is split off.

The gas phase acidities of the protonated neutral molecules corresponding to **1**, **2**, and **3** have been determined by bracketing experiments with a series of reference bases. The ΔH acidity values (298°K) for these neutral molecules are 390±2 kcal/mol, 360±3 kcal/mol, and 340±7 kcal/mol respectively. These values are close to values reported in bracketing experiments with similar alpha-silyl anions indicating that the silacyclobutane structure has no apparent affect on the gas-phase acidity of hydrogens in a beta position to silicon.⁶

Gas phase reactions of silicon and boron hydride cations in the FA-SIFT

Roustam Gareyev, Robert Damrauer and Charles H. DePuy
Department of Chemistry and Biochemistry, University of Colorado
Boulder, CO 80309-0215

Introduction. Previous studies of the gas phase chemistry of the title compounds were hindered by the abundance of products arising upon the ionization of B_2H_6 and SiH_4 . The electron impact (EI) on diborane in helium buffer gas (0.2-0.5 Torr) results in formation of nearly every imaginable ion $B_nH_m^+$, n being up to 10 depending on ionization conditions. Low pressure ionization under regular MS conditions give ions with $n = 1, 2$; but still m varies from 1 to 5. Another obstacle is the isotope distribution of boron (19% ^{10}B , 81% ^{11}B), resulting in isobaric ions having different composition. The ionization of silane also gives various SiH_n^+ ($n = 0-3$) and $Si_2H_m^+$ ($m = 0-5$) ions. That is why most of the studies of these ions to date were performed in the mixture of various ionic species.^{1,2}

Experimental. In our investigations we employed to the fullest extent the capabilities of our tandem flowing afterglow - selected ion flow tube instrument (FA-SIFT), which was recently upgraded by addition of the triple quadrupole MS-MS detection system. EI ionization of precursors in the source flow tube (FT) followed by quadrupole mass selection allows injection into the reaction FT (0.5 Torr helium buffer gas) of any ionic species with a given mass to charge ratio (M/Z). Furthermore, the ions may be accelerated before injection into the reaction FT to produce other ions of interest by dissociation due to collisions with the buffer gas. The neutral reagents may then be added to the reaction FT allowing the study of the reactions of the selected ions. The products may be further assayed by collision induced dissociation (CID) in the triple quadrupole detector.

Cations derived from silane. EI ionization of SiH_4 gives a spectrum of cations with major peaks at M/Z 28-31 ($Si^+-SiH_3^+$) and 57-61 ($Si_2H^+-Si_2H_5^+$), the latter group being due to secondary ion-molecule reactions. Although any of these ions may be mass selected for study, in some cases it was preferable to select an ion of higher hydrogen content and subject it to CID. This often allows a better signal and avoids contamination due to the isotope distribution of silicon (^{29}Si 4.7%, ^{30}Si 3.1%). One example is selecting $Si_2H_5^+$, CID of which gives $Si_2H_3^+$ or Si_2H^+ depending on the injection energy. Similarly $Si_2H_4^+$ may be converted to $Si_2H_2^+$ and Si_2^+ , SiH_3^+ to SiH^+ , and SiH_2^+ to Si^+ by collision induced loss of H_2 .

All the above ions were allowed to react with molecular deuterium and diborane. Only SiH^+ showed slow isotope exchange reaction with D_2 , all other ions did not react noticeably, either by addition or by isotope exchange. In the reactions with B_2H_6 various ionic products were observed for different reactant ions. The most common ones were $B_2H_5^+$ as a product of hydride transfer from B_2H_6 to SiH^+ , SiH_2^+ , SiH_3^+ , $Si_2H_5^+$; $SiBH_4^+$ which was formed in reactions with SiH^+ and Si_2H^+ ; and $SiB_2H_5^+$ from reactions of SiH^+ , Si_2H^+ and $Si_2H_3^+$. Most of the reactions have rates close to the collision rate. Ions $Si_2H_2^+$ and $Si_2H_4^+$ did not react with B_2H_6 .

The reactions of SiH_3^+ with benzene and toluene were also studied. The only product of the reaction with benzene is the adduct ion, whereas a small extent of hydride abstraction, along with adduct formation, was observed for the reaction with toluene. Both reactions occur at almost the collision rate. CID of the adduct ions $C_6H_6SiH_3^+$ (10^{-4} Torr argon as collision gas, 16 eV lab frame energy) resulted in the reverse reaction, giving SiH_3^+ and benzene, along with a small amount of $C_6H_5SiH_2^+$. In contrast, the major product of CID of $CH_3(C_6H_5)SiH_3^+$ is benzyl cation due to the elimination of SiH_4 ; some loss of SiH_3^+ was also observed. The experiments with perdeuterated benzene and toluene showed no incorporation of deuterium into SiH_3^+ ion leaving the adducts under CID, thus indicating that the hydrogens of the aromatic ring and those of the silyl group do not scramble. This result is in contrast to the behavior of CH_3^+ in the analogous reactions, for which it was shown that significant scrambling occurs between the ring and the methyl group hydrogens.

Cations derived from diborane. Although dozens of $B_nH_m^+$ ions form in the EI ionization of diborane, only the simpler ones ($n = 1-3$) have been studied so far. A thorough investigation of reactions of BH_2^+ was undertaken in our laboratory previously.³ In this work we studied some reactions of $B_2H_n^+$ and $B_3H_6^+$ ions. The ion $B_2H_5^+$ may be obtained by selection of M/Z 27, which contains only the ^{11}B isotope as evidenced by its CID spectrum, in which $^{11}B_2H_3^+$ is the major product and some $^{11}BH_2^+$ is present. No isotope exchange was observed in the reaction of $B_2H_5^+$ with D_2 , in contrast to BH_2^+ , which was found previously to exchange giving BHD^+ as a major product. At the same time $B_2H_3^+$ undergoes extensive exchange, along with the formation of an adduct, giving rise to species from $B_2H_2D^+$ to $B_2D_5^+$. Another ion which may be selected without isotopic contamination is $B_2H_2^+$. CID of this ion gives predominantly $^{11}B^+$ and $^{11}BH_2^+$ as ionic products. $B_2H_2^+$ is much less reactive towards D_2 , exchange and formation of adduct being observed only at relatively high concentrations of D_2 .

One of the ions that attracted our attention was $B_3H_6^+$. Recently it was predicted by calculations⁴ to have significant electronic delocalization. We observed this ion ($M/Z = 39$) in the EI ionization spectra of

The optimized structure of $B_3H_6^+$ from MP2/6-311G** *ab initio* calculation

diborane, isolated it, and studied some of its reactions. CID of $B_3H_6^+$ gives $B_3H_4^+$, but requires an activation energy somewhat higher than that for dehydrogenation of other hydroboryl cations. It also proved to be much less reactive; no reaction was observed with D_2 , CH_4 , C_2H_6 , C_2H_4 , or C_2H_2 . These results indirectly confirm the suggestion of the aromatic nature of this ion.

Hydrogen/Deuterium Exchange in the Reactions of Methyl Cation with Methane

Hack Sung Lee, Veronica M. Bierbaum, and Charles H. DePuy
Department of Chemistry and Biochemistry, University of Colorado
Boulder, CO 80309-0215

Reactions of methyl cation with methane have been studied with ICR¹ and crossed-beam^{2,3} methods in the past. At low energies, the reaction

proceeds at the collision rate and the products are ethyl cation and hydrogen exclusively. Crossed-beam studies have been performed with deuterated methyl cation and deuterated methane.² Deviation from a statistical distribution for product ions at nonthermal energies was observed and analyzed by varying the ratio between H/D exchange rate, k_s , in the collision complex and the dissociation rate, k_d . In this FA-SIFT study at thermal energy, we extend the degree of deuteration for methyl cation for complete assessment of H/D exchange. Deuterated acetonitrile, $\text{CH}_x\text{D}_{3-x}\text{CN}$ ($x = 0 - 3$), was synthesized from CH_3CN , D_2O , and KOH. The methyl cation, $\text{CH}_x\text{D}_{3-x}^+$, which is created by collision induced dissociation (CID) as the protonated acetonitrile, $\text{CH}_x\text{D}_{3-x}\text{CNH}^+$, is injected into the selected ion flow tube (SIFT), reacts with methane, $\text{CH}_y\text{D}_{4-y}$ ($y = 0 - 4$), in the reaction tube. In most cases, loss of H_2 , HD, and D_2 from the collision complex (protonated ethane) are statistical. However, in the 4H/3D case, both a deviation from a statistical distribution and a clear asymmetry in comparison with the 3H/4D case were observed (Table). These findings led us to include isotope effects in the mathematical methods developed in reference (2). Assumptions are made that the exchange rates within collision complexes are the same for both hydrogen and deuterium, and that the dissociation occurs only from the pentacoordinated carbon in the protonated ethane intermediate. The best fit gives the relative rate, $k_s/k_d(\text{H}_2)$, equal to 6.8 and $k_d(\text{H}_2) : k_d(\text{HD}) : k_d(\text{D}_2)$, equal to 1 : 0.82 : 0.75 (Table). The isotope effects are very close to the inverse square root mass ratios, i. e., 1 : $\sqrt{2/3}$: $\sqrt{2/4}$. This is reasonable if the dissociation rate depends on the vibrational frequency and therefore on the mass.

Reaction of methyl cation with methane in our drift tube

produces vinyl cation as well as ethyl cation. It is not clear whether the former comes from unimolecular dissociation of the latter, which may be internally excited. An increase of the reaction cross section of the vinyl cation with increasing drift energy shows that the heat of formation of vinyl cation is approximately 254 kcal/mol. This

value is consistent with 253.6 kcal/mol, recommended in the NIST database, but about 12 kcal/mol lower than the value derived from thermochemical cycles.⁴ Although drift experiments are best suited for rate measurements, a reasonable threshold energy for endothermic ion-molecule reactions can be obtained with an appropriate energy distribution for the drift conditions. An endothermic proton transfer reaction of known energetics, $\text{CH}_3\text{CNH}^+ + \text{C}_6\text{H}_6 \rightarrow \text{C}_6\text{H}_7^+ + \text{CH}_3\text{CN}$, has been studied to test our method. A preliminary study of the $\text{CD}_3^+ + \text{CH}_4$ reaction using our triple quadrupole mass spectrometer shows that hydride transfer becomes dominant above 7 eV laboratory energy.

Table. Product distribution (%) of loss of H_2 , HD, and D_2 in the reaction of methyl cation with methane, $\text{CH}_3^+ + \text{CH}_4 \rightarrow \text{C}_2\text{H}_5^+ + \text{H}_2$

Distinction between propenyl and allyl cations: H/D exchange with D₂O

G. van der Rest, P. Mourgues, D. Leblanc, H.-E. Audier
DCMR URA CNRS 1307, Ecole Polytechnique, 91128 Palaiseau Cedex, France

Introduction Structure of the $C_3H_5^+$ cations has been studied by several authors^{1,2}. They have shown the fragmentations of $C_3H_5X^{*+}$ (X =halogen) radical cations to yield a mixture of allyl $CH_2CHCH_2^+$ and 2-propenyl $CH_3CCH_2^+$ product ions. In this work this problem is revisited.

Method The $C_3H_5^+$ cations, generated in the ion source by fragmentation of $C_3H_5X^{*+}$ are allowed to react with D₂O in the cell of a Bruker CMS-47 FT-ICR. In such conditions, no D exchange is seen for the allyl cation, whereas the $CH_3CCH_2^+$ cation undergoes exchange of its five hydrogens with deuterium.

Results The great difference in reactivity of the two cations towards water allows a clear distinction between isomers and a measure of the branching ratio of the $CH_2CHCH_2^+$ and $CH_3CCH_2^+$ cations formed from various precursors. These results are consistent with those

previously published^{1,2} but this straightforward method is more precise. For instance, whereas electron impact fragmentations of allyl halogenides were reported to yield pure allyl ions, we found that 15 % of the other isomer is also present in the mixture.

Precursor	Allyl compounds			Others				
	1	2	3	4	5	6	7	8
Allyl cation	87	85	87	26	68	74	70	77
2-propenyl cation	13	15	13	74	32	26	31	23

1 3-chloropropene - 2 3-bromopropene - 3 3-iodopropene - 4 2-bromopropene - 5 1-bromopropene
- 6 bromocyclopropane - 7 cyclopropane - 8 propene

Discussion Thermochemical data and first results of *ab initio* MO calculations at the MP2/6-31G* level shows that:

- the $CH_3CCH_2^+ + H_2O$ final state lies in energy significantly above the $CH_2CHCH_2^+ + H_2O$ final state
- several stable structures correspond to interactions between the $C_3H_5^+$ ion and water. The first ones are the covalent structures $CH_2CHCH_2OH_2^+$ and $CH_2C(CH_3)OH_2^+$. The other ones are H-bonded species such as a, b and c.
- Isomerization $b \rightleftharpoons c$ could be the operative process leading to H/D exchange when the $C_3H_5^+$ ions react with D₂O. The implied transition state may lie below the $CH_2CHCH_2^+ + OH_2$ final state but above the other one. Therefore H/D exchange appears when $CH_3CCH_2^+$ reacts with D₂O but not with $CH_2CHCH_2^+$.

Distonic Ions of the "ate" Class

Brian T. Hill, Leonard J. Chyall, John C. Poutsma,
Jun Hu, and Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette, IN 47907

The term "distonic ion", as originally coined by Radom and co-workers, refers to an ion with formally separated charge and radical sites.¹ Distonic ions may be divided into two distinct classes, depending upon the nature of the charged site. The most commonly studied form of distonic ion possesses a coordinatively- and electronically-saturated charge site, such as in the so-called "ylidions" (ionized ylides) and their homologs. The other type of distonic ion corresponds to an ionized biradical or zwitterion, which possesses two coordinatively-unsaturated sites containing one or three electrons.

All of the saturated-charge type distonic radical ions that have been described in the literature possess "onium" charge sites. The corresponding negative ions would consist of a tetracoordinate group III element, such as in borates and aluminates, attached to a radical-bearing substituent. We call these species distonic ions of the "ate" class in reference to the hypercoordinate nature of the group III element from which the distonic ion is derived. In principle, distonic ions of the "ate" class may also be synthesized with pentacoordinate silicon species and other hypervalent metals.

The synthesis of "ate" class distonic ions was performed in a flowing afterglow apparatus by (termolecular) addition reactions between neutral BF_3 or B_2H_6 and open-shell negative ions generated in the flow tube. Distonic ions were synthesized from molecular negative ions, carbene negative ions, and biradical negative ions. We employed O^- to form biradical and carbene negative ions in the gas-phase by 1,n (n = 1,2,3,...) abstraction of H_2^{+} from hydrocarbons and other organic molecules.²

We also employed our recently developed synthetic procedure for generating gas-phase biradical negative ions from bis(trimethylsilyl)compounds.³

Other distonic ions were synthesized from molecular negative ion precursors.

These distonic ions are interesting because their charge sites possess negligible Brønsted and Lewis basicity, thus rendering the charge site chemically inert. As shown by Kenttämaa and co-workers, such species can be used to investigate the radical reactivities of radical anions without interference from ionic side reactions.⁴ Reaction studies show that "ate" class distonic radical anions undergo radical reactions with NO_2 and O_2 , and the BF_3O^- radical slowly abstracts H-atoms from organic compounds. Reactivity studies of these distonic ions are currently under investigation.

GAS-PHASE NEGATIVE ION CHEMISTRY OF LEWIS ACID-BASE COMPLEXES

Jianhua Ren, Derek B. Workman and Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette, IN 47907

Lewis acids have been widely used as catalysts in organic syntheses, which include catalyzed Diels - Alder reactions, aldol condensations and photochemical reactions. Although Lewis acid - base complexes have been studied extensively in condensed phases, little information exists concerning their gas - phase ion chemistry. Gas - phase ion techniques provide a powerful means to determine accurate thermochemical quantities such as bond energies, heats of formation, proton affinities and gas - phase acidities. These data may provide useful insights into the intrinsic properties of Lewis acid - base complexes.

We have investigated the gas - phase negative - ion chemistry of a series of prototype Lewis acid - base complexes: Me_2SBH_3 , Me_3NBH_3 , Et_3NBH_3 and Me_3PBH_3 with use of the flowing afterglow - triple quadrupole technique. Pronounced enhancements are found in the gas - phase acidity and reactivity of the Lewis acid - base complexes compared to the uncomplexed bases.

The reaction of OH^- with Me_2SBH_3 produces an ion with the formula $\text{C}_2\text{H}_5\text{SB}^-$. An authentic $\text{CH}_3\text{SCH}_2\text{BH}_3^-$ ion can be produced from the reaction between $\text{CH}_3\text{SCH}_2^-$ and B_2H_6 . The same four product ions are produced from collision - induced dissociation of both $\text{C}_2\text{H}_5\text{SB}^-$ and the authentic $\text{MeSCH}_2\text{BH}_3^-$, but the relative intensities are different. The energy resolved CID spectra of $\text{C}_2\text{H}_5\text{SB}^-$ and $\text{MeSCH}_2\text{BH}_3^-$ also show significant differences. The reaction of $\text{C}_2\text{H}_5\text{SB}^-$ with D_2O produces a product with a maximum of five H/D exchanges. This result indicates that $\text{C}_2\text{H}_5\text{SB}^-$ has the structure $\text{MeS}(\text{BH}_3)\text{CH}_2^-$ with five exchangeable hydrogens. In contrast, $\text{MeSCH}_2\text{BH}_3^-$ does not undergo any H/D exchange because it has no hydrogen - bearing carbanionic sites. The structure of $\text{MeS}(\text{BH}_3)\text{CH}_2^-$ is further confirmed by reactions involving CO_2 , BEt_3 and CS_2 . Both adducts and electrophilic substitution products are produced in the reactions with CO_2 and BEt_3 , while only substitution occurs with CS_2 . The results of these experiments strongly suggest that deprotonation of Me_2SBH_3 with OH^- produces a stable carbanion, $\text{MeS}(\text{BH}_3)\text{CH}_2^-$, which does not isomerize to $\text{MeSCH}_2\text{BH}_3^-$.

The gas - phase acidity of Me_2SBH_3 , $\Delta H_{\text{acid}} = 376 \pm 4$ kcal/mol, was obtained from bracketing experiments, and is found to be in good agreement with the value (373.4 kcal/mol) calculated by G2(MP2) theory. The gas - phase acidity of Me_2SBH_3 is 17 kcal/mol greater than that of uncomplexed Me_2S . Similar acidity enhancements are found for Me_3NBH_3 and Me_3PBH_3 . The acidity of these two complexes are increased by 16 kcal/mol and 20 kcal/mol compared with Me_3N and Me_3P , respectively. A novel gas - phase $\text{S}_\text{N}2$ displacement reaction takes place between Me_2SBH_3 and F^- :

In contrast, substitution with uncomplexed Me_2S does not occur. The further reaction between MeSBH_3^- produces a product ion with the formula CSB_2H_9^- . CID threshold measurements and *ab initio* molecular orbital calculations suggest that the structure of this ion is $\text{MeS}(\text{BH}_3)_2^-$. The CID threshold measurements indicate that the bond dissociation energy, $D[\text{MeS}(\text{BH}_3)_2^- \text{BH}_3]$ is 38.7 kcal/mol, which is in good agreement with the value of 39.1 kcal/mol calculated by G2(MP2) theory. G2(MP2) calculations predict a S-B bond dissociation energy in $\text{MeS}(\text{BH}_3)\text{CH}_2^-$ to be 43.4 kcal/mol.

Other reactions appear to be enhanced by complexation by borane. For example, Et_3NBH_3 reacts with OH^- by a Hoffmann elimination to produce $\text{Et}_2\text{NBH}_3^-$ and $\text{CH}_2=\text{CH}_2$, while uncomplexed Et_3N does not react at all with OH^- under identical conditions:

In conclusion, complexation of methyl sulfides, amines and phosphines with BH_3 causes a dramatic increase in the gas - phase acidity of the α - CH bonds. Deprotonation of borane - Lewis base complexes produces stable carbanions which do not appear to rearrange to the more stable "borate" forms. Complexation of alkyl sulfides, amines and phosphines with borane increases the reactivity towards substitution and elimination reactions.

ION REACTIONS OF H AND N ATOMS

Graham B.I. Scott, David Fairley, Colin G. Freeman and Murray J. McEwan*
Department of Chemistry, University of Canterbury, Christchurch, New Zealand

Atomic hydrogen is one of the most abundant species in the universe. Chemical reactions of ions and neutral species play an important role in the synthesis of molecules in the immense clouds of gas and dust existing between stars. Atomic hydrogen is a major component of these clouds. Atomic nitrogen also has a significant role in the atmospheres of planets and satellites containing nitrogen such as Earth and Titan.

The difficulty in measuring reactions of H and N lies in the determination of the atom density. We report rate coefficients and ion product distributions for a number of ion-H and ion-N atom reactions using a selected ion flow tube (SIFT) operating at room temperature. The reactions of H atoms were obtained by using the simultaneous reactions between $\text{CO}_2^+ + \text{H}_2$ and $\text{CO}_2^+ + \text{H}$ to provide an absolute measurement of H in the flow tube¹. The variation in H atom density with 10.7% H_2/He flow is shown in Figure 1.

Reactions of larger molecular hydrocarbon ions exhibit association, whereas ions of intermediate size (C_2 , C_3) show H atom abstraction.

The data for CO^+ and CO_2^+ with atomic nitrogen is at variance with the one published result for these reactions. Atomic N can be incorporated into hydrocarbon ions to form nitriles.

Acetonitrile is an important product of abiogenic synthesis in interstellar clouds and planetary atmosphere. Combined water/acetonitrile clusters are the most abundant positive ions in stratosphere but no data on the reactions were obtained up to date. Reactions of simple ions with acetonitrile are a good model to study reactive behavior in ion/dipole collisional complex due to linear N-C-C skeleton and great dipole momentum (~ 4 Debye). Geometry becomes "locked in" at a distance ~15 Å.

Flowing afterglow technique (varied reaction time, reactant flux, buffer gas pressure) was used to obtain rate coefficients from kinetic dependencies. SIFDT was used to study dependencies of rate constant for reactions of simple ions on E_{cm} energy.

Obtained from reactions pressure dependencies lifetimes of Xe^+ (CH_3CN) and Xe^+ (CH_3CN)₂ are about 10^{-8} s and 10^{-7} s.

The analysis of the results for water ion clusters with acetonitrile shows that the main way of formation of combined clusters in stratosphere are switch off reactions. Nevertheless the attachment reactions are rather fast and show second order kinetics behavior at pressure above several Torr.

The attachment acetonitrile to both Xe ion and complex $Xe^+(CH_3CN)$ is very effective. On the other hand the formation of protonated acetonitrile and complexes is very slower. This result indicates that the effect of alignment of dipole molecules in collisional complex plays an important role resulting in separation of CH_3 groups from positive charge. The migration of H atom that should produce protonated ion is inconvenient.

Endoergic by 3kT charge transfer channel is surprisingly slow at thermal energy. An increase of translational energy results in reducing of complex formation, while the gain of charge transfer products becomes greater a bit. Yet effective binary rate constant is pressure dependent up E_{cm} energy about 0.5 eV.

DIMETHYL ETHER CI MASS SPECTROMETRY OF ISOMERIC METHYLATED NUCLEIC ACID BASES AND NUCLEOSIDES

Elizabeth P. Burrows
USACHPPM Research Detachment
Fort Detrick, Frederick, MD 21702-5010

Dimethyl ether (DME) is known to be a useful reagent gas for differentiation among isomers by CI mass spectrometry, and in the past five to six years the ion-molecule reactions of DME with a variety of classes of organic substrates have been extensively studied. In this work, five isomeric methyladenines, three methylcytosines, and four methyluracils were readily characterized and differentiated by the identities and relative abundances of their fragment-molecule adduct ions formed with DME. In all cases except three of the methyluracils the most abundant adduct ion was the methoxy-methylene cation ($[M+C_2H_5O]^+$, $[M+45]^+$). Other adduct ions were present in lesser and varied abundances. In addition to protonated molecules, methyl adducts $[M+15]^+$, protonated DME ($[M+47]^+$) and methylated DME ($[M+61]^+$) adducts, and protonated methoxymethylene dimer adducts ($[M+91]^+$) were frequently observed.

Seven isomeric methylguanidines all gave rise to similar fragment-molecule adduct ion profiles, but could be differentiated by the collision-induced dissociation (CID) patterns of their $[M+45]^+$ adduct ions. With the exception of two of the methyladenines, the CID characteristics of the methoxymethylene adducts of the other methylated bases were also highly specific.

Previous work has demonstrated that $[M+45]^+$ cations can fragment according to two different pathways: loss of CH_2O followed by simple transfer of methyl to give a $[M+15]^+$ cation, or rearrangement with loss of methanol containing a hydrogen atom originally bound to the substrate to give a $[M+13]^+$ cation. A third pathway, involving loss of C_2H_4O or $CH_3OCH_2\cdot$ to give protonated molecules or molecular ions, respectively, has recently been observed in the cases of certain polynuclear aromatic hydrocarbons. In favorable cases, the propensities of the parent adducts to undergo CID fragmentation by one pathway or another are sufficiently different as to lead to significant differences in abundances of the product ions observed for each isomer.

The CID characteristics of the three methylcytosines, summarized below, constitute a simple illustration. The 1-methyl and O^2 -methyl isomers both displayed the product ion resulting from loss of CH_2O (m/z 140) as most abundant, but were readily distinguished by large differences in abundances of the other two product ions, m/z 138 and m/z 126. For the 3-methyl isomer, the ion resulting from loss of methanol (m/z 138) was the most abundant.

Isomer	Product Ion m/z (Neutral Lost)		
	140 (CH_2O)	138 (CH_3OH)	126 (C_2H_4O)
% Relative Abundance			
1-MeC	100	36	1
3-MeC	6	100	15
O^2 -MeC	100	6	29

In summary, both the fragment-molecule adduct ion profiles and the CID fragmentations of the $[M+45]^+$ adduct ions were useful for characterization and differentiation among the commercially available nucleic acid bases. Unfortunately this specificity of DME did not extend to the nucleosides in the study. Of 16 nucleosides investigated, only in two cases was it possible to differentiate among isomers on the basis of the fragment-molecule adduct ions alone. Initial attempts to achieve CID fragmentation of the $[M+45]^+$ adduct ions have not been successful.

A COLLISIONAL CELL WITH ELECTROSTATIC ION GUIDE FOR COLLISION CROSS SECTION STUDY OF PROTEIN IONS

P.V. Bondarenko and R.D. Macfarlane

Department of Chemistry, Texas A&M University, College Station, Texas 77843

Physical properties of gas-phase protein ions, such as size or conformation, can be derived from their collision cross sections (CCS). Covey and Douglas [1] developed a method for CCS determination by measuring the loss of axial energy of an ion as it passes through a collision cell in a triple quadrupole mass spectrometry system. We have recently designed an electrospray ionization (ESI) time-of-flight (TOF) mass spectrometer, which employs an electrostatic ion guide (EIG) as the interface between the electrospray ion source [2] and the linear TOF mass analyzer with orthogonal ion acceleration (Figure 1). We employed the principle of CCS determination mentioned above [1] by colliding the ions with molecules of residual gas (nitrogen) in a $S = 35$ cm long vacuum chamber (collision cell) equipped with the electrostatic ion guide. The EIG consists of a 0.13 mm diameter central wire (at -26 V) and 34 mm ID concentric cylinder (at -25 V). The electrospray ions from the source are accelerated by an acceleration grid to the axial energy of $E_0 = 25i$ eV, where i is the number of charges on the ions. Then ions are transported through the collision cell into the mass analyzer by the EIG. In the present system, the ions cannot reach the detector if they lose more than half of their axial energy in the collision cell, i.e. at $E/E_0 = 1/2$, where E is the axial energy at the exit from the collision cell (the exit is labelled (i) in Figure 1). The CCSs for the ions were calculated using equation 11 from [1], $E/E_0 = \alpha^{ms}$. The CCS can be expressed as $\sigma = (\ln E/E_0)/(n S \ln \alpha)$, where $\alpha = (m^2 + M^2)/(m + M)^2$, M is the ion mass, m is the collision gas mass, n is the number density of gas atoms ($n = p/kT = 2.5 \times 10^{16}$ p cm $^{-3}$ for $T = 20^\circ$ C). After substituting n and α , equation for the CCS is

$$\sigma = (\ln E/E_0)/(2.5 \times 10^{16} p S \ln (m^2 + M^2)/(m + M)^2) \text{ cm}^2. \quad (1)$$

Pressure in the cell (p) was the only variable parameter during the investigation. The pressure was varied in the range of 10^{-6} to 3×10^{-3} torr by partially closing the gate valve which separates the cell from the turbomolecular vacuum pump. Increasing the pressure from 5×10^{-4} to 3×10^{-3} torr reduces the intensity of the multiply charged ions of Cytochrome C in sequential order from $(M+11H)^{11+}$ to $(M+H)^+$ ions (Figure 2). At $p = 10^{-3}$ torr (Figure 2b), the intensity of multiply charged ions decreases significantly. This pressure ($p = 1 \times 10^{-3}$ torr) was fit to equation 1. The cross section of Cytochrome C multiply charged ions calculated from this procedure is $\sim 2000 \text{ \AA}^2$.

The experimental data also show that two other processes interfere with the measurement procedure, introducing error in the derived cross sections. Collisional focusing effect around the wire is the first. The integral intensity of the $(M+H)^+$ ions and multiply charged cluster ions ($2M^{3+}$, $3M^{4+}$) does not decrease but, actually, increases significantly as the gas pressure increases (Figure 2b). This is an indication of the collisional focusing around the wire, which increases the EIG transport efficiency. Charge stripping from the protein ions is the second process which may occur during the collisions. Charge is carried away by the low mass ions (m/z 12, 14, 28) which have relatively high intensity in the spectra at increased cell pressures (Figure 2b).

GAS-PHASE BASICITIES OF HISTIDINE AND LYSINE AND THEIR SELECTED DI- AND TRIPEPTIDES

Scott R. Carr and Carolyn J. Cassidy*
Department of Chemistry
Miami University
Oxford, OH 45056

Of the common α -amino acids, histidine, lysine and arginine have the highest gas-phase basicity (GB). GB is defined as the negative of the free energy change ($-\Delta G$) for a molecule's protonation reaction:

Interest in determining the GBs of these amino acids lies in the fact that they are potential protonation sites within proteins and peptides. With knowledge of the location of the protons in biomolecules, a better understanding of the protonated compound's structure, reactivity and dissociation may be developed.

Several determinations of the GBs of histidine and lysine have led to varying results¹⁻⁴. This is presumably due to the different methods by which the GBs were evaluated. The work presented here determines the GBs of the amino acids by employing both deprotonation reactions as well as the kinetic method. The results indicate no significant difference between the two methods for the amino acids and little difference for the peptides. Also, the same methods were used to examine the GBs of small peptides containing histidine or lysine and glycine residues. The GB values for all studied compounds are listed below in kcal/mol:

Compound	Deprotonation	Kinetic	Compound	Deprotonation	Kinetic
Histidine	220.8	223.2	Lysine	220.8	223.2
GlyHis	225.3	227.8	GlyLys	223.2	227.8
HisGly	225.3	227.8	LysGly	227.4	227.8
GlyHisGly	225.3	226.2	GlyLysGly	225.3	227.8
GlyHisGly	226.5	229.4	GlyGlyLys	230.7	231.8
HisGlyGly	226.5	227.8	LysGlyGly	230.7	231.8

These data suggest protonation on the highly basic functional group of the amino acids and their residues when they are incorporated into these small peptides. Also seen are trends signifying unique intramolecular hydrogen bonding within the small peptides. In both cases, GlyHisGly and GlyLysGly, the structures would indicate different intramolecular hydrogen bonding than seen in the other two structural isomers containing the same highly basic amino acid. The employed kinetic method results closely mirror the trends that are seen in the deprotonation reaction of the protonated peptides as well.

All experiments were carried out on a Bruker CMS-47X FT-ICR mass spectrometer. The ions were produced by fast atom bombardment in an external ion source and moved

into the cell via electrostatic focusing. The ions were collisionally cooled and resonant ejection techniques were employed to isolate the protonated molecular ion of interest. These ions were then allowed to proton transfer to a reference base of known GB present at a constant pressure in the cell. The kinetic studies were carried out over a range of reference bases when the protonated biomolecule formed a proton-bound dimer with the reference base. The GB of the biomolecule was assigned at the point where the lowest energy on-resonance collision-induced dissociation product switched from being protonated peptide to protonated base.

A representative spectrum of one of the kinetic reactions is shown below. Here, the proton-bound dimer of GlyHis and triethylamine (GlyHis $\cdot$ H $\cdot$ TEA)⁺ are collisionally dissociated with a laboratory energy of 27 eV. The TEA pressure was 7.1×10^{-8} torr, while the argon (collision gas) pressure was maintained at 3.0×10^{-7} torr.

**Apparent Gas-Phase Acidities of Multiply Protonated Peptide Ions:
Ubiquitin, Insulin B and Renin Substrate**

Xin Zhang and Carolyn J. Cassady*
Department of Chemistry
Miami University, OH 45056

The gas-phase deprotonation reactions of multiply protonated bovine ubiquitin, bovine insulin chain B, and renin substrate tetradecapeptide (horse) ions were studied. These peptides were chosen because they have ions with similar mass/charge ratios (m/z) but varying molar mass (m). All experiments were performed using a Bruker CMS-47X Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer coupled with an external Analytical of Branford Ultraspray™ electrospray source. Rate constants were measured for the reactions of these peptide ions with a series of reference compounds of known gas-phase basicities (GB) [1] ranging from 195.6 kcal/mol to 232.6 kcal/mol. The apparent gas-phase acidities [2] (GA_{app}) of these multiply protonated peptide ions were determined with deprotonation reactions. For deprotonation reaction of $[M+nH]^{n+} + B \rightarrow [M+(n-1)H]^{(n-1)+} + BH^+$, GA_{app} of $[M+nH]^{n+}$ was the sum of gas-phase acidity (GA) of $[M+nH]^{n+}$ and the reverse activation barrier due to the Coulomb repulsion of the two charged product ions. Although GA represents the fundamental acidity of a multiply charged ion, GA_{app} is also important since it is directly related to the observable acidity of a multiply charged ion. In the present study, reaction efficiency (which is the ratio of the experimental rate constant and the calculated rate by average dipole orientation theory [3]) of 0.1 was used as the break point between endoergic and exoergic processes for GA_{app} determination. The deduced GA_{app} s are adjusted to the scale of Lias *et al* [1] and listed in Table 1. The error is estimated as half of GB difference of two nearest reference compounds at the break point plus an additional 2 kcal/mol error for literature values. Although the error of the determined GA_{app} s is fairly large due to the large GB gap between reference compounds, the relative values among different charge states are readily established.

From Table 1, it is obvious that GA_{app} s generally decrease as the charge states of the peptide ions increase. This can be attributed to the fact that, at higher charge state, deprotonation reactions may occur at less acidic sites. As charge state increases, the coulomb energy increases significantly, which would also lead to reduced acidity. Moreover, at higher charge state, the ions may have less compact structures with low solvation energy. Therefore, the acidity of the peptide ions would decrease as charge state increases. Surprisingly, at a given mass-to-charge ratio (m/z), the GA_{app} s of these peptide ions agree within 10 kcal/mol despite large differences in their mass and charge. Interestingly, the ubiquitin and insulin B ions generated under the present conditions reveal multiple isomers at certain charge states, $n=4, 5, 6$, and 12 for ubiquitin and $n=4$ and 5 for insulin B, as evidenced by the fact that the isomers display distinctively different deprotonation reaction rates with certain reference compounds. The fact that isomers only distinguishable by near-thermoneutral reactions suggests that selection of appropriate reference compounds is critical for differentiating isomers through deprotonation reactions.

GAS-PHASE BASICITIES OF SMALL PEPTIDES OF PROLINE AND GLYCINE: THE ENHANCED BASICITY OF PROLYLPROLINE

Nigel Ewing, Xin Zhang and Carolyn Cassady*
Department of Chemistry, Miami University
Oxford, OH 45056.

It is a well established fact that proton transfer processes are innately important. In addition, fundamental information derived therefrom is significant to chemistry on a whole, and notably to the chemistry of biomolecules. The gas-phase basicity (GB), which is defined as the negative of the Gibbs free energy change ($-\Delta G$) for the protonation reaction:

is one of the thermodynamic parameters of proton transfer processes. GB measurements augment our understanding of the intrinsic properties of molecules in the absence of solvents. The major focus of the present study is the experimental determination of GBs of L-proline and its di- and tripeptides with glycine.

Among the twenty, common α -amino acids, proline is the only imino acid. In addition, proline may play a significant role in the process of protein folding. Because of their significant effect on the conformation of small peptides, proline residues may influence fragmentation patterns in tandem mass spectrometry.

The GB values were ascertained by observing ion/molecule reactions in a Bruker CMS-47X FT-ICR mass spectrometer. The ions were generated by fast atom bombardment in an external ion source and electrostatically guided into the cell. After the ions were trapped, they were isolated by resonant frequency ejection techniques and were collisionally cooled. These ions were then allowed to undergo proton transfer reactions with a series of reference bases with known GBs.

The GBs of the peptides studied are shown in Table 1. Our GB of 213.3 kcal/mol for proline agrees, within experimental error, to literature values of 212.4 kcal/mol¹ and 215.2 kcal/mol². A simple switch of the proline residue from the C-terminus to the N-terminus results in ProGly being 4.2 kcal/mol more basic than its structural isomer GlyPro. In addition, ProGlyGly is more basic than GlyGlyPro and GlyProGly. These results attest to amino N-terminal protonation. The disparity in GBs for structural isomers may be attributed to the increased inductive charge stabilization due to the bulkier pyrrolidine ring of the proline residue near the N-terminal protonation sites.

Interestingly, the dipeptide ProPro possessed the highest basicity of all the peptides studied. The unique conformational constraints induced by proline in peptides may lead to an enhanced intramolecular hydrogen bonding (H-bonding) interaction in ProPro; consequently, this may be a significant factor contributing to the elevated GB for ProPro. To investigate the above assertion, semi-empirical AM1 calculations with full geometry optimizations were performed to ascertain conformational characteristics and explore intramolecular H-bonding interactions for ProPro and the other peptides studied.

The three dimensional structure and the illustrated H-bond distances (Figure 1) suggest that ProPro has two intramolecular H-bonding interactions between the carbonyl oxygens (O5, O20) and protonated N-terminal hydrogens (H31, H15). Previous ab initio studies³ on dipeptides have found amino hydrogens to only be involved in intramolecular H-bonding with the N-terminal carbonyl oxygen. The additional intramolecular interaction coupled with the interaction between the amido carbonyl oxygen and the protonated N-terminus, may be responsible for the enhanced basicity of ProPro.

To gauge the accuracy of our semi-empirical AM1 results, AM1 calculations were also

conducted on GlyGlyH⁺ and the structures obtained compared with the ab initio. Our AM1 structure (Figure 2) qualitatively resembles the low energy ab initio structure⁴ (Figure 3). This comparison suggests that the optimized structures for the larger proline dipeptide systems calculated using AM1 are similar to structures that would be obtained using high level ab initio calculations.

Compound	GB* (kcal/mol)	Compound	GB* (kcal/mol)
Pro	213.3 $\pm$ 2.2	ProGly	219.0 $\pm$ 2.8
GlyPro	214.8 $\pm$ 3.4	ProGlyGly	219.0 $\pm$ 2.8
GlyProGly	217.0 $\pm$ 2.8	ProPro	223.3 $\pm$ 3.3
GlyGlyPro	217.0 $\pm$ 2.8

CATION ATTACHMENT TO MULTIPLY-CHARGED ANIONS OF BOVINE INSULIN A-CHAIN

Scott A. McLuckey, Douglas E. Goeringer, William J. Herron
and J.L. Stephenson, Jr.
Chemical and Analytical Sciences Division
Oak Ridge, TN 37831-6365

We have recently reported on studies of ion/ion reactions in the dilute gas-phase involving multiply-charged ions using quadrupole ion trap methodologies. Multiply-charged anions have been observed to react with singly-charged cations via proton transfer and electron transfer. Cation attachment to a small dianion has also been noted. In this presentation, we report and discuss the observation of cation attachment (and multiple cation attachment) to multiply-charged anions derived from a biopolymer, viz., oxidized A-chain bovine insulin.

All anions thus far studied in reactions with protonated pyridine have reacted exclusively by proton transfer. However, it was noted that under conditions of relatively high pyridine pressure, intense products from the attachment of cations of m/z 130 to the polyanions of oxidized bovine insulin A-chain could be formed, as shown in Figure 1. The α -labelled peaks in Figure 1 correspond to the attachment of a single cation of m/z 130, with an empirical formula of $C_9H_8N^+$, to an anion of the next higher charge state, viz.

whereas the β -labelled peaks represent product ions arising from the sequential addition of cations beginning with reaction (1) and ending with reaction (2), viz.,

The $C_9H_8N^+$ cations arise from the reaction of the intense $C_4H_4^+$ fragment ion, formed from electron ionization of pyridine by loss of HCN, with neutral pyridine, viz.

The ion/molecule reaction product formed via reaction (3) is isomeric with protonated quinoline. However, protonated quinoline, like protonated pyridine, reacts with anions of bovine insulin A-chain exclusively by proton transfer.

These observations can be rationalized on the basis of proton transfer and cation attachment being competitive processes from a common collision complex, as illustrated below in reactions (4) and (5). In reaction (4) the excited intermediate decomposes yielding the products of proton transfer whereas in reaction (5) the excited intermediate is sufficiently long-lived to be cooled.

The rate constants for the relevant processes in this simple scheme are k_c , the capture rate constant, k_p , the unimolecular decomposition rate for the excited complex, k_r , the IR emission rate, and k_{rel} , the rate constant for collision with the helium bath gas. Based on a simulation of collisional cooling in the ion trap, a k_p of 10^5 s^{-1} for the initially formed complex can be used as an approximate value to discriminate between observation of exclusive proton transfer versus observation of recombination.

To provide estimates of cluster ion lifetimes, we have performed a series of RRKM calculations using vibrational frequencies and other parameters listed in the Griffin and McAdoo paper on high mass ion decomposition rates¹, adapted for the oxidized bovine insulin A-chain-adduct system. Figure 2 shows the calculated $\log k_p$ values for the three sets of transition state frequencies, varying in the degree of "tightness" vs. "looseness", using critical energies of 0.25 eV and 1.0 eV. The range in k_p values for a given critical energy arising from the different sets of transition state frequencies is very nearly two orders of magnitude at an internal energy of 7 eV. Even more dramatic is the difference in k_p values (9.5 orders of magnitude!) in going from a critical energy of 0.25 eV to one of 1.0 eV.

We conclude from this exercise in RRKM modelling that it is likely that the critical energy for dissociation of the anion/protonated quinoline collision complex is significantly lower than that of the collision complex formed by collision of the anion with the $C_9H_8N^+$ ion/molecule reaction product. This difference largely accounts for the observation of proton transfer and cation attachment, respectively. For proton transfer reactions in which there is no significant barrier, the collision complex is expected to be short-lived with respect to the cooling rate. On the other hand, in cases in which there is a barrier to proton transfer higher than about 0.6 eV, cation attachment can be observed.

2,3-Dihydrofuran and 2,5-Dihydrofuran Radical Cations

Lan Gao, Jaakko Nousiainen, and Hilkka I. Kenttämäa
Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

The 2,3-dihydrofuran and 2,5-dihydrofuran radical cations have been proposed to undergo ring opening to form distonic ions in the gas phase. If the same process occurs in solution for other similar radical cations, it may have biological significance since ribose and deoxyribose radical cations are important intermediates in ribonucleotide reductase catalyzed reduction of RNA and in radical induced DNA cleavage. Little is currently known about the properties of ribose and deoxyribose radical cations. This study explores the thermochemistry and reactivity of 2,3-dihydrofuran and 2,5-dihydrofuran radical cations as simple models of the sugar radical cations.

The experiments were performed using two different Fourier-transform ion cyclotron resonance mass spectrometers, a 3 T Extrel FTMS Model 2001 instrument and a small custom built system based on 0.4 T permanent magnet (a loan from Finnigan FT/MS). The ionization energies of 2,3-dihydrofuran and 2,5-dihydrofuran were bracketed to be 8.3 ± 0.1 and 8.5 ± 0.1 eV, respectively. The recombination energies of the corresponding radical cations were bracketed to be 8.7 ± 0.1 and 8.6 ± 0.1 eV, respectively. BECKE3LYP/6-31G* calculations yield ionization energies 7.94 and 8.54 eV for 2,3-dihydrofuran and 2,5-dihydrofuran, respectively. The good agreement between the ionization energies obtained from calculation and experiment and the experimental recombination energy suggests that the 2,5-dihydrofuran radical cation retains its cyclic structure. The recombination energy of 2,3-dihydrofuran (8.7 eV) was found to be significant greater than the experimentally (8.3 eV) and computationally (7.94 eV) obtained ionization energies. These results suggest a structural change during the experiment. A possible explanation for these findings is that the 2,3-dihydrofuran radical cation isomerizes to crotonaldehyde upon the electron transfer process. The ΔH for this electron transfer reaction is 8.61 eV, which agrees well with the measured value of 8.7 ± 0.1 eV.

The 2,3-dihydrofuran and 2,5-dihydrofuran radical cations were found to be equally acidic, with a measured ΔH for deprotonation of 202 ± 3 and 200 ± 3 kcal mol⁻¹, respectively. The reactivity of the two radical cations were explored toward different H-atom donors. While some of these donors transfer a H-atom to the radical cations, this is not true for tetrahydrofuran. Hence, the ribose and deoxyribose radical cations may not be able to induce DNA cleavage through a mechanism initiated by H-atom abstraction.

ION MOLECULE REACTION IN GAS PHASE PART XXIII MECHANISMS OF WATER LOSSES FROM CIS AND TRANS INDANEDIOL ADDUCT IONS IN DIMETHYL ETHER CHEMICAL IONIZATION

V. Gervat, F. Fournier, M.C. Perlat, J.C. Tabet*
Laboratoire de Chimie Structurale Organique et Biologique, EP 103,
Université P. et M. Curie, 4 place Jussieu 75252 Paris 05, FRANCE.

Dimethyl ether (DME) was introduced in 1982 as a versatile CI gas reagent¹ in chemical ionization for structural elucidation. More recently, several investigations performed by Brodbelt *and al.* have illustrated its analytical capacity to produce specific decompositions from both primary ions, i.e. $[M+DMEH]^+$ proton-bound adduct ions and the $[M+(DME-H)]^+$ covalent ions. They are generated by ion molecule reaction induced by $DMEH^+$ (m/z 47)² and $(DME-H)^+$ (m/z 45)³ reagent ions, respectively. The present work reports some ion chemistry of *cis* (**1c**) and *trans* (**1t**) indane-1,2-diols and their reactions with DME-CI plasma (Scheme 1) achieved on a triple quadrupole instrument. The perdeuterated C_2D_6O reactant was used to promote in the elucidation of reaction and dissociation mechanisms.

Scheme 1. Supposed structures for epimeric *cis* and *trans* $[M+DMEH]^+$ (a_1 , a_2 and b forms) proton bounded and $[M+(DME-H)]^+$ (c_1 and c_2 forms) covalent adduct ions.

$DMEH^+$ ion induces mildly exothermic proton transfer with many substrates but doesn't promote extensive protonation of indanediols. Reactant $CH_3OCH_2^+$ ion, usually induces reactions resulting in product ions at $[M+13]^+$ (methylene substitution) or $[M+15]^+$ (methyl addition)³, whereas with indanediols, these reactions are strongly hindered. This unexpected behavior is attributed to competitive processes (i.e. water elimination) from adduct ions. The mechanism of these reactions has been investigated to explain the large observed stereochemical effects.

S_Ni mechanism appears to be the more favored pathway for water loss from $[M+DMEH]^+$ resulting in $[M+29]^+$ (m/z 179) formation. Investigation of the $\{m/z$ 179/ m/z 197 $\}$ ratio towards the P_{DME} values indicates that the $[1c+DMEH]^+$ and $[1t+DMEH]^+$ adduct ions are similarly stabilized by increasing pressure. So, water loss mechanism must be the same from both epimers. The reaction is shown to be regioselectivity at benzylic site. This has been evidenced using ^{18}O labelling which indicates that the benzylic ^{18}OH group is lost specifically from $[1t+DMEH, ^{18}O]^+$. Stereochemistry of the $[M+29]^+$ ion has been investigated by CAR (Collision Activated Reaction), by using NH_3 as reactive gas (Figure 1). Formation of the substituted $[M+29+NH_3-DME]^+$ ions, m/z 150, follows a like- S_N2 pathway with configuration inversion for both selected species. The $[m/z$ 150]/ $[m/z$ 179] ratio depends significantly upon the initial stereochemistry (i.e. 0.64 and 0.25 for $[1c+29]^+$ and $[1t+29]^+$, respectively). Then, the $[M+29]^+$ ions are produced in the source via the S_Ni pathway (retention of configuration). So, a relative enhanced reactivity of the $[1c+29]^+$ substituted ions towards NH_3 is expected, since the NH_3 approach to the opposite site is possible. Alternatively with the $[1t+29]^+$ epimer, the nucleophilic attack at the benzylic position is not favored since the homobenzylic OH group sterically hinders the NH_3 approach.

Figure 1. $CAR(NH_3)$ spectra of the m/z 179 ions ($E_{lab} = 2eV$, $P_{NH_3} = 2.10^{-3}$ torr).

A mechanism involving an internal acidic catalysis is proposed for the loss of water occurring from $[M+(DME-H)]^+$ ions. According to the position of the cationized site (benzylic or homobenzylic forms), a proton transfer should be favored or not. The set of the experimental results is consistent with a mechanism characterized by the c_2 formation (Figure 1) followed by a H migration to the benzylic OH group, inducing the water loss. Indeed, the CID spectra of the $[M+(DME-H)as, ^{18}O]^+$ shows that the water loss occurs regioselectively from benzylic position. Furthermore, $[M+27]^+$ product ions have a structure independent upon the initial stereochemistry as evidenced by $CAR(NH_3)$ experiences. CAR spectra of $[1c+27]^+$ and $[1t+27]^+$ ions (m/z 177) present similar fingerprints. This result confirms that a common structure characterizes the $[M+27]^+$ product ions.

REACTIVITY OF THE EPIMERIC 3,4-CHROMANEDIOLS TOWARDS THE $\text{NH}_3/\text{NH}_4^+$ SYSTEM

Y.-J. Kang, M. Meyer, G. Dana, F. Fournier, J.C. Tabet*
Laboratoire de Chimie Structurale Organique et Biologique, EP 103,
Université P. et M. Curie, 4 place Jussieu 75252 Paris 05, FRANCE.

Stereochemical effect investigations are useful to reach a fundamental understanding of the bifunctional species reactivities, as mechanisms of ion-molecule reactions¹ in order to develop analytical methods for characterizing related types of biomolecules. Monocyclic diols can serve as elementary models of more complex biologically relevant molecules which contain multiple OH groups. Under Ammonia Chemical Ionization conditions, several examples have been developed showing that protonation (based upon exothermic proton transfer) can compete with other ion-molecule processes².

In previous studies on behavior of the cis and trans 1,2-indanediols towards NH_3 and CH_3NH_2 in collision cell of triple quadrupole instrument, it has been demonstrated that low kinetic energy adduct ions reacted either by CID ways with nucleophilic reagents or *via* nucleophilic substitution as followed:

$\text{S}_\text{N}1$ reactions were produced by $\text{S}_\text{N}2$. In the present work, the behavior of the epimeric 3,4-chromanediols (**1c** and **1t**) system has been examined in a triple quadrupole in order to compare their respective reactivity towards the $\text{NH}_3/\text{NH}_4^+$ system relative to the **2c** and **2t** 1,2-indanediols.

CI mass spectra of **2c** and **2t**, with a rigid indane ring, are very similar whereas those of epimeric chromanediols, with a conformational flexibility, reveal structural differences. Nevertheless, energy-resolved CAR breakdown curves show that MsH^+ are produced within a common structure from both epimers for the two series of compounds. However, 1,2-indanediols give rise to formation of major MsH^+ ions while 3,4-chromanediols lead to minor MsH^+ ions *via* rough decrease as E_{Lab} increased. This behavior shows that $\text{S}_\text{N}1$ is more favored from 1,2-indanediols than it is from 3,4-chromanediols. This reflects the conformational flexibility for the latter heterocyclic skeleton. Under CAR conditions, main ion-molecule reactions produced from the adduct $[\text{M}+\text{NH}_4]^+$ ions are:

A stereochemical effect is exhibited from 1,2-indanediols and 3,4-chromanediols and reflects a pronounced differences in the extent of proton transfer to NH_3CH_3^+ (m/z 32) ions, more efficient from indanediols than from chromanediols. This allows to compare the relative proton affinities of both the epimers; especially, the ratio $\text{CH}_3\text{NH}_3^+ / [\text{M}+\text{CH}_3\text{NH}_3]^+$ measured at low energy is weaker from the cis epimer which indicates a higher PA value for the cis epimer. For 1,4-chromanediols, it is difficult to establish a PA order, on account of the competitive reactions which seem to be faster than the proton transfer. The selected $[\text{M}+\text{NH}_4]^+$ ion reacts toward S_N pathway in collision cell with CH_3NH_2 through different rate constants depending upon the cis/trans stereochemistry: formation of the substituted $[\text{M}+\text{NH}_4\text{-H}_2\text{O}]^+$ (MsH^+) and $[\text{M}+\text{NH}_3\text{CH}_3\text{-H}_2\text{O}]^+$ (Ms^+H^+) ions (Figure 1).

Figure 1 CAR spectra of the $[\text{M}+\text{NH}_4]^+$ ion (indane: m/z 168, chromane: m/z 184)
($E_{\text{Lab}} = 5\text{eV}$, $P_{\text{NH}_2\text{CH}_3} = 6,2 \cdot 10^{-3}\text{ torr}$)

Competitive nucleophilic substitution processes show $\text{S}_\text{N}1$ and $\text{S}_\text{N}2$ for the both series, but a higher reactivity of the cis/trans 3,4-chromanediols is observed towards $\text{S}_\text{N}2$ than that which characterizes the cis/trans 1,2-indanediols. By increasing of the collision energy, $\text{S}_\text{N}2$ pathway disappears as expected in favor to the $\text{S}_\text{N}1$ process only for indanediols. These effects are rationalized assuming a stereoelectronic effect induced by oxygen of the heterocycle consistent with the conformational flexibility ring. In complementary, study of the diethers derivatives is in progress, in order to investigate how the leaving group and the neighbored function influence the ion reactivity towards the $\text{NH}_3/\text{NH}_4^+$ system.

The Unexpected Reactivity of Phenylium Ions

Phillip K. Chou, Jaakko Nousiainen, James Pérez, and Hilkka I. Kenttämäa*
Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

Many aromatic compounds form phenylium ions upon electron ionization. Therefore, understanding the reactivity of phenylium ions is important. The phenylium ion ($C_6H_5^+$) has been reported to exhibit carbenium ion-like and carbene-like reactivity.¹ We recently discovered that the phenylium ion is able to abstract radical groups from certain neutral reagents. This reactivity is unexpected for a closed-shell species. In this work, we examine this unusual reactivity in a dual cell Fourier transform ion cyclotron resonance mass spectrometer.

The phenylium ion (formed by fragmentation of ionized halocarbons) reacts with dimethyl disulfide and dimethyl diselenide to yield a major product (95%) that corresponds to thiomethyl radical abstraction. Some ionized dimethyldisulfide (5%) was also observed. Similarly, the phenylium ion reacts with dimethyldiselenide to form a selenomethyl radical transfer product ($C_6H_5SeCH_3^+$, 85%) and ionized dimethyldiselenide (15%). The structure of the thiomethyl abstraction product was verified to be thioanisole, by comparison of its CAD spectra to those measured for an authentic ion.

The observation of thiomethyl radical abstraction by the phenylium ion was unexpected because even-electron organic cations generally do not react with dimethyl disulfide. Thiomethyl radical abstraction reactions are typically observed for distonic radical cations. Conventional radical cations either are unreactive or produce electron transfer products.² Analogous reactivity is observed for reactions with dimethyldiselenide.³

The 4-methoxyphenylium ion reacts with dimethyl disulfide and dimethyl diselenide in the same way as the phenylium ion, yielding radical-type abstraction products together with electron transfer products. In contrast, the 4-(dimethylamino)phenylium ion reacts with these reagents by exclusive thiomethyl and selenomethyl radical abstraction. This difference is likely explained by different ground state multiplicities for the phenylium and methoxyphenylium ions and the 4-(dimethylamino)phenylium ion. The former ions are known to be ground state singlets while the 4-(dimethylamino)phenylium ion is thought to be a ground state triplet.⁴ It is thermodynamically unfavorable for the triplet 4-(dimethylamino)phenylium ion to react by electron transfer with either dimethyl disulfide or dimethyl diselenide. Hence, the reactivity of the 4-(dimethylamino)phenylium ion toward dimethyl disulfide and dimethyl diselenide is consistent with the triplet electronic ground state.

The unusual radical-type abstraction reactions observed for the phenylium and the 4-(dimethylamino)phenylium ions may occur via a mechanism involving a series of electron transfer and radical abstraction reactions within the collision complex (Scheme 1).

Reaction of Chloroorganics With Oxygen in the Collision Cell of a Triple Quadrupole

F. Lépine¹, D. Boismenu², S. Milot¹ and O.A. Mamer²

¹ Institut Armand-Frappier, Laval, Qué., Can.,

² Biomedical Mass Spectrometry Unit, Mc Gill University, Montréal, Qué., Can.

Introduction

The electron capture negative chemical ionization (ECNCI) mass spectra of many chlorinated compounds show ions at M-19. The mechanism of this reaction proceeds through addition of O₂, present in trace amounts in the source, to the organochlorine to form an intermediate which subsequently loses OCl[•] to produce a M+O-Cl anion [1].

In a previous publication we reported the regioselective dechlorination of PCBs in ECNCI using methane as moderator gas [2]. When large amounts of oxygen were added to methane, the oxygen addition-induced dechlorination of PCBs was not regioselective [3]. Under these latter conditions, it is difficult to unequivocally assign a reaction mechanism due to the variety of reactants present in the source. The present work uses MS/MS in the study of the factors controlling the formation of these M+O-Cl ions and the regioselectivity of these dechlorination reactions for various chloroaromatic compounds, by selecting the molecular radical anion and reacting it with oxygen in the collision cell.

Material and Methods

The PCB congeners studied are identified by their IUPAC number. These are congeners **101** (2,2',4,5,5'-Cl₅), **118** (2,3',4,4',5-Cl₅), **146** (2,2',3,4,6,6'-Cl₆), **153** (2,2',4,4',5,5'-Cl₆), **180** (2,2',3,4,4',5,5'-Cl₇), **194** (2,2',3,3',4,4',5,5'-Cl₇), **200** (2,2',3,3',4,5',6,6'-Cl₈) and **209** (decachlorobiphenyl). Pentachlorobenzene (pheCl₅) and hexachlorobenzene (pheCl₆) were also used. The solutions of the chloroorganics were mixed in various proportions so that the intensities of the molecular ions were roughly equal for all compounds studied, and were introduced into the mass spectrometer through GC. The experiments were performed in negative chemical ionization mode using a VG Quattro II with methane as moderator gas. Pure oxygen was used in the collision cell.

For the regioselectivity determination experiment, a series of ³⁵Cl labelled PCBs was used. These compounds were synthesized by chlorination of **40** (2,2',3,3'-Cl₄), **47** (2,2',4,4'-Cl₄) and **77** (3,3',4,4'-Cl₄) using ³⁵Cl₂ as described previously [4].

Discussion

The oxygen addition induced dechlorination reaction proceeds through a radical intermediate which loses OCl[•] to produce the M+O-Cl ions:

The mass spectra of many of these chloroorganic, performed in daughter ion mode show of that the M+O-Cl ions were often more intense than their precursor ions. The ArO₂Cl_n^{•-} intermediate at M+32 amu was not detected.

The effect of varying the relative concentration of O₂ on the formation of the M+O-Cl ions was investigated. The plot of the intensities of the M+O-Cl ions (as the sum of the M-19 and M-21 ions) for various oxygen pressures shows that the oxygen pressure at which the M+O-Cl ion intensities maximize depends on the extent of chlorine substitution on the aromatic rings. This probably reflects the relative affinity of the radical anions for oxygen, the more highly substituted aromatic anions being less reactive than the lesser.

Another series of experiments monitored the M-19 and M-21 daughter ions of a precursor in the molecular ion cluster to determine whether an isotope effect could be detected in the dechlorination reactions. The precursor ions were chosen to obtain the highest M-21 intensities in order to get the best accuracy for the calculation of the M-21/M-19 ratio. The M-21/M-19 ratio should be identical to the ³⁷Cl/³⁵Cl ratio of the precursor ion, if the dechlorination reaction is not affected by chlorine isotope effect. The highest M-21 intensity for compounds containing six chlorines is obtained with the M+4 ion.

The measured M-21/M-19 ratios of the M+O-Cl ions of the various chloroorganics and the corresponding ³⁷Cl/³⁵Cl ratio of their precursor ions are identical for each compound, indicating that there is no measurable isotope effect in this dechlorination reaction.

The regioselectivity of the dechlorination reaction was also studied using ³⁵Cl labelled PCBs which were produced by adding two isotopically enriched ³⁵Cl atoms at various positions on a symmetrical tetrachlorobiphenyl. The precursor ion selected within the molecular ion cluster was the M+4 which contained 2 "natural" ³⁵Cl, 2 "natural" ³⁷Cl and two "enriched" ³⁵Cl.

If only one of the labelled chlorines was lost in the dechlorination, only a M-19 daughter ion would be detected and the M-21/M-19 ratio would be 0. If dechlorination occurs only at the positions where unlabelled chlorines are present, the M-19 and M-21 daughter ions should be equally intense, and the M-21/M-19 ratio would be 1. If dechlorination occurs randomly between the various positions the M-21/M-19 ratio would be 0.5, as there are 2 ³⁷Cl and 4 ³⁵Cl in the precursor ion. Simple calculations can provide the percentage loss of the label at a given position, which is a measure of the regioselectivity of the dechlorination. The percentage loss at various positions for various labelled PCBs show that, for hexachloro PCBs such as **153** and **138**, label loss was most important at the para position. For pentachloro PCBs like **118** and **105**, labels at the ortho position were lost preferentially.

Conclusion

The molecular radical anion of these chloroaromatic react efficiently with oxygen in the collision cell. The nature of the chloroaromatic, mostly the extent of chlorine substitution, is a key parameter that controls the formation of M+O-Cl ions. The dechlorination reaction giving rise to the M+O-Cl ion is not affected by a measurable chlorine isotope effect. This reaction presented considerable regioselectivity for many congeners, contrary to what was observed previously when oxygen was added in the ion source.

High Pressure Electron Capture Responses and Spectra of Substituted Nitrobenzenes. L.J. Sears, W.B. Knighton and E.P. Grimsrud, Department of Chemistry, Montana State University, Bozeman, MT.

High Pressure Electron Capture Mass Spectrometry (HPECMS) provides one of the most sensitive means of analysis available for numerous compounds. However, the method is often accompanied by mass spectral ions of unknown origin and by unexplained variations in sensitivities. Examples of this are provided here, where HPECMS measurements of numerous substituted nitrobenzenes (SNB's) are reported along with measurements of their EC rate constants, k_{EC} . It will be shown that for SNB's with large k_{EC} 's, relative HPECMS responses can be explained only by consideration of additional secondary processes involving the fate of EC reaction products upon contact with the walls of the ion source.

In Table I, k_{EC} values, %M⁻ abundance in the HPEC spectra, and relative HPECMS responses are listed. From this table and the accompanying figure, it is clear that the relative HPECMS responses of many of the SNB's are not proportional to their relative k_{EC} values. In order to gain some insight into the additional factors that influence the HPECMS responses, several cases are briefly discussed below.

For most of the SNB's having low k_{EC} values, the HPECMS responses correlate relatively well with the k_{EC} values. This is expected since only a small portion of these SNB's will be destroyed by their EC reactions within the ion source. Therefore, the HPECMS responses to these SNB's will be proportion to their k_{EC} values. For SNB's with large k_{EC} , however, most of the parent molecules will be quickly converted to negative ions. Unless the molecular anions, M⁻, thereby formed are converted back to M upon neutralization on the walls, the steady-state concentration of these compounds will be greatly reduced. Note, for example, the HPECMS response to 2-BrNB is low even though its EC rate constant is very large. Due to its large k_{EC} , essentially all 2-BrNB will undergo EC during its passage through the ion source. Since no M⁻ and mainly Br⁻ ions are observed in the EC spectrum of 2-BrNB, the parent molecule, M, can not possibly be regenerated by wall neutralization of the negative ions. The appearance of an ion of $m/z = 123$ in the spectrum of 2-BrNB indicates that nitrobenzene is being formed, however, undoubtedly by wall contact of the EC neutral product, NB radical. Since k_{EC} for nitrobenzene is not large, the intensity of the ion at $m/z = 123$ is not large and contributes little to the total ion HPECMS molar response of 2-BrNB. Note that the HPECMS responses for 3-NO₂NB and 4-NO₂NB are about the same, even though their k_{EC} values differ by an order of magnitude. Since an intense M⁻ ion is formed in the EC reaction of 4-NO₂NB, it appears that upon contact with the walls, the M⁻ ion for 4-NO₂NB is altered to other neutral substances that are not EC-active.

It is noted that the HPECMS responses of the three isomers of CF₃NB correlate quite well with their relative k_{EC} values, in spite of the fact that their k_{EC} values are all quite large. This suggests that the M⁻ ions formed in the EC reactions of these compounds are efficiently converted back to the parent molecules, M, upon their contact with the walls. In this way, a relatively high, steady-state concentration of these compounds is maintained as they pass through the ion source.

The relative HPECMS response of 3,5-diCF₃NB is uniquely high for a compound with a modest k_{EC} value. The mass spectrum for this compound includes two unexpected ions, at $m/z = 227$ and 228, that can not be rationalized in term of simple dissociative processes. These ions are thought to be formed by wall conversion of the M⁻ species to one or more altered neutrals that have relatively high k_{EC} values. The fast EC reactions of these species then lead to the unexpected ions at $m/z = 227$ and 228 that contribute significantly to the unusually large total ion HPECMS molar response to 3,5-diCF₃NB.

^a Electron capture rate constants ($10^7 \text{ cm}^3 \text{ s}^{-1}$) determined in the present study by an electron capture detector in argon-10% methane buffer gas at 640 Torr and 130°C. ECD responses were measured relative to that of CFCl₃, whose k_{EC} is well-known.

^b Percent molecular anion abundance observed in HPECMS spectra obtained with a VG 70-70 dual sector mass spectrometer with 0.35 Torr methane buffer gas at 150°C. Very small sample sizes of less than 1 ng were introduced by capillary gas chromatography to ensure that only a small fraction of electrons within the ion source are used up by the EC reactions.

^c Total ion HPECMS molar responses relative to that of 3-fluoronitrobenzene, based on measurements of total ion signals observed per mass spectral scan.

EI and CI Mass Spectra of Some Oligomeric Polyethylene Glycols.

Adebayo Onigbinde, Gordon Nicol, and Burnaby Munson.

Department of Chemistry and Biochemistry

University of Delaware

Newark, DE 19716-2522.

Polyethylene glycols (PEG) $\text{HO}(\text{C}_2\text{H}_4\text{O})_n\text{H}$, are widely used in industry. Because of their solubility both in water and organic solvents, they have been found useful in biomedical and biotechnical applications especially in affinity partitioning. Although, they are considered biodegradable, some PEG oligomers have been found in environmental samples. Despite the fact that higher molecular weight PEG are considered non-toxic, excessive consumption or inhalation of ethylene glycol and some of its oligomers have caused fatalities.

Despite the wide use of polyethylene glycols, few EI spectra are available in the literature, ($n = 1-4$). The 70eV electron ionization (EI) spectra of a series of oligomeric polyethylene glycols, $\text{HO}(\text{C}_2\text{H}_4\text{O})_n\text{H}$, $n = 1-11$, have been obtained by GC/MS. No molecular ions and no $(\text{M}-\text{H}_2\text{O})^+$ are observed in the EI mass spectra of oligomeric PEG. There are no high mass ions of significant abundances to allow an unambiguous determination of the molecular weight. However, there are low abundance ions in the upper mass region which would allow one to confirm the presence of specific oligomers in chromatographically well separated mixtures. The base peak in all of the spectra is m/z 45, with related ions at m/z 89, 133 in series, $(\text{C}_2\text{H}_4\text{O})_n\text{H}^+$. Metastable decompositions were observed for $133^+ \rightarrow 89$ and $89^+ \rightarrow 45^+$. A series of low abundance ions were also observed: 31, 75, ... $(\text{M}-75)^+$, $(\text{M}-31)^+$, possibly from alpha-cleavage reactions and other ions such as m/z 58, 59, 73 whose origin are not obvious. If large samples are introduced, low abundances of MH^+ can be detected.

The methane (CH_4) CI spectra are simpler than the EI spectra with major ions in the series, $(\text{C}_2\text{H}_4\text{O})_n\text{H}^+$: $n=1, 2 > n=3 > 4$. $(\text{M}+\text{H})^+$ ions are observed, whose abundances increase with increasing sample size but not with molecular weight. Protonated dimers M_2H^+ , are observed at large extent of conversion only for ethylene and diethylene glycol.

The methane/ammonia (3%) CI spectra contain $(\text{M}+\text{H})^+$ ions as the base peak with $(\text{M}+18)^+$ ion abundance varying between 5-30% of the base peak. $(\text{C}_2\text{H}_4\text{O})_n\text{H}^+$ are the major fragment ions in the spectra.

The isobutane CI spectra contain $(\text{M}+\text{H})^+$ ions as the base peak. However, the spectra are pressure dependent. At low pressure ($43^+/57^+ = .75$), formation of $(\text{C}_2\text{H}_4\text{O})_n\text{H}^+$ ions is extensive. At higher pressures, ($43^+/57^+ = .15$), fragmentation decreases and the spectra contain only the $(\text{M}+\text{H})^+$ ions. Formation of the $(\text{M}+57)^+$ ions was observed when $n \geq 3$. M_2H^+ ions were observed at high sample concentrations in CI spectra only for $n = 1, 2$. In general, the methane/ammonia and isobutane CI will give better quantitative information than the methane CI spectra.

The relative molar sensitivities for the GC/EI and GC/CI varies linearly with increasing molecular weight but was constant (~ 1.0) for FAB and ES.

Chemical Ionization of Methyl Esters

* Jason Evans, Burnaby Munson, Gordon Nicol
Dept. Chemistry and Biochemistry
University of Delaware
Newark, DE 19711

Heavy CI reagents, such as CS_2 , benzene, toluene, and xylene have been used in our laboratory for the analysis of saturated and unsaturated methyl esters. They have low ionization potentials and can be used to react with sample molecules in low energy charge exchange reactions. This work was done on a VG 7070E GCMS with a modified CI source that enables one to obtain higher pressures. In the present study, toluene CI was done on a VG Autospec with a standard CI source, and the results were compared to other forms of CI and to the toluene CI data obtained on the VG 7070E.

Past attempts at performing toluene CI on the VG Autospec failed because a high toluene pressure in the source could not be reached without tripping the pressure gauge. These pressures can be obtained on the VG 7070E because there are fewer leaks in the modified source and a 30/70 toluene/helium mixture was used. There is only one CI line on the VG Autospec. Therefore, helium was never used as the buffer gas. In the present attempt, a mixture of helium and toluene was obtained by using the CI line for helium introduction and the calibrant line for the toluene. With this introduction technique higher pressures in the source can be realized. However, the absolute pressure and composition of the mixture are unknown.

From the data obtained on the VG Autospec, plots of ion abundance (expressed as % TIC) vs chain length of the ester were constructed for a series of saturated and unsaturated methyl esters. The graph below indicates that isobutane CI gives mass spectra of the methyl esters with the least amount of fragmentation.

Proton transfer from the $i\text{-C}_4\text{H}_9^+$ to the saturated methyl esters is exothermic by only about 0.2 eV. The methane/ammonia spectra of methyl esters contain more fragmentation because CH_5^+ and C_2H_5^+ , which are 7% and 10% of NH_4^+ , respectively, react with the methyl esters through dissociative proton transfer reactions.

The methane/ammonia spectra of methyl esters contain an ion at m/z 35. A chromatographic trace of this ion provides evidence of an unusual ion-molecule reaction resulting in the formation of $\text{NH}_3(\text{NH}_4)^+$.

Proposed mechanism

The toluene CI data obtained on the VG Autospec with the new reagent gas introduction system do not match those spectra previously obtained on the VG 7070E. The spectra of the unsaturated methyl esters acquired on the VG Autospec contain more abundant adduct ions and fragments. Also the $[\text{M}+\text{H}]^+$ is as intense as the M^+ . This is difficult to rationalize since the C_7H_9^+ which is apparently the most intense proton transfer reagent ion in the spectra, is only about 8% of the M^+ of toluene. The toluene CI spectrum of methyl oleate ($\text{C}_{18}:1$) acquired on the VG 7070E contains a strong M^+ and one intense fragment at $[\text{M}-32]^+$. These data were taken with a 30/70 mixture of toluene/helium at an absolute pressure of 0.33 torr. One can conclude from the differences in the spectra obtained on the two different instruments that the conditions in the VG Autospec consisted of a much higher toluene composition at a lower absolute pressure. The CI conditions in the VG Autospec may not yet be optimal. Further experiment may yield spectra that more closely match the spectra obtained on the VG 7070E.

NEUTRAL PRODUCTS FROM REARRANGEMENTS OF 2-HYDROXYETHYL CATIONS
PRODUCED BY TRITIUM DECAY.

Jacqueline S. Bennett and Thomas Hellman Morton, Department of Chemistry,
University of California, Riverside, CA 92521-0403 USA

In 1960 Wexler, Anderson, and Singer reported the mass spectrometric fragmentation pattern of $C_3H_7^+$ ions produced by nuclear decay of the isomeric tritiopropanes $CH_3CH_2CH_2T$ and $(CH_3)_2CHT$.¹ From the proportions of m/z 43 and lower mass ions, they inferred that 33% of the ions from the former and 42% of the ions from the latter were superexcited (i.e. had internal energies ≥ 2 eV). Of the ions that were not superexcited, the energy distribution of the former were skewed more to the high end of the 0-2 eV energy domain than the latter. We propose a model to account for these seemingly disparate results: that there are a pair of concurrent mechanisms for energy deposition. Superexcitation comes from collision of an ejected particle with the ion left behind. Geometrical relaxation of the ion gives internal excitation from 0-2 eV.

Figure 1. Schematic representation of partition of rehybridization energy of initially tetrahedral RHe^+ ion into translation. Lower curve shows nearly complete planarization for initial He atom velocity = 0. Upper curve shows only partial planarization for initial He atom velocity = v_0 , which corresponds to the case when RHe^+ is produced by β -decay of R-T. For the upper curve rehybridization energy remains as vibrational excitation.

Geometrical relaxation can be represented by the figure above. For RHe^+ with an initially stationary helium atom the lower curve shows the partition of all the rehybridization energy into translation. When the 3He has initial translational velocity v_0 the expression is as follows:

$$\int_{r_0}^{\infty} \left(\frac{dV}{dr} \right) dr = \int_{r_0}^{\infty} \left(\frac{dV}{dr} \right) \left(\frac{dr}{dt} \right) dt = \int_{r_0}^{\infty} \left(\frac{dV}{dt} \right) dt \rightarrow \int_{r_0}^{\infty} \left(\frac{1}{v} \frac{dV}{dr} \right) \left(\frac{dv}{dt} \right) dt = \int_{r_0}^{\infty} \left(\frac{v}{v+v_0} \right) \left(\frac{dV}{dr} \right) dr$$

We have applied this picture to the decomposition of TCH_2CH_2OH . From ab initio calculations we estimate that expulsion of 3He from the ion formed by nuclear decay, $HOCH_2CH_2He^+$, should be exothermic by about 2.9 eV. Rehybridization of the initially tetrahedral cationic carbon is accompanied by a barrier-free bridging by the neighboring oxygen to give protonated oxirane. Taking into consideration the fact that the helium atom should have an initial velocity ca. $v_0 = 12$ km/sec from recoil of the nuclear decay, we have numerically integrated the expression on the right (which corresponds to $v_0 \neq 0$) from $r_0 =$ the normal C-H bond distance, at which the helium atom forms as a result of beta-decay, where v (the velocity imparted by rolling down the repulsive curve) is zero. Conversion of this rearrangement energy into translational velocity of the helium atom (v) is estimated to be about 40% efficient for $v_0 = 12$ km/sec. In other words, we expect the average nuclear decay event to leave about 1.7 eV of internal energy within the remaining ion, which should look like a nearly planarized primary cation with negligible neighboring group participation. RRKM theory gives a rearrangement rate for such protonated oxirane ions that is less than the ADO collision rate at pressures of $\frac{1}{2}$ atmosphere of trimethylamine.

Some of the nuclear decay events (less than half, we estimate) will result in a collision between the outgoing helium atom or the outgoing beta particle and the carbocation. These collisions may result in superexcited ions. Thus, if we allow TCH_2CH_2OH to undergo nuclear decay in the presence of $\frac{1}{2}$ atmosphere of trimethylamine, we expect at least $\frac{1}{2}$ of any protonated oxirane that is formed to be quenched by proton transfer to the amine base in the gas phase.

Experimentally we have looked at ethanol containing multiple tritium produced by catalytic tritiation at the National Tritium Labelling Facility at LBL. The principal compound is TCH_2CH_2OH : half the decay product should be protonated acetaldehyde from the tritium in position 1. We measure the ratio of neutral tritiated acetaldehyde to neutral tritiated oxirane to be at least 40:1. Based on estimates of rearrangement, decay at the 2-position yields less than 15% protonated oxirane.

Acknowledgment. This work was supported by NSF grant CHE 95-22604.

THE DETECTION AND STUDY OF ELECTRONICALLY EXCITED SPECIES IN THE CHEMICAL IONIZATION SOURCE

Elizabeth A. Stemmler and Bryan P. Wert
Department of Chemistry
Bowdoin College, Brunswick ME 04011

Electron ionization (EI) induced fluorescence has been used in the past as either a method for the generation of excited state species from simple gases¹ or for the production of emission signals suitable for the gas chromatographic detection of more complex organics². In general, these studies have been carried out under low pressure EI conditions. The production and detection of electronically excited species under chemical ionization (CI) conditions has the potential to provide diagnostic information regarding initial ionization rates and processes such as electron-ion recombination reactions as a function of ion source pressure, emission current, electron energy.

In this study, emission spectra produced by the electron ionization of six gases (He, H₂, Ar, N₂, CH₄, and i-C₄H₉) have been studied in the region of 300-700 nm using a fiber optic to transmit emitted light to a double monochromator. Under chemical ionization conditions, optical emission spectra were observed for He, Ar, N₂, H₂, and CH₄. Only very weak H Balmer lines were detected in the spectrum of i-C₄H₉. The spectrum of He showed only emissions from excited neutrals; both neutral and ionic emissions were detected in the spectrum of Ar. The spectrum of H₂ showed H Balmer line emissions.

Interesting differences were observed between the low pressure EI and CI emission spectra for CH₄ and N₂. The low pressure emission spectrum of CH₄ shows the Balmer series of the hydrogen atom ($n' \rightarrow n=2$) for $n' = 3$ through 7 with strong emissions from CH ($A^2\Delta \rightarrow X^3[I]$) at 431.4 nm. Under CI conditions, the emission spectrum for CH₄ shows CH ($A \rightarrow X$) emissions that are enhanced relative to the H atom emissions measured at low pressure (see Figure 1). A linear increase in the CH/H⁺ emission ratio with pressure is observed. The detection of excited state CH is of interest because this species and its ground-state analogue are highly reactive molecules that may play a role in the production of addition products, such as $[M+CH_2]^+$ ions observed in ECNI mass spectra.

Under low pressure EI conditions, the spectrum of N₂ is dominated signals from the first negative system of N₂⁺ ($B^2\Sigma_u^+ \rightarrow X^2\Sigma_g^+$) with weaker signals originating from the second positive system of N₂ ($C^3\Pi_u \rightarrow B^3\Pi_g$). The relative intensities of emissions from N₂ change considerably when the gas is ionized under CI conditions (see Figure 2). The emission spectrum for N₂ shows N₂ ($C \rightarrow B$) emissions that are enhanced relative to the N₂⁺ ($B \rightarrow X$) emissions measured under low pressure conditions.

At higher pressures, it becomes possible to excite with secondary electrons or primary electrons that have been reduced in energy following ionizing collisions. In addition, the higher ion/electron densities found under CI conditions can lead to signals resulting from radiative ion/electron recombination. For example, emission from CH ($A \rightarrow X$ and $B \rightarrow X$) have been

reported upon electron-ion recombination by CH₅⁺,³ and N₂ ($C \rightarrow B$) is observed when N₄⁺ undergoes electron-ion recombination.⁴ Preliminary experiments with CCl₄ suggest that these recombination reactions are not the dominant process responsible for producing CH ($A \rightarrow X$) or N₂ ($C \rightarrow B$) emissions under CI conditions.

A linear increase in optical emission signals with ionizing emission current was observed for optical signals from both CH₄ and N₂. In contrast, ionic signals from polyatomic species (CH₅⁺, C₂H₅⁺, N₂⁺, and N₄⁺) began to level off at higher emission currents, presumably because of losses due to electron-ion recombinations.

The detection of optical emissions from short-lived species in the CI source should provide information regarding initial ionization rates under CI conditions if we assume that excited state species in the source are formed at a rate proportional to the rate of production of ionic signals. Using the 486 nm H atom emissions from CH₄, initial ionization rates have been calculated for electron energies of 100 and 250 eV. The initial ionization rate maxima shifts to higher pressures with the higher electron energy, and a similar shift is detected for the total positive ionization signal.

These experiments suggest that electronically excited species detected under CI conditions have the potential to be used as probes to study initial ionization rates and other neutral and ionic reactions occurring in the CI source.

Increasing concern with regard to health and environmental effects of energy production has lead to a strict regulation of the emission of off-gases. Thus, the emission of NO_x and SO₂ from power plants has been significantly reduced. However, the combustion chemistry of sulphur is apparently not known as detailed as e.g. of nitrogen. The introduction of H₂S into a premixed methane/oxygen flame and, hence, simulating the presence of sulphur in more complex fuel systems, leads to highly significant changes of the flame chemistry. In this context, the reaction of atomic sulphur with hydrocarbons seems to be important.

A flame may regarded as a weak plasma as a result of highly energetic chemical reactions, e.g. between the parent methylidyne (CH) and atomic oxygen. This reaction leads to a highly excited formyl radical and subsequently, by expulsion of an electron, to the formyl cation. Proton transfer from the latter to other flame constituents gives rise to a large number of ions. In sulphur-rich flames an abundant m/z 59, $C_2H_3S^+$, which previously has been assigned to protonated thioketene has received attention [1].

The application of tandem mass spectrometry (triple quadrupole - Q³) to chemi-ions based on supersonic molecular beam sampling (MB) has previously been demonstrated. This methodology (MB-Q³) gives unique possibilities for studying reactivities and structures of chemi-ions [2-5].

Gas phase ion/molecule reactions of acylium ions have been compared with those of relevant isomeric species. In particular a polar [4+2⁺] Diels-Alder cycloaddition with isoprene as well as a formal oxirane addition with 1,3-dioxolanes were found useful in distinguishing acylium ions from isomeric counterparts, e.g. the heteroatom protonated species [6-8].

In line with the previous studies on the $C_2H_3O^+$ chemi-ion [5], ion/molecule reactions were used to disclose the identity of the $C_2H_3S^+$ species. The reactions of appropriate reference structures with 2-methyl-1,3-dioxolane were studied on a Q³ mass spectrometer [9]. The reaction of C2-protonated thioketene leads to 2-methyl-1,3-thiolanylium ion, whereas the reaction of S-protonated thioketene results in simple proton-/hydride transfers (m/z 87 and m/z 89). In Figure 1 the ion distribution following reaction of the $C_2H_3S^+$ chemi-ion with 2-methyl-1,3-dioxolane using the MB-Q³ setup is shown. The high yield of the adduct (m/z 103) indicates that the $C_2H_3S^+$ chemi-ion sampled directly from sulphur-rich flames predominantly is the thioacetyl cation.

Figure 1. Ion/molecule reactions of the $C_2H_3S^+$ chemi-ion with 2-methyl-1,3-dioxolane.

The $C_2H_3S^+$ system was studied by ab initio molecular orbital calculations by using the Gaussian94 program. The ionic structures were optimized at the restricted Hartree-Fock level of theory employing the polarization 6-311 G(d,p) level and by incorporating valence electron correlations calculated by second-order Møller-Plesset perturbation theory. The calculations predict the thioacetyl cation as the thermodynamically favoured by 33.1 kcal/mol relative to the S-protonated isomer. The isomerization of the thioacetyl cation to S-protonated thioketene may take place either via a 1,3-hydrogen shift or by two consecutive 1,2-hydrogen shifts with critical energies of 110 and 81 kcal/mol, respectively. Thus, taking into account the highly efficient thermal quenching (10^9 K/s) it is not likely, that relaxation plays a significant role. In sum, it can be concluded that the protonation of thioketene at the flame temperature takes place at the C2-carbon.

Gas phase ion/molecule reactions offer a powerful tool to elucidate the structures of isolated gaseous ions, or neutral molecules from which they are derived. It was recently reported that many acylium ions react with dioxolanes leading to the formation of cyclic, resonance stabilized dioxolanylium ions.¹ The reaction (Scheme) was named as oxirane addition for the analogy that can be drawn with a solution reaction invoking oxirane addition to carbonyl compounds. Oxirane addition can serve as a general method for identification and/or trapping of ions of the whole acylium ion class and also for the gas phase generation of the dioxolanylium ions. This reaction was also shown to occur for sulfinyl cations,² and to take place under acetone and 3-pentanone chemical ionization conditions, being useful for the CI characterization of 1,3-dioxolanes and their sulfur analogues.³ In this work, the generality of the oxirane addition was studied *via* MS² and MS³ experiments in order to find out if the reaction can also serve as a general, structurally diagnostic ion/molecule reaction for 1,3-dioxolanes and related compounds. In addition, the effect of heteroatoms and the reaction site with compounds having two different heteroatoms were studied using several O,S- and S,S-heterocycles. The reactions were carried out with mass-selected acylium ions in the reaction quadrupole of a pentaquadrupole mass spectrometer.⁴ *Ab initio* molecular orbital calculations (MP2/6-31G(d,p) + ZPE) were used to verify the thermodynamically most favorable products and the site of addition (ion affinity) in the oxirane addition.

The results show that the oxirane addition occurs predominantly for 1,3-oxathiolane *via* initial attack at the sulfur atom, thus indicating that the ion affinity at the sulfur atom is greater than that at the oxygen atom. They also show that the overall reactivity drops sharply when the oxygens are replaced by sulfur atoms, therefore the 1,3-O,S and particularly the 1,3-S,S-heterocycles are much less reactive than the 1,3-O,O-analogues. Several acylium ions show similar tendency to react predominantly but modestly at the sulfur atom.

The nature and the site of the substituents in the 1,3-dioxolane ring affect considerably the extent of the reaction. For example, charge stabilizing groups in the 2-position favor the reaction most likely by assisting the ring opening process (Scheme), and this effect is particularly clear for the phenyl group (Figure 1). On the other hand,

substitution by a methoxy group decreases the amount of the oxirane addition and the proton transfer reaction becomes predominant.

The oxirane reaction was also shown to be structurally diagnostic for 1,3-O,O-heterocycles and 1,3-O,S-heterocycles. For instance, both differently substituted 1,3-dioxolanes and 1,3-dioxanes (Figure 2) react with acylium ions giving rise to the dioxolanylium ions, instead 1,4-dioxane does not show any oxirane addition products at all.

Ab initio calculations confirm the greater acetyl cation affinity of 1,3-oxathiolane at the sulfur atom as shown in Figure 3. The calculations also indicate that the dioxolanylium ions are the most stable products of the oxirane addition reaction.

Oxygen Exchange in the Formaldehyd-Water Proton Bound Dimer

G. van der Rest, J. Fossey, P. Mourgues, H.-E. Audier

DCMR URA CNRS 1307, Ecole Polytechnique, 91128 Palaiseau Cedex, France

Introduction In the gas-phase, ethanol radical cation reacts with water leading among other things to a proton-bridged dimer between formaldehyd and water¹. These reactions were studied using FT-ICR techniques described therein.

Experimental Results By reaction of $\text{CH}_3\text{CH}_2\text{OH}^{+\bullet}$ with water labelled by oxygen eighteen (written H_2^{18}O in the following) $\text{H}_2\text{COH}^+ \cdots {}^*\text{OH}_2$ ion is formed. Collisionnally induced dissociation shows the eighteen oxygen to belong exclusively to the water part of the dimer. A slow further reaction leads to $\text{H}_2\text{C}^+\text{OH}^+ \cdots {}^*\text{OH}_2$, although protonated formaldehyd does not undergo a similar oxygen exchange with labelled water. The O-exchange is thus a specific reaction of the dimer.

A first possible mechanism occurs through simple oxygen exchange in the PBD followed by further fast exchange of the water part of the dimer. This pathway involves an intermediate 4-center transition state (TS2) which MO calculations at MP2/6-31G** level have shown to be energetically impossible (+30,7 kcal/mol).

A second mechanism was devised, in which an other water molecule was involved. This pathway is energetically possible due to the great complexation energy of the second water molecule and also to the ease of hydrogen transfer in the critical step (TS5).

¹Audier H.-E., Fossey J., Mourgues P., McMahon T.B., Hammerum S., submitted for publication

Conclusion When both mechanisms are compared, it can be noticed that the second one is related to the first one by adding a water molecule to each intermediate or transition state. This solvation strongly decreases the energy of the intermediates, particularly that of the barriers, and therefore makes possible the different steps of the process.

The $\text{CH}_3\text{OH}^+/\text{H}_2\text{O}$ and $\text{CH}_3\text{CH}_2\text{OH}^+/\text{H}_2\text{O}$ systems : a M. O. study

J. Fossey, F. Dahanni, P. Mourgues, H. E. Audier
URA CNRS 1307, Ecole Polytechnique, F-91128 Palaiseau cedex

It is well known that the unimolecular isomerization of the methanol radical cation to its α -distonic ion is impossible since a high energy barrier separates both isomers.

However, it has been recently shown by experiment that water can catalyze this isomerization in the gas phase (1). $[\text{CH}_3\text{OH}^+, \text{H}_2\text{O}] \rightleftharpoons [\text{CH}_2\text{OH}_2^+, \text{H}_2\text{O}]$

The $\text{CH}_3\text{OH}^+/\text{H}_2\text{O}$ system

This system has been calculated by our group and by L. Radom et al (2). In this work, calculations were performed at G2MP2 level. They indicate that the interaction between CH_3OH^+ ions and a water molecule leads to three stable complexes depending on the bonding site of H_2O which can be:

- i/ the hydroxylic hydrogen of CH_3OH^+ in order to yield a $[\text{CH}_3\text{O}^+ \dots \text{H}^+ \dots \text{OH}_2]$ (complex I);
- ii/ the C-Hydrogen of CH_3OH^+ in order to give a complex II $[\text{OH}_3^+ \dots \text{CH}_2\text{OH}]$;
- iii/ the hydroxylic hydrogen of CH_2OH_2^+ in order to yield a $[\text{CH}_2\text{OH}^+ \dots \text{H}^+ \dots \text{OH}_2]$ (complex III).

Isomerization between complexes II and III goes through two transition structures while isomerization between complexes I and II requires a transition structure of higher energy. Complex III decomposes into CH_2OH_2^+ and water.

The $\text{CH}_3\text{CH}_2\text{OH}^+/\text{H}_2\text{O}$ system

Similarly the reaction of $\text{CH}_3\text{CH}_2\text{OH}^+$ with H_2O yields also to the three complexes I to III similar to those shown in Scheme I.

The main difference with the $[\text{CH}_4\text{O}^+, \text{H}_2\text{O}]$ is that the reaction also yields a methyl radical loss with formation of a $[\text{CH}_2\text{OH}^+ \dots \text{OH}_2]$ product ion (3).

The reaction of the $\text{CH}_3\text{CD}_2\text{OH}$ radical cation with water highlights the presence of two reaction channels. One, involving a rapid exchange of the hydroxylic H and one α -H may be explained by the formation of II followed by its reversible isomerization into III. The other, involving a methyl expulsion is not preceded by H/D exchange and comes from a simple cleavage of I.

Therefore experiment and calculation indicate that a significant energy barrier separates I and II.

Fluorine Substitution Enhances the Reactivity of Substituted Phenyl Radicals Toward Organic Hydrogen Atom Donors

Ruomei Li, Rebecca L. Smith and Hilkka I. Kenttämä^a

Department of Chemistry, Purdue University, West Lafayette, IN 47907

Hydrogen atom abstraction by polyatomic radicals plays an important role in many chemical and biological processes. However, the factors that control these hydrogen atom abstraction reactions are not well understood. Phenyl radicals with different positively charged, chemically inert substituents in the para-position (a-e) were generated by collision-activated dissociation of para-substituted iodobenzene ions in the gas phase inside a FTICR and their reactivity was examined toward several organic hydrogen atom donors. The findings parallel those made by others for neutral radicals in solution. For example, the efficiency of hydrogen atom abstraction increases in the expected order phenol < thiophenol < benzeneselenol. In spite of great exothermicity, hydrogen atom abstraction by the charged phenyl radicals occurs at a small fraction of the gas-phase collision rate, suggesting the presence of a significant energy barrier on the reaction coordinate. Fluorine substitution on the phenyl ring was found to drastically enhance the reaction efficiency for all the substrates studied. For example, hydrogen abstraction from thiophenol by the ion e occurs at 21% of the collision rate while the ion c reacts by hydrogen atom abstraction at less than 0.3% of the collision rate (Table 1). This finding suggests that electron-withdrawing substituents in the radical lead to a significant reactivity enhancement.

The C-H bond dissociation energies calculated at the ROMP2/6-31G*//ROHF/3-21G* + ZPVE level of theory for 3-fluorophenylsulfonium ion and for neutral fluorobenzene suggest that the introduction of a fluorine atom increases the exothermicity of hydrogen atom abstraction reactions. The effect is the same for neutral and charged phenyl radicals.

In order to probe whether a similar rate enhancement is expected for hydrogen atom abstraction from a sugar unit in DNA, a key step in the action of many antitumor drugs, tetrahydrofuran was examined as a simple model for the sugar moiety. This substrate was found to demonstrate even greater sensitivity toward fluorine substitution in the phenyl radical than the other hydrogen atom donors studied (Table 1 and Figure 1). Hence, fluorine substitution is likely to drastically increase the activity of those antitumor drugs whose action is based on DNA cleavage by polyatomic organic radicals.

Distonic Biradical Anions. Synthesis and Characterization of 3,5-Dehydrophenyl and 1,3,5-Trimethylenebenzene Negative Ions

Jun Hu and Robert R. Squires

Department of Chemistry, Purdue University, West Lafayette, IN 47907

We recently developed a regioselective method for producing intense beams of structurally defined biradical negative ions ("distonic radical anions") in a flowing afterglow-triple quadrupole instrument.¹ This synthetic procedure has been used to generate trimethylenemethane anion and the *m*- and *p*-benzyl anions for use in negative ion photoelectron spectroscopic measurements of the electron affinity and singlet-triplet splittings in the corresponding neutral biradicals.² We have now extended this procedure to the rational synthesis of triradicals negative ions ("distonic biradical anions"). Here we report the synthesis and characterization of 3,5-dehydrophenyl anion, **1**, and 1,3,5-trimethylenebenzene anion, **2**.

Organic polyradicals are of fundamental interest for understanding ferromagnetic coupling, Jahn-Teller effects, and electron delocalization in open-shell molecules.³ They are also interesting building blocks for designing organic ferromagnets.⁴ Our synthesis provides a means to examine the properties and reactivity of distonic biradical ions and neutral triradicals using gas-phase ion techniques. Moreover, negative ion photoelectron measurements can be carried out with these species to determine doublet-quartet splittings in the corresponding hydrocarbon triradicals. These important physical quantities are unknown at present.

The gas-phase syntheses of **1** and **2** involve sequential desilylation of the corresponding *tris*-trimethyl-substituted hydrocarbons. Thus, reaction between F[•] and 1,3,5-*tris*-(trimethylsilyl)benzene produces the *bis*-(trimethylsilyl)phenyl anion which, upon further reactions with F₂ (added as 5% mixture in helium), yields the monosilylated (*meta*) benzyne radical anion and the fully-desilylated carbanion C₆H₃⁻ ion **1** (Scheme 1). Similarly, high yields of 1,3,5-trimethylenebenzene anion **2** can be obtained from 1,3,5-*tris*-(trimethylsilylmethyl)benzene.

The reactivity of the two ions has been probed with a variety of neutral reagents such as CO₂, CS₂, NO, NO₂, SO₂, O₂ and *t*-butyl alcohol. The observed reactivity of the two ions is consistent with the assigned structures. Radical-type reactions of **1** and its derivatives are not observed, suggesting

Scheme 1

singlet ground states, whereas characteristic radical-type reactions of **2** suggest a triplet ground state. Electron affinities of 1,3,5-trimethylenebenzene, 3,5-dimethylenetoluene and mesityl radical have been measured using the kinetic method.⁵ The electronic structures of **1** and **2** have also been investigated with *ab initio* molecular orbital theory. Preliminary results support the inferences from the reaction chemistry, i.e., a singlet ground state for **1** and a triplet ground state for **2**.

The Brønsted Acidity of Simple Aldehyde and Ketone Radical Cations

H.C. Michelle Byrd and Hilka I. Kenttämää, Department of Chemistry,
Purdue University, West Lafayette, Indiana 47907-1393

Radical cations play a significant role as intermediates in organic and biochemical reactions, e.g., oxidation of organic compounds and UV-induced mutagenesis.¹⁻³ The acidity of these intermediates directly influences the outcome of their reactions and is therefore of interest. Gas-phase experiments enable one to learn about the intrinsic acidity of organic radical cations. In this study, the Brønsted acidity of several aldehyde and ketone radical cations, i.e., acetaldehyde, acetone, acrolein, methyl vinyl ketone, benzaldehyde, and acetophenone radical cations, was examined by reacting them with cyclopentanone and pyridine in a Fourier-transform ion cyclotron resonance mass spectrometer.

Reactions were carried out in a dual Extrel FTMS 2001 Fourier-transform ion cyclotron resonance mass spectrometer equipped with a 3 T superconducting solenoid magnet, operated at 2.3 T. The chamber is differentially pumped with a series of turbomolecular and mechanical pumps to baseline pressure of 10^{-9} torr. Neutral reagents were introduced into the cell by a heated batch inlet system and a pulsed valve assembly. Typical nominal sample pressures were $0.6\text{--}1.2 \times 10^{-7}$ torr. Ions were generated by electron ionization or by reactions of ions generated by electron ionization. The desired ion was isolated by ejection of unwanted ions from the mass spectrometer by using a series of tailored inverse Fourier-transform excitation waveforms. The ion of interest was then allowed to react with a neutral reagent as a function of time.

Protonation of cyclopentanone by the radical cations mentioned above is exothermic by more than 21 kJ/mol and hence may be expected to be facile.⁴ All the aldehyde radical cations were found to readily transfer a proton to cyclopentanone. Deuterium labeling studies show that the proton originates from the carbonyl carbon. Although proton transfer is thermodynamically favorable for the ketone radical cation/cyclopentanone systems studied, these radical cations fail to protonate cyclopentanone. Acetone and methyl vinyl ketone react with cyclopentanone by electron transfer, while no reaction was observed between the benzyl methyl ketone radical cation and cyclopentanone. The experimental results indicate that protonation of cyclopentanone is associated with a significant energy barrier.

Ab initio molecular orbital calculations were carried out to compare the transition state energies for protonation of a carbonyl-containing molecule by an aldehyde and a ketone radical cation. Calculations at UHF/6-31G⁺ level predict a difference of 67 kJ/mol for deprotonation of aldehydic versus methyl sites in an acetaldehyde radical cation. Upon deprotonation, the methyl carbon undergoes a dramatic geometric change from tetrahedral to planar.

Reactions with pyridine showed that a stronger base is able to deprotonate the ketone radical cations. Deuterium labeling studies confirmed that both the aldehydic and methyl hydrogens of the acetaldehyde radical cation and the methyl hydrogens of acetone radical cation protonate pyridine.

The experimental and theoretical results obtained suggest that 1) the aldehyde radical cations are stronger Brønsted acids than the corresponding ketone radical cations and 2) the exothermicity of the proton transfer reaction must provide a huge driving force to overcome the

significant energy barrier encountered especially for the ketone radical cations.

The Role of Proton-Bridged Intermediates in Gas-Phase H-D Exchange Reactions

M. Kirk. Green, Eric Gard, Sharron G. Penn and Carlito B. Lebrilla
UC Davis, Davis CA 95616

Earlier studies of gas-phase H/D exchange between CH_3OD and protonated amino acids^{1,2} have been extended to examine the reactions of CH_3OD with a series of protonated diamines, including $\text{NH}_2(\text{CH}_2)_n\text{-NH}_2\text{H}^+$, $n = 2-5$ in an external source Fourier transform mass spectrometer. Gas-phase protonated diamines were produced by fast atom bombardment (FAB) of the corresponding hydrochlorides. For the alkyl diamines, up to five exchanges, corresponding to the proton plus the four amine hydrogens, were observed. Deconvolution of the rates observed indicates that when independent exchange sites are assumed, all exchange sites of the alkyl diamines and lysine react with equal efficiency. Histidine, on the other hand, showed four equally fast exchanges and one much slower exchange. Exchange efficiencies for the first exchange, k/k_{ADO} , varied with the separation between the two amine groups, with 1,4 diaminobutane exhibiting the lowest efficiency, $k/k_{\text{ADO}} = 0.01$, while species at either end of the range studied reacted with efficiencies of about 0.1. For the dialkyl amines and lysine, there is a nearly linear inverse correlation of proton affinity with exchange efficiency.

The effects of arginine, lysine, histidine and proline as protonation sites in peptides were investigated by measuring the H/D exchange rates for singly and doubly protonated bradykinin analogues produced by ESI. All of the singly protonated species exchange very slowly, because the preferred protonation site is arginine. Doubly protonated analogues which have arginine or proline as the second protonation site are more reactive than the singly protonated species, but much less reactive than those whose second protonation site is lysine or histidine.

The ability of lysine and histidine to facilitate exchange is also apparent in multiply-protonated proteins: cytochrome c, with two arginines, 11 lysines and 3 histidines, exchanges rapidly, while lysozyme, with 11 arginines, 6 lysines and one histidine exhibits no measurable exchange reactivity for the lowest nine charge states, and slow, nearly equal, exchange rates for the $^{+}10$ - $^{+}12$ charge states.

PROBING SUBSTITUENT EFFECTS ON THE REACTIVITY OF CHARGED PHENYL RADICALS

Kami K. Thoen, Ruomei Li and Hilkka I. Kenttämäa
Department of Chemistry, Purdue University, W. Lafayette, IN 47907

Distonic radical cations, e.g., ions with spatially separate charge and radical sites, can undergo ionic as well as radical reactions. Distonic ions with chemically inert charge sites react predominantly at the radical site. Hence, charged phenyl radicals are ideal models for the study of gas-phase radical reactions by mass spectrometry. The factors controlling the reactivity of phenyl radicals are of biological importance since these radicals have been found to cleave DNA by hydrogen atom abstraction. This study examines the effects of the size, charge-radical site separation, type of charge site, and the presence of electron-withdrawing and electron-donating substituents on the reactivity of charged phenyl radicals.

*Ips*o-substitution of a halogen atom by a nucleophile in the radical cations of substituted dihalobenzenes, followed by collision-activated cleavage of the carbon-iodine bond, provides a general approach for the gas-phase synthesis of charged phenyl radicals inside a FT-ICR mass spectrometer. This approach was used to form phenyl radicals with various charge sites and substituents. The reactions of the charged phenyl radicals with commonly used spin traps, such as dimethyl disulfide and allyl iodide, were studied and the reaction efficiencies and product distributions were determined.

The reactivity of the radical site is independent of the type of charge site for the phenyl radicals studied. Radicals with phosphorus, sulfur, and nitrogen-centered, coordinatively saturated charge sites were found to show similar reactivity. Further, radicals with pyridinium and 3-fluoropyridinium charge sites react at the same efficiencies. *Ab initio* molecular orbital calculations support these findings. These calculations suggest that charged phenyl radicals effectively model neutral phenyl radicals since they bear nearly identical spin densities at the radical site. However, the charge density at the radical site is greater for the charged phenyl radical than for the neutral phenyl radical.

The placement of a neutral substituent *meta* to the radical site eliminates the

possibility of π -donation to the radical site and restricts the electronic effects to σ -withdrawal. Hence, charged phenyl radicals with the radical site, a neutral substituent and the charge site *meta* to each other were generated. Electron-withdrawing *meta* substituents (F, Cl, Br, and COOH) were found to enhance the reactivity of charged phenyl radicals toward allyl iodide and dimethyl disulfide, presumably due to the decrease in electron density at the radical site. In contrast, electron-donating substituents (CH₃) decrease the reactivity of the charged phenyl radicals.

Phenyl radicals containing a charge site *para* to the radical site and fluorine substituents in various positions were also examined. A single fluorine substituent *ortho* to the radical site dramatically increases the reactivity of the charged phenyl radical; four fluorine substituents further enhance the reactivity toward the spin traps studied. This result is surprising since the ability of the fluorines to π -donate to the radical site was expected to largely counterbalance the σ -withdrawing effects. A charged phenyl radical with a trifluoromethyl substituent *meta* to the radical site showed little reaction rate enhancement. The reasons for the observed fluorine substituent are currently unclear.

The effects of size and shape of the phenyl radical and the proximity of the charge site to the radical site were examined by using phenyl radicals with pyridinium, 3-phenylpyridinium and 4-phenylpyridinium charge sites, as well as a phenyl radical with a pyridinium charge site separated from the phenyl ring that carries the radical site by an additional phenyl ring. The species with the charge site separated from the radical site by one phenyl ring react at approximately the same rate, while the ion with the charge and radical sites separated by two phenyl rings reacts at a significantly slower rate. These results imply that the reactivity of the charged phenyl radicals is controlled by the charge radical site separation and that the size of the ion is relatively insignificant.

THE STRUCTURE OF PROTONATED ANILINE IN THE GAS PHASE

*Michael J. Nold and Chrys Wesdemiotis

Department of Chemistry, The University of Akron, Akron, OH 44325-3601

Neutralization reionization (NR) mass spectrometry has been employed to distinguish N- and C-protonated aniline in the gas phase. By using this method, one can determine an ionic structure by examining the stability and reactivity of the corresponding neutral. According to molecular orbital theory, the NH_2 substituent and the aromatic para carbon, which is the most basic site on the ring, have similar proton affinities, with the amino group being favored by approximately $4\text{--}12\text{ kJ mol}^{-1}$.¹ This is sufficient for the amino group to be the thermodynamically favored site of protonation as in equilibrium experiments. When protonation proceeds under kinetic control, such as by chemical ionization (CI), the protonation site is not necessarily dictated by the proton affinity (PA). The CI-generated protonated aniline has so far been interrogated by several mass spectrometry studies,²⁻⁶ mainly involving collisionally activated dissociation (CAD)²⁻⁴ and ion-molecule reactions.^{5,6} Based on the behavior of deuterated isotopomers, all of these investigations have pointed out that CI generates both tautomers.²⁻⁶

A serious problem in the characterization of the structure of protonated aniline is that N- and C-protonation generate ions that can dissociate similarly making it impossible to distinguish which process took place. N-protonation generates the phenyl ammonium (anilinium) cation; in contrast, C-protonation generates a benzenium cation. Neutralization of N-protonated aniline produces a hypervalent ammonium radical which decays immediately by cleavage of ammonia or a hydrogen radical. On the other hand, neutralization of the ring-protonated form produces a bound amino benzenium radical. Only the benzenium radical can survive intact to yield a "survivor ion" or "recovery peak" at m/z 94. Therefore, the presence of such a peak confirms the presence of benzenium ions and that ring-protonation has taken place. Alternatively, an m/z 17 peak (NH_3^+) identifies N-protonation. Based on the CAD spectrum of protonated aniline, in which NH_3^+ is essentially absent, reionization of the benzenium radical is not expected to generate any measureable NH_3^+ ; m/z 17 is also negligible in the CAD and NR spectra of aniline (a possible dissociation product from both tautomers). Consequently, a significant amount of NH_3^+ can only originate from the anilinium radical, thus serving as a signature for N-protonation.

TABLE 1. Chemical Ionization of aniline

Reagent	protonating species	PA ^a	Structure indicative products in NR spectrum		
			$[\text{NH}_3^+]$ ^b	$[\text{C}_6\text{H}_8\text{N}^+]$ ^b	$[\text{C}_6\text{H}_8\text{N}^+]:[\text{NH}_3^+]$
CH_4	(CH_5^+)	551	0.0024	0.026	10.8
CH_3OH	$(\text{CH}_3\text{OH}_2^+)$	761	0.0029	0.028	9.7
$\text{C}_2\text{H}_5\text{OH}$	$(\text{C}_2\text{H}_5\text{OH}_2^+)$	788	0.0026	0.024	9.2
$n\text{-C}_3\text{H}_7\text{OH}$	$(n\text{-C}_3\text{H}_7\text{OH}_2^+)$	798	0.0034	0.029	8.5
$i\text{-C}_4\text{H}_{10}$	$(i\text{-C}_4\text{H}_9^+)$	820	0.0034	0.042	12.4
NH_3	(NH_4^+)	854	0.0044	0.033	7.5
FAB			0.0083	0.0058	0.7

^aIn kJ mol^{-1} , from S. G. Lias, J. F. Liebman and R. D. Levin, *J. Phys. Chem. Ref. Data* 13, 695 (1984).

^bRelative to total ion current in NR spectrum using peak areas.

The NR spectrum of fast atom bombardment (FAB) protonated aniline yielded a $\text{C}_6\text{H}_8\text{N}^+ : \text{NH}_3^+$ ratio of 0.7 indicating that N-protonation was predominant. This finding supports the preformation of protonated aniline in the glycerol matrix. The CI reagents studied generated mixtures of both tautomers, consistent with the previous studies, with the ring-protonated species being preferred (see Table 1). Additionally, ring-protonation is favored with increasing exothermicity of protonation.

SYSTEMATIC STUDIES TO TEST THE VALIDITY OF THE MOBILE PROTON MODEL FOR FRAGMENTATION OF PROTONATED PEPTIDES

Ashok R. Dongré[†], Árpád Somogyi[†], Jennifer L. Jones, Vicki H. Wysocki[†], Hari Nair[†]

Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006

[†] Current Address: Department of Chemistry, University of Arizona, Tucson, AZ 85721

Surface-induced dissociation has proved to be an effective ion-activation technique for structure elucidation of peptides (500u-5000u).^{1,2} The combination of electrospray ionization with surface-induced dissociation (ESI/SID) has unveiled new avenues to probe relative energetics and mechanisms of peptide fragmentation. The data obtained by ESI/SID experiments are represented as fragmentation efficiency curves (% fragmentation of a given peptide as a function of laboratory collision energy). These curves are a measure of how easily a protonated peptide fragments in the gas-phase.³ Based on the experimental results and theoretical calculations⁴ a model emerges (*mobile proton model*) where the proton is located at the most basic sites prior to activation, gas-phase activation (SID or CID) leads to mobilization of the proton to less basic sites along the backbone which are then the final fragmenting structures.

To confirm whether proton localization and subsequent proton transfer is being monitored by the experiments mentioned above, selected chemically modified peptides and doubly-protonated peptides were analyzed. Site specific acetylation such as diacetylation (N-terminus and side chain) of peptides containing N-terminal basic amino acid residue (RPPGFSPF and YGGFL) leads to a shift in fragmentation curves to lower onsets, which is consistent with the decreased gas-phase basicity of the peptide. However, in the case of the monoacetylated (only the N-terminus) form, the basic side-chain can still protonate and there is no significant change in basicity which is reflected by the lack of an appreciable change in the onset for fragmentation (Figure 1). Another way to confirm proton transfer is to compare a protonated peptide and the fixed-charge counterpart of the same peptide. Fragmentation efficiency curve for N-terminal fixed-charge leucine enkephalin shifts higher than that observed for protonated leucine enkephalin. The shift is expected since a fixed site of charge requires that fragmentation occur by charge-remote mechanisms which often require higher energy deposition.

Another test to confirm the model would be to study the effect of a second proton to a protonated peptide which contains a basic amino acid residue. Fragmentation efficiency curves for doubly-protonated peptides shift to lower onset energies due to the presence of a second more "mobile" proton. The amount of shift could also be related to the basicity of the other basic sites (e.g., the N-terminal proline of PPGFSPFR is more basic than amide N or O of RPPGFSPF). However, addition of another arginine to PPGFSPFR and RPPGFSPF to yield PPGFSPFRR and RRPPGFSPF respectively, leads to shift in onset energies to considerably higher values (Figure 2). These high onset energies can be attributed to localization of the two protons on the two arginine side-chains.

COMPARISON BETWEEN SID AND THERMAL DECOMPOSITION KINETICS OF PROTONATED PEPTIDES AND THEIR PROTON BOUND DIMERS

Árpád Somogyi, Hari Nair, Ashok R. Dongré, Vicki H. Wysocki
Department of Chemistry, University of Arizona, Tucson, AZ 85721

Michael Mautner (Meot-Ner)
Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006

The relative stability of protonated peptides plays an essential role in the analytical utility of tandem mass spectrometry for sequencing peptides. In addition to their mass spectral fragmentation, a considerable and increasing interest is focused on thermal stability of protonated peptides and their noncovalent complexes.¹⁻⁴ An important advantage of thermal dissociation experiments is that kinetic parameters, such as activation energy (E_a) and Arrhenius A factor, can directly be determined from variable temperature thermal kinetics. These kinetic parameters are related to ion structure and they are fundamental to the understanding of mass spectrometric processes and binding properties of noncovalent complexes.

Recently, unimolecular decomposition of protonated leucine enkephalin and its proton bound dimer by thermal dissociation and surface-induced dissociation have been measured and compared in our laboratory.⁴ By using the Arrhenius parameters of E_a and $\log A$, we evaluated "effective" SID temperatures, from which the internal energy content of the projectile ion can, in principle, be estimated. For leucine enkephalin, both SID and thermal decomposition results are similar with regards to the relative stabilities of the dimer and monomer.

The present work is a continuation of our studies on leucine enkephalin: we report a comparative investigation on the thermal and SID dissociation of protonated pentapeptides: G_5 , A_5 , PA_4 , and KA_4 . In this work, we changed and controlled the temperature of the capillary of the electrospray ionization source. The main results are collected in Tables 1 and 2.

Based on the inflection point energies of ESI/SID fragmentation efficiency curves⁵ (Table 1) two different relationships have been developed for the relative stabilities of monomers and dimers (original and modified MAD SOW equations; see footnote at Table 1; for the original definition, see Ref. 4). These, together with the E_a and $\log A$ values, provided us information on the structure and energy randomization in the proton bound dimers. Thermal dissociation provides better "resolution" for distinguishing relative stabilities of dimers and monomers (Table 2). For example, KA_4 , which contains the most basic amino acid residue (K) of the peptides investigated, forms the least stable dimer but the most stable monomer.

An interesting application of the present results is that, by using a simple model calculation and the "effective" SID temperature related to the inflection point of a given ESI/SID fragmentation efficiency curve, we predicted the internal energy content of protonated G_5 , A_5 , and YGGFL. The ratio of the internal energy/inflection point energy gives the value of the kinetic energy - internal energy (T-V) conversion on the octadecanethiolated self-assembled monolayer surface. The estimated T-V values are: 10 % for protonated G_5 , 13 % for protonated A_5 , and 18.5 % for protonated YGGFL. These values are in good agreement with those reported earlier for smaller projectiles (12-17%).

Table 1 Inflection point energies (eV) of the ESI/SID fragmentation efficiency curves (on an octadecanethiolate surface) and the energy relationship between the fragmentation processes

Influence of "Proton Transfer" on SID Fragmentation of Doubly Protonated Peptides.

Hari Nair, Vicki H Wysocki, Department of Chemistry, University of Arizona, Tucson AZ-85721.

Scott Summerfield and Simon J Gaskell, The Michael Barber Center for Mass Spectrometry, UMIST, Manchester, England.

Peptide dissociation by tandem mass spectrometry is known to be influenced by many factors such as the nature of residues present (basicity),^{1,2} DOF,³ charge state of the precursor ion^{2,4} and the activation and ionization techniques utilized.¹ According to the mobile proton model,^{1,6} energetics of fragmentation leading to the charge directed formation fragment ions would depend primarily on the ease with which a proton can be transferred along the backbone (charge heterogeneity) which in turn could depend on any or all of the factors mentioned above. Recently, Gaskell and co-workers reported⁷ the low energy CID results for a systematic study of a series of doubly protonated peptides which indicated significant influence of charge heterogeneity on the ease of fragmentation. CID of doubly protonated peptides RLCIFSCFR, RLCIFSAFR and RLAIFFSCFR provided very poor fragmentation yields. However, the fragmentation improves significantly upon removal of an Arg residue or oxidation of the cysteine residue(s) to cysteic acid. By removal of an Arg residue, the precursor ion population is expected to be more heterogeneous as one proton may be retained on the Arg side-chain while the other proton is relatively "mobile" and could enhance charge directed dissociation. A significant improvement in the fragmentation was also observed in the CID spectra of the peptide analogs in which the cysteine residues were oxidized. Based on the fragmentation patterns it is suggested that an electrostatic interaction between the cysteic acid side-chain and an Arg residue prevents the Arg from retaining a proton thus making one of the protons "mobile" resulting in enhanced fragmentation.

SID experiments were performed for the same peptides and their oxidized analogs to qualitatively assess the influence of the oxidation of cysteine on the fragmentation of these peptides. To study the relative energetics of fragmentation of oxidized vs. unoxidized cysteine containing peptides, SID fragmentation efficiency curves were obtained and compared. Fragmentation efficiency curves are obtained by plotting the % fragmentation vs. SID collision energies. They provide information regarding the relative ease of fragmentation for the various peptides investigated. SID spectra and fragmentation efficiency curves indicate that oxidation of cysteine residue(s) have a significant impact on the energetics of fragmentation of these peptides. Figure 1 shows 55 eV SID spectra of doubly protonated RLAIFFSCFR and its oxidized analog. At a given SID collision energy, the extent of fragmentation of the unoxidized peptide is much lower compared to that of its oxidized analog. Figure 2 shows the fragmentation efficiency curves obtained for the three peptides and their oxidized analogs. Curves are shifted to lower energies for the peptides containing one oxidized cysteine residue with respect to the peptides containing intact cysteine residues. For the peptide containing two oxidized residues, the curve is shifted even lower in energy, which indicates additional enhancement in the mobility of the ionizing

protons for that peptide with respect to peptides in which one cysteine or no cysteine is oxidized. The fragmentation of unoxidized peptides by SID occurs at higher collision energies (>70eV) providing a series of sequence specific b_n and y_n ions.

Effect of Alkyl Substitution at the Amide Nitrogen on Amide Bond Cleavage: ESI/SID Fragmentation of Substance P and Two Alkylated Analogs.¹

Hari Nair, Arpad Somogyi and Vicki H. Wysocki, Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006, USA. Current Address: University of Arizona, Tucson, AZ 85721

Fragmentation of protonated peptides by low energy tandem mass spectrometry provides partial or complete sequence information. Low energy CID and SID yields series of *b*, *a* and *y* ions among other fragment ions. "The mobile proton model" was developed and is being refined to understand peptide dissociation. According to the mobile proton model,^{2,4} the proton resides at the most basic site in a peptide prior to activation. Upon activation the proton may be transferred from this site to less basic sites depending on the energy requirement for this process. Based on observations of many researchers^{2,4} it is generally concluded that transfer of a proton from an Arg side chain to less basic sites requires more energy than from other basic side chains. However, not all sites on the peptide backbone to which the proton may be transferred lead to fragmentation. *Ab initio* and MNDO bond order calculations⁵ indicate that the amide nitrogen protonated form may be the most plausible fragmenting structure because the amide bond order is lowered significantly (~35%) in such a structure. A typical amide nitrogen is relatively less basic than the other sites in the peptide backbone that can be protonated. The present work was done to obtain experimental evidence for the involvement of amide N-protonated forms in the fragmentation of peptides. A peptide modification, N-alkylation, is expected to alter the basicity of the amide nitrogen. Relevant calculations suggest that alkylating the amide nitrogen could enhance its proton affinity. In order to understand the role of N-alkylation on fragmentation of protonated peptides, we investigated the ESI/SID spectra of doubly protonated substance P (RPKPQQFF-Gly-LM) and two analogs containing N-alkylated residue at the ninth position, namely Sar⁹-substance P (RPKPQQFF-Sar-LM) and Pro⁹-substance P (RPKPQQFF-Pro-LM).

Figure 1 shows 55eV SID spectra of the selected doubly protonated precursors of substance P and its two alkylated analogs. The spectra contain both singly and doubly charged product ions. A comparison of the spectra in the figure and spectra obtained over a range of collision energies indicate that both singly and doubly charged *b₉* ion formation are enhanced in the spectra of the alkylated analogs while the singly charged *b₉* ions are almost completely absent. The relative intensities of *b₈* ions indicates that alkylation significantly enhances the cleavage of the amide bond at that site while the relative intensities of the singly charged *b₈* ions indicate that the amide H one residue away may be involved in the formation of the singly charged *b* series ions. In the formation of doubly charged product ions, the alkylation could enhance the amide N-protonation and could lead to extensive charge directed amide bond cleavage as observed in the spectra of the alkylated analogs. The enhancement of the singly charged *b₈* ions in the spectra of the alkylated analogs may be due to a combination of enhanced proton affinity and increased nucleophilicity that may be important in a possible 1,4 H rearrangement.

AVERAGE ACTIVATION ENERGIES OF LOW-ENERGY FRAGMENTATION PROCESSES OF PROTONATED PEPTIDES DETERMINED BY A NEW APPROACH

Károly Vékey,^a Árpád Somogyi,^b Vicki H. Wysocki^b

^aCentral Research Institute for Chemistry of the Hungarian Academy of Sciences, P. O. Box 17, H-1525 Budapest, Hungary

^bDepartment of Chemistry, University of Arizona, Tucson, AZ 85721, U. S. A.

Mass spectrometric fragmentation of protonated peptides gives important information on their structure. Tandem mass spectrometry has been widely used for sequence determination of peptides, and this has become one of the most important biochemical applications of mass spectrometry. There is, however, little known about the energetics of fragmentation processes of protonated peptides, mainly because of a lack of suitable methods for determination of activation energy (E_a).

The combination of electrospray ionization and surface-induced dissociation (ESI/SID) has recently proved to be a useful method to experimentally determine relative energetics of fragmentation of protonated peptides.¹ The relative positions of ESI/SID fragmentation efficiency curves (percent fragmentation vs. laboratory collision energy) are a good measure how easily singly and/or multiply protonated peptides fragment. As an alternative method, thermal dissociation of protonated peptides has also provided useful qualitative and, in some cases, quantitative data for peptide fragmentation.²⁻⁵ In our laboratory, thermal dissociation of protonated model peptides, such as leucine enkephalin⁴, G_5^5 , A_5^5 and KA_4^5 , and their proton bound dimers has been studied in a heated tube reactor which was attached to, or a part of, an electrospray ion source. In these studies, good correlation was found between the position of electrospray ionization/surface-induced dissociation (ESI/SID) fragmentation efficiency curves¹ and thermal decomposition for the peptides studied. Arrhenius activation energies and A factors were also estimated for fragmentation of the pentapeptides listed above.

In the present work,⁶ an approach has been developed to estimate the average activation energies of selected oligopeptides. In this approach, the characteristic collision energy (E_{chr} , or inflection point energies) of the ESI/SID fragmentation efficiency curves and the kinetic energy - internal energy conversion factor in SID is used to estimate the internal energy of a protonated peptide deposited by the SID ion activation method. (Other internal energy terms originate from thermal excitation in the capillary region and collisional activation in the capillary skimmer region.) Using the internal energy and the "RRKM Large" program,⁷ average activation energy values can be obtained. Four transition state models in RRKM calculations have been tested and compared. (For further details on the approximations, see Reference 6.)

The application of this approach for protonated leucine enkephalin resulted in an average activation energy of 36 ± 5 kcal/mol, which is in good agreement with the value reported by thermal dissociation⁴ (38.3 ± 4 kcal/mol). Results on various small and medium size peptides indicate that the average activation energies of peptide fragmentation fall in a relatively narrow range of 35-47 kcal/mol (see Table 1). The actual value depends on the presence and/or absence of a basic residue and the size of the peptide. Peptides with basic residues have slightly higher (ca. 4-5 kcal/mol) activation energies than those containing no basic residues.

Table 1 Average activation energies^a (E_a , in kcal/mol) for fragmentation reactions of protonated peptides (eV). The degree-of-freedom (DOF) of the protonated peptide, the characteristic collision energy (E_{chr}) of SID fragmentation efficiency curves obtained on an octadecanethiolate surface and the E_{chr} /DOF ratio are also shown. The mean error of the method is estimated to be ± 5 kcal/mol. See Reference 6 for details.

ADDITION OF H, F, AND CH₃ TO SMALL ORGANIC PROJECTILES IN LOW-ENERGY ION-SURFACE COLLISIONS

Árpád Somogyi, Vincent J. Angelico, Vicki H. Wysocki
Department of Chemistry, University of Arizona, Tucson, AZ 85721

Donald D. Shillady
Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006

Several papers¹⁻³ have been published recently describing reactions between low-energy (several 10s of eV) projectile ions, such as benzene, pyridine, acetone, dimethyl sulfoxide, W(CO)₆, and alkanethiolate and fluorinated alkanethiolate self-assembled monolayer surfaces. Different mechanisms have been suggested for these low-energy ion/molecule reactions, including direct charge exchange, multiple additions, and neutralized projectile - sputtered ion reactions occurring in the gas phase.³

In the present study, we investigated whether a concerted mechanism can be operative for H, F, and CH₃ addition reactions. Our related aims are i) to study how Surface-Induced Dissociation (SID) efficiency¹ is related to the recombination energy of the projectile ion, ii) to reveal the reasons for large differences between the SID efficiencies of [benzene]⁺ molecular ion and CH₃⁺ cation, iii) to study whether direct charge exchange between the projectile and the surface is a prerequisite for ion-molecule reactions, and iv) to estimate and compare the energetics of direct neutralization and concerted ion-surface reactions (H, F, and CH₃ additions).

An Extrel 4000 u tandem quadrupole system⁴ is employed in our experiments. A conventional electron ionization (EI) source was used at 70 eV electron energy. CH₃ cations were generated from nitromethane. Octadecanethiolate and 2-(perfluorooctyl)-ethanethiolate self-assembled monolayer surfaces were used.

We modeled selected reactions by using *ab initio* quantum chemical calculations at the MP2 6-31G* level (for systems including methyl cation) and at the HF 6-31G* level (for systems including benzene molecular ion). In the latter case, the UHF formalism was used for the investigated open shell systems.

$X^+ + C_nY_{2n+2}$, where X⁺ represents the molecular ion of benzene or the methyl cation,
Y=H (for alkenethiolate surfaces; n=3, and 4), and
Y=F (for fluorinated alkanethiolate surfaces; n=3)

The distance between the projectile and the surface was varied and the total energy, net charges, bond orders of significant bonds were analyzed as a function of this distance. Different projectile-surface orientations have also been considered. All calculations have been performed by using Gaussian 94.⁵

Simple thermodynamic calculations based on experimental heats of formation suggest that the H or CH₃ addition to the methyl cation is an exothermic process (Figure 1). This is also supported by *ab initio* energetic calculations (MP 6-31G*). In addition, the theoretical calculations also indicate that there is no activation energy for these processes (Figure 2). The unit positive charge of the methyl cation is partially reduced (to ca. 55 %) at a distance where the lengthening

of the appropriate C-H or C-C bond of the chain is maximized. An appreciable amount of methyl cations can, therefore, leave the octadecanethiolate surface in the form of neutral CH₄ or C₂H₆. A direct neutralization (electron transfer) is necessary to reduce the projectile ion beam intensity at the surface.

Depending on the relative orientation of the methyl cation and a fluorinated surface, a concerted F-addition can also be an exothermic process without activation energy. This may explain why the SID efficiency (% of beam not neutralized) of methyl cation is lower (ca. 2 %) on a fluorinated surface than that of benzene (66 %).⁶ Although the CF₃ addition can also be an exothermic reaction, preliminary calculation indicate that this process has an activation energy. This results from the repulsive effect of the lone pair of the fluorine atoms that can reduce the probability of the C-C bond formation.

The addition of H or CH₃ to benzene is predicted to be an endothermic reaction at the HF 6-31G* level. Further calculations are necessary to better predict the barriers for reaction; preliminary results indicate that they could be in the range of 1-1.5 eV (for H addition) and 1.5-2.0 eV (for CH₃) addition.

Microchannel Plate SID Reactions at the Entrance of a r.f.-only Quadrupole.

Yves Mouget and M. J. Bertrand,

Regional Center for Mass Spectrometry, Dept. of Chemistry,
University of Montreal, Montreal, Canada, H3C 3J7.

The use of surfaces as a means of inducing ion dissociation (SID) has been shown to convert a larger and narrower amount of translational energy into internal energy, to improve the control of energy transfer, and to maintain a lower background pressure in the instrument than is the case with gas collision induced dissociation (CID). Microchannel plates (MCP) have recently been introduced as an alternative approach, and results using an in-line MCP equipped collision cell, installed in the third field free region of an EBEQ geometry mass spectrometer, were recently presented [1]. While this previous arrangement allows access to high collision energies, the ESA cannot resolve ions formed at low collision energies (<500 eV). The additional loss of signal encountered with the second deceleration could be avoided by installing a microchannel plate assembly after the decelerating lenses at the entrance to the r.-f.-only quadrupole. The geometry of the normal deceleration lens assembly was modified in order to accommodate a hinged lens upon which the MCP is fastened, allowing the angle of the plate to be changed with respect to the ion beam while the instrument is in operation. The r.-f.-only quadrupole focusses the ions after their interaction with the MCP. The collision energy is determined by the potential of the r.-f.-only quadrupole and can be varied from 10 eV to 500 eV.

As was suggested previously, ions entering a channel in the plate can undergo one or several grazing collisions with the surface. The shallow angle of impact would result in a much lower transfer of kinetic energy to internal energy than is the case with other SID approaches. The internal energy distribution $P_c(E)$ can be approximated with $\text{Fe}(\text{CO})_5$ and tetraethylsilane [2]. The distribution is much wider than is observed for other SID approaches (Fig. 1). However, while a sharp decline is more characteristic of high energy or single low energy collisions, the rise around 5 eV is more characteristic of multiple low energy collisions. While the average internal energy is approximately 3.8 to 4 eV, fragment ions with appearance energies above 10 eV relative to the molecular ion are observed. It is possible for the ions to undergo several glancing collision with interior of a channel, which could lead to a progressive increase in internal energy, or perhaps several consecutive dissociations. The wider $P_c(E)$ would be the result of not all ions undergoing the same number of collisions or acquiring the same internal energy. The possibility that ions with high appearance energies relative to the molecular ion could be formed by consecutive fragmentations, thus lowering their appearance energy, is further supported by the study of the $91^+/92^+$ ion intensity ratio formed from the molecular ion of butylbenzene (m/z 134). Since the fragments are not the result of consecutive fragmentations, they are a better indicator of the maximum internal energy acquired by the molecular ion. Fig. 2 shows the fragment ion spectrum of the molecular ion of butylbenzene, with a collision energy of 250 eV. A ratio of 6 is observed in the spectrum, corresponding to an internal energy of approximately 6.2 eV. Further increases in collision energy had a more profound effect on the sensitivity than on the 91/92 ratio. An internal energy of 6 eV is above the values reported for gas collisions, however far below what has been reported for other SID approaches. It would seem more likely that a fragment ion with a high appearance energy is the result of consecutive collisions alternated by consecutive fragmentations rather than an increase in the internal energy followed by the dissociation of the ion.

Another observation supporting the possibility of multiple collisions is the similarity of certain spectra obtained using this MCP collision cell and spectra obtained using a slanted plate device when similar collision energies are used [3]. Since the collision angle is more important with the slanted plate device by an order of magnitude, the ions could have undergone several collision within a channel in order to acquire similar internal energies and produce a similar fragment ion spectrum. Figure 3 represents the fragment ion spectrum of the peptide leucine-enkephalin obtained with a collision energy of 175 eV. Several A, B and Y series fragments are observed, along with several internal cleavages. These are more frequently associated to lower collision energy reactions, as is the absence of significant side chain reactions.

While it is not possible to attain the collision energies of previous arrangements, sufficient fragmentation is observed, with a greatly improved resolution and transmission efficiency. The internal energy distribution is significantly wider than with other SID approaches, possibly due to the multiple collisions the ions undergo as they pass through the MCP. The resulting spectra are similar to those obtained under multiple gas collision conditions at low collision energies, however, higher internal energies, as well as fragments with high appearance energies are observed.

Probing proton sputtering and related reactions occurring during surface induced dissociation (SID) tandem mass spectrometry (MS/MS) at hydrocarbon surfaces

Lynn M. Manzella-Phelan[†], Mark J. Hayward^{†‡}, and Steven L. Bernasek[†]

[†]Department of Chemistry - Princeton University and

[‡]Agricultural Research Division - American Cyanamid Princeton New Jersey

Low energy (25eV) polyatomic ion/surface collisions were probed using surface induced dissociation (SID) tandem mass spectrometry (MS/MS) of perdeuterated ions colliding with a hydrocarbon covered surface. Characteristic features of the resulting SID spectra include the molecular ion, sputtered ions, associative ion/surface reaction products and fragments of both the molecular ion and associative reaction products. A focus of this work has been to examine the sputtered ion mechanism, which it is postulated that these ion/surface reactions follow (Scheme 1). This mechanism proposes that sputtered protons react with the neutralized incident ions (~90 % of the incident beam) to form the protonated product. A positive aspect of the sputtered ion mechanism is that it is possible to experimentally verify, through the observation of both the sputtered ions and the protonated product ions.

Deuterium labeled compounds have been used to test the sputtered ion mechanism. The primary reason for using perdeuterated organics has been the ability to assign fragments which originate from the molecular ion (denoted as non-protonated fragments) from fragments of the $[M+H]^+$ ion (denoted as protonated fragments.) Additionally, it permits assignment of sputtered ions. It is advantageous to use the relative abundances of the fragment ions as opposed to the molecular ion and the $[M+H]^+$ ion in order to quantitate the extent of protonation. The main reason is that the precision is improved when using the sum of the relative abundances for each fragmentation channel compared to using the M^+ or $[M+H]^+$ ion relative abundances (which are often very small).

Based on the sputtered ion mechanism, the extent of protonation should depend mainly on two known thermodynamic parameters, the ionization potential and the proton affinity of the neutral compound (Scheme 1). The SID spectra of a series of proto- and deuterio- organic ions with a range of proton affinities and ionization potentials were examined. The results indicate that there is a direct correlation between the relative abundance of protonated fragment ions and the enthalpy of protonation. As protonation becomes more favorable the relative abundance of the protonated fragments increases (Figure 1a). Similarly, the relative abundance of non-protonated fragments decreases when protonation becomes more favorable (Figure 1b). The results obtained support a sputtered ion mechanism for the formation of protonated ions upon collision with hydrocarbon surfaces.

Scheme 1: Thermodynamics of the sputtered ion mechanism for proton transfer

^a S refers to the bulk surface. It remains ~ constant over the course of the experiments.

^b The exact value is unknown, however the process should be the same for each of the ions examined and thus so should the ΔH .

^c Proton affinities are defined as the negative of the enthalpy change of the protonation reaction.

Analysis of Kinetic Energy Distributions During Surface-Induced Dissociation

Samuel B. Wainhaus, Hanjo Lim, David Schultz, and Luke Hanley
University of Illinois at Chicago
Department of Chemistry, m/c 111
Chicago, IL 60607-7061

The kinetic energy distribution spectra (KEDS) of fragment ions produced during surface-induced dissociation (SID) can be used to provide detailed information regarding the SID process. This includes a better understanding of the collision dynamics, and a quantitative measure of the energy transfer to the surface. These in turn are useful in developing SID as a viable analytical technique for tandem mass spectrometry.

The trimethyl silyl ion (SiMe_3^+) was used as the projectile in these experiments. Three different surfaces were examined to probe the effect of surface composition on the SID MS and KEDS: clean Au(111), hexanethiolate covered Au(111) (C_6), and NiO(111). SiMe_3^+ is unique in that it fragments by both sequential methyl elimination as well as a more complex rearrangement. Additionally, hydrocarbon potential functions are readily available for the $\text{SiMe}_3^+/\text{C}_6$ system which are currently being used to perform trajectory calculations. The experiments were performed using a tandem quadrupole instrument coupled to an ultrahigh vacuum surface analysis chamber.

20 to 70 eV SiMe_3^+ was scattered off the three aforementioned surfaces and the SID MS and KEDS were measured as a function of energy for each surface. The KEDS for 30 eV SiMe_3^+ using clean Au(111) is shown in Figure 1. The fragments have similar velocities and the energy of each fragment at a given energy is directly proportional to the incident ion energy. This implies that the collision is fairly elastic. This is in stark contrast to C_6 and NiO(111) (not shown) where the fragments have similar energies and are not affected by the incident ion energy, implying a highly inelastic collision. The timescale for dissociation by both mechanisms is the same since the KEDS for the SiCD_3^+ and $\text{Si}(\text{CD}_3)\text{D}_2^+$ fragments are similar. The amount of neutralization on clean Au(111) was less than the other two surfaces.

The energy resolved mass spectra (ERMS) for clean Au(111) and C_6 (not shown) clearly indicate that the kinetic to internal energy transfer is much greater for clean Au(111). This is supported by the KEDS for both surfaces. The ERMS are used to measure the internal energy of the parent ion imparted by the collision event (E_{int}).

The KEDS data is used to calculate the energy transfer to the surface (E_{surf}) for clean Au(111) and C_6 (Figure 2). This is done by conservation of energy for the parent ion: $E_i = E_f + E_{\text{int}} + E_{\text{surf}}$ where E_i is the incident ion energy, E_f is the kinetic energy of the parent ion after the collision event, and E_{int} is defined above. The results provide a functional form for E_{surf} versus E_i . E_{surf} for clean Au(111) is greater than C_6 by more than a factor of two. This functional form for E_{surf} will soon be compared with results from trajectory calculations and is a key part of current efforts to extract thermochemical information from SID data.

Thermochemical Measurements with Surface-Induced Dissociation

Samuel B. Wainhaus, Eric A. Gislason and Luke Hanley
University of Illinois at Chicago
Department of Chemistry, m/c 111
Chicago, IL 60607-7061

It has been shown that surface-induced dissociation (SID) can be effectively used to fragment ions in tandem mass spectrometry. We have begun an effort to use SID to extract thermochemical information such as fragmentation energies for polyatomic ions. We have developed a model which is conceptually similar to that used for threshold analysis in gas phase collision induced dissociation (CID) to calculate the fragmentation energy for $\text{Cr}(\text{CO})_6^+$ scattered off hexanethiolate and heptafluorobutyrate covered Ag(111) (H-SAM and F-SAM respectively). This model should be applicable to any polyatomic ion for which one can collect accurate energy resolved mass spectra (ERMS) and kinetic energy distribution spectra (KEDS).

CID has been used to obtain accurate fragmentation energies for a variety of small polyatomic ions [1]. However, RRKM effects become important as the size of the molecule increases. SID has been shown to effectively dissociate large ions at low collision energies. Due to its unique collision dynamics, SID may partially alleviate the RRKM problem and permit the measurement of thermochemical data for large ions.

Data Analysis Method

The SID cross section (Q_{sid}) is shown below for three energy regions:

$$\begin{aligned} Q_{\text{sid}} &= 0 && \text{if } E_{\text{rel}} < A \\ Q_{\text{sid}} &= (E_{\text{rel}} - A)^{n+1} / [(n+1)B^{n+1}E_{\text{rel}}] && \text{if } A \leq E_{\text{rel}} \leq A+B \\ Q_{\text{sid}} &= [E_{\text{rel}} - A - (n/n+1)B] / E_{\text{rel}} && \text{if } A+B < E_{\text{rel}} \end{aligned}$$

$$\text{where } E_{\text{rel}} = E_i - E_{\text{surf}}$$

E_i = ion beam kinetic energy

E_{surf} = energy transfer to the surface

A = fragmentation energy

B = slope

n = constant

E_{surf} is obtained by energy conservation of the parent ion: $E_i = E_f + E_{\text{int}} + E_{\text{surf}}$.

E_{int} and E_f are the internal and kinetic energy of the parent ion after collision with the surface. These are measured using ERMS and KEDS data respectively [2].

The ion beam energy spread is included in our analysis and is given by a Gaussian function: $P(E_i, E')$. We then calculate the ion fraction ($F_{\text{calc}}(E')$) for a given E' by integrating over all E_i .

$$F_{\text{calc}}(E') = \int_0^\infty Q_{\text{sid}} \cdot P(E_i, E') \cdot dE_i$$

We finally obtain F_{calc} by a non-linear least squares fit to ERMS data (F_{exp}) in order to get the best value of A and B for a set n .

We have used this model to predict the fragmentation energy for the reaction $\text{Cr}(\text{CO})_6^+ \rightarrow \text{Cr}^+ + 6\text{CO}$ by fitting the model to experimentally determined Cr^+ points as shown in Figure 1. Values ranging from 5 to 7 eV have been reported for this system [1]. We obtain values of ~13 and ~16 eV from the F-SAM and H-SAM respectively, with our SID model. The accuracy of this analysis is currently limited by the insufficient number of data points near threshold. We are currently collecting more extensive data in the hopes of obtaining more accurate fragmentation energies. We are also beginning to use trajectory calculations to predict E_{surf} .

Soft-Landing of Polyatomic Ions at Fluorinated Self-Assembled Monolayer Surfaces

S.A. Miller, H. Luo, and R.G. Cooks

Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

S.J. Pachuta

3M Corporate Research Lab, 201-2S-16 3M Center, St. Paul, MN 55144

Soft-landing is the low energy deposition of intact polyatomic ions at surfaces. This long-sought capability¹ is of interest due to its possible application for creating chemically unique materials. We report soft-landing of various silicon-containing and substituted pyridine ions at fluorinated self-assembled monolayer (F-SAM) surfaces. Experiments were performed on a custom-built, tandem hybrid mass spectrometer of the BEEQ configuration.² Deposition of the soft-landed species was achieved by treating the surface for 1 to 2 hours at low collision energies (< 10 eV) with the chemically and isotopically selected ion. Xenon ion chemical sputtering (60 eV) was used to probe the chemical composition of the surface before and after modification. Independent analysis of modified surfaces was performed by high resolution TOF-SIMS.

The deposition, 'soft-landing', of an intact ion was attempted using ions 1 (*m/z* 116) and 2 (*m/z* 147) at an F-SAM surface (Figure 1). Figure 2 illustrates the 60 eV xenon ion chemical sputtering spectrum of a clean F-SAM surface (a) before and (b) after modification with 1. Liberation of the intact soft-landed species, 1 (*m/z* 116), from the modified surface is observed in Figure 2b. Chemical sputtering experiments show that the deposited projectile remains at the surface for several days when it is kept under vacuum (1×10^{-9} Torr).

A related process, 'dissociative soft-landing', in which dissociation accompanies soft-landing occurs for 3 (*m/z* 181). This ion, which is known from gas phase experiments to fragment very readily, dissociates upon 10 eV collisions at the surface by losing C_2H_4 and leaves the fragment, $C_3H_9Si_2OCl^+$ (*m/z* 153), lodged in the F-SAM surface. Xenon ion chemical sputtering data on a surface treated with 3 and an isotopic variant at *m/z* 183 in a ratio of 1:1 gave the expected 1:1 ratio of the fragments *m/z* 155⁺/153⁺. High resolution TOF-SIMS data confirmed the 1:1 isotopic ratio of *m/z* 155⁺/153⁺ and the mass measurement of the peaks agreed with expected values to within 0.01 Da. Yet another related process, 'reactive soft-landing', occurs when the soft-landed projectile reacts with the surface to form adduct ions. This process was observed when soft-landing radical cations of substituted pyridines. Subsequent xenon ion chemical sputtering revealed the $[M-H]^+$, M^+ , and $[M+H]^+$ product ions in low abundance.

The chemical nature of the soft-landed species was investigated using chemical sputtering as a probe. The collision energy needed for the release of the soft-landed ion coincided with the threshold energy for chemical sputtering. This result indicates that the soft-landed molecule is held tightly by the F-SAM surface but there is no evidence for covalent bonding (no ions due to surface adducts). The possibility of steric interactions being responsible for soft-landing was tested by examining a series of methyl-substituted pyridines and is supported by the fact that at least two methyl groups are required for successful soft-landing.

The charge state of the soft-landed species was also investigated. Xenon is an efficient chemical sputtering reagent because it readily transfers an electron to an F-SAM surface (a nearly resonant process). Ferrocene (*m/z* 186) on the other hand, has a very low ionization energy of 6.75 eV³ and electron transfer with the surface does not occur. However, ferrocene does sputter the soft-landed species, providing evidence that the soft-landed molecule is charged, viz., exists as a matrix-isolated cation. Spectroscopic evidence is being sought on this point. Note that an ion should be stable provided it is kept a sufficient distance from a metal surface to minimize electron transfer (stabilization of the charged ion is achieved by an offsetting image potential in the metal surface^{4,5}). The F-SAM surfaces used in this work can, from 3D modeling calculations⁶, trap intact ions at distances of 10 - 15 Å from the surface. Molecular ions, isolated in monolayer matrices, are of interest in connection with their electronic and surface spectroscopic properties.

Blackbody Infrared Radiative Dissociation: Binding Energies of Non-Covalent Biomolecule Complexes in the Gas Phase

Paul D. Schnier, Deborah S. Gross, William D. Price, Yuexing Zhao and Evan R. Williams
Department of Chemistry, University of California, Berkeley, CA 94720

We have recently demonstrated that Arrhenius activation energies for the dissociation of large ions can be measured using blackbody infrared radiative dissociation (BIRD),¹ a technique in which ions are activated through the absorption of blackbody infrared photons generated from the heated chamber walls of a Fourier-transform mass spectrometer. From the temperature dependence of the unimolecular dissociation rate constants, Arrhenius activation energies can be obtained. Here we demonstrate the applicability of BIRD to probe both the primary and tertiary structure of large ions as well as the gas-phase specificity of non-covalent complexes.

Salt Bridges in the Gas Phase: Zwitterions play a critical role in the structure and function of biological systems. Despite the prevalence of these structures in solution, calculations² and experiments³ have shown that zwitterionic forms of small amino acids do not exist in the gas phase. Here, we demonstrate salt bridges do exist in larger gas-phase biomolecules.

Arrhenius activation parameters for bradykinin and a series of its analogues are obtained by measuring the temperature dependence of the unimolecular rate constants for dissociation. The lowest energy dissociation process for singly protonated bradykinin is loss of NH₃ (Figure 1a) with an Arrhenius activation energy (E_a) of 1.3 eV and a frequency factor (A-factor) of 10^{12} s^{-1} . Dissociation of both des-Arg¹ and des-Arg⁹ bradykinin yield b₂ and/or y₆ as well as loss of H₂O (Figure 1b, 1c); no loss of NH₃ is observed. For the 11 analogues studied, only those which have arginine on both the N and C terminus lose NH₃. This indicates that both arginine residues must interact for the molecule to lose ammonia. Proton bound arginine dimers also lose NH₃, consistent with this conclusion.

The C-terminal methyl ester of bradykinin (which eliminates the possibility of interactions with this group through a salt bridge) does not lose significant amounts of NH₃, loss of methanol is the primary dissociation channel. This ion has an $E_a = 0.6 \text{ eV}$, 0.7 eV below that of bradykinin. This indicates that blocking the C-terminal acid destabilizes bradykinin in the gas-phase. This loss of methanol is not simply due to a lower energy dissociation process for the loss of this neutral fragment, since methyl esters of des-Arg¹ and des-Arg⁹ do not lose methanol, and both have activation energies 0.1 eV higher than their unmethylated counterparts. These results indicate that the two arginine residues in singly protonated bradykinin interact with the C-terminal carboxylic acid through a salt-bridge structure in the gas phase. Similar experiments on individual charge states of the protein ubiquitin indicate that salt-bridge structures play a role in larger gas-phase protein ions as well.

Binding Specificity of Non-Covalent Complexes in the Gas Phase: Mass spectrometry has been increasingly used to characterize non-covalent complexes of large biological molecules in the gas phase. In many cases, the abundances in the mass spectrum appear to be an accurate indication of relative binding energies in solution. A key question is whether these specific interactions are retained in the gas phase.

We have used BIRD to probe the dissociation of heme from individual charge states of two proteins with similar heme binding sites, myoglobin and the α -chain of hemoglobin. A comparison of the rates of heme loss from these proteins, electrosprayed from water(80%)/methanol(20%) solutions, shows that gas-phase hemoglobin α -chain ions (9+) consistently lose heme faster than myoglobin (9+), over the temperature range studied (Figure 2). In solution at pH = 5.5, the rate constants for heme loss from myoglobin and hemoglobin α -chain follow the same trend, with rate constants of 0.1 and 1.0 hr⁻¹, respectively.⁴ Both in the gas phase and in solution, these proteins have similar activation energies for heme

loss. This shows that the relative solution phase binding affinities for these non-covalent complexes are the same in the gas phase.

In addition, the loss of heme from myoglobin ions electrosprayed from a solution in which it is in its native conformation (water(80%)/methanol(20%)) and an acidic solution (water(50%)/methanol(50%)/acetic acid(0.1%)) was compared. Myoglobin in the acidic solution has lost ~50% of its secondary structure and the proximal histidine residue is protonated, disrupting the heme binding interaction.⁵ The rate of heme dissociation is similar for all charge states in each solution. The Arrhenius activation parameters measured for the 9+ - 12+ charge states of myoglobin electrosprayed from both solutions are given in Table 1. All charge states electrosprayed from the water/methanol solution have similar E_a 's and A-factors, suggesting similar binding of heme to each of these ions. However, ions electrosprayed from the acidic solution have dramatically lower E_a 's than the same charge state from the water/methanol solution. This lowering of the E_a for removal of the heme indicates that the ions from the acidic solution bind the heme less tightly, indicating a more unfolded conformation. These results show that these gas-phase ions retain memory of their solution phase conformations, and these differences can be probed using BIRD.

ENRICHMENT AND CHARACTERIZATION OF THE NOBLE GAS FULLERENE Ar@C₆₀*

Robert Hettich, Barbara DiCamillo, Robert Compton, and Georges Guiochon
Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6365

Fullerene molecules are capable of encapsulating atoms inside the hollow carbon cage through endohedral chemical bonding or physical trapping. Rare-gas endohedral fullerenes can be synthesized by using high pressure, high temperature conditions (Saunders, et al. *J. Amer. Chem. Soc.* (1994), **116**, 2193). Unfortunately, these methods yield rare gas endohedral fullerenes in extremely low amounts ($\leq 0.1\%$). Further progress in the characterization of these novel compounds would be greatly enhanced by their isolation from the parent fullerenes. Simple calculations of the van der Waals size suggest that the inner π -electron distribution would be slightly pushed outward for Ar@C₆₀. This observation along with the increased mass of Ar@C₆₀ relative to C₆₀ itself indicates that HPLC may be useful for separating endohedral fullerenes.

The objective of this research was to purify and characterize the noble gas endohedral fullerene Ar@C₆₀. The approach to accomplish this goal was twofold: 1) develop HPLC conditions for purification of Ar@C₆₀ from empty fullerenes C₆₀, and 2) use laser desorption FTICR to help optimize the HPLC conditions for purification and to examine the properties of this noble gas endohedral fullerene. In particular, the latter work involves comparing laser-induced dissociation with collisional dissociation to investigate fragmentation differences, and studying charge exchange reactions to bracket the ionization potential of Ar@C₆₀ to determine how an endohedral argon atom alters ionic properties of C₆₀.

Samples of endohedral Ar@C₆₀ were generated at Yale University by M. Saunders, et al. by exposing purified C₆₀ to argon at high pressure (15,000 psi) and high temperature (600-620 °C) for several hours. This sample was dissolved in toluene and injected into a Hewlett-Packard HP-1090 liquid chromatograph equipped with a diode array detector (330 nm). A 2-(1-pyrenyl)-ethylidylated silica column was used as the stationary phase. Mass spectra were obtained with a Finnigan FTMS-2000 Fourier transform ion cyclotron resonance mass spectrometer equipped with a SpectraPhysics DCR-11 pulsed Nd YAG laser (355 nm).

Positive ion laser desorption FTICR of the starting material (i.e. C₆₀ fullerene soot with ~0.1% Ar@C₆₀) reveals primarily C₆₀⁺. Ar@C₆₀⁺ could only be observed for this sample when the more abundant ions of C₆₀⁺ and C₇₀⁺ were ejected prior to detection. Injection of the endohedral fullerene sample into the HPLC yielded primarily one peak at $t_r = 5.4$ min, which is C₆₀. Fourteen fractions, each one with a width of 0.4 min., were collected from this chromatogram in the $t_r = 4.9$ -10.5 min. window. While the amount of Ar@C₆₀ observed by mass spectrometry was very low in any sample, this component was only observed in the fractions with $t_r = 5.7$ -6.1 min., which is slightly displaced from the C₆₀ peak at 5.4 min. Because of the relatively poor chromatographic separation, the experimental approach chosen consisted of sequential fraction collection and reinjection. Mass spectrometry was used to evaluate subsequent fractions.

An HPLC fraction corresponding to the 5.7-6.1 min. region of the initial HPLC chromatogram was collected and reinjected into the HPLC. Collection of the 5.7-6.1 min. fraction from this run yielded a sample which contained a substantial amount of Ar@C₆₀ with respect to C₆₀. In fact, the Ar@C₆₀⁺ ion was easily observable in the mass spectrum even without ejecting the C₆₀⁺, representing an enrichment of Ar@C₆₀ in this HPLC fraction by a factor of 400 relative to its concentration in the starting material.

Laser-induced dissociation of Ar@C₆₀⁺ was studied by increasing the fluence of the desorption laser to about 10⁷ W/cm². To examine the Ar@C₆₀⁺ ion (m/z 760), the C₆₀⁺ ion must be ejected prior to ion detection. Note that laser-induced dissociation results in sequential loss of C₂ to generate Ar@C₅₈⁺ and Ar@C₅₆⁺, as shown in Figure 1a. Empty fullerenes at C₅₈⁺ and C₅₆⁺ are also observed, and may result either by sequential loss of (C₂ + Ar) from the parent Ar@C₆₀⁺ or may be generated by C₂ losses from the C₆₀⁺ before it is ejected from the FTICR cell.

Collision-induced dissociation was accomplished by accelerating the isolated Ar@C₆₀⁺ ion via sustained off-resonance irradiation (SORI) into argon as a collision gas ($E_{\text{com}} = 5$ eV). This low energy, multiple-collision process reveals C₅₈⁺ as the primary fragment product, as shown in Figure 1b. Note that C₆₀⁺, Ar@C₅₈⁺, and Ar@C₅₆⁺ are not observed (a small amount of these components may be present in the background). For comparison, high energy, single-collision experiments on a sector instrument reveal sequential C₂ and Ar losses (Giblin, Gross, et al. *Proc 42nd ASMS Conf.*, ASMS Publishing, Santa Fe, NM, 1994, p. 584).

These dissociation differences may be due to the manner in which the excitation energy is added to the ion. The laser-induced fragmentation is a multiphoton absorption process in which the energy is rapidly added via electronic excitation followed by internal conversion into rotations and vibrations. For the collisional dissociation, the energy is added via multiple low-energy collisions until a threshold for dissociation is achieved, providing substantial time for energy randomization and ion rearrangement to occur prior to dissociation.

Carbohydrate Analysis Using Electrospray/Photodissociation in the Quadrupole Ion Trap

Stephen M Boué, James L. Stephenson, and Richard A. Yost

Department of Chemistry, University of Florida, Gainesville, FL 32611

Carbohydrates have long been recognized for their roles as structural materials and sources of energy, but recently the accumulating evidence suggests that carbohydrates are primary markers for cell recognition. In order to determine their biological function, improvements are needed in the analytical methodologies for the determination of carbohydrate structure. Recently, infrared photo-induced dissociation (PID) has developed into an effective alternative to collision-induced dissociation (CID) within the ion trap for the activation of carbohydrate ions. This presentation will examine some of the operational parameters of PID in the ion trap using several carbohydrates as chemical probes.

PID experiments were conducted using both continuous-wave (cw) and pulsed CO₂ lasers. In order for PID to occur, the rate of photon absorption must be faster than the rate of collisional deactivation. To overcome collisional cooling, helium was introduced into the ion trap only during ion injection using a pulse valve and pumped away before laser firing. Before conducting PID experiments, the effect of a short pulse of helium on the trapping efficiency of injected ions was investigated. Figure 1 shows a plot of ion intensity versus pulse width (time pulse valve is open) for caffeine and the peptide MRFA.

In addition to the complete fragmentation of oligosaccharides, PID can also selectively cleave sugar moieties from the aglycone units of antibiotics. Figure 2 shows a comparison between pulsed and cw IR PID for erythromycin. Using 5 laser pulses and an irradiation time of 100 ms produces similar results. The ions at m/z 698 and m/z 716 detail the loss of neutral H₂O. The ion ($M+H-158$)⁺ at m/z 576 occurs due the loss of a single monosaccharide unit. Preliminary data suggests that L-Cladinose is preferentially cleaved and further experiments are necessary to verify this phenomenon. Further losses of neutral water are detailed by the ions at m/z 558, m/z 540, and m/z 522. The ion at m/z 158 is due to the protonation and cleavage of the D-Desosamine residue.

A comparison between CID and PID for the protonated adduct of erythromycin is shown in Figure 3. For efficient CID of erythromycin at m/z 734, a high RF level ($q = 0.3$) is necessary. At this RF level, very few fragment ions below a m/z 250 remain stable inside the ion trap before detection. However, the PID process is independent of a given ion's secular frequency. Typical values of q during IRMPD are between 0.07 - 0.2, which enables the trapping of lower mass fragment ions.

Figure 4 shows the PID spectrum of the ($M+H$)⁺ of the peptide antibiotic vancomycin using a cw laser with an irradiation time of 450 ms. Successive cleavage of both sugar moieties gives the ions at m/z 1306 and m/z 1144. A fragment ion of low intensity at m/z 1333 occurs due to the sequential loss of the covalently linked N-methyl-D-leucine residue and ammonia from the protonated vancomycin.

For the structural elucidation of carbohydrates, IR photo-induced dissociation of electrosprayed ions inside the quadrupole ion trap is an effective alternative to collision-induced dissociation for MS/MS experiments. When compared with CID, PID provides more fragmentation information within the quadrupole ion trap due to the lower RF levels during ion activation. Also, PID allows full control of the energy deposited during MS/MS experiments (easily vary number of pulses or irradiation time). For carbohydrate antibiotics, PID can deposit just enough energy to break the weaker glycosidic bonds without disrupting the aglycone core.

A Step on the Road to Rationalization of Photo-Induced Dissociation (PID) Mass Spectra

Tina A. Erickson, Douglas J. Beussman, and Christie G. Enke

Department of Chemistry, University of New Mexico, Albuquerque, NM, 87131

As photo-induced dissociation (PID) emerges as a potentially practical method of ion fragmentation for commercial tandem mass spectrometry, the ability to interpret the resultant product spectra is increasingly important. Mass spectral interpretation is aided by rationalization of the product spectra in terms of presence or absence and relative intensities of mass spectral peaks. This paper focuses on establishing the groundwork for rationalization of spectra resulting from PID at 193 and 248 nm.

In this work, *ab initio* calculations were performed using Gaussian 94¹ Hartree-Fock and CI Singles theory levels were used with the 6-31+G* basis set. Quantum Chemistry Program Exchange (QCPE) program number 151 was used to perform all RRKM kinetics calculations. The experimental data was collected using a home-built tandem time-of-flight mass spectrometer using 193- and 248-nm photons for precursor fragmentation.

We chose a relatively small ion, $C_3H_3^+$, and its fragmentation by subsequent loss of H^+ to m/z 38, 37, and 36 as the focus of this work. Experimental results indicate that this entire process occurs from interaction with only one 193-nm photon. (Figure 1) Geometry optimizations were performed which indicate that the difference in energy between the successive ground state ions was about 5 eV in each case. (Figure 2) However, the reaction barrier for the loss of H^+ from ground state $C_3H_3^+$ to form $C_3H_2^+$ was calculated using *ab initio* and RRKM programs as 12.7 eV. Because the entire reaction takes one photon, the evidence suggests strongly that the formation of m/z 38 from m/z 39 does not proceed via the ground electronic state of $C_3H_3^+$.

It is clear that the methods so far employed are not fully adequate to describe the process observed. Continued studies are planned which will allow improved understanding of the absorption and fragmentation processes occurring during PID at 193 and 248 nm.

Background Reduction in Photodissociation Spectra by Improved Sample Preparation

D. C. Barbacci, R. D. Edmondson, and D.H. Russell, Laboratory for Biological Mass Spectrometry Department of Chemistry, Texas A&M University, College Station, Texas 77843

Introduction

We previously showed the ability to photodissociate (193nm, ArF) MALDI generated peptide ions to provide structurally significant fragment ions. Photofragment ion spectra are obtained by scanning the voltage applied to a two stage reflectron and subtracting the metastable product background. The assignment is complicated because the photofragment spectra is convoluted with MALDI metastable ions. The background subtraction method is further complicated by the instability of the ion current from the conventional dried droplet sample preparation. Therefore, reduction of the abundance of metastable ion signal and increased ion current stability are two key elements in producing high quality photofragment spectra.

Discussion

Sample preparation methods developed in our laboratory (1) showed reduction in metastable ion and uncorrelated ion signals. Figure 1 shows spectra of the $[M+H]^+$ for (a)dried droplet sample preparation and (b)overlay sample preparation. A significant decrease in matrix and metastable product ions is observed when the overlay preparation is used. Signal to noise ratios and resolution increase as well (2).

Ion current stability from shot-to-shot of the desorbing nitrogen laser is improved and at lower fluences. Figures 2a and 2b show sixteen spectra (each spectra is the average of 10 shots) for the dried droplet and overlay methods respectively. From spectrum to spectrum, the overlay method provides for a more consistent ion current. The final few spectra of the dry droplet method show the "hot spot" on the probe.

Addition of two wire ion guides and removal of a number of grids provides increased sensitivity for these experiments (Figure 3).

Conclusion

Overlay sample preparation methods provide the necessary reduction of metastable product ions and uncorrelated ions and increase the stability of ion current to produce high quality photofragment spectra.

Infrared Multiphoton Photodissociation in a Quadrupole Ion Trap
 Armando Colorado and Jennifer Brodbelt, Department of Chemistry, University of Texas at Austin, Austin, Texas, 78712

Introduction. The interaction of photons and gas-phase ions to effect dissociation in conventional mass spectrometers and ion traps has been in use for over a decade. More recently, Stephenson and co-workers explored photodissociation of carbohydrate, protein, and nucleotide ions generated by electrospray in an ion trap¹. In the present study, we provide a comparative evaluation of collisional activated dissociation and photodissociation in a quadrupole ion trap. We also explore the utility of SWIFT for the determination of fragmentation pathways. Finally, IRMPD is combined with laser desorption as a means of activating ions whose secular frequency shifts during each ionization event, making application of CAD ineffective.

Experimental. All experiments were performed using a Finnigan ion trap mass spectrometer (ITMS) operated in the mass selective instability mode. Samples were introduced into the vacuum chamber via a heated solids probe at pressures ranging between $0.9\text{--}2.0 \times 10^{-6}$ torr raised to a nominal helium pressure of 1 mtorr. A cw Laser Photonics 575 tunable CO₂ laser was employed for the IRMPD experiments. A 3 mm hole in the ring electrode allowed the unfocused infrared beam (6 mm diameter) to enter the trap. For most PD experiments, helium was held at a static pressure of nominally 1.0×10^{-5} torr. The SWIFT waveforms were generated using National Instruments (Austin, Texas) LabView 4.0 for Windows 95 and was adapted with minimal modification to the quadrupole ion trap from a system originally designed for FT-ICR. Photodissociation/laser desorption experiments were all performed at a nominal helium pressure of $1\text{--}2 \times 10^{-5}$ torr. A metal foil attached to a probe-mounted fiber optic interface assembly was used as the source of the metal ions. A Nd:YAG laser operated in the Q-switch mode at 532 nm provided the desorption pulse.

IRMPD and CAD of Biomolecules: δ -Gluconolactone. Collisional activation (tickle = 350 mV p-p, $q_z = 0.3$, 10 ms) of protonated gluconolactone results mainly in the primary loss of 46 u or formic acid (133^+ , 76%) and other minor fragments (Figure 1A). Photodissociation of protonated gluconolactone ($t_{\text{exp}} = 30$ ms, 30 W), unlike CAD, produces much more fragmentation and an increase in the dissociation efficiency (Figure 1B). Many of the fragment ions, however, may in part be due to ongoing activation of the primary fragment ions to produce secondary fragments.

IRMPD and SWIFT. Because photodissociation is a non-selective excitation technique, the primary fragment ions generated from the precursor ion may undergo further activation to produce secondary fragment ions, as noted above for protonated gluconolactone. To determine fragment ion genealogy, tailored excitation waveforms can be used to selectively eject specific fragment ions during the PD interval. Disappearance of other fragment ions confirms that these fragment ions stemmed from dissociation of the ejected ions. For example, the two most abundant ions in the photodissociation spectrum of protonated gluconolactone were ejected during the irradiation period by application of the SWIFT technique. Ejection of the 133^+ ion (secular frequency = 80,325 Hz) from the PD spectrum of gluconolactone results in the complete disappearance of the total fragment ion population, confirming that the 133^+ ion undergoes photodissociation to produce all other fragment ions (Figure 2). Thus, SWIFT permits mapping of the photodissociation pathways.

IRMPD/SWIFT For Hydrogen-Bonded Complexes. The combination of SWIFT and PD also proves useful for evaluation of hydrogen-bonded complexes, such as polyether/ammonium ion complexes. The complex formed between 18-crown-6 and methylamine dissociates by cleavage of the hydrogen-bonds, resulting in formation of protonated 18-crown-6 or protonated methylamine, and cleavages of the macrocyclic skeleton of 18-crown-6, resulting in fragment ions at m/z 89, 133, and 177. The formation of protonated methylamine is not detected upon CAD of (18-crown-6 + H^+ + CH_3NH_3) because it falls outside the mass-to-charge range of stable fragment ions. The photodissociation spectrum of the complex, acquired at a q_z value of 0.09, is shown in Figure 3. The formation of protonated methylamine is confirmed in the PD spectrum. Photodissociation/SWIFT

results reveal that the generation of the product ions is stepwise and not direct. SWIFT ejection of the 177^+ fragment ion results in the ejection of the 133^+ , 89^+ , and the 45^+ fragments (Figure 4).

Photodissociation of Dye Molecular Ions in an RF Ion Trap

Michisato Toyoda, Masahiro Kimura and Takekiyo Matsuo

Department of Physics, Faculty of Science, Osaka University

1-16 Machikaneyama, Toyonaka, Osaka 560, Japan

The study on slow reactions of ions without suffering from unwelcome effects (e.g. wall effect) has been carried out in an RF ion trap, because ion trap can store ions in vacuum for sufficiently long time. In the present study we have observed the photodissociations of molecular ions and obtained information on energy states and relaxation processes of the ions.

The experimental apparatus is shown in Fig. 1. The compact ion trap employed in the present study is composed of three cylindrical electrodes. Rhodamine 6G ions produced by laser desorption ionization by nitrogen laser (337 nm) were stored in the trap, and were photodissociated by a second harmonic light (532 nm, $\sim 1 \text{ W/cm}^2$) of cw-YAG laser. This device was capable of storing rhodamine 6G ions for more than 20 hours without substantial loss. The product ions were then mass-analyzed through TOF method.

The mass spectra without and with the irradiation of 532 nm light are shown in Figs. 2 (a) and (b), respectively. A large fraction of the rhodamine 6G ions was seen to dissociate into species of low m/z ratio. Rhodamine 6G ions, which are more stable in conventional liquid solutions, were found to be photodissociated easily when they are in the isolated condition, although we could not identify at present the species of the fragment ions definitely.

A large proportion of the molecular ions was found to be produced in a metastable excited state. The molecules in the metastable state can absorb a visible photon and make a transition to a higher electronic state ('superexcited' state) which causes the dissociation of molecular ions. Without the irradiation of 532 nm light the excited molecular ions relax to the ground electronic state by emitting photons or by collisions with buffer gas. From the ground state the molecules need at least two-photons to be dissociated. Such process is unlikely to occur with the presence of weak laser employed in this study.

We produced precursor ions by a nitrogen laser and then illuminated the ions with a laser light of 532 nm after a lapse of varied relaxation time. The dependence of photodissociation on the relaxation time was measured, and the results are shown in Fig. 3. As seen, dissociation became negligible after 200 ms. We have estimated the lifetime τ of the metastable excited state as 80 ms when the buffer gas (N_2) pressure was 6.0×10^{-6} Torr. The pressure dependence of the lifetime of the metastable excited state was then measured (see Fig. 4). By extrapolating it to zero pressure, we could determine the lifetime of the metastable in the isolated condition to be about 100 ms.

Evaluation of an Internal MALDI FT-ICR Design

Easterling, Michael L.; Pittsenberger, Cynthia C.; Kulkarni, Shubhada; Taylor, Kristi; Amster, I. Jonathan
Department of Chemistry, University of Georgia, Athens, 30602-2556

The design and specification for a high field internal MALDI Ion Cyclotron Resonance mass spectrometer was presented in a poster at the last meeting in Atlanta. This instrument, designed to analyze singly charged synthetic and bio polymers in the 50 - 10,000 Da range has been constructed and various results are shown below. The data illustrate efforts at experimentally unifying several innovations in FTICR to increase the overall effectiveness for trapping and detecting ions of interest throughout the useful mass range. Details of efforts to integrate the capacitively coupled open cell with high mass MALDI are also provided.

Unlike capped cell geometries that uniformly provide most of the applied voltage along the trapping axis, the potential of the open cell design decreases to about 60% of the applied voltage at the centerline axis. Since the trapping field will only efficiently trap ions with kinetic energies less than the effective trapping potential, the open cell has an upper mass trapping limit that is lower for ions formed by MALDI than a similarly configured closed cell. To extend the useful mass range, a homemade dual channel amplifier is used to boost the trapping voltage up to 65 V to facilitate stopping ions of larger m/z . Since the linear flight space between end electrodes is tripled over that of most cubic cells, the passband filter behavior of the cell during gated trapping is broader and wider distributions of ions may be collected during an experiment. Examples of the high mass trapping capability of our instrument are shown in Figure 1 for MALDI of two samples of poly(ethylene) glycol. Here, single laser shots followed by the amplified trapping event provide the observed signal with similar trapping times used to obtain both ion distributions covering almost 28 electron volts of kinetic energy.

In order to provide flat RF field distribution across the cell volume and reduce z-axis excitation, capacitive coupling between the excitation electrodes and corresponding trap plates was included in the instrument design. Since the RC circuit normally used for this enhancement forms a low pass filter for the trapping voltage, a modification was made to the external electronics used for RF coupling. This modification bypasses the RC circuit to give direct control of the trap electrodes with response times amenable to gated trapping.

Using a cubic cell design at low field, we previously reported remeasurement efficiencies of $\geq 99.5\%$. Repeating this experiment with the 45-mer of PEG 2000 ($m/z = 2022$) with the current instrument has yielded a 100% remeasurement efficiency over 200 cycles as shown in figure 2. The increased axial and radial dimensions of this cell provides a larger three-dimensional trapping volume to better accommodate ion cloud expansion. Although the data obtained for this experiment demonstrates unity QE efficiency, it more importantly indicates the elimination of significant axial ejection during the detect event.

Figure 2: Mass spectra showing the sodium cationized peaks of poly(ethylene) glycol with MR (a) 8000 and (b) 4600. The similar signal-to-noise ratio for both mass spectra shows that trapping efficiency is comparable across wide mass ranges.

Figure 1: (a) Ion chromatogram showing ion intensity during 200 remeasurement cycles of the 45-mer of PEG 2000 taken over a period of 2.5 hours. (b) Individual spectra after 4 and 200 remeasurement cycles showing similar signal-to-noise. (c) The same experiment performed with RF coupling disabled showing a sharp loss in intensity due to axial ejection.

MALDI/FTICR Mass Spectrometry in a 20 Tesla Resistive Magnet

Virtually every aspect of Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry improves dramatically at higher magnetic field, B (see Figure 1). For example, mass resolving power scales linearly with B . Other FT-ICR performance parameters scale even more favorably as B^2 . Thus, upper mass limit, tendency of peaks to coalesce, maximum ion translational activation energy (essential for efficient fragmentation of macromolecular ions and thus for protein and DNA sequencing), maximum number of trapped ions (for extending the dynamic concentration range), and lifetime of trapped ions (for increased versatility in analysis of ion-molecule reactions and other multistage experiments) should improve quadratically with B . Such benefits, taken collectively, should allow routine mass measurement of antibody-size proteins (~150 kDa) to within 1 Da, making it possible to count disulfide bonds as well as identify various adducts and chemical modifications.

The highest-field superconducting magnet currently available for FT-ICR is 9.4 Tesla. Here we report the construction and initial results of a FT-ICR mass spectrometer for operation at more than twice that field: namely, in a 20 Tesla resistive magnet installed at NHMFL. A schematic diagram of the complete system is shown in Figure 2. The resistive magnet has a 50 mm diameter bore and spatial inhomogeneity of ~1000 ppm over 1 cm diameter spherical volume, and consumes 8.5 megawatts of power during operation at the maximum field strength of 20.5 T. The ICR ion trap and MALDI probe were tailored for maximal use of bore diameter. Internal MALDI is achieved by a pulsed N_2 UV laser guided by a probe-mounted optical fiber assembly [1] to a sample tip just outside a 1.3" diameter open cylindrical cell [2]. The sample tip may be simultaneously rotated and translated to maximize the number of laser shots available for each analyte.

Our first results (Figure 3) are encouraging. Noise associated with the magnet power supply is evident but is shielded to an acceptable level by our vacuum chamber. The achieved resolving power is much greater than the magnet homogeneity, presumably due to field-averaging from rapid ion cyclotron and trapping motions. Moreover, much higher homogeneity is possible: NHMFL has already built a 24 Tesla resistive magnet (32 mm bore) with 40 ppm spatial inhomogeneity and a 25 Tesla, 50 mm bore magnet with 1 ppm inhomogeneity is planned for 1997. Future work will focus on high mass ions, as well as the effects of magnet spatial and temporal instability. This work was supported by the NSF National High-Field FT-ICR Mass Spectrometry Facility (CHE-94-13008) and the National High Magnetic Field Laboratory at Florida State University.

Luteinizing hormone releasing hormone (LHRH) is a hypothalamus-produced decapeptide that regulates the synthesis and release of luteinizing hormone and follicular stimulating hormone. In humans, endogenous LHRH is cleaved from a 92 amino acid pre-proprotein along with other fragments that have been implicated in regulating prolactin secretion [1]. Therapeutic applications of analogs of LHRH include the treatment of prostatic carcinomas, hypogonadism and infertility. Although the primary amino terminal sequence of LHRH has been well conserved throughout evolution, the carboxy-terminal sequence varies among species and has been proposed to play an active role in inter-species variants. Because radioimmunoassay fails to distinguish between primary sequence variants of LHRH, we are developing a sequence-specific assay based on matrix assisted laser desorption/ionization (MALDI) Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR/MS).

MALDI FT-ICR/MS spectra were acquired by use of a 3 Tesla Finnigan FTMS-2000 dual-trap instrument. Figure 1 shows a high-resolution mass spectrum of 100 pM/ μ L LHRH with 2,5-dihydroxybenzoic acid/fructose ($1:1 \times 10^6:5 \times 10^5$ molar ratio). This spectrum illustrates the typical resolving power ($>200,000$) obtained on the analyzer side of the dual trap for human LHRH. Fragmentation of the peptide permits the primary amino acid sequence to be determined. LHRH was fragmented by both laser-induced dissociation and collision-induced dissociation (CID). Both methods reveal partial sequence information, but MS^n CID fragmentation provides a higher certainty that the fragments produced are in fact generated from a specific parent molecule. Figure 2 shows MS^3 CID fragmentation of human LHRH. The upper panel shows the spectrum of the stored waveform inverse Fourier transform (SWIFT) isolated B_8 product ion of LHRH after previous SWIFT isolation of the parent ion and subsequent CID by off-resonance excitation and collision with argon gas. The lower panel of Figure 2 shows further CID fragmentation of the isolated B_8 product ion, eliciting specific MS^3 product ions: B_5 , B_6 , and B_7 . This technique provides for the specific sequencing of the 5-10 amino acid segment of the LHRH molecule required to determine inter-species variants of the peptide.

Coupling rapid desalting of LHRH dissolved in biological salt solutions by ion metal affinity chromatography (IMAC) [2] directly on a copper probe tip, with the high resolution and MS^n sequencing capabilities of MALDI FT-ICR/MS provides an unequaled technique for the analysis of this biologically active neurohormone. These techniques can be adapted to numerous *in vivo* biochemical/biomedical problems.

Characterization of MALDI/FTICR Performance with an Inhomogeneous Superconducting Magnet,

J. S. Anderson and D. A. Laude, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas, 78712

The primary feature of FTICR mass spectrometry is the strong magnetic field directed along the z-axis of the trapped-ion cell. A recent trend in the FTICR community has been the acquisition of higher magnetic fields to study the ICR phenomenon. From an analytical standpoint, this movement to larger field yields theoretical improvements in mass resolving power, mass measurement accuracy, and a host of other merits. In addition to field strength, field homogeneity considerations also contribute to both the theoretical performance available [1-3] and the overall cost and size of the magnet.

In this work, a low cost superconducting magnet with poor field homogeneity is employed to investigate various factors of the FTICR experiment. The utility of quadrupolar excitation is demonstrated to have a dominant influence on the ability to obtain analytical performance in this system. A second component of this poster is a description of ion loss at increased ion radii. Due to the radial component of the magnetic field, this mechanism shows a mass dependence as low mass ions are prematurely ejected.

Of primary importance is the limited spatial homogeneity of the superconducting magnet. Experiments designed to probe analytical performance required quadrupolar excitation (QE) for a dual purpose. First, the radial dispersion of laser desorbed ions coupled with magnetron motion and a drift velocity due to the radial field gradient [1] lead to reduced trapping times and minimal detection periods. Furthermore, ions are inherently confined to a smaller spatial volume by QE and the ΔB magnitude which ions encounter is limited. In experiments conducted without QE, the average transient lifetime is approximately 10-30 ms. Because the analytical benefits of FTICR are based on transient observation time, the non-QE data does not lead to useful FTICR mass spectra. In Figure 1, the combination of QE and proper ion densities results in a mass resolution of 16,000 and mass accuracy of 7-13 ppm for individual isotopes of gramicidin-D.

Within a typical FTICR superconducting magnet the dominant B_z term is homogeneous over the volume of the cell. As the field lines for B_z diverge, a necessary perpendicular component, B_r , appears. Known primarily as a fundamental element in the magnetic mirror effect, we present the effects of the axial-directed B_r force on ions which are already trapped. The 1 part per Thousand specifications for our magnet indicate a substantial divergence along the z-axis. As a result, the degree of B_r within the cell is quite significant. Using data from the manufacturer, a plot of B_r versus axial displacement within a 2" cell is shown below. The B_r component is negligible at small radii and along the z-axis ($r=0$). A mechanism to describe B_r influenced ion loss is described below.

The electrostatic restoring force from the applied trapping potential, and magnetic force along the z-axis are described by [4]:

$$F_{E_z} = -\frac{4qaV_T}{d^2}z \quad \text{FORCE INWARD}$$

$$F_{B_r} = qv_c B_r(z) \quad \text{FORCE OUTWARD}$$

For the case where $F_{B_r} > F_{E_z}$ ions will be ejected axially from the cell.

Circumstances where ejection is probable include large radii, low mass, large trapped-ion cell, and small applied trapping potentials. Studies of axial ion loss due to B_r consisted of varying mass, final cyclotron radius, and applied trapping potential to illustrate a mass dependent ejection that is independent of pressure. Shown in Figure 3, a theoretical plot indicates predominant loss of low mass ions at a final radius 80% of the cell radius. In an effort to experimentally demonstrate this mass dependence, excitation profiles were generated for a range of MALDI generated ions in a 1" cell. The excitation profiles in Figure 4 illustrate the cell size factor regarding ion retention along the z-axis. For the 1" cell, a 1 V increase in trapping potential permits the excited gramicidin-S ions to achieve a far greater cell radius. In the 2" cell, ions are not retained in a 1 Volt trapping well, and a 6 V applied potential is required to trap ions at a radius approaching the allowed maximum. A final indication of the importance of trapping potential and mass dependence is the time domain transients of different masses. Using identical final radii for both compounds, the lower mass ion is ejected during detection at low trapping potential. A simple increase of the trapping potential improves ion retention and further verifies the presence of an axial loss problem.

Techniques for Uncoupling Coalescing Isotopic Distributions in MALDI/FTICR

J. S. Anderson and D. A. Laude, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas, 78712

A significant aspect of space charge conditions is the coalescence of closely spaced ion frequencies in the final mass spectrum. This phenomenon has been increasingly studied both experimentally and theoretically in the FTICR community [1-4]. McIver and co-workers used electron ionization to produce conditions of coupled and uncoupled ion behavior [1]. Theoretical examinations by Naito and Inoue [2], Peurrung and Kouzes [3], and Mitchell and Smith [4] presented various factors that contribute to ion coupling, and the implications on performance in FTICR mass spectrometry.

In this work, we present experimental methods to minimize ion coupling that exists between closely-spaced isotope frequencies in the gramicidin-Dubos polypeptide. Initial conditions produce spectra with single lineshapes and limited analytical performance. Our studies indicate that manipulation of the trap potentials, or the amplitude of the applied quadrupolar excitation affects the ion density and the degree of ion coupling that is observed in the final mass spectrum. Analytical figures of merit such as mass resolving power as well as simple mass assignment and concomitant mass accuracy improve substantially with the application of these experimental methods.

These investigations were instigated by the observation of lengthy time-domain transients similar to the gramicidin-D transient in Figure 1a. The magnitude-mode Fourier transform produces a spectrum containing a single lineshape (Figure 1b), instead of the expected chemical heterogeneity illustrated in Figure 1c. In an effort to correct the observed ion coupling post-ionization techniques were used to minimize the ion densities and ion coupling within the trapped-ion cell.

The MALDI ionization source employed a fiber optic probe to allow simple combination and efficient transfer of desorbed ions in our vertical-bore, superconducting magnet. Laser energy was transmitted by means of a nitrogen laser (Laser Science, Inc., Cambridge, MA) using wavelength of 337 nm through the fiber setup onto the sample surface. The gramicidin-D polypeptide was mixed with an abundance (1000-5000/1 molar ratio) of 2,5 dihydroxybenzoic acid matrix compound for the final sample composition. Pulse sequences were performed by either extending the delay time during which MALDI ions enter the cell, or by placing a suspended trapping event directly after injection.

At certain time periods, application of either modified pulse sequence produces a spectrum in which the isotopic envelope becomes uncoupled and isotopic resolution is available. Shown in Figure 2, sequential uncoupling of additional C^{13} isotopes is achieved at increased suspended trapping times. In addition to isotopic resolution, the mass resolving power of individual isotopes is also enhanced as the coupling efficiency is diminished. Shown in Figure 3a, mass resolution for the most abundant C^{13} isotope increases from an initial value of 3800 to approximately 16,000 at a suspended trapping time of 800 μ s. An additional benefit is the improved mass measurement accuracy that is available. Illustrated in Figure 3b, the coulombic component of the frequency shift is minimized at increased suspended trapping times, and mass accuracy is improved by two-orders of magnitude.

Another factor in evaluating the coupling process is the effect of quadrupolar excitation (QE) on coupling efficiency. The role of QE in the FTICR experiment is the axialization and localization of selected ions at the center of the trapped-ion cell [5]. Illustrated in Figures 4a and b, QE voltages optimized for large signal abundances also demonstrate decreased cyclotron frequencies. Experimental mass spectra for these data points indicate ion coupling

to be prevalent at large abundances/decreased frequencies. Shown in the Figure 5, careful selection of the QE voltage results in the uncoupling of gramicidin-D isotopes at decreased ion signals.

Electrospray ionization in combination with Fourier transform ion cyclotron resonance mass spectrometry has become accepted as the most powerful tool for characterizing large biomolecules, due to its unrivaled resolving power, mass accuracy, sensitivity, and capabilities for MSⁿ. Here we report the construction of a high-performance electrospray instrument for the ICR user facility at the National High Magnetic Field Laboratory. The instrument is built around a passively shielded 8"-bore 9.4 T superconducting magnet (Oxford Instruments), currently the largest magnet in the world used expressly for ICR. The system incorporates a Chait-style home-built ESI source, octupole ion guides, hybrid turbo-drag pumps for high speed pumping and oil-free vacuum, and a Finnigan FT/MS Odyssey data system. Components within the magnet bore are constructed entirely from aluminum, titanium, and copper to minimize any distortion of the high-homogeneity magnetic field.

Figure 1. Schematic diagram of NHMFL external source electrospray ionization FT-ICR mass spectrometer.

Figure 1. Single-scan ESI FT-ICR mass spectrum of porcine serum albumin

The high magnetic field in combination with a 4" trapped ion cell provide an instrument that is very tolerant of large ion populations. A single-scan signal-to-noise level of >10,000:1 has been obtained for bovine insulin. Tolerance to large ion populations significantly reduces ion-ion coupling, which can lead to distorted isotopic distributions.

Instrument performance is enhanced by operating in an external ion accumulation mode. In this mode, ions are initially accumulated in a first octupole (60 cm long) at ~1 mtorr for 1-2 s. Ions are then transferred into the magnet by a second octupole and gated into the trapped ion cell, where excitation and detection are performed immediately at 1×10^{-9} torr (i.e., without the use of pulsed gas). Benefits include a pre-axialized ion cloud for enhanced resolving power, and fast scan rate for coupling to chromatographic methods due to the lack of pulsed gas. This mode of operation has yielded broadband unit-resolution spectra for molecules as large as 50 kDa. With the assistance of pulsed gas to cool the ions to the center of the trap, and SWIFT excitation to reduce space charge, the instrument has produced unit mass resolution for proteins >100 kDa. Dept. of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

INTRODUCTION

Although there are several instrument designs in the literature for coupling liquid chromatography/electrospray ionization sources (LC/ESI) to quadrupole mass analyzers, there are few demonstrated for Fourier transform ion cyclotron resonance mass spectrometers (FTICR). The main obstacle to introducing any external ion source to an FTICR system is transportation of ions into the strong magnetic field while achieving low pressures in the detection cell for optimal FTICR performance. In overcoming this obstacle, many research groups have utilized a series of differentially-pumped vacuum stages that are separated by conductance limits. However, because this approach has several inherent disadvantages our group has built a differentially-pumped concentric tube network to interface ESI to FTICR. This design uses the magnetic field of the FTICR instrument to focus the ions into the trapped ion cell. Presented here are the recent performance advances which have been made on our electrospray instrument as well as modifications that have been implemented which allow the coupling of our ESI source to high performance liquid chromatography (HPLC).

DEVELOPMENT OF SHORT-BORE ESI FOR CHROMATOGRAPHY

Because the concentric tube/shutter design offered higher sensitivity and better resolution than previous designs, we decided to develop this instrument for use with on-line separation techniques. However, the long length of the ESI probe needed to position the source within the magnetic field makes coupling this source to chromatography impractical. In particular, the probe length in the concentric tube design is 72 inches. Therefore, the sample must pass through 6 feet of tubing before reaching the electrospray needle, resulting in severe degradation of chromatographic resolution. Consequently, a "short-bore" ESI source was designed and built as detailed in Figure 1. As shown, the probe length has been shortened to 24 inches. This was achieved by removing one stage of differential pumping and by shortening the length of the remaining stages to their practical limit. Nevertheless, when the shutter is closed, pressures in the detection region reached the mid- 10^{-8} Torr. In addition, the design also includes a larger diameter probe. This was done so that the separation column could be easily placed within the probe, thus shrinking the distance from the column to the electrospray needle to less than 5 inches (or a 2.4 μ L volume).

EVALUATION OF ESI SOURCE AND TRAPPING CONDITIONS

Because one stage of differential pumping had to be removed to implement the short-bore design, studies were conducted to evaluate the instrument performance. For example, the electrospray current that arrives at the cell as a function of the distance between the desolvating capillary and the skimmer, Dc-s, was evaluated. As the Dc-s is reduced the electrospray current that reaches the detection cell increases. However, the pressures in the cell region when the shutter is open also increase necessitating a longer pumping delay and a reduced duty cycle. The capillary-skimmer distance also affects the kinetic energy of the ions and, consequently, the optimal trapping potential.

Furthermore, it has been found that using a gated trapping event rather than an accumulated trapping event provides at least a 2 fold improvement in signal-to-noise. This negates the need for a pulsed gas for axial cooling during the trapping event and, most importantly, has reduced the duty cycle from 8 seconds to less than 2 seconds. This reduction in duty cycle will ultimately improve the chromatographic performance.

DETERMINATION FTICR DETECTION PERFORMANCE

In order to evaluate the new short-bore instrument, continuous infusion studies were first conducted to optimize shutter manipulation, data acquisition, pumping delays, and other parameters. For example, experiments were performed to determine the limit of detection for the instrument. Figures 2a-c show the spectra achieved as the amount of sample consumed in an entire 2.3 second scan was varied by reducing sample concentration. Even at the 7.6 attomole/scan rate a signal-to-noise ratio of 4 is still achievable. This spectrum corresponds to an ion injection of only 2.3 attomoles.

CONCLUSIONS

The implementation of a shutter to reduce pressures in the FTICR cell has allowed for the removal of one stage of differential pumping while still attaining low pressures for detection within a second of ion injection. In addition, the use of gated trapping has increased the signal-to-noise and prevented the need for axial cooling by collisions with background neutrals. These two features have provided for a reduction in duty cycle to less than one second. Most importantly, the low attomole detection limits and the reproducibility data furnish clear evidence that this electrospray interface will be sufficient to obtain chromatographic detection on the FTICR instrument.

Electrospray Ionization FTICR Spectrometry of Metalloproteins

Kulkarni, Shubhada S; Taylor, Kristi; Amster, I. Jonathan
Department of Chemistry, University of Georgia, Athens, 30602-2556

Metalloproteins play an important role in many biochemical processes, such as respiration, metabolism, photosynthesis, nitrogen fixation, nerve transmission, muscle contraction, and signal transduction. The primary goal of this project is to examine the binding of metal atoms to proteins using electrospray FTICR. It is critical to preserve the weak interaction between the metal and the protein. It is a challenge to use a nondenaturing solvent to detect such interactions, because the proteins are more stable in high ionic strength buffers.

We are particularly interested in applying mass spectrometry to measuring the multimeric nature of holoproteins and to measure the metal constitution of metalloenzymes. ESI-FTICR is used to examine hemerythrin and rubrerythrin, multimeric proteins containing two or more weakly bound irons per subunit. The electrospray method is advantageous because it produces multiply charged species, thereby extending the upper m/z limit. For characterization of these multiply charged ions, FTMS provides unique features such as non-destructive detection, very high resolution, and tandem MS capabilities. An important advantage of FTMS detection is that ions can be collisionally relaxed back to the center of the cell where they can be manipulated and remeasured.

The experiments were performed on a Bruker BioApex FTICR with a 7.0 T magnet. The instrument is equipped with an Analytica electrospray ionization source and has the capabilities to perform pneumatically assisted electrospray and nanospray. We know that under nondenaturing conditions, rubrerythrin and hemerythrin are capable of maintaining their noncovalent, multimeric forms. We would like to use FTMS to examine these ions under nondenaturing conditions, but we have been unsuccessful so far. We are using two different approaches to solve this problem. First, we have evaluated the softness of the ESI source through pneumatically assisted electrospray of myoglobin in water. We can identify the intact protein with little evidence of the denatured protein, demonstrating that the ESI source has the ability to ionize a sample without destroying the noncovalent interactions within the sample. The second approach involves nanoelectrospray, which should allow us to examine small quantities of sample in pure water solutions, thereby enabling us to combine efficient use of analyte with the conditions necessary to maintain the nondenatured state of the protein. We have performed nanoelectrospray of ubiquitin using tips pulled in our laboratory from 50 micron ID fused silica.

Fig. 1 Nondenatured myoglobin containing the heme group. The sample was sprayed out of pure water at a flow rate of 55 mL/hr.

Fig. 2 Nanospray of ubiquitin. The flow rate was 1 mL/hr, using 87 fmol of analyte. The tips were pulled from 50 mm ID fused silica and a syringe pump was used to achieve the stable flow rate.

Ion Storage Mass Spectrometry for Sequencing MHC Class-II Peptides

Robert E. Settlege, Jarrod A. Marto, Nathan A. Yates, Jeffrey Shabanowitz, and Donald F. Hunt
University of Virginia, Charlottesville, VA 22901

Triple quadrupole mass spectrometry coupled with reverse-phase HPLC has proven invaluable in the separation and sequence analysis of 9-11 residue peptides presented to the immune system in association with class I MHC molecules (1). One of these peptides will soon be placed in trial as a potential vaccine against cancer (2). Peptides presented to the immune system in association with class II MHC molecules play an important role in a number of autoimmune diseases such as arthritis, diabetes, and multiple sclerosis. These peptides are typically 15-30 residues long, contain multiple basic residues, and may carry 4 or 5 charges under electrospray conditions. In this work we utilize the MS^n capabilities of a quadrupole ion trap mass spectrometer to structurally characterize several model class II peptides.

Model class II peptides were synthesized, purified on RP-HPLC, and subsequently infused, through a home-built micro-electrospray source, into a Finnigan LCQ ion trap mass spectrometer. The low flow rates (20-200 nL/min) used with the ion source allowed substantial sequence information to be obtained from no more than 500 fmol of material. Figure 1 shows an MS/MS spectrum obtained from the $[M+3H]^{3+}$ ion of the peptide NSQKDLLEQKRAAVDTY. Complete sequence information was obtained for this peptide by carrying out up to five stages of MS on several of the MS/MS product ions. Similar success was obtained for a class II peptide, derived from myelin basic protein, which has been implicated in the onset and progression of multiple sclerosis.

In the course of this work, several interesting observations have been made with respect to peptide fragmentation pathways; for example, we obtain predominantly y-type product ions when collisionally activating b-ion precursors. Also, in many instances we observe multiple water losses, beyond those which may be expected based on the presence of particular amino acid residues. The low-energy, multi-collision conditions inherent in the ion trap CAD experiment may allow for extensive gas-phase rearrangements; we discuss one potential mechanism, based on cyclization along the peptide backbone, which may account for these observations.

Sources of Negative Peaks in Hadamard Transform/Fourier Transform Mass Spectrometry/ Mass Spectrometry

Xuling Gao and Troy D. Wood

Department of Chemistry, State University of New York at Buffalo,
Buffalo, NY 14260

In the last ten years, two different approaches have been developed which introduce the multiplex advantage of FT-ICRMS into a second dimension. The first approach, developed by Gäumann et al. [1,2], is analogous to the 2D FT-NMR experiment NOESY (in which the abundances of certain magnetic resonances are modulated by rf irradiation of another resonance) by modulation of ICR orbital radii and energy prior to dissociation. A second tandem 2D FT-ICR MS/MS method [3] takes advantage of the Hadamard S-matrix encoding procedure [4], whereby shaped rf waveforms based on Hadamard S-matrices are created to selectively retain exactly $(N+1)/2$ and eject $(N-1)/2$ precursors (N = number of precursor ions). These waveforms are referred to as "masks". The selected precursor ions may then be subjected to ion dissociation simultaneously, followed by broad-band excitation and detection. The experiment is repeated N times using masks retaining different combinations of $(N+1)/2$ precursors. From the N different MS/MS spectra of multiple precursors, individual MS/MS spectra can be decoded for each precursor ion based on the Hadamard S-matrix encoding. Even though the same number of experiments, N , is acquired in the Hadamard experiments vs. one-at-a-time MS/MS for each of the N precursors, there is a signal to noise (S/N) enhancement of $(N+1)/2(N)^{0.5}$ in the Hadamard MS/MS because each precursor is selected $(N+1)/2$ times and dissociated. In its initial application, the Hadamard approach showed spurious peaks, including some product ion peaks which had *negative* relative abundances. The presence of anomalous and negative peaks in the original experiments prompted Gäumann et al. to refine the Hadamard transform FT-ICR MS/MS approach using shaped waveforms and difference measurements [5]. These developments have led to a reduction in the number of residual peaks associated with Hadamard decoded FT-ICR MS/MS spectra. To date, explanations for the existence of "negative" peaks in Hadamard transformed FT-ICR MS/MS spectra have not been offered. Here, theoretical treatment of two factors which can contribute to the appearance of negative peaks in Hadamard transform FT-ICR MS/MS are given.

Pictorial representations of the difference spectra, $M1(\omega) - M2(\omega)$ obtained between two Lorentzian shaped magnitude-mode signals at exactly the same frequency are shown in Figure 1: (a) $M1(\omega)$ is positively valued while $M2(\omega)$ is a blank; (b) $M1(\omega)$ has twice the amplitude of $M2(\omega)$; (c) $M1(\omega)$ and $M2(\omega)$ have identical amplitudes; (d) $M1(\omega)$ has half the amplitude of $M2(\omega)$; (e) $M1(\omega)$ is a blank while $M2(\omega)$ has a positive value. As is evident, negative peaks are obtained in the difference spectra whenever the amplitude of $M2(\omega)$ exceeds that of $M1(\omega)$. Thus, negative peaks in the Hadamard transform FT-ICR MS/MS experiments originate from product ions deriving from precursors other than the one of interest due to incomplete cancellation after Hadamard transformation. Sources for product ion abundance irreproducibility include variations in initial precursor ion population and ion dissociation efficiency. Several factors influence ion dissociation efficiency, including final precursor ion radius (and hence energy) and collision gas pressure.

Frequency variability can lead to negative peaks in the Hadamard FT-ICR MS/MS experiment. Consider the difference spectra, $M(\omega) - M(\omega')$ obtained between two Lorentzian shaped magnitude-mode signals of exactly the same amplitude but different frequency, as shown in Figure 2. The frequency difference $\omega_c' - \omega_c$ between the two peaks are (a) $2\Delta\omega$, (b) $\Delta\omega$, (c) 0, (d) $-\Delta\omega$, and (e) $-2\Delta\omega$. Well-known capabilities of FT-ICRMS are its very high resolution and spectral reproducibility in the one dimensional experiment. However, in each Hadamard transform experiment, a different set of precursor ions is selected each time; since the precursor ion combination and total ion abundances will vary between applications of each "mask", the charge density in the ion trap will also vary between experiments. This may cause relatively large differences in ion cyclotron frequency for the product ions

due to space charge effects [6,7]. The residuals arising from frequency shifts cannot simply cancel each other by Hadamard transformation. Hence, such frequency variations are likely to be a major factor causing the appearance of negative peaks in the Hadamard transform FT-ICR MS/MS experiment. Frequency shifts for product ions resulting from different precursor encodings can also be attributed to factors such as magnetic field drift, though such factors are probably negligible in most cases compared with space charge effects.

A plot of residual peak amplitude (measured from the apex of the positive peak to the base of the negative peak) produced from the difference spectra of two Lorentzian magnitude-mode peaks of equal amplitude as a function of their frequency difference, $2p$, is shown in Figure 3. To get residual peaks of 2% relative amplitude (percent amplitude based on one peak), $2p$ must be smaller than 0.026 Hz. If $2p = 0.5$ Hz, the error is 37%. The percent amplitude of two peaks approaches 200% as $2p$ increases.

Typically, FT-ICR mass spectra are displayed in the magnitude-mode, which has only positively-valued peak ion abundances; however, time domain information can be Fourier transformed and displayed in the absorption/dispersion mode, which contains both positive and negative peak abundances. Thus, negative peaks produced after Hadamard transformation of the absorption/dispersion spectra will become *positively-valued in the magnitude-mode* since they are squared. Hence, to eliminate negative peaks from Hadamard transform FT-ICR MS/MS, we propose that time domain data first be Fourier transformed into the absorption/dispersion modes, followed by Hadamard transformation and conversion to magnitude-mode. It is noteworthy that while the residual peaks which appear in such spectra will no longer possess negative values, they will still be unrelated to the precursor ion of interest.

DISTINCTION OF COULOMBIC AND CONFORMATIONAL EFFECTS ON THE DISSOCIATION OF ELECTROSPRAYED PROTEINS

E. Stevenson., B. J. Bolanos, B.J., D. A. Laude, Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712

INTRODUCTION

The widespread application of electrospray ionization to the analysis of proteins and peptides requires a fundamental understanding of gas-phase protein structure. Dissociation experiments have been employed historically to determine the sequence of amino acids along a peptide chain. Recent work suggests that the fragmentation of large biomolecules may also provide insight into their tertiary structure. It is generally accepted that coulombic repulsions contribute to the dissociation of multiply charged ions. However, the diversity in the fragmentation patterns generated by the different charge states indicates that conformation may also play an important role in dissociation.

In the work presented here, the dissociation patterns for three of the charge states of bee venom melittin were obtained. This protein was selected for study for its relatively small size (molecular weight of 2846.5 Da), limited number of charged residues along the backbone chain, and well-known solution phase structure. These characteristics were considered in order to alleviate the difficult interpretation of complex spectra usually generated by larger proteins and to elucidate the contribution of the factors on the location and degree of fragmentation.

EXPERIMENTAL

All data were collected on a 30 T superconducting magnet which was equipped with a system of differential pumping to interface to an electrospray source. 10 μ mol solutions of the commercially obtained bee venom melittin were made up in a 60:40 mixture of methanol and water. The electrospray spectrum of the +3, +4, and +5 charge states was generated as shown in Figure 1a. Selected ion accumulation of each charge state was accomplished using quadrupolar excitation with a frequency offset of approximately 200 Hz from the cyclotron frequency of the ion. After a single charge state was isolated, a low energy off-resonance radio frequency was applied for 1.5 seconds to enable the dissociation of the ion. The resulting spectra for the QE and SORI steps of the +3 charge state are presented in Figures 1b and 1c.

MELITTIN

The solution phase conformation of melittin consists of two α -helices linked by a hinge. Protonation can occur at any of the five basic residues or N-terminus amine. The arrangement of the charge sites can be explained by three theories. First, the distribution of the charges can be random. Second, the charges attach in positions which minimize coulombic repulsion. Finally, the relative basicities of the amino acids determine which sites most likely accept a proton. Melittin contains two of the most basic protein residues, arginine and lysine. Previous observations have shown that fragmentation occurs at sites remote from basic residues (1).

SUMMARY

The fragmentation patterns at the threshold energies for each of the three charge states are displayed in Figure 2. It is evident that the different number of charges on the protein produce significantly different spectra. Figure 3 describes the marked variation in the energy required to induce dissociation for each of the charge states. Figure 4 is a representation of the primary sequence of melittin with the location of the major and minor fragments highlighted for each of the charge states. The +3 and +4 charge states are similar in that they demonstrate fragmentation at sites along the entire length of the peptide chain. In contrast, the +5 charge state dissociates primarily along the N-terminus. This result underscores the significant role other factors such as conformation have in determining fragmentation pathway. It is also noteworthy that in each of the spectra, cleavages occur in the region of the hinge connecting the two α -helices of melittin.

Approaches to Ion Mobility Measurements in an FTICR Spectrometer

E.G. Schmidt*, B.J. Bolanos, and D.A. Laude

Dept. of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

INTRODUCTION

Of increasing interest to mass spectrometrists is the ability to distinguish ions of a particular mass-to-charge ratio on the basis of differences in gas-phase conformation. The opportunity to couple ion selection on the basis of mobility with powerful mass spectrometric methods for detection is particularly intriguing. Unlike injected ion mobility drift tube techniques, FTICR provides ultrahigh mass resolution as well as the ability to investigate the structure of a specific conformer using standard reactivity and dissociation techniques.

Essential to these FTICR ion mobility studies is the ability to distinguish between ions due to differences in their kinetic energies.

A model has been developed to characterize the trap potential required to distinguish ions based upon their kinetic energies (1). This model assumes that the kinetic energy (KE) must match the trap potential for an ion to be confined within the cell. The KE in equation 1 has two terms. The first term represents the KE contribution due to the supersonic expansion while the second term represents the contribution due to the skimmer potential.

IMPLEMENTATION OF ION MOBILITY WITH ESI/FTICR

The spectrometer used to collect the ESI/FTICR data included a 6" bore diameter magnet into which the vacuum chamber was inserted. Of particular merit to this design are the four concentric vacuum chambers of increasing diameter which allow the electrospray ions to be formed in the high field region of the magnet. The elimination of the need for electrostatic focussing is of primary importance to ion mobility measurements. The source for this particular instrument has been shown to produce KE distributions as little as 0.01 eV wide.

APPLICATIONS OF ION MOBILITY WITH ESI/FTICR

Narrow kinetic energy distributions provided by our ESI system offer the ability for selective conformation trapping. As shown in Figure 1, under modulated skimmer potentials, a single broad envelope of cytochrome c is obtained (2). By narrowing the KE, as provided by our system, selective conformation in the bi-modal envelope of cytochrome c is possible. In addition, as demonstrated in Figure 2, these conditions can be utilized for preferentially trapping an adducted from a non-adducted cytochrome c ion. These differences in trapping are due to changes in ion kinetic energy which is as a direct result of differences in ion mobility.

IMPLEMENTATION OF ION MOBILITY WITH LD/FTICR

The success achieved with the ESI/FTICR have encouraged us to construct an instrument for performing additional ion mobility studies. Pulsed laser desorption of carbon has been shown to produce clusters of varying conformation at the same m/z (3). Our initial studies will concentrate on the production and selection of varying carbon clusters utilizing the FTICR to select a particular m/z while differences in ion KE will discriminate among conformations.

The FTICR which will be used initially for high pressure laser desorption studies is a 4.7 T vertical bore superconducting magnet with a 98mm bore was configured to accommodate an FTICR vacuum chamber with three differentially pumped regions. Ions travel a 25 cm path from the ionization source to the trapped ion cell and incur collisions from a pulsed gas along the path.

Although mass spectrometry has shown its ability to provide an abundance of primary and some secondary information concerning ions, the availability of higher order structure is somewhat limited. The use of ESI/FTICR has been shown to differentiate between different gas-phase conformers of the same m/z based on the ability to isolate ions of different kinetic energies. Narrow kinetic energy distributions resulting from the use of magnetic field focussing are the means by which ion mobility data was obtained. Future work will focus on the implementation of high pressure LD for cluster production on the 4.7T concentric tube system including fundamental studies of ion mobility coupled with FTICR.

Using the classical Gibbs distribution, we obtain the density distribution of ions in Penning (FT-ICR) [1], Paul (quadrupole) [2], and combined ion traps [3] in high- and low-temperature limits. Ion-ion and ion-neutral collisions make it possible to treat a cloud of trapped ions as a classical gas at thermal equilibrium. With the usual assumptions that the number, energy, and total angular momentum of ions are conserved, the ion cloud rotates at a constant frequency in both Penning and combined traps. This rotation about the magnetic field direction provides a radial confining force (Figure 1) to balance other outward forces: namely, the radial electric force due to the applied electric potential and Coulomb interaction between ions, the radial pressure gradient (due to concentration of ions near the trap center), and centrifugal force (due to ion rotation motion). This rotation frequency is larger than the single-ion magnetron frequency and smaller than the single-ion cyclotron frequency in Penning and combined traps. Therefore both the collective rotation and ion transitional temperature appear in the distribution function. Combining this distribution function with Poisson's equation, we generate an ion velocity distribution (Maxwell distribution) and ion density distribution.

At high temperature and low density (typical FT-ICR conditions), ion-ion Coulomb interactions may be neglected and the ion density distribution is Gaussian and depends on the ion kinetic and potential energy (Figure 2). At low temperature and high density, the kinetic energy is much less than the Coulomb interaction energy between ions and we may neglect the kinetic energy. The ion density distribution is then determined by a balance between the ion-ion Coulomb interactions and the potential energy from the electric trapping field. The low-temperature ion density distribution thus represents the maximum achievable ion density. For a Penning trap (Figure 3), this maximum ion density is proportional to B^2/m (in which B is magnetic field and m is ion mass). For ions of 1,000,000 u in a magnetic field, $B = 10$ tesla, the maximum ion density is $\sim 100,000 \text{ cm}^{-3}$. Ergo, a high magnetic field strength is needed to trap large numbers of heavy ions. For a Paul trap (Figure 4), maximum ion density is also related only to the trapping field and ion mass, but not to the ion charge.

The decay envelope of an ICR time-domain signal determines the corresponding Fourier transform mass spectral line shape. The commonly accepted FT-ICR frequency-domain spectral line shape is Lorentzian, resulting from a Langevin ion-neutral collision model. The classical motion of an ion of mass, m , and charge, q , moving at velocity, $\mathbf{v}$ ($= \dot{x}\mathbf{i} + \dot{y}\mathbf{j} + \dot{z}\mathbf{k}$), in a magnetic field, $\mathbf{B}$, and in the presence of collisional damping force is described by the modified Lorentz equation, $m\dot{\mathbf{v}} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) - m\eta v_c \mathbf{v}$, in which $\eta = M/(M + m)$ and M is the mass of the neutral. v_c is the collision frequency, $v_c = N\sigma\bar{v}$, in which σ is the collision cross section and $\bar{v}$ is the average ion speed relative to the neutral. In the Langevin model, collision cross section, σ , is inversely proportional to ion speed, v , (relative to a neutral) and collision frequency, v_c , is independent of v : an ion is treated as a point charge which induces an electric dipole moment in a neutral collision partner. For the Langevin model, ion cyclotron radius and time-domain ICR signal amplitude are each proportional to $e^{-t/\tau}$ (see Figure 1), and spectral peak shape (see Figure 2) is Lorentzian. [1,2], $\frac{\tau}{1 + (\omega - \omega_0)^2 \tau^2}$

The Langevin model provides a good description of reactions of low-energy collisions of low-mass positive ions with neutrals. However, the Langevin model is inappropriate for collisions of high-mass gas-phase biopolymer ions with low-mass neutrals. Here, we examine the ion trajectory dependence on both Langevin and *hard-sphere* models. For the hard-sphere model, collision frequency is proportional to ion speed and the equation of ion motion is no longer linear. However, the equation can still be solved, leading to a non-exponential time-domain ICR signal. The collision cross section, σ , is independent of ion speed and collision frequency is proportional to ion speed. Ion cyclotron radius and time-domain ICR signal amplitude are each proportional to $\frac{1}{(1 + t/\tau)}$ (see Figure 1) and the spectral peak shape (which has no analytical solution) shows a sharper peak and broader base than a Lorentzian line (see Figure 2). ICR signal modeling has important implications for FT-ICR line shape and signal processing, collision-based ion activation, and ion axialization. Azimuthal quadrupolar excitation in the presence of collisions of high-mass ions with low-mass neutrals effectively axializes the ions for enhancement by factors of 2 to 100 in virtually every FT-ICR performance parameter: mass resolving power, mass accuracy, signal-to-noise ratio, mass selectivity for MS/MS, ion remeasurement efficiency, external ion injection efficiency, etc. [1] However, during axialization, ions may acquire several eV of kinetic energy, some of which may be converted by means of ion-neutral collisions to *internal* ion energy, and may lead to ion dissociation. The question then becomes how to axialize ions without breaking them apart? Here, we report theoretical simulations of the *kinetic* energy acquired by ions, and initial experimental characterization of the *internal* energy deposited by the axialization process (by observing the decrease in rate of ion-neutral association reactions).

Theory. We show that *resonant* single-frequency azimuthal quadrupolar excitation (~ 1 V) amplitude can increase ion kinetic energy by up to several tens of eV in less than 1 second. Moreover, it is difficult to control the excitation voltage amplitude when it is reduced to less than ~ 10 mV required to limit ion kinetic energy to less than ~ 1 eV. Here, we propose *off-resonant* quadrupolar excitation (by analogy to off-resonant dipolar excitation for CID). Although off-resonant excitation lowers the magnetron-to-cyclotron (ω_-/ω_+) conversion rate, the maximum ion kinetic energy produced by moderate azimuthal quadrupolar excitation amplitude is greatly reduced.

Experiment. Experimentally, we characterize the internal energy deposited by the axialization process by observing the degree of collisionally-activated dissociation of the "internal energy thermometer" species, $\text{W}(\text{CO})_6^+$. For resonant axialization, if ions do not collide with Ar atoms (9 collisions/sec at 1.2×10^{-7} Torr of Ar) during quadrupolar excitation (2 ms, which is long enough to select a single isotopic species), ion kinetic energy may be calculated numerically from the initial ion magnetron radius and excitation amplitude and frequency offset (if any). Ion *internal* energy is calculated from ref. 2 [2]. Resonant axialization leads to oscillation of ion kinetic energy between zero and a large maximum value, due to complete ω_-/ω_+ conversion cycles, whereas off-resonance axialization produces near-continuous conversion, thereby holding ion kinetic energy below a value which depends on azimuthal quadrupolar excitation amplitude and frequency offset (Figures 1 and 2). Off-resonance axialization thus provides better control of ω_-/ω_+ conversion and lower internal energy deposition. Work supported by NSF (CHE-94-13008) and the National High Magnetic Field Laboratory at Florida State University.

SELECTIVE BROADBAND QUADRUPOLEAR AXIALIZATION IN FTICR

Karpinski, M.L.*, Blakney, G.T., Bolanos, B.J., Laude, D.A.
University of Texas at Austin, Austin, Texas 78712

Quadrupolar axialization is of increasing importance in the FTICR experiment for cooling and shaping the ion cloud in the trapped ion cell prior to detection. Although axialization is most readily applied to a single ion resonance, there are continued efforts to extend the application to broadband experiments. Some successes have been reported for this experiment, but the mass range for cooling is often limited and overall efficiency is reduced. A major problem is that although the broadband experiment is conceptually feasible, it is difficult to implement given the limitations of many FTICR data systems in executing the desired pulse sequences. We have recently constructed a more flexible data system driven by LabView software that greatly increases the flexibility for implementing more intricate pulse sequences. Evidence of the facility of the data station is the ability to perform an experiment utilizing repetitive, continuous output of a SWIFT waveform for selective broadband quadrupolar axialization of the entire charge state envelope of horse heart myoglobin (MW 16952).

The spectra were obtained using a 3 Tesla superconducting magnet equipped with a concentric tube electrospray source. The FTICR experiments were controlled by a 90 MHz pentium microcomputer running LabView software. Excitation waveforms were created in LabView and executed by a LeCroy model 9100 arbitrary function generator. When creating the SWIFT waveforms in our LabView virtual instrument, the number of data points used can be varied for the clock rate thereby determining the length of the waveform. Transients were collected using a LeCroy model 9410 digital storage oscilloscope and processed in LabView. 20 μ molar solutions of commercially obtained horse heart myoglobin were prepared in 69:30:1 mixture of methanol:water:acetic acid. The spectra were obtained using the following execution sequence:

**Generate SWIFT waveforms / Open shutter / Accumulate ions /
Close shutter / Pulse argon gas / Apply QE / Pump Down / Apply QE**

The initial myoglobin spectrum collected without a QE event (Figure 1) had a poor signal to noise ratio that was much improved when quadrupolar axialization is applied across a 50 kHz bandwidth using a 16k data point SWIFT waveform (Figure 2a). A similar, but smaller improvement in signal to noise ratio is also seen when a 100 kHz bandwidth 16k datapoint SWIFT waveform is used for quadrupolar axialization (Figure 2b). When a smaller waveform is used for quadrupolar axialization, the axialization is not as efficient or as uniform as when a 16k or 32k SWIFT waveform is used. Applying a SWIFT waveform with a notch from $m/z = 1350$ to $m/z = 1450$ to exclude the +12 peak at 1413 produces peak discrimination (Figure 3) that also improves with an increasing number of data points.

Figure 1
Initial Myoglobin Spectrum

In summary, broadband quadrupolar axialization is demonstrated for bandwidths of up to 100 kHz or more using a continuously broadcast SWIFT waveform. Furthermore, one can selectively exclude ions from this cooling by using selected notches when forming the SWIFT waveform. This exclusion should be further enhanced by running the experiment under conditions that enhance axial loss of ions, such as remeasurement experiments or the use of higher trap potentials to increase the magnetron motion of the ions. The efficiency and uniformity of the axialization is found to be dependent upon the number of data points in the SWIFT waveform used; application of larger broadband excitations requires a greater SWIFT resolution than a small set of data points can deliver.

FTICR Remeasurement Techniques for Small Molecules
G. T. Blakney, D.A. Laude, Department of Chemistry and Biochemistry,
The University of Texas at Austin, Austin, TX 78712

A distinct advantage of FTICR is a non-destructive detection procedure in which the image current of an ion packet is measured. This suggests the possibility that the ion cloud can potentially be returned to the center of the trapped ion cell for remeasurement. Potential advantages of this procedure include signal averaging for sensitivity improvement and application to sequential dissociation and ion molecule reactions.

Following work by McLafferty and Williams which demonstrated the potential of remeasurement, Laude and coworkers applied the remeasurement procedure to large electrosprayed ions. Unit remeasurement efficiency was demonstrated for a single packet of ions over hundreds of scans. At the same time, Amster and coworkers evaluated the use of remeasurement techniques for smaller ions (about 400 Da/z) formed by laser desorption. Following the alleviation of space charge highly efficient remeasurement was demonstrated for hundreds of FTICR scans on the same ion packet.

One last area of FTICR for which the remeasurement experiment has not been demonstrated is small molecules formed by electron ionization. The ability to perform efficient remeasurement in this mass range would be of significance to researchers interested in consecutive ion/molecule reactions in which products ions were returned to the center of the cell for remeasurement, or similar multi-stage dissociation experiment. In work to be presented, the feasibility of the remeasurement experiment for small molecular ions formed by electron ionization will be evaluated. This experiment is significantly more difficult to perform than high mass experiments because scattering and chemical effects are more pronounced.

All experiments were performed on a 1T electromagnet with a cubic 1" cell. Naphthalene was introduced through a leak valve above a background, diffusion-pumped pressure of 5×10^{-9} torr. Quadrupolar excitation following the pulsed introduction of Ar permitted efficient cooling of ions for remeasurement. All data acquisition was performed on a LabView-based data system.

A first measure of the feasibility of the low mass remeasurement experiment required that the storage of low mass ions for long delay times be achieved. A control experiment was performed in which a delay time following the formation of ions was evaluated. The half life for ion loss was on the order of 15 s for the data shown with loss due to charge exchange likely reducing overall ion residence time in the trapped ion cell. This control experiment indicated that even under ideal remeasurement conditions, it would be necessary to correct for ion loss processes that would effectively eliminate all ions from the cell after about one minute even if remeasurement was ideal. These results need to be considered in the evaluation of remeasurement performance.

Remeasurement experiments were performed at a variety of cell radii. It would be expected that at lower cell radius, remeasurement experiment would be superior because of the quadrupolar nature of the potential in the cubic cell. Thus the QE experiment used to promote efficient cooling would be more effective. At larger radius, the ability to promote efficient cooling would degrade because of trap imperfections and increase scattering at higher kinetic energies.

Two sets of remeasurement experiments are shown here, a sequence of profiles for naphthalene collected at 25 % of the cell radius exhibit 82% remeasurement efficiency and a sequence of profiles acquired at 75% of the cell radius which exhibit 65% remeasurement efficiency. These spectra indicate that the ability to perform remeasurement for low mass ions is possible and can immediately be applied to efficient reaction and dissociation chemistry. Minimization of interfering ion/molecule reactions that reduce ion residence time and limit remeasurement efficiency should allow much higher remeasurement efficiency to be achieved.

Efficient Ion Remeasurement Using Broadband Quadrupolar Excitation FT-ICR Mass Spectrometry

Cynthia C. Pitsenberger, Michael L. Easterling, I. Jonathan Amster
Department of Chemistry, University of Georgia, Athens, GA 30602-2556

Techniques for performing multiple stage mass spectrometry (MS)ⁿ experiments hold great promise for the structural characterization of biological compounds and synthetic polymers. Biopolymer analysis is often accomplished by sector based instruments, yet these methods are limited in the number of (MS)ⁿ stages that can be achieved. The unique features of Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS), particularly the nondestructive nature of ion detection, make it particularly well-suited for multiple stages of tandem mass spectrometry. The capability of remeasurement is necessary for performing tandem MS of limited sample quantities. Quadrupolar excitation, introduced by Savard *et al.*,¹ and first adapted to analytical FT-ICR by Marshall and coworkers,² has attracted considerable recent attention for increasing the performance and capabilities of FT-ICR. When ions undergo collisional damping during quadrupolar excitation (QE), they move to the center of the analyzer cell, a process called axialization. QE can be used to refocus ions that are scattered throughout an analyzer cell after the detection process, so that they can be remeasured. Remeasurement of ions using QE has been demonstrated for single frequency³ and over a limited mass range.⁴ Examples of quadrupolar excitation over a larger range of masses (i.e. 1000 m/z units) have been published,⁵ yet none have demonstrated efficient broadband ion remeasurement over a wide mass range. In principle, broadband axialization could be used to refocus the products of collisionally activated dissociation (CAD), so that ions can be selected and re-excited for further stages of CAD (i.e. MSⁿ).

We have found that quadrupolar excitation is achieved over a wide mass range (i.e. up to 2000 m/z units), in a 4.7 FT-ICR spectrometer, by using chirp excitation, filtered white noise excitation, and burst excitation for matrix assisted laser desorption FT-ICR mass spectrometry. Ions over a 2000 m/z range for polyethylene glycol 4600 have been axialized. Remeasurement is demonstrated to be efficient for broadband quadrupolar excitation of ions over a range of 1000 m/z units. Remeasurement efficiencies of 99% or better have been found for each of these broadband axialization methods.

In the mass spectrum shown in Figure 1a, ions formed by MALDI of PEG 2000 were axialized by a continuous linear frequency sweep from (28,767-47,924) Hz, corresponding to a mass-to-charge range of 1500-2500. The ions formed by a single laser desorption event were then remeasured 80 times with signal averaging to produce the mass spectrum of Figure 1b. The polymer distribution in Figure 1a is nonstatistical due to the few number of ions that were present in the cell. Remeasurement of the ions maintains the same distribution, as seen in Figure 1b, demonstrating that the efficiency of remeasurement is constant over the entire mass range. Figures 1c and 1d show an expansion of the mass scale around m/z 2200, and demonstrate that remeasurement increases the S/N while maintaining isotopic resolution. Experiments are in progress to demonstrate the utility of these methods for performing multiple stages of tandem mass spectrometry.

Optimization of an Ion-Ion Pulse Sequence for a Five-Electrode Trapped-Ion FTICR Cell

An experimental pulse sequence for ion-ion chemistry in a five-electrode trapped-ion cell is optimized for laser desorption/electrospray ions. This novel trapped-ion cell, which was previously developed in our laboratory, provides simultaneous trapping of both positive and negative ions (1). The gas phase ion-ion experimental pulse sequence requires dual ionization sources and quadrupolar axialization to selectively cool reactive ions to the center of the overlapping potential wells. Our recently modified 3-T FTICR system now includes an electrospray ionization source with tradition laser desorption and electron ionization capabilities. The ability to generate multiply-charged ions with electrospray offers the exciting possibility of studying macromolecules with relative ease. Optimization of the experimental pulse sequence for simultaneous trapping of anion and cations for ion-ion chemistry is presented here.

A potential well diagram using SIMION is shown in Figure 1. Here the potential depressions are produced by applying -5V to the outer traps and +5V to the inner traps. Two separate potential wells for positive and negative ions are formed. Nested within the negative depression is a central positive well formed by the application of the positive voltage to the inner pair of the electrodes. The two small potential lobes form two regions into which negative ions are trapped. Variations in the potential well depth can be achieved by altering the applied potentials. In general, good spectra are acquired when the well depths are adjusted to produce adequate potential depressions to trap sufficient number of ions formed by EI.

Figure 1

An experimental pulse sequence was developed and optimized to include dual trapping of ions generated by two independent ionization sources. The two examples presented here include EI, LD, ESI and LD/ESI experiments. A general diagram of the pulse sequence is presented in Figure 4. Briefly, the inner traps of the 5-electrode trapped-ion cell are biased negatively to trap negative ions generated by LD/EI, while the outer traps are grounded. After a delay the inner trap negative potential is decreased slightly, while the outer trap potential is biased positive to trap electrospray ions. Before excitation and detection the potential on both sets of traps are dropped significantly to minimize space charge effects.

Figure 4

The ability to trap both positive and negative ions generated by dual ionization sources offers the exciting possibility of studying ion-ion reactions. Experimental trapping conditions were optimized for the LD/ESI experiment with gold and myoglobin using the ion-ion pulse sequence. Future work will include a more extensive study of the ion-ion chemistry of negatively charged oligonucleotides with protonated chemically ionized positively reactants. In addition, the reactions of oligonucleotides and protonated species can be investigated with the incorporation of quadrupolar excitation (QE). QE has proven to be an effective means of axializing an ion of specific m/z . This will enable us to selectively isolate reactant ions for enhance control of product formation.

Charge State Inversion of Substituted Sulfurhexafluorides

Iris Spieß, Florian Kuhnen, Karl P. Wanczek
Institute of Inorganic and Physical Chemistry, University of Bremen

Introduction

Sulfurhexafluoride is an inert compound however with a large electron affinity. In the gas phase only the anion is formed by thermal electron attachment. No positive cation is formed.

Sulfurhexafluoride with a fluoride substituted by chlorine or bromine is examined in the gas phase, using an open ICR cell, capable for the simultaneous trapping of positively and negatively charged ions. Sulfurhexafluoride is pulsed into a vacuum system, where the neutral halogen is already present. The observed substitution products differ in charge polarity when the halogen is changed from chlorine to bromine. Besides the examinations with ICR spectrometry, semi-empirical AM1 Mo-calculations [1] for the substitution products in the different charge states are performed.

Experimental

The observed reactions take place in a cylindrical, 38 mm diameter open ICR cell, consisting of five electrode rings of 56 mm, 5.6 mm, 44.8 mm, 5.6 mm and 56 mm length. The cell is used in a 7T superconducting magnet.

The reactions are invoked by pulsing the sulfurhexafluoride into the ultra high vacuum chamber, that already contains the halogene. The sequence of events is { -- D_p -- P_p -- P_G -- P_i -- D_R -- P_E -- Aq -- }

D _p :	pump delay	P _p :	quench pulse
P _G :	gas inlet pulse	P _i :	ionization pulse, electron impact ionization
D _R :	reaction delay	P _E :	excitation pulse
Aq:	data acquisition		

ICR spectra are acquired with chlorine and bromine as reactands with sulfurhexafluoride, where the cell is switched for dual mode (simultaneous trapping of positive and negative ions), positive and negative mode. The analyzer cells electrodes are set to -5V, 9V, 0V, 9V, -5V in the dual mode, 5V, 0V, 0V, 0V, 5V in the positive mode and -5V, 0V, 0V, 0V, -5V in the negative mode.

Results

The transformed spectra show a formal substitution product of sulfurhexafluoride with chlorine or bromine, besides lower sulfurfluorides, halogenes, its dimers and trimers. Analyzing the polarity of the two substitution products, it turns out, that the monochlorosulfurpentafluoride is negatively charged (Fig. 1), while the monobromosulfurpentafluoride is positively charged (Fig. 2).

DETERMINATION OF EXCITATION FREQUENCY FOR FIXED-FREQUENCY PULSE EXCITATION WAVEFORM IN FT-ICR/MS

Yasuhide Naito and Masao Inoue

Department of Applied Physics and Chemistry, University of Electro-Communications, 1-5-1 Chofugaoka, Chofu-shi, Tokyo, 182 Japan

INTRODUCTION Since the FT-ICR peak height results from the amplitude of the time-domain signal of an ion packet rotating in a circular orbit, to determine the number of ions in the packet the ions must be accelerated to a well-defined orbit by an rf excitation electric field at a frequency precisely adjusted to the effective cyclotron resonance frequency of ions. However ions can undergo incomplete acceleration at a frequency close to the exact cyclotron frequency. This "off-resonance" effect appears in the various excitation waveforms used in FT-ICR and makes quantitative measurement of ions difficult. In this respect the fixed-frequency pulse excitation (burst) waveform at an exactly tuned frequency seems the best to obtain the quantitative information of ions. In this paper we wish to propose an iterative frequency tuning method for the fixed-frequency pulse excitation in FT-ICR spectrometry.

ITERATIVE METHOD In this method ions are firstly accelerated by an rf electric field at an approximate frequency and the time-domain signal is fast Fourier-transformed to yield a frequency-domain spectrum. The frequency at the spectral peak of the ion is used as an excitation frequency for the next excitation. This procedure is repeated until the peak frequency becomes equal to the excitation frequency.

The convergency of iteration at different excitation conditions has been checked by computer simulation and experiment. Trajectories of an ion of $m/z=132$ in a 1 T magnetic field during the excitation and detection period were calculated. Figure 1 shows the variation of the excitation frequency with iteration times obtained at a trapping voltage of 15V. It is seen that too high excitation voltage of 3V makes the excitation frequency oscillate between the two frequencies. Figure 2 shows the similar results at a trapping voltage of 5V. In this case too small excitation voltage of 1V seems to make the frequency convergence difficult.

MEASUREMENT OF XENON ISOTOPE ABUNDANCE AND COMPARISON WITH OTHER EXCITATION METHOD Table 1 gives the peak heights of the xenon isotopes whose natural abundance exceed 5%. Three frequency swept spectra were obtained by varying the frequency range and the sweep time. Of the three the frequency range from 1 MHz to 100 kHz and the sweep time of 0.2 ms yield the best result. Sum of the square of the deviations from the natural abundance is found to be 8.5%. The same value obtained by the frequency tuned burst excitation is 2.3%.

CONCLUSION Our results have demonstrated that the frequency tuned burst excitation improves remarkably the quantitative performance of FT-ICR spectrometry. Two minor problems have been observed with this method. First, in

some excitation conditions the spectral peak frequency does not converge to a constant value. Second, the excitation amplitude has to be adjusted at every iteration step. This may bring in complexity when the method will be automated.

Fig 1 Simulation result of the excitation frequency tuning for $V_t=15$ V, $t_e=0.25$ ms, and $V_{a0}=1$ (x), 2 (+), and 3 V (o and ●). Other simulation conditions are written in the text. In the case of $V_{a0}=3$ V tuning is unsuccessful and ω_e oscillates between two values denoted by ●.

Fig 2 Simulation result of the excitation frequency tuning for $V_t=5$ V, $t_e=0.25$ ms, and $V_{a0}=1$ (o and ●), 2 (x), and 3 V (+). In the case of $V_{a0}=1$ V tuning is unsuccessful and ω_e oscillates between two values denoted by ●.

ASSESSMENT OF ION-TRAPPING EFFICIENCY IN FTMS-SORI BY COMPUTER SIMULATION OF ION TRAJECTORIES

Yasuhide Naito² and Masao Inoue¹

¹ Dept. of Applied Phys. and Chem., Univ. of Electro-Communications, Tokyo, Japan

² Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, UK

1. INTRODUCTION

Low-energy CAD carried out in an rf-only multipole collision chamber of a MS/MS instrument often yields product spectra including prominent decomposition peaks of peptide precursor ions via rearrangement processes involving loss of the C-terminal amino acid residue rather than simple cleavage fragmentation peaks. These rearrangement decomposition peaks have shifted mass and confuse interpretation of the product spectra at routine measurements. A powerful and simple C-terminal sequencing procedure based on sequential losses of C-terminal residues in a MSⁿ experiment depends on improved understanding of the mechanism of the C-terminal rearrangement.

A low-energy CAD method of FT-ICR, the sustained off-resonance irradiation (SORI), is based on trajectories of ions undergoing acceleration-deceleration cycles consequent on an off-resonance electric field pulse. The method realizes an extremely low and finely controllable kinetic energy of precursor ions, hence, can be expected to reveal the energetics of the C-terminal rearrangement process. This study aims at assessing the capability of SORI for measuring the energetics of the C-terminal rearrangement.

2. THEORY

A motion of an ion in a SORI event, in which the ion-neutral collisions play an important role, must be treated by a statistical kinetics theory to take account of the collision effect. Unless the elastic collision rate between the ions and the target neutrals strongly depends on the velocities of the ions and the neutrals, we can approximate the equation of ion motion;

$$\frac{\partial \mathbf{v}}{\partial t} = \frac{q\mathbf{E}(t)}{m} + \frac{q\mathbf{v} \times \mathbf{B}}{m} - \nu_c \mathbf{v} \quad (1)$$

where ν_c denotes the average ion-neutral elastic collision rate.

Solving Eq.1 in the simplest case, we obtained an expression for the terminal ion kinetic energy which was employed to draw Fig. 1, in which an outline of the SORI-CAD property was elucidated. The SORI electric field can excite not only the precursor ions, but also the CAD product ions. The SORI activation selectivity becomes lower in a higher target pressure region.

3. SIMULATION

In order to take account of the inhomogeneous electric field in a cubic ion trap, a numerical simulation for ion trajectories in SORI process was carried out. The SORI excitation electric field acting on the ion in the cubic ion trap was calculated by the analytical solution of the boundary condition for the cubic ion trap. An instantaneous value of the electric field was substituted into Eq.1, which was integrated by using the 4th order Runge-Kutta-Gill method.

4. CONCLUSION

Owing to the low kinetic energy of precursor ions, SORI seems to be promising method for mechanistic studies of C-terminal rearrangement process, however,

- The method may require a quite fine adjustment of the target gas pressure, which relates to i) SORI activation selectivity, which is decreased by increasing the pressure, and ii) spatial uniformity of the kinetic energy, which is degraded by decreasing the pressure.
- In a finite collisional condition, the kinetic energy does not strongly depend on the initial z-displacement of the ion. This fact is favorable for an external ion source incorporated with FT-ICR, where the introduced ions have a large trapping oscillation amplitude.
- A prominent r-dependence of the kinetic energy can affect the activation process. Axialization must be required for mechanistic studies of the rearrangement using SORI.

Unlike the z -dependence, ion-neutral collisions don't effectively improve the r -dependence of the kinetic energy

A Systematic Approach to Improve Mass Accuracy in FTICR Mass Spectrometry at Zero Trapping Potential

Clifford H. Watson, Kevin Goodner, and John R. Eyler
Department of Chemistry, P.O. Box 117200, University of Florida, Gainesville, FL 32611-7200

A systematic approach for reliably obtaining high mass accuracy in Fourier transform ion cyclotron resonance (FTICR) mass spectrometry is discussed. This approach minimizes the mass (frequency) shifts arising from variations in instrumental parameters, especially shifts resulting from differences in the number of ions stored in the analyzer cell and fluctuations in the trapping potential. The apparent cyclotron frequencies are determined from a series of measurements made over a range of trapping potentials, followed by extrapolation to the "zero trapping potential" limit.

Deviations from linearity which introduce errors in the exact mass measurement often arise due to changes in the trapping potential [1] and differences in ion population in the cell [1,2] and can have a profound effect on the measurement of exact mass. In our experience (see Table 1), errors in the exact masses, as calculated from either of the more common calibration approaches [2-4], range from 5 to 10 ppm when using broadband detection to cover a relatively wide mass range (1 to 5 MHz bandwidth). Unfortunately, much larger errors can be introduced if unknown analytes are measured under different conditions than those used for the reference compounds.

Standard data calibration: Table 1 shows a typical calibration report for EI on PFTBA obtained by digitizing 128k data points over a 2 MHz bandwidth (BW) at a constant trapping potential of 1 volt. Substantial errors in the exact mass measurement can be introduced due to changes in various instrumental parameters during signal optimization. Consider the data for m/z 264 from PFTBA shown in Figure 1; a 0.5 volt shift in the trapping potential can result in up to a 14 Hz (80 ppm mass error) shift in the apparent cyclotron frequency. These data also demonstrate that shifts in frequency occur when the number of ions in the analyzer cell is increased [1] as the EI beam duration is increased from 50 to 150 ms. At a constant 1V trap potential the different ion density shifts the apparent cyclotron frequency by ca. 30 Hz (180 ppm mass shift).

Calibration via extrapolation to zero trapping voltage: To compensate for changes in the trapping potential and number of ions in the cell, a series of reference spectra are collected over a range of trapping voltages. For example, Figure 1 also shows the frequency shift for m/z 264 (PFTBA) as a function of trap voltage for 3 different ionization times. Table 2 shows the calibration report obtained by acquiring data in a similar fashion to that shown in Table 1, but over a range of trapping potentials and extrapolating the measured frequencies to zero trap potential. By making a series of measurements and extrapolating to zero trapping voltages the uncertainty in the mass has been reduced from ca. 30 Hz with a 1 volt trapping potential to ca. 3 Hz at 0 voltage. The uncertainty of the measurement for the extrapolated frequencies approach the limit of the digital resolution (detection BW/number of data points).

Procedure for the determination of an "unknown" by extrapolation to zero trapping potential:

- Step 1. Collect a series of calibration spectra as a function of trapping voltage and extrapolate the reference frequencies to zero trapping potential.
- Step 2. Calibrate the instrument using these extrapolated "zero trap" frequencies.
- Step 3. Measure a series of spectra for an "unknown" sample as a function of trapping potential.
- Step 4. Use unknown's extrapolated "zero trapping potential" frequency with calibration constants derived in Step 2 to calculate exact mass.

The method outlined here provides a systematic approach for obtaining exact mass measurements reproducibly over a much wider range of instrumental parameters. By making a series of measurements over a range of trapping voltages and extrapolating to the "zero trapping potential" limit the frequency shifts are minimized. While the accuracy of this method is not superior to that possible using the conventional approach (compare Tables 1 and 2), the uncertainty of the measurement can be reduced by an order of magnitude, 30 Hz to 3 Hz, over a wide range of measurement conditions.

Characterization of open ICR cells with trajectory computation
Florian Kuhnen, Karl-Peter Wanczek
Institute of Inorganic and Physical Chemistry
University of Bremen, 28359 Bremen

Introduction

The use of open endcap ICR cells became more pronounced the last years [1]. In physical applications [2] the open endcap ion trap was implemented mainly because of its accessibility towards particle beams or lasers. In the 80's Gabrielse introduced a compensated open trap of cylindrical geometry. Laude et. al [3] finally introduced the concept of an open endcap ICR cell in the chemists community. Open endcap ion traps are interesting for all techniques where ions are injected into the trap, or where a free access to the center of the trap is necessary for other reasons.

Closed cells define boundary conditions on a closed surface, so that Laplace's equation can be solved exactly for the interior region. In the case of an open ICR cell, there are approximations to be made, concerning the boundary conditions. If periodicity is assumed for the boundary conditions, an easy to calculate potential representation is obtained.

Here the behaviour of the cell is to be examined with the help of computer experiments. The trajectory of a single ion in an electrical potential, represented by a power series up to sixth order, is simulated with a Runge Kutta routine [4]. The x compound of the trajectory is Fourier transformed, so that the effective cyclotron frequency can be detected for different trajectories, resulting out of different starting parameters. The intention of numerical experiments is to detect the correlation of the cyclotron frequency of parameters that are difficult to measure, as there are the axial amplitude or the cyclotron radius

Methods

The potential inside an open trap is solved analytically with a Fourier Bessel series set up for periodic boundary conditions on a cylindrical surface. Approximating the open trap to be periodic is a valid description of the potential if the endcaps are long. These boundary conditions lead to the trapping potential

$$V(\rho, z) = V_c \cdot \left(\frac{H-C}{H} - \sum_{k=1}^{\infty} \frac{2 \sin(\gamma_k C)}{\pi k I_0(\gamma_k r_0)} \cos(\gamma_k z) I_0(\gamma_k \rho) \right)$$

$$\gamma_k = k \frac{\pi}{H}$$

where H denotes the half length of the ICR cell, C denotes the half length of the central ring of the ICR cell and r_0 is the cell radius. That means, that the length of the trapping rings are H - C each. To obtain an analytic representation of the trap, a representation of the trapping potential in polynomials is employed.

The trapping potential is expanded into polynomials of the form

$$V = V_c \sum_{k=-\infty}^{\infty} C_k \left(\frac{r}{r_0} \right)^k P_k(\cos(\theta)) \quad (2)$$

Analytical equations of motions are derived out of the representation (2) with k up to 6. The equations are solved numerical with the help of the Runge Kutta method. A number of steps, sufficient to be Fourier transformed with a certain resolution are stored. The x or y motion is transformed to obtain the effective cyclotron frequency.

Experiments are performed in a virtual trap of the following dimensions:

$$H = 6 r_0$$

$$C = 2 r_0$$

This trap is characterized by coefficients $C_2 = 7.1 \cdot 10^{-1}$, $C_4 = 1.3 \cdot 10^{-1}$ and $C_6 = -1.2 \cdot 10^{-2}$. The ion mass is chosen to be 50000 amu to cause a low cyclotron frequency. To obtain a frequency resolution of 10 Hz, we need a simulated signal of 0.1 s duration. Since the Runge Kutta method needs about 20 steps per cyclotron rotation, this means to much calculation steps in conjunction with a high cyclotron frequency.

For the given trap, two types of experiments are performed. The cyclotron frequency is plotted against different axial amplitudes in one experiment and plotted against the cyclotron radius in another experiment.

Characterization of a multi-electrode ion trap

Peter Engelmohr and Karl Peter Wanczek

Institute of Inorganic and Physical Chemistry, University of Bremen,

D-28334 Bremen, Germany

The new electrode structure of the multi-electrode ion trap generates an ideal electrical trapping field. Y Wang and K.P. Wanczek have described the theory for an electric FT-ion trap for the generation of an exact three dimensional quadrupole electric field [1]. From the results follows, that a cone-shape closed boundary with a linear variable potential can be used to generate such a field

We have employed these principles to construct the new ICR-cell. This cell is designed (Fig.1) with a set of 13 parallel metallic sheets with different circular holes inside the electrodes to form the inner surface of a cone. Inside the trap a homogeneous field in the direction of the symmetry axis can be generated and superimposed without interaction with the quadrupolar trapping field. This field is used for excitation of the ions

The symmetry of the used electrode structure has a great advantage. There are always two electrodes with the same trapping potential and with the use of the following potential distribution there are two electrodes with a zero trapping potential. These electrodes can easily be used as detection electrodes

Fig.1: The multi-electrode ion trap

The radius of the trap is $r_0 = 15\text{mm}$ ($z_0 = 10.7\text{mm}$). The electrodes are connected with $0.5\text{ M}\Omega$ resistors (SMD 0.8×0.5) and the distance between them is 1.2mm .

Fig 2: Applied voltages and resulting potential distribution

For the simultaneous trapping and detection of positive and negative ions a potential distribution inside the trap with regions for positive and negative ions is needed. In the literature additional electrodes are employed to generate such fields. With the multi-electrode trap only the applied voltages have to be changed. In Fig.2 the voltages applied to 9 electrodes and the resulting potential calculated with the program SIMION is shown. The first experiments with the ions Ar^+ (m/z 40), SF_5^+ (m/z 127), SF_6^- (m/z 146) show the simultaneous trapping of ions with both polarities

The theoretic z-frequency is:

$$\nu_z = \frac{1}{2\pi} \sqrt{\frac{4qU_z k}{mr_0^2}}$$

The first experiments show the square root dependents of the z-frequency from the trapping voltage, and the experimental determined z-frequencies of N_2^+ and H_3O^+ ions are in good agreement with calculated z-frequencies.

Scaling Factors for Excitation and Trapping Potentials in Tetragonal and Cylindrical traps

George S. Jackson*, Jesse D. Canterbury, Shenheng Guan*, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab, Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

* Member of the Department of Chemistry, Florida State University

An FT-ICR mass spectrometer is based on a Penning ion trap. The performance of such a trap is best expressed by comparison to idealized electrode geometry: e.g. a perfectly dipolar excitation/detection potential corresponding to opposed infinitely extended flat electrodes. The two most popular finite-dimensioned Penning ion trap geometries are tetragonal and cylindrical, with considerable discussion as to which one is "better." Here, we compare tetragonal and cylindrical Penning trap potentials to idealized potentials for the two most important FT-ICR excitation modes: dipolar and azimuthal quadrupolar. We also compare the idealized static quadrupolar trapping potential to the trapping potential generated by each trap. Although exact solutions for the electric potential are available for the closed cylindrical and tetragonal trap (e.g., expansion of the electric field in a Taylor series for dipolar excitation in the tetragonal trap), it is much faster and simpler to compute the potential numerically by use of Simion 6.0, which can also accommodate traps of lower symmetry. Not only is it possible to calculate scaling factors for traps of lower symmetry by this general method, but it is also easy to see how the generated electric field deviates from the ideal field, by subtracting out the field inhomogeneity. Finally, this method provides a simple check on analytical calculations that involve expansion of the electric field, since it is easy to make an error in those long and arduous expansions.

Consider dipolar excitation for a closed cylindrical or tetragonal trap. The field that one wants to mimic is the one that would be obtained by applying $\pm V$ volts to two infinitely extended parallel flat electrodes separated by d meters. The potential of this field is $\pm Vx/2d$, in which x is measured from the midpoint between the electrodes. A tetragonal or segmented cylindrical trap to which the same voltages are applied will produce (to first order) a potential, $\pm Vx\beta_1/2d$, in which β_1 (Figure 1) is a "scale factor" between zero and one. Also shown is the β_2 term which is the coefficient of the leading (x^3) term for the excitation field inhomogeneities (the x^2 term vanishes by symmetry). Since most nonlinear resonances depend on excitation field inhomogeneity (1), and since β_2 is usually the largest of the higher-order scale factors, we seek to minimize β_2 . Once β_2 is available, one can then evaluate the effects of change in trap aspect (length-to-width) ratio and/or trap shape, a significant aid to future ion trap design.

Here, we calculate the scaling factors, β_1 and β_2 , as a function of aspect ratio for closed tetragonal and cylindrical traps by use of Simion 6.0. Analytical expression for the electric field was expanded in a Taylor series, and the coefficients of that expansion compared to the scaling factor obtained numerically from Simion. To facilitate the comparison, the theoretical equation was plotted as a function of aspect ratio in Lab Windows/CVI, thereby providing a simple and easy double-check of the theoretical results.

Next, the idealized portion of the electric field potential was subtracted from the "actual" electric field (calculated to ninth order for all 3 geometries!) and the inhomogeneous part was obtained for the cubic trap. Figure 2 shows how the inhomogeneity magnitude varies in proceeding from the center of the trap to the edge. Work supported by NSF (CHE-93-22824) and the National High Magnetic Field Laboratory at Florida State University.

Figure 1. Scaling factors, β_1 and β_2 (see text), for dipolar excitation as a function of aspect ratio, calculated from Simion contour plots (●) and from Taylor series expansion (—) of an analytical expression for the electric field. A suitable analytical expression for β_2 for the cylindrical trap is not yet available.

Figure 2. Deviation from linearity in a cubic trap of edge length, a , as a function of x -distance from the trap center on the $y, z = 0$ midplane. A voltage of ± 1 V is applied to the excitation plates at $x = \pm 0.5a$. The detect plates are at $y = \pm 0.5a$, and the trap plates are at $z = \pm 0.5a$.

Theoretical Description of the Wire Ion Guide (WIG) Cell

Brian K. Bluhm, Kent J. Gillig, David H. Russell

Laboratory for Biological Mass Spectrometry

Department of Chemistry

Texas A&M University

College Station, TX 77843

Since the development of matrix-assisted laser desorption ionization (MALDI), researchers have attempted to extend the mass range (> 6,000 daltons) and high mass resolution of Fourier-Transform Ion Cyclotron Resonance mass spectrometry. We recently introduced the Wire Ion Guide (WIG) cell as a means of trapping singly charged high mass ions (BSA=66,000, Transferrin=78,000, Transferrin Dimer=156,000).¹ At the time it was introduced, the trapping efficiency for high mass ions was not completely understood. We developed a theoretical description for the WIG cell by modeling it as a Kingdon trap² with variable endplates residing in a constant axial magnetic field. From this description we are able to accurately evaluate the WIG cell's performance at high mass.

The WIG cell consists of an elongated cylindrical cell coaxially surrounding a thin wire as shown in Figure 1. Included in Figure 1 are boundary conditions defining trap parameters used in subsequent calculations. The potential for the WIG cell (eqn. 1) is

$$V(r, \theta, z) = \sum_{n=1,3,5} \left[A_n I_0 \left(\frac{n\pi r}{L} \right) + B_n K_0 \left(\frac{n\pi r}{L} \right) \right] \sin \left(\frac{n\pi z}{L} \right) \quad (1)$$

where I_0 and K_0 are modified Bessel functions of zero order, and A_n and B_n are constants defined by the boundary conditions.³ The isopotential surface of the WIG cell is shown in Figure 2, illustrating the logarithmic nature of the potential. From the potential, the electric field is derived and has both radial and axial components

$$E_r = - \sum_{n=1,3,5} \left[A_n I_1 \left(\frac{n\pi r}{L} \right) - B_n K_1 \left(\frac{n\pi r}{L} \right) \right] \frac{n\pi}{L} \sin \left(\frac{n\pi z}{L} \right) \quad (2)$$

$$E_z = - \sum_{n=1,3,5} \left[A_n I_0 \left(\frac{n\pi r}{L} \right) + B_n K_0 \left(\frac{n\pi r}{L} \right) \right] \frac{n\pi}{L} \cos \left(\frac{n\pi z}{L} \right) \quad (3)$$

where I_1 and K_1 are modified Bessel functions of first order. An important feature to note is the inward direction of the electric field, to which we attribute the high mass capabilities of the cell. In standard ICR cells the electric field is opposing the magnetic field, thereby reducing the effective magnetic field. By inverting the electric field we have essentially increased the effective magnetic field strength, thus allowing the trapping of high mass ions.

Ion motion within the WIG cell is described by

$$\frac{d\theta}{dr} = \pm \frac{1}{r} \frac{\left(\frac{B_0 r}{2} \right) + \left(\frac{C}{r} \right)}{\left[hV_0 + hE_0 \log r - \left[\left(\frac{B_0 r}{2} \right) + \left(\frac{C}{r} \right) \right]^2 \right]^{1/2}} \quad (4)$$

where r is the radius, E_0 is the constant electric field, B_0 is the magnetic field, C is a constant associated with the initial slope of the ion's orbit, and $h = 2mc^2/e$ (m =mass, c =speed of light,

and e =elementary charge).⁴ The voltages applied to the wire have an obvious affect on the ion trajectory as can be seen in Figure 3. As the voltage on the wire increases negatively, the ion trajectory begins to assume that of a purely electrostatic Kingdon trap, demonstrating that the electrostatic force is overpowering that of the magnet. However if the voltage remains low (≤ -20 Volts) then ion trajectory approximate that of a standard ICR cell.

The WIG cell offers high mass capabilities not found in other ICR cells, thus making it attractive for biological applications of FT-ICR. An added advantage of the cell is the damping of magnetron motion during collisional cooling, thus diminishing the need for quadrupolar axialization as shown in Figure 4. Studies dealing with resolution and mass accuracy will be presented at a later time.

MODELING OF ION INJECTION AND TRAPPING FOR A VERSATILE EXTERNAL SOURCE FTMS SYSTEM

Authors: Eugene Nikolaev*, Sergey Rakov, Jean Futrell and Douglas Ridge, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716 and Bruce Becker, Brian Winger and Joe Campana, FT/MS, Madison, Wisconsin 53711

Although several methods are extant for injecting ions generated in external ion sources into the solenoid field of FTMS spectrometers (1-5) no detailed simulation of ion motion and experimental confirmation of optics principles has been reported. In the present research project the Delaware FTMS-2000 has been equipped with a flexible prototype external source which permitted us to explore several strategies for ion injection. This highly versatile external ion source provides excellent differential pressure isolation between the ion generation and detection regions. It also provides kinetic energy selection of ions, enables precise control of ion trajectories and time-of-flight selection of mass groups of injected ions. The electrostatic optics components are a series of cylindrical lenses which can be configured as Einzel lenses, zoom, linear and exponential lens arrays. This enabled us to test several schemes for ion injection into the solenoid by simply rearranging power supplies and voltage dividers. This system has been tested with electron impact and chemical ionization ion sources to confirm design concepts and optimize operating parameters.

The fundamental physics determining whether or not ions are successfully injected into a superconducting solenoid magnet is the ratio of velocity components parallel to and perpendicular to the solenoid axis as ions enter the gradient magnetic field at the entrance to the solenoid. Assuming that the magnetic moment and kinetic energy are conserved,

$$(U = \frac{1}{2} mv(\text{perpendicular})/\sqrt{B} = \text{Constant}) \quad (1)$$

$$E = \frac{1}{2} mv^2(\text{perpendicular}) + \frac{1}{2} mv^2(\text{parallel}) = \text{Constant} \quad (2)$$

so that as B increases the perpendicular velocity increases with a corresponding decrease in the parallel velocity. When the parallel velocity becomes zero and all the kinetic energy of the ion is motion perpendicular to the field (e.g., in magnetron and cyclotron motion) the ion trajectory is reversed. Consequently ions meeting these conditions will be reflected. For velocity components perpendicular to the field equal to zero (injection parallel to the solenoid axis, hardly realizable in practice) no interconversion of kinetic energy occurs and injection follows simple electrostatic optics considerations. Accordingly, if ions are accelerated strongly before entering the strongest gradient of the magnetic field, ion velocity parallel to the solenoid field is dominant and injection can be highly efficient. Conversely, if ions are formed over a broad area and weakly accelerated into the gradient region, the magnetic field lines serve essentially as "guide wires" which focus them onto the center of the solenoid as the field lines bunch together and become a parallel bundle in the center of the solenoid.

In addition to these limiting cases of predominantly electrostatic lens focusing and predominantly magnetic focusing we have investigated the interesting case of comparable magnetic

field and electric field gradients. Here the optical properties of both fields may be combined to provide highly efficient ion injection. Ion trapping with high efficiency is accomplished by retarding ions to low velocity in the uniform magnetic field of the solenoid with optimum timing of lifting of trapping fields or by conversion of V_{parallel} into magnetron motion. The number density of ions rises sharply at the turning point of the trajectory and a large fraction of the ions can be trapped by lifting an electrostatic gate at just the right time to prevent ions from leaving the trap. This trapping method, for which we suggest the name "dynamic potential trapping" has been modeled and successfully demonstrated.

The entire system has been modeled utilizing a test version of SIMION 6.0 kindly furnished to us by David Dahl of the DOE Idaho Test Site Laboratories. Modifications of SIMION 6.0 have enabled us to combine rectangular parallelepiped and cylindrical geometries and to model both the uniform and gradient magnetic fields of the FTMS-2000 superconducting magnet solenoid. We also express our appreciation to Finnigan FTMS for the loan of an external ion source prototype on which these experiments were conducted. This research was supported by NSF Grant CHE-9021014.

Magnetic Field Focusing Electrospray FTICR on a High Field Magnet

J. J. Drader, C. L. Hendrickson*, J. M. Robinson, and D. A. Laude
Dept. of Chemistry and Biochemistry, University of Texas at Austin
Austin, TX 78712

*National High Magnetic Field Laboratory, Tallahassee, FL

There are several approaches to coupling electrospray ionization sources with the Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. Most sources use external ion generation and rely on an ion transport device (quadrupole, wire ion guide, etc.) to guide the ions to the ion trap positioned in the magnetic field. Some problems associated with ion transport include loss of ions due to poor transmission efficiency and kinetic energy broadening which decreases trapping efficiency. This magnetic field focusing electrospray source eliminates problems associated with the magnetic mirror effect and instead uses the magnetic field to confine ions radially as they exit the desolvating capillary.[1] Here we describe the construction and initial evaluation of a magnetic field focusing ESI/FTICR built around a 6 Tesla magnet. A new approach to the magnetic field focusing source, featuring a 36" desolvation capillary, is also presented.[2] The long capillary is desirable because ionization occurs outside of the current spray probe while the exit end of the capillary (where the pressure is low enough for electric and magnetic fields to dominate ion trajectories) remains in the high field. This allows x-y-z manipulation of the needle to optimize the spray conditions and will also facilitate interfaces with separation techniques.

A schematic diagram of the instrument is shown in Figure 1. The system is constructed around a 6 Tesla 6" bore superconducting magnet (Oxford Instruments). The source consists of three concentric pumping stages combined with a mechanical shutter resulting in low 10^{-8} Torr pressure at the analyzer. The capillary skimmer region is pumped by a mechanical pump capable of 25 cfm pumping speed which lowers the pressure to 2 Torr. The post skimmer region is pumped by a 2,700 l/s diffusion pump bringing the pressure down to 5×10^{-4} Torr. The mechanical shutter is capable of sustaining a pressure drop of four orders of magnitude. The region between the shutter and the conductance limit is pumped by a 1,500 l/s cryopump. The analyzer region is also pumped by a 1,500 l/s cryopump. The cell is a 2-1/4" diameter, open cylindrical cell with an aspect ratio of 2:1.

Preliminary results from the instrument are shown in Figures 2 and 3. The presence of high charge states of carbonic anhydrase, shown in Figure 2, demonstrates the ability of the long capillary to effectively transport the electrospray ions without reducing the quality of the spray (ie, charge stripping). An example of high resolution is shown in Figure 3 with horse heart myoglobin (MW = 16,951 Da) having a resolving power of 56,000.

The initial results show this instrument to be a viable approach to ESI/FTICR. The source is simplified by eliminating the need for an ion guide, but is still capable of producing high quality results. The ability to move the ionization source outside of the magnetic field makes the system more suitable for interface with online separation and new ESI techniques such as nanospray.

A Small Permanent Magnet FT-ICR Spectrometer

Peter Kofel,

Institute of Organic Chemistry, University of Bern, Freiestr. 3, CH-3012 Bern, Switzerland

During the last decade ion cyclotron resonance (ICR) mass spectrometers employing superconductive magnets have found widespread use in mass spectrometry due to their ultra high resolution, high sensitivity, long trapping times and the ease of consecutive mass spectrometry. Fields of application range from ion molecule reaction studies to electrospray ionization mass spectrometry, where the ICR technique has specific advantages. At the sacrifice of ultra high resolution ion storage as well as resonance experiments and detection are also possible with much lower magnetic fields as they are produced with relatively small and inexpensive permanent magnets. Recently, ICR instruments have been built using permanent magnets [Zeller et al., Anal. Chem. 1993, 65, 2116]. Permanent magnets are attractive since they can be used in a stand-alone detector and, apart from the magnetization procedure, do not require cryogenics, electric current and cooling water.

Based on extensive calculations a permanent magnet system shown schematically has been built. Good homogeneity in the cell region was obtained by using two bored cylindrical magnets. Calculations showed that over the total cell volume a homogeneity of better than 6% can be obtained with this design.

The measurement of magnetic and electric field homogeneity has not yet been done because it is not easily made using ICR

experiments alone. As a starting point, the ICR calibration law could be used:

$m w^2 + B w + eT = 0$ (eq. 1), where m is the mass-to-charge ratio, w the observed cyclotron frequency, B the magnetic field strength and eT the radial electric trapping field gradient. This equation generally holds for a radially symmetric system. Plotting $m w^2$ for different known m as a function of w yields the desired calibration parameters B and eT . However, already this simple and generally used procedure is based on two assumptions: the magnetic field B and the electric field gradient eT must be homogeneous throughout the region of ion motion during the measurements. Even if the magnetic field has been shimmed by NMR, the presence of magnetic materials can seriously disturb field homogeneity. Also the electric field gradient is only strictly homogeneous for a hyperbolic cell.

If B or eT are not constant, then using the calibration law generally assumes that the ions experience the same fields, i.e. that they have been excited to the same cyclotron radius. This assumption neglects the fact, that the cyclotron radius depends on the field homogeneity via the equation: $(B + 2 eT / w) dr/dt = E_x$ (eq. 2), where dr/dt is the rate of cyclotron radius increase during excitation with an excitation field E_x (which circularly rotates at the observed cyclotron frequency). Even if the excitation is independent on radius (which only is the case for the rf shimmed cells), the cyclotron radius after excitation depends on B , eT and via w even on the mass-to-charge ratio m . For m approaching the upper mass limit, the second term in eq. 2 should also be considered when calibrating non-hyperbolic cells. For a homogeneous strong

magnetic field ($B w \gg 2 eT$), the second term in eq. 2 can be neglected and the field gradient eT can be calculated from eq. 1 and the corresponding radius from eq. 2.

To determine the magnetic field strength is more complicated. If eT is known (can be calculated from cell geometry as can E_x), then B can be eliminated from eq. 2 using eq. 1. Integrating eq. 2 yields r , and from this B is again calculated from eq. 1.

Trapping:

The bottom trace of this figure shows the spectrum taken 10 ms after ionization, the mid trace 100 ms and the top trace 1 s after ionization. These spectra show that ions can be stored for times useful for studying ion molecule reactions, which was one of the goals for building the permanent magnet ICR. Experimental conditions were: pressure 10^{-8} mbar, 25 sweeps average.

Resolution:

Spectrum showing a mass resolution of 3000 (FWHM) at m/z 18. The spectrum was taken under the same conditions as the spectra above, but with a lower number of ions.

The field strength determined from these measurements is 0.37 Tesla, which is close to the theoretically expected value. Over a period of one year the field strength did not decay measurably, but certainly less than 1 percent.

Below a trapping voltage of 5 V no signal could be observed. This may be due to magnetic field inhomogeneities. Currently ongoing research focusses on getting the analyzer to function with lower trapping voltages, which is expected to dramatically improve the analytical capabilities of the instrument.

The preliminary results shown here demonstrate the feasibility of small ICR analyzers based on permanent magnets.

The author is indebted to Prof. U.P. Schlunegger for his ongoing interest in and support of this work.

Financial support from the Swiss National Science Foundation is gratefully acknowledged.

Semiconductor Gas Purity and Process Characterization by FT-ICR

*Smith, Derek; Brooks, Larry; Hoffman, John; **Hogan, Jeremiah; Chorush, Russell

*University of Texas at Dallas Richardson, Texas **Texas Instruments, Inc. Dallas, Texas

Fourier transform ICR, Fourier transform MS, trace analysis, residual gas analysis, quantitative analysis

Gas quality and process chamber integrity play crucial roles in the manufacture of integrated circuits. The presence of particulates and molecular impurities can have devastating effects on individual process step yields, which are compounded by losses in subsequent steps. Mass spectrometry is playing an increasingly key role in monitoring both bulk gases and vacuum environments in the semiconductor industry; however, the bulk, expense and complexity of these instruments have limited their application at point of use (in, or just prior to, the process chamber). Ideally, an instrument should be powerful enough to allow quantitation of a wide variety of trace analytes, small enough to allow point of use monitoring without sacrificing excess fabrication site space and inexpensive enough to allow individual instruments at a large number of locations.

For these uses, Fourier transform ion cyclotron resonance (FT-ICR) spectrometry possesses several attractive qualities. High resolution¹ allows differentiation between isobaric components. Multichannel detection and ion remeasurement capabilities portend high sensitivity, and temporally, rather than spatially, resolved events suggest the possibility for extensive miniaturization. Further space minimization should be realized by handling instrument control and data analysis for multiple data acquisition sites with one data station (microcomputer).

This research focuses on the development and characterization of a compact FT-ICR instrument designed for quantitation of trace impurities in semiconductor process gases at the sub-ppm level. FT-ICR has seldom been exploited as a quantitative technique, though it is theoretically capable.² However, an inherent limitation of FT-ICR is the finite number of ions that can be stored and detected in a trapped-ion cell volume.³ Thus, quantitation at these levels will likely require preferential generation or retention of desired analyte ions and/or ejection of undesired bulk background ions. A variety of ionization techniques, in addition to selective and quadrupolar excitation,⁴ present the potential for these capabilities. Quadrupolar excitation is performed through both excite and detect plates and provides a mechanism for converting magnetron motion to smaller-radius cyclotron motion, thereby retaining ions of interest in the cell as other species collide radially with the detect plates.

For this research a miniaturized (0.9"i. d. x 1.1"l.) cylindrical cell has been developed and is currently being characterized on the basis of linear dynamic range and accurate mass and resolution measurements within a commercial electromagnet. The remainder of the system consists of discrete components, including an arbitrary function generator, a digital storage oscilloscope, commercial excite and detect amplifiers and a data collection system based on LabVIEW® software.⁵ All aspects of experimental sequence, the trap potential and data collection and processing have been programmed using the graphical interface. This assembly has successfully generated and detected ions from a gas-phase sample.

A calibration system based on mass flow controller (MFC) technology (Fig. 1), allowing the dynamic generation of standards of widely varying concentrations, has been developed and characterized for this work. In addition a molybdenum microtip-based field emission electron source is being evaluated as an alternative to the less efficient tungsten filament-based electron source. Charge-transfer ionization techniques are also under investigation, as they could lead to benefits similar to those realized with APIMS.

Introduction

The determination of crop protection agents and their metabolites in soil poses a challenge for residue analysis because of the complex nature of the matrix. A sensitive, specific, accurate and reproducible analytical method was developed to quantitate BAS 490 F, an experimental fungicide, and two metabolites in soil.

Experimental

The extraction procedure for the analytes employs sequential extraction of the soil with methanol to remove BAS 490 F, followed by extraction of the soil with sodium hydroxide and subsequent back-extraction with methylene chloride : ethyl acetate to isolate the polar metabolites from the soil. Soil extracts were reconstituted and analyzed by selected reaction monitoring (SRM) liquid chromatography mass spectrometry (LC/MS) using a PE/SCIEX API III^{Plus} triple quadrupole mass spectrometer in the Turbo IonSprayTM mode. No internal standards were employed during the quantitative analyses.

Results and Discussion

Initially samples were analyzed using an SRM/LC/MS method (Method 1) with an ionization polarity switch during the separation where the early eluting metabolites were determined as negative ions and BAS 490 F was determined in the positive ion mode. This Method 1 was adequate for less challenging soils. However, further application of the method revealed limitations when it was employed for the analysis of extracts from soils with a high organic acid content. The presence of co-extractants led to suppression of BF 490-1 and to a lesser extent BAS 490 F so that low apparent recoveries were obtained. Additionally, sample carryover was a minor problem for BF 490-1 and BF 490-5.

For extracts from soils with high organic content a second SRM/LC/MS method (Method 2) was developed where the metabolite BF 490-1 was more retained and separated from interfering co-extractants. This employed an acidic mobile phase so that the analytes were subsequently monitored as positive ions. In comparison to Method 1, the sensitivity for the metabolites was reduced but was sufficient for the analysis of samples. Sample carryover did not occur. Representative chromatograms representing extracts from a 0.01 ppm spiked soil (equivalent to 5 ng/mL assuming 100% recovery) analyzed using Method 2 are shown in Figure 1.

For both methods, quadratic standard curves were obtained from analytical standard solutions over the concentration range 2.0 ng/mL to 200 ng/mL. The assay has a lower level of quantitation (LLQ) of 10 ppb for BAS 490 F and its metabolites based on 10 g aliquots of soil. The recovery of the analytes was soil dependent and the mean recoveries for the analytes at spiking levels of 0.01, 0.10, 0.35 and 1.0 ppm were greater than 70%. The recoveries obtained for three different soils are summarized in Table 1.

Direct Capillary Column Desorption for GC/MS Analysis at High Helium Flow Rate

Lindy E. Dejarne, Prasenjit Ray, Sara J. Lawhon and Laurence E. Slivon
Battelle, Columbus, Ohio 43201

The advent of capillary columns has revolutionized the GC/MS technique. Instead of using high helium flow rates and jet separators, capillary columns allow helium flow rates as low as 1 mL/min which reduced the gas load to the vacuum system of the mass spectrometer. While this technique is suitable in many instances, there are applications where a higher helium flow rate (20 - 30 mL/min) is desirable as in sorbent tube thermal desorption analyses. We have developed a method for performing thermal desorption analyses at high flow rates using helium as the carrier gas.

The method uses a commercially available analytical capillary column (30 m, 0.32 ID, 1 μ m Rtx-5, Restek) cut unequally into two as shown in Figure 1, one section is about 4 meters long while the other is the remainder of the column. The two unequal length columns are connected with a glass Y connector (Supelco). The shorter column (cryofocusing column) is connected to the sorbent tube port and the longer column (analytical column) is connected to the mass spectrometer. The open end of the Y connector is connected to a venting valve. During thermal desorption of the sorbent tube, the valve is vented to the atmosphere and the GC oven is maintained at subambient temperature using liquid nitrogen. Under this configuration, the flow rate achieved through the short capillary column is 20 to 60 mL/min depending upon the head pressure. The analytes are cryofocused in the shorter column. When the GC temperature program is started, the vent valve is closed and the helium flow is diverted through the longer column into the mass spectrometer. This column configuration was installed into a single quadrupole Finnigan 4500 GC/MS instrument.

This method was applied successfully to the thermal desorption analysis of test compounds to include non-deuterated and deuterated methyl benzoate, methyl ethyl ketone, cocaine hydrochloride. All of these compounds were collected in tenax sorbent tubes. Figure 2 shows a GC/MS chromatogram from a thermal desorption experiment of deuterated methyl benzoate (10 ng) and non-deuterated methyl benzoate. The deuterated methyl benzoate was used as a standard. The non-deuterated methyl benzoate was collected from a plug flow reactor containing cocaine hydrochloride exposed to a continuous stream of humidified air. It is clear that resolution of the deuterated from the non-deuterated methyl benzoate is achieved. The mass spectra of these two compounds are shown in Figure 3.

In Figure 4 are GC/MS chromatograms for the analysis of illicit cocaine hydrochloride. When the vent was closed the flow rate was slowed down to about 2.8 mL/minute, effectively reducing the flushing efficiency of the cocaine hydrochloride from the sorbent tube. In fact no cocaine was seen, instead degradation products of cocaine hydrochloride at scans 1580, 1828, 1967, 2055, 2129 were detected. The degradation was expected since cocaine hydrochloride is noted to degrade even at the heated GC interface to the mass spectrometer. When the vent is opened, cocaine hydrochloride was flushed out of the sorbent tube immediately that minimal decomposition was observed.

The advantage of this method is that a) it allows high flow rate during thermal desorption and acceptable flow rates for GCMS, b) minimal decomposition of thermally labile compounds such as cocaine hydrochloride is achievable, c) losses due to the plumbing is eliminated and d) most importantly, all the desorbed compounds are delivered into the capillary tube which is advantageous particularly for low concentration analytes.

Rapid Analysis of TO-14 Airborne Contaminants By Fast GC-TOFMS

Ben D. Gardner¹, Richard E. Berkley², and John F. Holland³

Departments of Chemistry¹ and Biochemistry³, Michigan State University, East Lansing, MI 48824
Atmospheric Research Laboratory, Methods Research Branch, U.S. Environmental Protection Agency²,
Research Triangle Park, NC 27711

Air quality monitoring has become increasingly important as a consequence of the proliferation of industrial processes and the toxic nature of many of their discharges. The potential effect on human and environmental health is of major concern to both industry and government. Appropriately, the Environmental Protection Agency (EPA) monitors air quality as specified by the federal clean air act amendments of 1990.

The most commonly used protocol for analyzing organic air pollutants is specified in the EPA TO-14 method. This method details the analysis procedure for 41 organic ambient air contaminants, ranging from chloromethane and Freon 12 to hexachlorobutadiene. Air samples are collected in passivated SUMMA[®] canisters and transported to the laboratory for analysis. The analytical protocol dictates cryotrapping of a known quantity of air sample with subsequent rapid transfer for chromatographic separation of the analytes by capillary gas chromatography and multi-channel detection using either a combination of discrete single channel detectors, such as flame ionization and electron capture, or multi-channel mass selective detection by mass spectrometry. The mass spectrometer is the most competent detector and provides the greatest information. The limited scan rates of the mass spectrometers typically used, however, limit the speed of the chromatographic separation and, consequently, the overall analysis. This problem is exacerbated by the high numbers of samples typically analyzed, creating a sample "glut" for the laboratories in this field.

We are currently developing a new protocol for the analysis of volatile organic contaminants in ambient air using the emerging technologies of "fast" gas chromatography (GC) and time-of-flight mass spectrometry (TOFMS). A modified Hnu fast gas chromatograph has been interfaced to a LECO FCD-1000 time-of-flight mass spectrometer capable of time array detection. Using this system, a 0.5 mL air sample is cryotrapped and subsequently ballistically desorbed to form a narrow injection band at the head of the chromatographic column. The analytes are separated in a 10-m, 0.25 mm i.d. DB-5 column with a 0.25 μ m stationary phase, held in an isothermal oven at 160 °C. The helium carrier linear velocity is 160 cm/sec. Full range spectra are produced at a rate of 100 spectra/sec.

As shown in figure 1, the chromatographic analysis time has been reduced from a typical 30 minutes to 1 minute. While the temporal separation of the analytes is greatly reduced, the analytical information is preserved using mathematical deconvolution. The analytical resolution of 3 target analytes, whose peak maximas differ by only 0.03 seconds, is illustrated in figure 2. Ions unique to each of these compounds within this elution window clearly and exactly define their chromatographic behavior providing information upon which both qualitative and quantitative analyses can be made. It is possible to deconvolute all co-eluting TO-14 analytes with the exception of *m,p*-xylene and the 1,3- and 1,4-dichlorobenzenes. In these cases, the spectra for the isomers are indistinguishable as no ion fragment unique to either isomer is present.

The combination of fast GC and TOFMS/TAD significantly reduces the analysis time for TO-14 listed contaminants, while maintaining detectability levels of 1–10 pg on column.

Figure 1. Reconstructed selected ion chromatogram showing a 1-minute analysis of TO-14 listed target compounds.

Figure 2. Unique-ion mass chromatograms of co-eluting compounds. The peak positions for these compounds differ by 0.03 seconds. Forty spectra were obtained during the 200-msec elution of these compounds.

Assessment Of VOC Emissions From Chlorinated Drinking Water In Showers

Frank M. Benoit*, Brian T. Mor†, Carl S. Alleyne†, Helen Nicolidakis† and Cathy E. Holme†

Introduction

Trichloromethane (TCM) is a major volatile disinfection by-product formed in municipal water supplies during the treatment process when chlorinated disinfectants are used. During showering activities, human uptake of TCM occurs via inhalation of the contaminated shower air and via dermal contact with the contaminated water¹. A test shower facility was constructed in order to monitor and control the relevant operating parameters that affect the emission of VOC during showering activities. The selected target VOC for this study, TCM, is volatile, is ubiquitous at significant levels in municipal water supplies, was used in other studies and has toxic properties. In a first approach, a mass balance was used to account for the disposition of the TCM entering the facility into the available compartments. In a second approach, an empirical relationship between the TCM influx and the TCM air levels in the breathing zone was established.

Methods

Water samples were collected, preserved (sodium thiosulphate & acidified upon collection) and stored according to EPA Method 501.3. Air samples were collected using stainless steel tubes packed with 300 mg 20/40 Carbotrap C, 300 mg 20/40 Carbotrap B and 250 mg 60/80 Carbosieve S-III pumped with a Dupont Alpha 1 air pump at a rate of 100 mL/min for 1.5 min, typically. Trichloromethane (TCM) was analyzed using a Hewlett-Packard 5988A GC-MS equipped with a Tekmar LSC 2000/2016 Purge and Trap (water samples) and a 6016 Thermal Desorption unit (air samples) and fitted with a Restek DB-604 (30 m x 0.325 mm i.d. x 1.8 µm film) capillary column programmed as follows: 25 °C hold 3 min to 100 °C at 8 °C/min to 220 °C at 25 °C/min hold 2.75 min. The mass spectrometer was operated in the selected ion monitoring, (DCE - m/z 62, 64, TCM - m/z 83, 85) EI mode. Quantitation was obtained from response factors, using 1,2 DichloroEthane (DCE) as internal standard.

Results and Discussion

The operating conditions for the shower were selected from typical showering practices (10 minute) within the general public. The shower enclosure was obtained commercially (volume 1.22 m³) and fitted with a Plexiglas door (spring latched) which sealed the entrance completely. The ventilation (58 L/min) of the enclosure was obtained from a cylinder of compressed air (medical grade). The water temperature (40 ± 1 °C) was selected for the comfort of the occupant and the flow rate (5.6 L/min) was typical of a low flow shower head. The air temperature (34 ± 1 °C) in the shower enclosure rose rapidly following discharge of water from the shower head and was averaged over the duration of the shower. The shower was fed from a municipal drinking water supply that contained ca 10 µg/L TCM. In a series of 22 experiments, the average ratio between the warm and cold water TCM levels was 4.0 ± 0.2 indicating that a substantial amount of TCM was formed during storage in the hot water tank (at least 16 hrs at ca 60 °C). The TCM influx (I, µg/min) into the shower stall was obtained from equation (1), where W is the water flow rate in L/min. The fraction of TCM volatilized (F) is

given by equation (2). In a series of 20 experiments, F was constant and equal to 0.71 ± 0.04. (Literature² value = 0.65, W 9.7 L/min and T_w 42 °C). Combining (1) and (2) yields (3),

$$I = W ([TCM]_{\text{water in}} - [TCM]_{\text{water out}}) \quad (1)$$

$$F = ([TCM]_{\text{water in}} - [TCM]_{\text{water out}}) / [TCM]_{\text{water in}} \quad (2)$$

$$I = F \cdot W \cdot [TCM]_{\text{water in}} \quad (3)$$

The [TCM]_{air} varied throughout the shower stall. In mass balance calculations the averaged [TCM]_{air} were unable to account completely for the TCM emitted from the water (recovery 86 ± 15 %). Previous workers assumed – incorrectly – that the TCM concentration was uniform throughout the shower air in their calculations of exposure. Furthermore, we have found that Henry's constant is a poor predictor of airborne VOC concentrations because of the short transit time of the water in the shower enclosure. Estimates of the exposure to TCM using Henry's constant could severely overestimate the actual human exposure. Consequently, we focused our efforts on the breathing zone situated directly below (ca 8 ") and near (ca 6 ") the wall of the shower head. When the breathing zone levels, [TCM]_{bz,t} were plotted vs L_{TCM,t} (= I_{TCM,t} · t) as a function of time for a series of 14 experiments, a linear trend ([TCM]_{bz,t} = 0.998 L_{TCM,t}) was observed but there was some scatter (r² = 0.87) in the data. [TCM]_{calc,t} was calculated from equation (4) assuming that TCM was distributed evenly into the expanding volume (V_{s,t}) of shower air (inflow of ventilation air and rising temperature of the shower air). The plot of [TCM]_{calc,t} vs time showed slight curvature which could be approximated as linear ([TCM]_{calc,t} = 144 t, r² = 0.97). The plot of [TCM]_{bz,t} vs time was also linear ([TCM]_{bz,t} = 91 t; r² = 0.98). In a series of 14 experiments, the average ratio of [TCM]_{bz,t} / [TCM]_{calc,t} was 1.8 ± 0.3. Combining this ratio with equations (3) and (4), [TCM]_{bz,t} can be calculated (equation 5) directly from the level of TCM in the influent water.

$$[TCM]_{\text{calc,t}} = I_{\text{TCM,t}} \cdot t / V_{s,t} \quad (4)$$

$$[TCM]_{\text{bz,t}} = (1.8) W F t [TCM]_{\text{water in}} / V_{s,t} \quad (5)$$

Conclusions

Showering with municipal water, that has been treated with chlorine, contributes to the exposure of humans to TCM. Although the TCM influx was constant, the air levels were different throughout the various sections of the shower largely because of non reproducible air ventilation patterns. An empirical relationship describing the rise in TCM in the breathing zone as a function of the influx of TCM was developed for the test shower facility and operating conditions of the present study.

Abstract A method for quantifying chlorinated *n*-alkanes (chlorinated paraffins, CPs) in environmental samples by HRGC-ECNI/HRMS in the SIR mode is presented. CP levels have been determined in fish and sediments by this method.

Introduction CPs are chlorinated derivatives of *n*-alkanes with the general formula $C_nH_{2n+2-2x}Cl_x$. Commercially available products consist of a complex mixture of isomers and homologues having carbon chain lengths from C_{10} to C_{30} and chlorine content from 30 to 70% by mass. In laboratory studies CPs have been found to bioaccumulate and biomagnify in fish¹. Since they are thought to be persistent in the environment, sensitive and specific methods for their quantitative analysis are being sought in order to assess their ecological impact.

Owing to varying carbon chain length and chlorine percentage, CPs provide a range of properties for different applications. In Canada and the US, CPs are used mainly as flame retardant plasticizers in vinyl plastics and as high-pressure lubricants in metal-working machinery.

Present methods for quantifying CPs in environmental matrices rely on low resolution mass spectrometry. A major problem associated with this method is a lack of *specificity*. Monitoring ions at nominal mass presents the problem of potential interferences from higher chlorinated PCBs, toxaphene and chlordane products which all have molecular weights similar to short and medium chain length CPs (*i.e.*, 350-500 u). Other procedures using less characteristic ions, *viz.*, m/z 70-73, present the problem that potentially any chlorohydrocarbon present in environmental matrices could fragment to yield such ions.

We present here a highly selective, specific, and sensitive method for quantifying CPs in environmental matrices by HRGC-ECNI/HRMS in the SIR mode. By this method we have established the presence, and determined the levels, of CPs in fish and sediment samples from the Detroit River in the Great lakes region.

Experimental Paroil 1160, C_{10} - C_{13} chain length and ~60% chlorine, was provided by Dover Chemical Corp. (Dover, Ohio). A standard solution was prepared by weighing a known amount of

the mixture, and diluting with hexane to a known concentration. The GC conditions were as follows: the initial column temperature was 80°C, hold for 1 minute, then ramped to 260°C at a rate of 7°C/min⁻¹, hold for 8.18 min, and ramped to 280°C at a rate of 10°C/min⁻¹ and held for 13 minutes. The injector temperature was held at 220°C. ECNI/HRMS in the SIR mode was performed at a spectrometer resolving power ~12 000. Additional MS conditions have been described elsewhere².

Results and Discussion Figure 1 shows the elution profile for one of the seventeen components found in Paroil 1160. The component shown is not an individual congener but a complex mixture containing both positional and stereo isomers and, as a result, elutes over a very broad retention time range. The areas of the ions monitored in the standard are electronically integrated and summed. Quantitation of CPs in samples is then achieved by comparison of the ratio of the signals for samples to that of the standard, calculated in the same manner.

Table 2. CP (C_{10} - C_{13} , 60%) levels (ng/g) in sediment and fish in samples from the Detroit River

Sample	C_{10}	C_{11}	C_{12}	C_{13}	Total CPs
Yellow Perch	521	1490	985	152	3148
Sediment	81	368	470	144	1062

Figure 1. Elution profile for one of the components found in Paroil 1160.

Conclusion These results represent the first data on CP levels using HRMS, and the first which reports CP concentrations according to homologue groups. Our future plans are to establish the linearity of the response of industrial standards, and develop methods to analyze higher chain length mixtures.

INTRODUCTION

Metsulfuron methyl (MET) and chlorsulfuron (CHLOR) (Figure 1) are members of the sulfonylurea class of herbicides which are commonly used in agriculture to control broad leaf weeds in cereal crops. Typical application rates are 7.5g/ha, therefore sensitive techniques are required to study persistence and degradation in a variety of environmental matrices.² GC and GC/MS methods have relied upon derivatization or conversion to thermal or hydrolytic products. One such recent method in which the analysis of MET and CHLOR is performed following conversion of the parent compounds to their respective sulfonamides, methyl 2-(aminosulfonyl)benzoate (SULF) and 2-chlorobenzenesulfonamide (CB)³ (Figure 1) and analysed utilizing GC/ECD. During the course of method validation of this procedure to quantitate using GC/MS(SIM) a response enhancement was observed for (SULF) in concentrated matrix. CB, the internal standard, did not exhibit any GC/MS response enhancement. The objectives of this work were to verify whether the observed enhancement was related to: ion-source geometry, ion interference, sample matrix, and linear range of the detector.

EXPERIMENTAL

Sample preparation has been described previously in Thompson et al.³ In brief, aqueous samples are extracted with DCM followed by separation of the native SULF and CB from the parent compounds. The parent compounds then undergo acidic hydrolysis to form their respective sulfonamides. In the present work the final extracts were five times more concentrated than those in the original method. Based on the full scan spectrum of SULF, m/z 215, 199, 184, and 120 were selected for the SIM experiments. To determine if enhancement was matrix related water samples were collected from two locations, South Saskatchewan River and a boreal forest lake in northern Ontario (Green Water Lake). The extracts (in triplicate) including Millipore water, were spiked at 10ng/L and area counts obtained for all SIM ions. A response factor was calculated relative to SULF standard in ethyl acetate, monitoring m/z 199 (Figure 2). In addition ion ratios were compared to the standard to determine if enhancement was due to ion interference (Figure 3). Non-fortified extracts were analysed under the same conditions. Experiments were performed using the same extracts on three different mass spectrometers. In an attempt to simulate conditions of ECD, where no enhancement was observed, these experiments were repeated using negative ion electron capture MS. To determine if the enhancement factor was constant within the linear range of the detector the same extract was spiked at increasing concentrations of SULF. The areas were then compared to the equivalent amount injected using standards in ethyl acetate (Figure 4). In addition, to determine if the enhancement is compound related similar experiments were performed using CB.

Instrument	GC Conditions	MS Conditions
HP 5989A	Column: 30m DB-17ft, 0.25mm I.D., 0.11m film thickness. Temp program: 60-300°C @ 600°C/min, hold for 6 min. On column injector 600°C	Source Temp.: 2750°C, Transfer line Temp.: 2800°C, 70eV, Scan range 40-300 daltons. SIM conditions: dwell time - 100ms
TRIO 1000	Column: 30m HP-5, 0.32mm I.D., 0.251m film thickness. Temp program: 700°C(1 min)-2300°C @ 100°C/min, hold for 1 min. Splitless injector 2100°C	Source Temp.: 2250°C, Transfer line Temp.: 2800°C, 70eV, Scan range 50-500 daltons. SIM conditions: dwell time - 150ms
Autospec Q +ve ion	Column: 30m SPB-1, 0.25mm I.D., 0.251m film thickness. Temp program: 700°C(1 min)-2300°C @ 100°C/min, hold for 1 min. Splitless injector 210°C	Source Temp.: 2250°C, Transfer line Temp.: 2800°C, 70eV, Scan range 50-500 daltons.

Table 1 Instrumental Conditions

RESULTS AND DISCUSSION

Relative enhancement ranges derived by various instruments using the three sample matrices are as follows: HP 5989 - 1.75±30%, Trio 1000 - 2.5±20%, Autospec +ve - 1.35±12%, Autospec -ve - 1.0±12% and ECD - 1.0±0%. There is evidence of a

higher degree of enhancement on the quadrupole instruments as compared to the sector instrument used. In contrast to positive ion detection, ECD and NIEC/MS did not exhibit this phenomenon. As illustrated in Figure 2, there was significant enhancement for SULF in sample matrix relative to the standard. The degree of enhancement appears to be matrix related as shown by the difference observed for the extracts of millipore water and the natural waters. Ion interference does not appear to be a cause of this matrix effect as shown in Figure 3. Ion ratios remain constant for each sample extract relative to the standard. Non-fortified extracts of blanks containing the same matrix did not show any monitored ions at the same retention time of the analyte. The E_r was constant within the linear range of the detector (Figure 4). The enhancement was not concentration dependent with respect to the analyte of interest. An appropriate internal standard with similar enhancement properties could thus be utilized to compensate for the increased response. No enhancement was observed for CB in any matrix relative to the standard in ethyl acetate. This may indicate that enhancement is compound related.

CONCLUSIONS

It has been shown that matrix effects may contribute to response enhancement for some analytes during GC/MS analysis. This can have significant impact for quantitative analysis and lead to the reporting of erroneous results. Internal standards may not compensate for this error if they do not exhibit similar enhancement properties. Calibration standards should be prepared in blank matrix extracts to reduce errors arising from matrix effects.

A Study of the Equivalence Ratio on Combustion Emissions by GC/MS

Joel Carlson, Yuriy Dunayevskiy, Paul Vouras, Ajay Atal², Thomai Panagiotou² and Yiannis Levendis²
Dept. of Chemistry, Northeastern University, Boston, MA, 02115

²Dept. of Mechanical Engineering, Northeastern University, Boston, MA 02115

The semi-volatile PAH emissions resulting from the combustion of polystyrene, polyvinyl chloride, polyethylene, tire crumb, and coal were extensively studied by GC/MS as a function of the equivalence ratio ϕ (where $\phi = (m_{fuel}/m_{air})_{actual}/(m_{fuel}/m_{air})_{stoichiometric}$). The PAH emissions were produced as a result of combustions in a laminar drop tube furnace at constant temperatures (1150°C) and nominal residence times of 0.75 seconds. The semi-volatile emissions were extracted from the soot/filter paper and XAD-4 resin beds by soxhlet extraction with methylene chloride. The semi-volatile components were identified and quantitated by GC/MS over equivalence ratios of $0 < \phi < 5$ [1].

Combustion took place in a vertical drop-tube externally heated furnace (4.8kW maximum) [2,3,4]. Fuel particles were fed through a particle fluidizer system [4,5,6]. In such a device, particles from a fixed bed in a vial were entrained in a flow of air. The bed was advanced at a constant velocity by a syringe pump. The fluidized particles were carried through vibrated tubing and were introduced into the furnace by a water-cooled injector. Injection took place at the top of a 25cm long, 3.5cm in diameter, isothermal zone (alumina tube) and combustion of the dispersed particles (aerosols) took place at approximately middle height.

The GC-MS system consisted of a Hewlett-Packard (HP) Model 5890 Series II GC and an HP Model 5971 Mass Selective Detector. The GC was equipped with an autosampler and tray. The GC column was an HP Ultra-2, 5% phenyl-methyl-silicone with a length of 25m, an inside diameter of 0.2mm and a film thickness of 0.33 μ m.

Coal and Tire. At low values of ϕ , very small (if any) amounts of PAHs are observed for either coal or tire crumb. At ϕ s higher than stoichiometric values, an exponential behavior is observed and the PAH emissions increase rapidly with small increases in ϕ . While PAH emissions for values of ϕ larger than 5 were not examined, it is presumed that an asymptotic relationship between PAH emissions and ϕ will result. However, since at the most extreme fuel-rich conditions explored herein, a $\phi \approx 5$, the amounts of PAHs detected approached those emitted under pyrolytic conditions in N₂ (effectively a $\phi \rightarrow \infty$) it was assumed that an asymptotic maximum was reached thereafter. The onset of the exponential relationship between ϕ and the level of PAHs detected appears to be a function of the material being combusted.

Individual PAH emissions from the pyrolysis of tire particle aerosols were higher by a factor of 1.5 to 10 times that of coal. Combustion of fuel-rich, $\phi > 1$, aerosols of coal and tire particles resulted in comparable PAH emissions (within a factor of 2), with those from tire being higher than coal. Practically no PAHs were detected for coal particles burning under stoichiometric or fuel-lean conditions ($\phi \leq 1$). Traces of PAHs were detected for tire particles burning in stoichiometric aerosols ($\phi = 1$), but they disappeared as the combustion became progressively fuel-lean. Unlike tires, batch combustion of pulverized coal in fixed beds resulted in small amounts of PAHs and soot, comparable to those from burning aerosols of particles at slightly fuel-rich ϕ s. Both coal and tire contain extractable PAHs. The total amount of the PAHs identified in the Title III amendments to the Clean Air Act and detected in the unburned extracts were 1mg/g-tire and less than 0.5mg/g-coal.

The total amounts of PAHs detected as well as those for pyrene, phenanthrene, 4H-cyclopenta[cd]pyrene and benzo[a]pyrene are presented in Figure 1, as a function of the equivalence ratio, for tire (A) and coal (B).

Polystyrene, Polyethylene, Polyvinylchloride. At ϕ values of less than 1, few if any PAH emissions were detected from the combustion extracts of polymer particles. The emission from the combustions increased exponentially at $\phi \geq 1$. The highest amounts of PAHs detected (accounting for 0.7wt%, 4wt% and 4wt% for PVC, PE, and PS, respectively) were emitted during pyrolysis in N₂ at $m_{N_2}/m_{pol} \leq 12.8$.

No polyaromatic hydrocarbons were detected in the combustion extracts of polystyrene or polyethylene from substantially fuel-lean conditions ($\phi < 0.8$). PVC was less sensitive to ϕ even when burned in finely shredded particles, at moderately lean ϕ . Flash pyrolysis of PVC resulted in large diffusion flames that impeded the oxidation of PAHs. Complete combustion of PVC required very fuel-lean conditions. The combustion emission of polyaromatic hydrocarbons increased exponentially when $\phi \geq 1$.

The specific amounts of PAHs from the pyrolysis of PE and PS in N₂ were found to increase with the particle loading in the furnace. There was no such indication for PVC. This difference may indicate the importance of intramolecular cyclization in the formation of PAHs from PVC, and intermolecular reactions for PS and PE.

Figure 1. The emission of polyaromatic hydrocarbons from the combustion of tire (A) and coal (B) as a function of the equivalence ratio at $T_{gas} = 1150^\circ C$

Comparison of PAH Emission Among Diesel Fuel, Biodiesel Fuels and Their Blends On Diesel Engine

Joseph Pan*, Thomas McIntire, Patrick Merritt, and Christopher Sharp
Southwest Research Institute, San Antonio, Texas 78238
Howard Haines, Montana Department of Environmental Quality
Helena, Montana 59620

An effort was made to compare PAH emission among seven fuels namely : a typical diesel fuel (2-D), rapeseed ethyl ester (REE), rapeseed methyl ester (RME), 20% and 50% REE in 2-D (REE20 and REE50), 20% and 50% RME in 2-D (RME20 and RME50). The transient emissions characterization was performed using a 1995 Cummins B5.9L diesel engine, and was performed both with and without catalytic converter under cold and hot start conditions. The 20"x20" filter used to collect particulates and the PUF used to collect gas-phase PAH were spiked with three deuterated PAH surrogates prior to sampling. The filter and PUF cartridge were then mounted on a double dilution tunnel in which about 4.4% (155 cubic feet per minute, 155 CFM) and 0.042% (1.5 CFM) of the diluted emission gas passed through the filter and the PUF, respectively.

Emission tests were performed using EPA heavy-duty transient test procedure, wherein each individual emission test was 20 minutes long. The temperature of the sampling media was about 90°F. The filter and PUF were each spiked with three additional surrogates and Soxhlet extracted with toluene and hexane:diethyl ether (94:6), respectively. A Fisons MD800 GC/MS with a 60-M DB-5 capillary column was used in SIM mode to quantify the PAHs. Calibration range was 0.01 µg to 10 µg per target compound per sample.

Part of PAHs emission data are tabulated in Table 1. Most lower molecular weight PAHs showed up in gas-phase (PUF) whereas higher molecular weight PAHs showed up on particulate-phase (filter). This observation is consistent with the results that low recoveries were obtained for lower molecular weight surrogates such as fluorene-d10 on filters. Acenaphthene and 1-nitropyrene were not found in any test. Only trace amount of dibenzo(a,h)anthracene was found in some samples. A high resolution mass spectrometer operated in full scan mode was used to resolve interference problems on acenaphthene and fluorene.

Table 2 summarizes total PAH produced by each fuel after cold start and hot start data have been merged based on 1/7 and 6/7 ratios, respectively. The total PAH and most of the individual PAH emission generally increased in the order of neat biodiesel fuels, diesel-biodiesel (50/50) fuel blends, diesel-biodiesel (80/20) fuel blends, and diesel fuel. However, such a trend did not exist for benzo(a)pyrene, the most carcinogenic PAH. Biodiesel fuels and their blends produced much less PAH than diesel fuel. A catalytic converter drastically reduced total PAH emission in all fuels. However, it appeared to be somewhat more efficient in doing so when the biodiesel fuels were used.

Compound	2-D	REE	RME	REE50	RME50

Special thanks to Mr. Jeffrey James, Program Manager, and Mr. Craig Chase of DOE who provided project oversight and technical consultation. The test engine and catalyst were provided by Dr. Vinod Duggal of Cummins Engine Company. The biodiesel fuel was produced at University of Idaho under the supervision of Dr. Chuck Peterson. Ethanol for the fuel was provided by J.R. Simplot Company and rapeseed oil was provided by Koch Ag Services.

Ultra Trace Analysis of Atmospheric Halocarbons by High Resolution Selected Ion Mass Spectrometry.

M.A. Engen, E.P. Grimsrud Montana State University, Bozeman, MT 59717

Introduction: Since 1974, interest in the environmental effects of halogenated compounds in the Earth's atmosphere has steadily grown. As that interest extends to an increasing number of specific compounds, greater demands are placed on the instrumental methods that are used for their detection and quantitative determination. The two methods that have been used most extensively for this purpose are the Electron Capture Detector and Selected Ion Quadrupole Mass Spectrometer, along with Gas Chromatography. In this poster, we describe what we believe is the most sensitive, most compound-specific, and most generally applicable analysis system to be applied to the trace analysis of atmospheric halocarbons. It is based on High Resolution Capillary Column Chromatography with detection by High Resolution Selected Ion Mass Spectrometry. While we have measured several atmospheric halocarbons at the low parts-per-trillion level in our initial uses of this instrument (see Table I), its measurement capability will be demonstrated here by focusing on the fire retardant, CF_3Br , that is currently thought to constitute about 3 parts per trillion of the Earth's atmosphere. This compound has been chosen for demonstration here because its atmospheric analysis by Selected Ion Quadrupole Mass Spectrometry has proven to be particularly difficult due to interference's encountered at the nominal mass of the base peak having $m/z = 69$. With the high resolution capability of the present mass spectrometer, it will be shown that high quality analyses of CF_3Br can be made by monitoring one of several minor ions produced by electron ionization, including that of the molecular ion.

Method: Air samples are collected in five liter glass flasks from remote areas around Bozeman, MT. The flasks are pressurized to 10 psi which allows 5 - 10 analysis to be performed from each flask. One hundred to one thousand milliliters of air is concentrated for each analysis on a two stage cryogenic system developed and built in our laboratory. The chromatography displayed in our example was accomplished on a 0.32 μm x 30 meter J&W GS-Q PLOT column. The detector is an ultra high resolution ($R=100,000$) reverse geometry double focusing mass spectrometer (VG-ZAB-2F). The spectrometer is

Figure 1. CF_3^+ monitoring at resolution 1000, 1500, 3000.

operated in the voltage-switching single ion monitoring (SIM) mode and tuned with a hydrocarbon compound (presently dodecane). This hydrocarbon is continuously leaked into the ion source for the generation of reference ions of known exact masses. **Figure 1:** Several experiments are typically performed at different resolutions to optimize signal-to-noise ratios for each particular ion. This example of CF_3^+ monitoring shows that as resolution is increased the transmission of interfering ions decreases considerably relative to the transmission of the CF_3^+ ion. **Figure 2:** Because of the restrictions on mass range imposed by voltage-switching SIM, only ions relatively close in mass to a selected reference ion can be monitored simultaneously in the same experiment. Therefore, a number of experiments may be needed to monitor all of the ions in the mass spectrum of a given compound. In this example of CF_3Br , a number of fragment ions and the molecular ion were analyzed in three different SIM experiments at a resolution of 1500. The sum of the molecular ion intensities shown in figure 2c provided the best means of detecting the compound and was used for quantitation.

Results: Table 1 lists some of the compounds that we have identified in background air samples. To our knowledge, CF_3H has not been measured before in background air, and HFC-134a is currently being quantitated for the first time by NOAA's CMDL. At this time we have calibrated our responses only for the brominated compounds, CF_3Br and CH_3Br . Quantitative determinations were made for CF_3Br and CH_3Br by both the standard additions method and by comparison of responses to standard working curves.

Gas standards were prepared in our laboratory by dilution of the pure compound with nitrogen gas. The standards were stored in large glass carboys.

GCMS ANALYSIS OF AIR SAMPLES AND METALWORKING FLUIDS FROM AN ENGINE PLANT

P. Subramanian*, P.S. Thorne and J.A. DeKoster. Department of Preventive Medicine and Environmental Health Sciences Research Center, University of Iowa, Iowa City, IA-52242

INTRODUCTION

Metal cutting fluids are routinely used to cool and lubricate cutting tools in metalworking industries. In the last 20 years, these industries have adapted water based first order emulsions of synthetic and semi-synthetic oils as metal cutting fluids. However, they continue to combat corrosion problems and growth of micro-organisms by adding a myriad of organic additives and 'biocides'. When workers are exposed to these complex mixtures of chemicals and possibly their breakdown products, significant health problems arise: contact dermatitis and acute respiratory illness. The bulk metalworking fluids (MWF) and their aerosols consist of several organic and inorganic species having sulfur, phosphorus, borate, chloride and possibly transition metal particulates. We have been studying the acute respiratory health problems associated with inhalation of aerosols of metalworking fluids using guinea pig and mouse models. In our approach to understand the nature of the chemical constituents of the aerosols (in the metal work setting) inhaled by the test animals, we have undertaken the analysis of volatile heterocycles and aldehydes in the air and in MWF. Preliminary findings on the presence of volatile and semi-volatile organic compounds and their possible degradation products in air samples and bulk 'in-use' MWF samples are presented.

EXPERIMENTAL

Air samples for aldehydes were collected on DNPH coated glass fiber filters by passing 200 L of air at a flow rate of 0.5 L/min. DNPH filters were prepared in house. Following sampling, DNPH filters were transferred to 15 mL glass vials containing 10 mL acetonitrile and stored at 4°C. The following gradient was developed for the separation of formal-hydrazone from DNPH: solvent A was water; solvent B was 90% acetonitrile in water. The linear gradient profile for solvent B was established to deliver 0%, 70%, 70%, and 0% at 0, 5, 10 and 12 min respectively. The flow rate was 1.0 mL/min. The chromatographic separation was monitored at 360 nm. Air samples were collected for volatile and semi-volatile organic species on Orbo-100 tubes by passing 600 L air at a flow rate of 0.5 L/min. The contents of the Orbo tubes were transferred to 15 mL glass vials; 5 mL methylene chloride was added, capped with teflon coated tops, ultrasonicated for 5 min and stored at 4°C. The supernatants were filtered through a preconditioned disposable cellulose column, prior to GCMS analysis. Bulk samples for GCMS were prepared as described: a bulk sample (5 mL) was mixed with saturated NaCl solution (40 g in 100 mL water), vortexed for 30 sec and stored for layer formation. The clear aqueous layer was separated from the viscous oil and semi-solid and then extracted with methylene chloride (5 mL) and dried over anhydrous sodium sulfate. GCMS analyses were carried out on VG Trio-1 GCMS or HP-5989A spectrometer using DB-1 or HP-1 column (15 m; 0.32 mm i.d.; film thickness 1 mm).

RESULTS

GCMS analysis of air samples collected onto Orbo tubes suggested the presence of short chain and long chain aliphatic hydrocarbons, halogenated hydrocarbons, oxiranes and alkylated aromatic hydrocarbons, the finger prints characteristic of petroleum oil. Volatile heterocyclic biocides and their products (1, 2, 3 and 5) were identified from the air sample.

Airborne HCHO was less than 0.5 mg/m³ with the exception of one sampling site (0.62 mg/m³, 200 L air). High concentration of HCHO was directly related to the addition of biocide 3 to the bulk fluid to combat the growth of microorganisms at this sampling site. The biocide 3 is highly volatile heterocycle (vapor pressure 71 torr Hg at 15°C). Bicyclic heterocycle 5 was also identified from the air at four of the eight sampling sites 5 possibly originated by the elimination of ethane or methanol from the parent oxazole 3 or 4 (Figure 1),

present in the bulk MWF.

The exposure limit for HCHO is 1 mg/m³ (TWA, US OSHA) and 0.5 mg/m³ (MAC, IARC). The low concentration of airborne HCHO directly relates to 'aqueous phase HCHO' concentration (Figure 2). The measured HCHO levels in the bulk solutions demonstrate the release of HCHO from the biocidal additives 1, 2, 3, 4 and triazine triethanol. These oxazolines and triazine derivatives used in the metal working fluids are expected to generate 1 to 3 mole equivalents of HCHO. GCMS analyses of bulk fluids collected from three out of eight sampling sites (NS3B, 493B and 493A, Figure 2) confirmed the absence of methylene chloride extractable 'formaldehyde yielding oxazolines'.

Figure 2. Conc. of HCHO in air and bulk solution against the biocide (s) present in the MFW (07-01-93).

Isothiazoline 6 was found to be accumulated in the bulk fluids up to 35 mg/L. This corresponds to the total addition of 115 mg/L of 7 to the metal cutting fluids, even though 7 is known to undergo continuous degradation by the microorganisms and other chemical nucleophiles such as alkanol-amines, sulfonates and mercapto pyridine-N-oxide are present in the bulk fluids.

Two new heterocycles 8 and 9 containing isothiazoline and oxazoline structural units were identified from the bulk MWF. In addition, bicyclic 4 was identified from two sampling sites. Microbiological demethylation of C₄-Me from 4,4-dimethyloxazoline (1 to 9), and demethylation of N-Me group from N-methylisothiazolines (6 or 7 to 8) are predicted. Alternatively, 9 could also be derived from the facile chemical condensation reaction of 2-aminopropan-1-ol with HCHO. However, 2-aminopropan-1-ol was not used as one of the constituents in the metal working fluids. Identification of these demethylation reactions by specific microbe(s) are underway.

Static SIMS Investigation of Phosphazene Polymers used for Contaminant Adsorption

G. S. Groenewold, R. L. Cowan, J. C. Ingram, A. D. Appelhans, J. E. Delmore
Idaho National Engineering Laboratory, Idaho Falls, ID 83415-2208

Polyphosphazenes are a class of materials which have large potential application for membrane separations. For example, extremely efficient separations of organic contaminants from air and water have been demonstrated.¹ Furthermore, the polymers are attractive for these applications because their structure (Figure 1) is stable under conditions of high temperature and extreme pH, and they are resistant to high radiation fields.² These attributes motivated the present study, which was undertaken to determine if facile contaminant/polymer surface interactions could be exploited for surface detection using a static secondary ion mass spectrometry (SIMS) approach.

R = -H, -OMe, -CO₂H, -CO₂Et
Fig. 1. Structure of phenoxypolyphosphazenes.

The detection of adsorbed contaminants has been an area of active research in our laboratory. Molecules such as tributyl phosphate,³ organophosphonates,⁴ cyclohexylamine,⁵ and organosulfides⁶ have been effectively detected on environmental surfaces using SIMS instrumentation which employs a ReO₄⁻ (perhenate) primary ion beam,⁷ and pulsed secondary ion extraction.⁸ Together, these two technologies serve to effectively manage sample surface charging, and facilitate efficient desorption of analyte ions.

Phenoxypolyphosphazene (PPOP) derivatives were the focus of this study. Their static SIMS spectra contained ions which originated from both the P=N backbone, and from the pendant aromatic moieties.⁹ These categories of ions could be distinguished on the basis of their behavior under prolonged primary ion bombardment. The pendant aromatic-derived ions were observed to decay at a rate that was two- to four-times greater than backbone-derived ions. This observation is consistent with the expectation that the pendant aromatic groups are oriented at the surface of the polymers, and that they are less strongly bound to the polymer.

Gas-phase organic phosphates, amines, and aqueous organic cations may be observed on the surfaces of the polymers subsequent to their exposure to the contaminated media. In

order for the contaminants to be observed, they must be adsorbed onto the contaminant surface, and they must be capable of undergoing desorption and ionization in vacuum when bombarded by the primary ion beam. Thus, failure to observe a contaminant secondary ion does not necessarily mean that the contaminant did not adsorb into the polymer. The absence of a facile ionization process is an equally likely explanation.

Tributyl phosphate (TBP) readily adsorbs from the atmosphere onto the surface of HO₂C- and EtO₂C-PPOP derivatives. When the exposed polymers were analyzed, an abundant ion at *m/z* 99⁺ was observed, which is the primary fragment ion in the SIMS spectrum of adsorbed TBP. Other polymers were not capable of producing a significant TBP signature when exposed to the compound.

When the polymers were acidic, or acidified, organic amines were adsorbed from the atmosphere, and could be observed in the SIMS spectra as ammonium cations. Both cyclohexyl- and tributylamine were observed to behave in this fashion. The PPOP surfaces were acidified for these experiments by exposing them to HCl vapor, prior to exposing them to the gaseous organic amines. If the polymers were not acidified, then no ammonium cation signature could be observed: this indicates that either no adsorption was occurring, or no surface protons were available for ionization.

The polymers were also tested for their ability to adsorb contaminants from aqueous solutions. It was found that the polymers would adsorb, and produce secondary ion signatures, when exposed to aqueous organic cations. The pesticide paraquat, and also tetrahexylamine were observed to behave in this manner. Paraquat could be observed on the surface of PPOP that had been exposed to low ppm solutions. Significantly, neutral or anionic organic contaminants did not produce a SIMS signature (cation or anion).

Generally, the polymers are good substrate materials for organic cations; this group includes amines, provided there is a source of protons on the surface. Contaminants which lack a facile ionization mechanism are not readily observable by using SIMS to interrogate the surface of these polymers.

GC-MS Confirmation Analysis of a Low Volatility Organophosphorus Toxic Agent in Air Samples
E M. Jakubowski and G.M. Deel SciTech Services Inc., Abingdon, MD 21009

Air samples are routinely screened for chemical warfare agents at many potentially contaminated areas using adsorbent tubes and gas chromatography with flame photometric detection. Environmental air samples with positive screening results are confirmed by gas chromatography-mass spectrometry (GC-MS) when possible. For most agents such as sarin (GB), soman (GD), and sulfur mustard (HD) confirmation at low levels by GC-MS is possible. However, O-ethyl-S-(2-diisopropylaminoethyl) methyl phosphonothiolate (VX) cannot be confirmed routinely by GC-MS procedures in air samples at the time weighted average (TWA) limit established by the US Army which is 0.00001 mg/m³. VX suffers from a lack of volatility (bp 298°C calculated) and stability. Currently, confirmation is achieved by analysis of a second sample by gas chromatography-flame photometric detection using a column of different polarity. In many cases, the current confirmation technique is inadequate because of interferences.

Silver fluoride has been shown to convert VX to a more volatile compound called G-analog (Smith et al., U S. Army Report: ARCSL-CR-82052). G-analog has been assumed to be O-ethyl methylphosphonofluoridate which resembles the G-series of nerve agents. A felt pad is impregnated with silver fluoride and air samples collected through it. Generating G-analog in this manner has been used in many field monitoring events, however, the reproducibility of the data is questionable because reactivity of the impregnated pad is difficult to control. Efficiencies of the pad to convert VX have been estimated to be 75% at best. The impregnated pad will degrade over time and control of the process is not always possible on site. Furthermore, many of the degradation products of VX will produce G-analog when exposed to the silver fluoride reagent.

A new procedure has been developed and tested to confirm the presence of VX in environmental air samples. It was designed to allow a greater degree of certainty in the verification of the presence of the chemical warfare agent in air using available equipment. The procedure uses a silver fluoride impregnated felt pad to convert VX in the laboratory. Standard curves for G-analog are prepared using GC-MS in the selected ion mode with ions at 81, 99, and 111 m/z. Other products of the VX conversion to G-analog can be used to mirror the levels of VX. The sulfur containing side chain of VX can be observed quantitatively and at picogram levels in the selected ion mode with ions at 69, 113, and 127 m/z. The best control of the process occurs when VX is converted to G-analog in the laboratory. Therefore, air samples are collected without the impregnated pad on adsorbent tubes in the field and brought back to the laboratory for conversion.

Instrumentation

Dynatherm ACEM 900 (Dynatherm Instr., Kelton, PA)

Hewlett-Packard Model 5890 GC (Hewlett-Packard Co., Avondale, PA) and Model 5970 MSD

Materials

Sample collection tube: 12cm long, 6mm OD, 4mm ID glass tube packed with 20:35 mesh Tenax-TA

Focusing trap: 18cm long, 6mm OD, 1mm ID glass tube packed with 20:35 mesh Tenax-TA

Silver Fluoride Pad: MINICAMS conversion pads (CMS Research Corp, Birmingham, AL)

Chromatography Conditions

Column: Rtx-5, 30m x 0.25mm ID, 0.5um film

GC Temp 40°C (hold 1.5min) to 80°C at 20°C/min

80°C to 250°C at 35°C/min (hold 7.21min, total 15.6min)

Carrier Gas: Helium, 32cm/sec at 40°C

Sample Inlet: glass sorption tube via ACEM 900

ACEM 900: Temp: Valve 235°C, Tube Desorb 265°C, Transfer line 250°C, Trap Desorb 260°C

Events: Tube Dry 1min, Tube Heat 3min, Tube Cool 2min, Trap Heat 2min.

Flows: Tube purge and flow 10mL/min, Focus Trap 1mL/min

Sample Preparation

Spiked samples were prepared from 0.062ng to 1.4 ng of VX by injecting a Tenax sample tube via a spiking block and syringe standard solutions of VX diluted in isopropanol under a flow of nitrogen gas. The spiked tube was placed on another spiking block, surrounded by a heating sleeve and coupled frit-to-frit using Teflon swagelok fittings containing a silver fluoride conversion pad. The VX was transferred from the first tube to the second through the conversion pad at 250°C under a flow of nitrogen gas. The second tube was analyzed for G-analog by GC-MSD with desorption via The ACEM 900.

Results and Discussion

The full scan total ion chromatogram from a 100ng spike of VX after conversion via the silver fluoride pad shows that G-analog elutes at 4.4min. Peaks at 5.1min and 5.3 min also appeared to be related to the conversion process. For comparison, the retention time of VX under the conditions of this analysis was approximately 9min and that of GB (sarin, isopropyl methylphosphonofluoridate) was 4.8min. Unreacted VX was not detected under these conditions. The spectrum of G-analog indicates the molecular ion at m/z 140 was not present but this typical of the alkyl substituted methylphosphonofluoridates. Ions at m/z 99 and 81 are prominent in the fragmentation of similar compounds such as GB. For selected ion monitoring purposes, ions at m/z 81, 99, 111, and 125 were used. G-analog was quantified in the selected ion mode and calibration curves were generated with correlation coefficient better than 0.99.

The spectrum of a peak that may be mistakenly identified as G-analog was present. The exact structure has not been determined, but there appears to be structural components related to the thiolate side chain of VX. This peak was present in proportion to the amount of VX injected and a calibration curve was generated. The spectrum of the unknown is similar to VX's with one notable exception being the base peak which for VX is m/z 114. It is possible when less informative detectors are used, such as the flame photometric detector which detects phosphorus or sulfur, the side chain peak is actually utilized. In this case the method could still be valid but the analyte could not be called G-analog.

Analysis of G-analog by GC-MS is a viable confirmation method for the presence of VX. Peaks related to the sulfur side chain of VX are also confirmatory in nature. The major problem with converting to G-analog is a false positive response elicited by a breakdown product of VX that yields the same product after reaction with silver fluoride. This aspect is very important when monitoring areas or items that are being decontaminated. During decontamination of VX many breakdown products are generated and these can yield false positive responses. Confirmation ideally should depend on intact VX. Work has begun using ion trap technology for the confirmation of VX and related materials at low concentrations.

DIRECT SAMPLING MS AND MS/MS FOR REAL TIME AIR MONITORING

C. Remigi, P.T. Palmer, Dept. of Chemistry & Biochemistry, SF State University, SF, CA
D. Karr, Teledyne Scientific Instruments, Mountain View, CA

A number of investigators have shown the utility of direct sampling ion trap mass spectrometry (DSITMS) for on-line, real-time monitoring applications. While ion trap instrumentation continues to become smaller, more sensitive, and equipped with more high performance features (i.e., tandem MS, extended mass range, increased mass resolution), the development of improved sample introduction systems and tandem MS methods for target compound analysis are essential to making DSITMS techniques more widely used for these applications.

This work involves the characterization of two different sample introduction systems for real-time monitoring of trace levels of CFCs in air. Gas standards of CF_2Cl_2 (CFC12), CFCl_3 (CFC11), and CCl_4 in a balance gas of air were obtained from commercial sources or generated with an EnviroNics gas dilution system. A Teledyne model 3DQ ion trap mass spectrometer was employed for the analyses.

The first sample introduction system, termed the SIS/ORNL inlet for this work, was developed by Scientific Instrument Services based on a design by researchers at Oak Ridge National Labs (1). This device mixes the air sample with helium and passes the resulting mixture through a heated open-split interface which is connected to the ion trap via a short section of 75 μm ID deactivated fused silica capillary. Analysis was done in a continuous fashion, with the sample inlet being presented with either the sample or lab air as background. Results from replicate analyses of a sample containing 50 ppbv CCl_4 in air via MS/MS are shown in Figure 1. Detection limits were on the order of 50 ppbv in MS, selected ion monitoring (SIM), and MS/MS modes for CF_2Cl_2 , CFCl_3 , and CCl_4 . Precisions were on the order of 5%. These results are comparable to those of other investigators using similar inlet systems (1-5). This inlet system is easy to install and optimize, provides better than unit mass resolution, and gives minimal hysteresis and carryover.

The second sample introduction system employs a valve in the sample loop configuration. The valve is enclosed in a heated oven, equipped with a 15 μl sample loop and is connected to the ion trap via a 0.25 mm ID deactivated fused silica capillary. Analysis was done in a discrete fashion, with the contents of the sample loop flushed into the ion trap using zero-grade air. This air also serves as a buffer gas for the ion trap. Results from replicate analyses of a sample containing 50 ppbv CCl_4 in air via MS/MS are shown in Figure 2. Detection limits were on the order of 50 ppbv in MS, SIM, and MS/MS modes for CF_2Cl_2 , CFCl_3 , and CCl_4 . Precisions were on the order of 5%. These detection limits are 2-3 orders of magnitude lower than the only other work reported in the literature using air as a buffer gas (6) and comparable to those obtained using the SIS/ORNL inlet. More importantly, they corroborate the results of Lammert and Wells and show that the ion trap can be operated using air as a buffer gas and provide unit mass resolution and comparable sensitivities for mass ranges less than 200 amu (7,8). On a more practical note, it should be stated that tuning ion trap parameters to obtain these results is not straightforward, and that charge exchange and the large amount of air present in the ion trap with this inlet may yield unanticipated ion-molecule reactions.

Figure 1. Replicate analyses of 50 ppbv CCl_4 in air via MS/MS using the SIS/ORNL inlet and DSITMS. The first two plots show a total ion chromatogram and a selected ion chromatogram for m/z 82, and the third plot shows the product ion spectrum of m/z 117.

Figure 2. Replicate analyses of 50 ppbv CCl_4 in air via MS/MS using the valve inlet, air buffer gas, and DSITMS. The first two plots show a total ion chromatogram and a selected ion chromatogram for m/z 82, and the third plot shows the product ion spectrum of m/z 117.

A TRANSPORTABLE ISOTOPIC DILUTION GC-MS SYSTEM FOR ATMOSPHERIC MONITORING WHILE DRIVING IN TRAFFIC

***E. Davoli, L. Cappellini, M. Moggi, S. Ferrari and R. Fanelli.**
Istituto di Ricerche Farmacologiche Mario Negri, Via Eritrea 62,
20157 Milano, Italy

While information about the average benzene concentrations in urban air are quite available, there is a lack of information concerning microenvironment exposure, such as car interiors while driving in various traffic conditions. The main reason of this lack of data is that no analytical instrumentation was available to measure on-line atmospheric trace amounts of benzene in such situations. We have recently proposed a highly accurate, high-speed cryofocussing GC/MS system for monitoring benzene concentrations in air (1). The same principle have been applied to a new instrument, specifically designed to be operated on an electric vehicle (Ducato Elettra, FIAT). The zero emission vehicle and the fully transportable GC/MS system give the unique possibility of monitoring benzene exposure in real everyday situations such as while driving a car.

INSTRUMENTATION

All power consumption have been reduced so as to achieve a battery-operated GC/MS system. The pumping system is a oil-free group that comprises a ceramic-bellow turbo pump and a graphite mechanical pump. Liquid nitrogen cryofocussing has been replaced by a packed, inductively heated, graphitized charcoal micro trap. In order to maximise accuracy (2), the air sample is enriched with an internal standard through a permeation tubes device that delivers known amounts of benzene d_6 and toluene d_8 in the sample stream.

IN-VEHICLE BENZENE MEASUREMENTS

The instrument has been installed on a zero emission vehicle (FIAT *Ducato Elettra*, photo 2,3) and powered by a 1.2 kW UPS. It has been operated continuously in parking and in driving conditions. Air samples were collected in the driver's compartment, under high ventilation conditions (obtained by opening front windows 30 cm, opening outside vents and turning the interior fan on)

RESULTS

INSTRUMENTAL

- The maximum monitoring period without external power supply is 6 hours.
- The full analytical cycle is 4 minutes.
- The limit of detection is 0.3 ppb (of benzene).

IN VEHICLE AIR-MONITORING

Moving from a parking lot to traffic situation the average increase is three fold, rising from 30 to 65 $\mu\text{g}/\text{m}^3$ (values are average of one hour)

Experiment 2.

Driving in rush hour results in an extremely variable situation, with as high as 500 $\mu\text{g}/\text{m}^3$ driver compartment benzene peak values related to traffic and environmental condition.

Experiment 3.

Smoking simultaneously two cigarettes inside the van yields a sudden increase of indoor benzene concentration of 90.9 $\mu\text{g}/\text{m}^3$ (starting from an average of the last hour of 23.7 $\mu\text{g}/\text{m}^3$).

FUTURE DEVELOPMENTS

A data system based on a data acquisition board equipped with a 486 processor (DAP 3000/212, Microstar Laboratories, Bellevue, WA) is under development.

This will have a complete control of all the mass spectrometer parameters, of the sampling line and of the chromatographic peak data reduction to the actual analyte air concentration.

Part of this communication has been presented at the 4th European Meeting on Mass Spectrometry in Occupational and Environmental Health (1995).

This study has been supported by the CNR-ENEL Project Interactions of the Energy Systems with Human Health and Environment, Rome, Italy and Fondazione Lombardia per l'Ambiente.

The FIAT Ducato Elettra was provided by FIAT Auto S.p.A.

The technical assistance of RIAL Vacuum S.p.A. and of DANI S.p.A. is gratefully acknowledged.

The DAP 3000/212 board was a kind gift from Microstar Laboratories Inc.

SAMPLE PREPARATION FOR A MOBILE GC-MS-SYSTEM

Gerhard Matz, Alfred Schillings, Alexander Harder, Wolfgang Schröder
Environmental Measurement Technology, Technical University Hamburg-Harburg
Harburger Schloß-Str. 20, 21071 Hamburg, Germany

In case of fires and chemical accidents complex mixtures of organic compounds can be released into the environment. To protect environment and population, information about the hazardous substances that have been released is of great importance. We are working closely together with the technical division of the fire department of Hamburg equipped with a GC-MS-system in an emergency container. Simple solutions for sampling and sample preparation are necessary for field-application. Methods we use in our laboratory and in the field had to undergo extreme simplifications. To analyze hazardous organics in air, water and soil on-site by fast GC-MS we have simplified methods without time consuming clean-up. These methods are:

- Direct on-line air measurement (without sample preparation)
- Air analysis with preconcentration using adsorbent cartridges
- Water analysis by Spray & Trap and Purge & Trap
- Water analysis by liquid-liquid extraction
- Headspace soil analysis
- Ultrasonic liquid soil extraction
- Special methods to analyze solid and liquid surface contamination

Sampling and sample preparation procedures as well as GC-MS parameters have been standardized and adapted to the mobile GC-MS-system EM640 resulting in working instructions for fire-fighters. Based on the standard methods a simple operating software has been developed together with Bruker-Franzen-Analytik that can be handled by non-specialist staff. For fast emergency response the entire mobile GC-MS instrumentation is arranged for transportation by helicopter (Fig. 1).

Fig. 1: Fast emergency response by mobile GC-MS

The EM 640 provides three different sample introduction devices: a sniffer probe for on-line measurement, one gaschromatograph for volatiles and another for semi-volatiles. These

modules can be changed without venting the vacuum system. To avoid any risk of contamination the methods of sample preparation are designed for thermal desorption only. Three different glass tubes for sample introduction are used: tubes with Tenax and multi-bed-adsorbents for enrichment of VOC and tubes filled with silicone coated spun glass (silicoat tubes) for solvent extraction.

The equipment is constructed for analyzing under rough conditions. Glass bottles are plastic coated to provide protection against mechanical damage. Disposables are used to eliminate cross-contamination.

On the basis of several hundred samples taken by fire-fighters under real conditions the following adsorbents have been chosen for enrichment of air samples:

1. Combustion gases: for sampling air with high humidity Tenax is used because of its low breakthrough volume for water.
2. Chemical spills: multi-bed-adsorbent tubes containing Tenax in combination with more active adsorbents like Carbosieve SIII or Carboxen 569.

Adsorbent tubes are stored in metal cartridges with teflon sealings and swagelok fittings on both sides. For sampling the cartridges are connected to a hand gas pump. Internal standards are preloaded on the adsorbent prior to sampling. For liquid-liquid extraction bottles of PE are used. The extract is transferred from the squeezed PE-bottle onto a silicoat tube by using a pipette (Fig. 2). Soil samples are taken by syringes integrated in screw caps of sample bottles or test-tubes. For VOC trapping in the Purge and Trap and in the headspace method sample cartridges filled with Tenax are integrated in preparation caps.

Dependent on the method internal standards in different solvents are added to the samples for quantitation purposes:

- benzene- d_6 , toluene- d_8 and naphthalene- d_8 in methanol and ethylene glycol for VOC
- naphthalene- d_8 , anthracene- d_{10} and pyrene- d_{10} in acetone and n-hexane for SVOC

The entire equipment is installed into portable instrument cases

Fig. 2: Liquid-liquid extraction of water

Conclusion

The presented set of methods provides analyzing at different environmental sites. The methods are simple and easy to handle. Standardization and integration in a simple operating software enables non-specialist staff analyzing in the field. The entire equipment can be transported by ambulance or helicopter. Fast emergency response is possible within a few minutes.

On-Site Strategies for Mobile GC/MS Analysis

Birgit Nölke, Gökhan Baykut, Thomas Zey, Jochen Franzen
Bruker-Franzen Analytik GmbH, Fahrenheitstr. 4, 28359 Bremen, Germany

Standard methods of environmental analysis are usually tailored for analytical determinations in the laboratory. However, experiences show that high-quality laboratory analysis takes in general too much time and is too costly [1-3] to be used on all contaminated sites. Transport of samples to laboratories, as well as their storage automatically increases the risk of losing volatile organics (VOCs) or contaminating the sample. These are some basic reasons why on-site analysis has been increasingly used in the last years. In the following we suggest a series of on-site strategies [2] for mobile GC/MS analysis, based on our experiences.

High sample throughput: Sampling on a contaminated site is a very critical operation. The amount of the analytes can differ enormously from one sampling point to another, and the results of the analysis should not be expected to be "better" than the sampling. Therefore, it is extremely important to have a high sample throughput to obtain a complete pollution profile of the site in a relatively short time.

The analyst is on site: During the field analyses the analyst has to use the opportunity to follow the sampling operations and to get the samples directly, to watch the sampling, to correct or repeat it if basic errors are made, and to notice problems in sampling that may help evaluating the analytical results.

Fast and easy sample preparation: For field analyses the sample prep should be simple and fast. Gas samples should be measured direct or after preconcentration in a sorbent tube with thermal desorption unit. VOCs in water samples can be measured using spray-and-trap technique [4,5], where water sample is sprayed and the compounds extracted into the gas phase are preconcentrated in a sorbent tube in the desorption unit. VOCs in soil samples can be sampled by headspace technique. Involatile compounds, however, should be extracted using a solvent extraction method. When using a mass spectrometer with membrane inlet, the extracts can be injected directly without extra cleanups. Complicated and time-critical preparations like standard procedures under clean and quiet laboratory environment do not really apply to the field analysis. It has to be considered, that on-site operations are usually performed under stress, under pressure of time, heat, noise or other unpleasant environmental conditions.

Fast GC/MS analysis: The time consuming step in GC/MS is the GC separation. The use of short GC columns and fast GC programs [6-9], wherever possible, can accelerate this process. It is useful to optimize the GC separation time to the individual analytical task. In GC/MS, a compromise between the required separation and the GC can dramatically increase the efficiency. It is not necessary to completely separate all compounds, if intelligent peak separation algorithms are used. The DISSECT algorithm [9] can separate overlapped GC peaks. It calculates the mass spectrum of a compound out of a mixture of mass spectra.

Flexibility of data processing software: For laboratory analysis, usually automated quantitation routines are used. For the quantitation a characteristic "target ion" is defined and for the identification secondary characteristic "qualifier ions" can be used. In complex environmental samples, where the analyte is completely hidden behind matrix components, qualifier ions may fail and the compound may not be found by the automatic procedure. To avoid errors, a combination of automated software procedure and manual control is a better way to go. An average mass spectrum of a GC peak can be calculated. Is the identified compound the one from quantification table in this GC time window, the ion trace is automatically integrated. If it is not, the software switches from automatic to the manual mode. Here, the analyst can decide, if the compound is the right one or not. For simple mixtures this software procedure works completely automated. For safer and in most cases faster identifications, several MS libraries can be used in a specified order. The first one should be a small specialized library, for example the compounds of the EPA method 8260 when measuring VOCs. The next one can be a more general environmental library and the

third one can be the NIST library.

On-site analytical equipment should comply with the requirements of fast analysis and high sample throughput and the modularity of the different sampling systems in order to be able to switch them quickly when necessary. The ability to allow the instrument set-up while driving to the site is always of advantage. We use in our field measurements the mobile quadrupole mass spectrometer EM640 with modular GC and various modular sampling systems. The software includes the DISSECT algorithm [10] for peak separation and the automated/manual flexibility in compound identification routine.

Quality assurance requirements to work with internal standards and surrogates for each quantitative GC/MS analysis. Although all system checks are performed before analysis, it is better to have a permanent control over the performance of the system. For example, if air is used as carrier gas a continuous MS system control can be performed by monitoring the m/z 40 ion of argon.

Errors in analysis: A series of errors in sampling, the mixture of samples, sample vial or containers, homogenization, sample preparation and of course in the analysis itself occur during on-site investigations. Specialists agree [11] that in the field analysis, if a sample is re-analyzed, one should always count with an error of roughly a factor of 2. That means in practice, the real concentration of the analyte, which is analyzed to be 10 ppm, is with a probability of 95% between 5ppm and 20ppm. To avoid many of the errors, sample preparations have to be as simple as possible. Also, based on these uncertainty factors, it is better to perform fast, multiple analyses rather than a single one with a very high analytical accuracy. Therefore, high sample throughput is a crucial point.

Establishing on-site procedures: The standard laboratory procedures have to be dramatically changed and adapted to the on-site analysis to create really new, faster, and more simple field methods (e.g. the use of a 3m GC capillary instead of a standard size). Experiences support the fact, that it is very crucial to watch the sampling, or at least to be informed about the history of each sample. It is useful to apply the analytical results to guide the sampling operations, which may drastically reduce the number of samples analyzed for the complete characterization of the site. A major interest in the field analysis is to reduce costs. This can only be achieved with a high sample throughput and by avoiding unnecessary waiting times to produce reliable results for the characterization of the whole site.

Analyses of Airborne Species with a Field-Portable Large-Volume Air Sampler Mass Spectrometer

Jon H. Wahl, Thomas S. Zemanian, William H. Robins, Bob W. Wright
Pacific Northwest National Laboratory, POB 999 MSIN P7-07, Richland, WA 99352

To improve real-time sampling and monitoring of atmospheric contaminants, including their sources and concentrations, a field-portable, aircraft-ready air concentrator-ion trap mass spectrometer (AC-ITMS) has been developed. The AC-ITMS was designed for use in the third pod, which mounts to the wing of a P-3 aircraft, of the Department of Energy (DOE) Airborne Multisensor Pod System (AMPS) program. In brief, the AC-ITMS incorporates a reusable dual-stage air concentrator sampling system with an ion trap mass spectrometer for detection. In practice, outside air is sent through a large-volume sampler, the primary concentrator, after which the trapped species are sent to a smaller sampler, the secondary concentrator, where they are further focused. After this secondary enrichment, the focused air sample is analyzed with an ion trap mass spectrometer. The AC-ITMS provides the option for both real-time sample collection with subsequent mass spectrometric analysis and direct atmospheric sampling with mass spectrometric analysis. In either case, the entire operation and chemical examination of the atmosphere is performed while the system is airborne.

Shown in Figure 1 is a pictorial illustration of the AC-ITMS in the third pod of AMPS. In general, the AC-ITMS consists of three modules; the large-volume air sampling system, the mass spectrometer (Teledyne 3DQ ITMS with FNF capabilities), and the ancillary component devices (e.g. temperature controllers, switches, vacuum components, etc.). Inside the pod, two trapezoid frames, which are spaced approximately 22 inches in width, represent the individual compartments to mount the experimental instrumentation. The primary concentrator is attached directly to the air inlet duct. Diaphragm roughing pumps are mounted to the support frame of the pod. The ion trap and support electronics, including computer systems, are attached to two reinforced plates, which in turn are attached to the trapezoid supports, using shock mounts to dampen vibration. The entire systems weighs approximately 220 pounds.

Preliminary flight testing of the prototype instrument has been performed using the PNNL* G-1 aircraft. Shown in Figure 2 is the total ion chromatogram obtained from a 30 minute air collection. From Figure 2, two sharp chromatographic peaks appear at approximately 19.0 and 19.5 minutes. The mass spectra obtained by averaging the data contained from these peaks are illustrated in the inserts in Figure 2. Although exact analyte determination is not possible for these initial attempts, the differences between these two mass spectra, suggest that the two peaks contain different or unique species.

We have demonstrated that a dual-stage air concentrator sampling system with an ion trap mass spectrometer offers a simple, rugged and light weight experimental platform for air analyses. We have shown experimental data that illustrates different mass spectral signals are obtained while using the primary/secondary configuration. These preliminary results represent encouraging progress towards the goal of real-time sampling and monitoring atmospheric contaminants.

Monitoring Volatile Organic Compounds in Gaseous Process Streams

Kevin J. Hart, Amy B. Dindal and Rob R. Smith
Chemical & Analytical Sciences Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

Direct sampling, ion trap mass spectrometry (DSITMS) has been shown to be a valuable method for process monitoring applications such as incinerator emissions monitoring. Monitoring levels have been demonstrated in the low part-per-billion to part-per-trillion range for a number of volatile organic compounds (VOCs). The field studies performed to explore the use of DSITMS instrumentation for continuous monitoring of emissions include tests at the K-25 Site TSCA Incinerator in Oak Ridge, TN and an EPA sponsored continuous emission monitor (CEM) test conducted at the EPA Incinerator Research Facility (EPA-IRF) in Jefferson, AR [1,2]. The thermal desorption (TD) and continuous air monitor (CAM) DSITMS interfaces were utilized in the EPA-IRF test. Sorbent traps (ST) packed with three different sorbents with varying retentive characteristics were used to sample the flue gas emitted during the test. The flue gas was spiked at three different target analyte concentrations, which are detailed in the Table 1 caption below. The sorbent traps were analyzed immediately after collection using a field-portable DSITMS instrument. Thus, the concentrations of VOCs detected in the flue gas were available within ca. 5-10 minutes after sampling the flue gas. The CAM was used to monitor the flue gas in "real-time" at the high VOC concentration. The CAM interface often provides better results than the ST/TD setup for monitoring transient process events such as the VOC spike step changes illustrated in Figure 1.

One figure of merit used to evaluate performance of CEMs is relative accuracy (RA), which is a term that compares CEM results to those obtained using standard reference methods. The RAs obtained for three CEMs participating in the EPA-IRF test at three concentration levels

CAM/DSITMS Response for Naphthalene During Step Changes

Figure 1

was not yet at an acceptable level for deployment, further development can be reasonably

are summarized in Table 1 below. A dual detector (flame ionization and electron capture) online GC CEM and a CEM that used selective charge exchange ionization mass spectrometry were tested in addition to the ST/TD/DSITMS prototype CEM. The results obtained using the fieldable DSITMS instrumentation were encouraging because of the ability of this instrumentation to monitor VOCs in a gaseous matrix containing ca. 34% by volume water with comparable RA to other methods. While the RAs obtained for these CEMs

expected to solve this problem. Probably the largest source of error reflected in the RAs was the measurement of gas volume using a rotameter. Other sources of error include calibration drift, temperature fluctuations in the transfer line and conversion of the "wet" measurements to "dry". Furthermore, the ion trap instrument employed for this test lacked MS/MS, selective ion accumulation and automation capabilities so there remains considerable room for improvement over the results reported here, in terms of practical monitoring levels, maintenance of calibration with automated calibration checks, elimination of potential isobaric interferences and ease of use.

A Field-Portable Aerosol Time-of-Flight Mass Spectrometer (ATOFMS)

Tas Dienes, Eric Gard, David Fergenson, Brad Morrical, and Kimberly A. Prather^{*}
Department of Chemistry, University of California, Riverside

In order to fully understand and effectively regulate atmospheric pollution, it is necessary to know the role aerosols play in pollution, and how the size and composition of individual aerosol particles is related. Recently, the real-time measurement of both the size and composition of individual aerosol particles has been made possible by the development of Aerosol Time-of-Flight Mass Spectrometry (ATOFMS)¹. We are now constructing two field portable ATOFMS instruments which may be taken out of the laboratory in order to sample atmospheric aerosols as well as particles produced from specific sources in real time.

The ATOFMS instrument works by allowing particle-containing air to expand through a series of differential pumping stages, whereby the gas is pumped away and a stream of aerosol particles remains. The particles pass through two Ar⁺ laser beams oriented orthogonally to the particle stream and to each other. Two PMTs detect the light scattered by the particles, and trigger a timing circuit which measures the velocity of each particle and fires a Nd:YAG laser at the appropriate time to intercept the particle at a third point along its path. Ions produced from molecules desorbed from the particle are accelerated and detected in a dual polarity reflectron time-of-flight mass spectrometer.

Data collected from the instruments will be analyzed with custom-developed software to classify the particles into different types based on composition. The abundance of each type may be correlated with particle size.

Once the instruments are completely operational, we will conduct studies to compare them with the first generation ATOFMS. After calibration is complete, initial field studies in Riverside and other parts of Southern California will be undertaken, including a side-by-side comparison study of ATOFMS versus traditional aerosol sampling methods. In the future, we expect to use these instruments to develop a better understanding of atmospheric and other aerosol sources and reactions. Studies will include: characterization of "pristine" air far from manmade sources; characterization of atmospheric pollution in different regions; source profiling of factory emissions, automotive and truck emissions, and natural aerosol sources; characterization of specific health-related particulate sources, such as tobacco smoke; studies of gas-phase reactions which lead to aerosol formation; and heterogeneous gas-particle reactions.

ATOFMS design and data from the first generation instrument is also discussed elsewhere in this publication.^{2,3}

ATOFMS P1 Advantages over previous instruments include:

- Compact dual-ion TOF-MS simultaneously captures both positive and negative ion spectra of each particle
- Two 500 MS/s Analog-to-Digital boards on the PC Bus for fast data transfer (up to 10 spectra per second)
- Improved timing circuit with greater reliability and efficiency than first generation
- Improved data acquisition software
- More compact lasers, electronics, optics, interface, and vacuum systems
- Completely self contained on a wheeled cart - designed to fit through doors and elevators
- Requires only 110/220V AC power
- Operation is completely computerized - no need to follow complex startup/shutdown procedures
- More efficient light scattering/particle detection optics
- Nozzle can be removed and replaced without breaking vacuum

Ruggedized

- Rack-mounted industrial computer
- No ceramic in vacuum chamber
- Two-piece coffin chamber design for strength and vacuum integrity
- Shock mounted pumps and air-cushioned wheels
- All components are modularized and rack-mounted

Ambient Particle Classification Capabilities of Aerosol Time-of-Flight Mass Spectrometry

Christopher A. Noble and Kimberly A. Prather*

Department of Chemistry, University of California, Riverside, California 92521

Single particle characterization of ambient aerosols is an increasing priority because it is the only means to distinguish between "average" and "unique" particles. Bulk aerosol methods may identify what elements/compounds are present in a certain size range, however, the results of such analyses assume an "average" particle based on the average composition. Only methods which analyze aerosols on a single particle basis can determine "unique" or chemically specific particle types within the aerosol sample.

Experimental Section

Our research group has recently developed aerosol time-of-flight mass spectrometry (ATOFMS), a technique which allows for real-time determination of the size and chemical composition of individual aerosol particles, by coupling two techniques: time-of-flight aerosol beam spectrometry (TOFABS) and time-of-flight mass spectrometry (TOFMS). TOFABS is similar in principle to TOFMS. TOFMS relates an ion time-of-flight to a specific mass-to-charge ratio; TOFABS relates a particle time-of-flight to an unique aerodynamic diameter. TOFABS particle sizing measurements are performed using two perpendicular lasers prior to TOFMS mass spectral analysis. Two laser aerodynamic sizing allows for size analysis of polydisperse aerosol samples over the size range from ~ 0.1 - $10 \mu\text{m}$ in diameter.

Results and Discussion

The purpose of this presentation is to demonstrate the advantages of ATOFMS for analysis of ambient aerosol systems. The uniqueness of ATOFMS is the two laser particle sizing system coupled with a mass spectrometer, allowing for measurement of both the size and chemical composition of individual particles. Shown in Figure 1 is an empirical size calibration curve determined by measuring the times-of-flight, or transit times, of monodisperse ammonium nitrate calibration aerosols. This curve is used to determine the size of ambient particles by relating a measured transit time to the corresponding diameter.

Figure 2 shows a comparison between ATOFMS and an Aerosizer (Amherst Process Instruments) for an ambient aerosol sample, simultaneously introduced into both systems. This demonstrates that not only is ATOFMS comparable with the Aerosizer in sizing accuracy, but it also agrees well with the relative particle count in each size mode. That is, ATOFMS is similar to the Aerosizer in regard to size biasing (at

Figure 1: Empirical size calibration curve for determining particle size from a measured transit time.

least over the size range of ~ 0.2 - $2 \mu\text{m}$).

For particles made in laboratory known to be of uniform composition, the spectra may be averaged to provide more accurate information on peak area and, therefore, ion count (Figure 3). This may possibly aid in attempts at quantification of various compounds, not only in particles created in the laboratory but also in particles from ambient aerosol samples.

Also in this presentation will be samples of several spectra from ambient particles sampled in Riverside, California, which are representative of chemically distinct particle types. Initial results from computer automated mass spectral analysis will also be shown. By changing user input on various search parameters, the number of peaks which are identified in a mass spectrum may change slightly. These search parameters mainly affect the identification of smaller, less intense peaks.

Laser Desorption Ionization TOF Mass Spectrometric Analysis of Chromium Containing Particulates

Todd M. Allen[†], Dawit Bezabeh[†], Ian M. Kennedy, A. Daniel Jones, and Peter B. Kelly[†]
[†]Chemistry Department, University of California at Davis, Davis, CA 95616

Chromium is widely used in alloys, electroplating, leather tanning and dyes. Emissions of chromium into the atmosphere result from these activities and from incineration of wastes containing chromium. The toxicity of chromium depends on the oxidation state; where the hexavalent form of chromium [Cr(VI)] is known to be highly carcinogenic, while the trivalent form of chromium [Cr(III)] is non-carcinogenic and an essential nutrient for humans. Combustion of chromium compounds results in the formation of an aerosol containing micron and submicron particles which can stay airborne for long periods of time and penetrate deeply within the lungs, and thus have the potential for mutagenic and carcinogenic effects.

Chromium aerosols are difficult to analyze because some forms (e.g. Cr_2O_3) are insoluble and resistant to digestion, even when subjected to vigorous conditions such as $\text{HNO}_3/\text{H}_2\text{O}_2$ digestion. As a result, chromium recoveries are often poor when Cr is analyzed using atomic absorption spectroscopy or ICP-AES.

Laser desorption ionization (LDI) time-of-flight mass spectrometry (TOF-MS) has been used for examining the fate of chromium in a model incinerator. The coupling of lasers as an ionization source with mass spectrometric techniques provides molecular, fragment and cluster ion information about inorganic materials¹ which is not easily obtained by conventional techniques. LDI TOF-MS offers the advantages of minimal sample handling and preparation which leads to cost-effective analysis times.

LDI mass spectra were obtained using a custom built linear TOF mass spectrometer. Simultaneous laser desorption ionization of the sample was performed with pulsed UV radiation at 266 nm from a Nd:YAG laser. Low laser pulse energies (2-10 $\mu\text{J}/\text{pulse}$) were used for generating the negative ion mass spectra. Each mass spectrum represents averages obtained from 100 laser pulses.

In model incineration experiments, different fuel mixtures of hydrogen and nitrogen were utilized to examine the effect of temperature on the formation of chromium compounds. Nitrogen is added to dilute the hydrogen fuel and lower flame temperatures. Two different sources of chromium compounds were used: an aqueous solution of chromium (III) nitrate was introduced to the burner after nebulization, and chromium (0) hexacarbonyl was introduced as a vapor. The incineration process forms an aerosol of micron and submicron particles, which are collected on an alumina filter.

The top three mass spectra in Figure 1 illustrate the negative fragment and cluster ions produced for three standard chromium compounds: chromium (III) nitrate, chromium (III) oxide and chromium (VI) oxide. Chromium (III) and chromium (VI) oxide are two of the major chromium products expected to be formed from non-chlorinated waste flames. The most abundant peaks for pure Cr_2O_3 are CrO_2^- and CrO_3^- , which are used for the identification of the Cr(III) oxide. The three low intensity peaks in the Cr_2O_x^- ($x=4-6$) region of the mass spectrum may also be used for identification of the Cr(III) oxide, but are not unique to the Cr(III) oxide. The most abundant peaks for pure CrO_3 form polymeric units of $(\text{CrO}_3)_n^-$, where $n=2-5$, and are used as markers of the Cr(VI) oxide. The high mass cluster ions observed for chromium nitrate are very similar to those observed for chromium (III) oxide. However, there are several significant differences in the low mass region (abundant formation of NO_2^- , NO_3^- , and HCrO_4^-) of the chromium nitrate which allow for distinction between the two pure compounds.

The fourth LDI mass spectrum in Figure 1 shows the fragment and cluster ions observed for a filter which contained the trapped chromium particles. An aerosol from a 67% $\text{H}_2/33\% \text{N}_2$ flame with chromium nitrate was collected on the filter. The fragment and cluster ions (CrO_2^- , CrO_3^- and Cr_2O_5^-) observed in the mass spectrum of the filter are strongly indicative of the chromium (III) oxide, Cr_2O_3 . The particles on the filter were green and insoluble in water, also indicators of Cr_2O_3 . Peaks at m/z 46

and 62 indicate the presence of nitrate on the filter. However, there are no cluster ions in the high mass region which correspond to the those observed for chromium nitrate or chromium (VI) oxide.

LDI TOF-MS Analysis of Chromium Standards and Filter

Figure 1

LDI TOF-MS Analysis of Filters from Incineration of $\text{Cr}(\text{CO})_6$

Figure 2.

In Figure 2, the mass spectra illustrate the effect of different hydrogen/nitrogen fuel mixtures on the formation of chromium products from chromium (0) hexacarbonyl, $\text{Cr}(\text{CO})_6$. Each mass spectrum is labeled with the trial number, the type of fuel mixture used and the color of the particles captured on the filter. When different amounts of nitrogen (67%, 50% and 33%) were added to the hydrogen flame, there were little to no differences observed for the color of the particles on the filters or the three mass spectra. The most abundant chromium fragment and cluster ions for the three filters, 11B, 10B and 9A, exposed to a hydrogen/nitrogen fuel mixture were CrO_3^- and Cr_2O_5^- , which are indicative of chromium (III) oxide.

Unlike the hydrogen/nitrogen flame mixtures which formed green particles on the filter, the 100% hydrogen flame produced particles which had a yellow-orange appearance on the filter. However, not only was the particle color different, but the ratio of abundances of CrO_2^- and CrO_3^- differed from any of the standards tested. Thus the mass spectrum of the yellow-orange filter does not appear to be due to the Cr(III) oxide. The lack of high mass peaks, which are indicative of the Cr(VI) oxide, suggests that the yellow-orange particles may possibly result from the formation of another chromium species, the Cr(IV) oxide.

In conclusion, the flame temperature affects the formation of chromium species in model incineration experiments. The incineration process forms an aerosol of micron and submicron particles. When a hydrogen/nitrogen flame is used, the mass spectra of the green chromium particles captured on the filter indicate that the majority of the chromium is present in the trivalent form as Cr_2O_3 . However, when using a pure hydrogen flame, the mass spectrum of the yellow-orange particles indicate that the chromium present on the filter is most likely not trivalent chromium, but may either be hexavalent or tetravalent. If only 1% of the chromium on the micron and submicron size particles on the filter is in the hexavalent oxidation state, severe health effects could result from inhalation of the particles.

We gratefully acknowledge support from the National Institute of Health "Superfund" program (Grant 3-P42-ES04699).

COMPARISON OF SCANNING CCD ARRAY AND POINT DETECTION FOR SMALL MOLECULE ANALYSIS

Karen Light Wahl and James A. Campbell,
Pacific Northwest National Laboratory P.O. Box 999 MS P8-08, Richland, WA 99352
and Jeffrey W. Finch and Shinichi Miki
JEOL USA Incorporated, Peabody, MA 01960

Minor components in environmental samples such as biodegradation breakdown products or plant extracts are typically low molecular weight analytes of interest and represent real detection challenges due to the complex matrix. Consequently, the enhancement of ion sensitivity for these minor components is required for accurate analyte identification when the signal intensity relative to the background is relatively small.

A scanning array detector based on a charge-coupled device (CCD) was developed for a magnetic sector instrument (Finch et al. 1995). This detector was shown to be 50 to 100 times more sensitive for protein analysis by electrospray ionization than the standard point detector. This project shows some examples of utilizing the scanning array detector for MS/MS analysis of small organic molecules with varying ionization modes. A JEOL SX102/SX102 four sector mass spectrometer was used for these MS/MS experiments with a JEOL scanning CCD array detector on MS2.

One test of the CCD array detector capabilities was for MS/MS analysis of sesquiterpene lactones isolated from sagebrush. While most of these lactones have previously been identified, it was important to find a relatively simple mass spectrometric technique to differentiate the isomers and determine the capabilities of the array detector. Positive ion fast atom bombardment (FAB) ionization with glycerol matrix gave reasonable signal strengths for the $(M+H)^+$ or $(M-H_2O+H)^+$ ions of the lactones analyzed. For dihydroarbusculin-A, the ion due to water loss is the base peak, whereas the protonated molecular ion is very weak (Figure 1). However, strong fragment ions were detected with the CCD array from MS/MS analysis of the $(M+H)^+$ ion of dihydroarbusculin-A (Figure 2). The expected water loss and subsequent loss of the carbonyl group are very strong fragment ions. Even though the parent ion was relatively weak, a good MS/MS spectrum was obtained with CCD array detection.

Negative ion electrospray ionization was used to analyze methylphosphonic acid monoisopropyl ester (IMPA). The mass spectrum obtained from direct infusion of IMPA in 50/50 methanol/water is shown. The $(M-H)^-$ ion at m/z 137 was selected for B/E linked scan (MS1) and four sector MS/MS dissociation experiments. Comparison of the B/E linked scan dissociation spectrum of MS1 with point detection and the four sector MS/MS dissociation with CCD array detection was made. Both experiments were conducted with exponential-down scanning. Similar fragment ions are observed for both experiments. The relative intensity of the fragment ions to the parent ion, in general, were stronger for the CCD detector data (approx. 30%) than the point detector (approx. 3%). Some extra noise spikes were observed in the data from the CCD detector. Further optimization of the experimental and array detector conditions could have minimized these noise spikes if they interfered with data analysis.

Performance of a scanning CCD array detector for small molecule analysis was evaluated by performing four sector MS/MS experiments on a degradation product of an explosive, sesquiterpene lactones, and organophosphorous compounds utilizing a variety of ionization techniques. Results presented show that interpretable MS/MS data can be obtained from relatively weak parent ions in complex mixtures with CCD array detection. The relative

intensities of the fragment ions to the parent ion are much stronger for the experiments utilizing CCD array detection than point detection which results in more interpretable MS/MS spectra for weak parent ion species with CCD array detection. Even though the signal strength of the ion of interest may be just above signal - to - noise levels, a good fragment ion spectrum can be obtained with the use of increased sensitivity afforded by CCD array detection utilized.

Polycyclic aromatic hydrocarbons (PAHs) are known carcinogens listed by the US Environmental Protection Agency (EPA). The analysis of these compounds by the EPA protocols (550.1, 620 and 8310) involve gas chromatography mass spectrometry (GC-MS) and high performance liquid chromatography (HPLC). The EPA GC-MS method is unable to detect PAHs with molecular masses higher than 300 amu. These compounds would require high gas chromatographic column temperatures (>300° C) and long analysis time (>30 minutes). Other drawbacks common for both chromatographic techniques include laborious and time consuming extraction procedures, e.g., Soxhlet extraction and/or sonication techniques.

This study describes direct laser desorption time-of-flight mass spectrometry (LD-TOF MS) measurements at 280 nm to characterize PAHs in environmental samples. In the molecular mass range 128–370 the compounds of interest were identified from untreated solid samples. The instrumentation used in this investigation was described earlier [1]. The identification of PAHs in soil, soot, and aerosol filters was rapid (with duration of 5–10 minutes) with no pre-requisite for extraction and preconcentration procedures.

Soil Samples : The direct LD-TOF MS analysis of contaminated soil samples indicated the presence of several PAHs with m/z 178 to 352 amu (Figure 1). Each peak may belong to one or more structural isomers with the same molecular weight. Similar soil samples from the same area were analyzed independently by GC-MS. The compounds with lower molecular mass (from 128 to 278 amu) were readily characterized by both techniques. The comparison between direct LD-TOF MS and GC-MS results lead to the conclusion that the two major drawbacks of the direct LD-TOF MS are its inability to characterize different structural isomers and its limited dynamic range (one order of magnitude) in quantitation. The advantages include short analysis time, simple sample preparation, and wider mass range of detection.

Soot Samples : Figure 2 shows the spectrum obtained from soot collected from automobile exhaust and immobilized on the probe tip by double sided Scotch tape. The spectrum indicated the presence of higher molecular weight PAHs (from 228 to 352 amu) which demonstrated the ability of the LD-TOF MS technique to detect the target compounds in soot samples. LD-TOF MS exhibits a clear advantage over GC-MS in soot analysis for its coverage of larger PAHs ($m/z > 300$) and much faster sample preparation and analysis.

Filter Samples : Figure 3 and 4 show the spectra of polycarbonate membrane filters (aerosol grade 47 mm diameter, 0.4 μ m pore size) exposed at different days and time in February 1992 near the town of Karasuk, Siberia, Russia [1]. Filter segments were mounted on the probe tip in a manner similar to the ones described for the soil and the soot samples. One of the filters did not exhibit any PAHs. This can serve as a proof that the filter itself did not generate interfering peaks in the area of m/z 120 to 370. The spectrum in Figure 3 contained a number of peaks that were not typical for PAHs. The only m/z ratios that can belong to PAHs were 228, 278, and 424. Figure 4 reveals a cluster of peaks in the range of m/z 166 to 328 that are characteristic for PAHs.

In conclusion, direct LD-TOF MS can be used for rapid screening and detection of PAHs in various solid environmental samples without preliminary extraction and preconcentration procedures.

Semiquantitative determination of PAHs with molecular masses from 228 to 278 in the ppb region was possible. In contrast to the conventional LC and GC-MS methods currently used in practice, direct LD-TOF MS is capable of detecting PAHs of high molecular weights (>300 amu) with good sensitivity at ppt levels [2]. These features make LD-TOF MS a promising method for fast environmental analysis of PAHs.

Ethylenediaminetetraacetic acid (EDTA) is a common contaminant of solid nuclear waste at disposal sites managed by the U.S. Department of Energy because it is a strong chelating agent which is known to bind ^{60}Co , ^{239}Pu , ^{238}U , and other radionuclides. The detection of EDTA is of primary importance to the remediation of nuclear waste sites. Large quantities of NaNO_2 and NaNO_3 are also found there as a result of chemical processing. The pH of those wastes can be very acidic or basic. This work demonstrates the use of laser desorption ion trap mass spectrometry for the identification and quantitative analysis of EDTA alone and in the presence of NaNO_2 or NaNO_3 at various pHs.

Solid samples are introduced into the vacuum chamber on the end of a solids probe which is mechanically rotated to allow desorption to occur from a fresh spot with every laser shot. Laser desorption/ionization is done with 212 nm pulses formed by fifth harmonic generation from a Nd:YAG laser. The ion trap is operated in the mass selective ejection mode, with the occasional addition of auxiliary SWIFT pulses to eject unwanted low mass ions. Two surfaces are used here, stainless steel and basalt. Solutions are prepared by dissolving the salts in water. A few droplets of an EDTA solution are placed on the surfaces and dried at room temperature.

Figure 1.

Figure 2.

Figure 1 shows the negative ion spectra for neutral pH solutions. Na_2EDTA or Mg_2EDTA are used in all experiments. When non-neutral pH solutions are required, NaOH or HNO_3 is added to the EDTA solution to adjust its pH to ~ 12 or ~ 2 . Figure 2 displays the negative ion spectra of Na_2EDTA and

NaNO_3 mixture at three different pH values (2, 7, and 12) dried onto stainless steel surfaces. SWIFT ejection of ions below m/z 26 (CN $^-$) does not affect the mass spectra since there are few negative ions in this mass range.

We do not observe any molecular or pseudo-molecular ions in either the positive or negative ion mass spectra of EDTA. All significant ion signals occur below m/z 140. Nevertheless, we are able to easily identify EDTA in any sample by the appearance of several "fingerprint" ions. These fingerprint ions are completely reproducible and are formed from all samples which contain EDTA, both in the presence and absence of sodium nitrate and nitrite. Figure 3 shows the positive ion spectra from three different mixtures of EDTA and NaNO_3 , at three different pH values (2, 7, and 12) dried onto stainless steel surfaces.

Figure 3.

Figure 4.

The EDTA limit of detection for a single laser shot from the basalt surface is found to be 200 pmol by taking into account the laser spot size and the concentration and volume of Na_2EDTA solution deposited on the surface. The negative ion spectra of the 200 pmol and 1400 pmol EDTA samples are shown above on the right. The ion signal from EDTA is linearly dependent upon the surface concentration. When the origin is included as a data point, the correlation coefficient for the linear least squares fit is found to be >0.998 for all ions. It is clear that either positive or negative ion spectra can be used to identify and quantify EDTA from solid waste samples.

We have demonstrated that 212 nm laser desorption ion trap mass spectrometry can be used for the direct analysis of EDTA salts on stainless steel and basalt surfaces. Analysis must be accomplished by the identification of several fingerprint ions since no intact molecular ions are observed. The most reliable method would be to record both the positive and negative ion spectra for a given sample. Limits of detection are 200 ± 100 pmol, and appear to depend upon the sample preparation and matrix. Addition of NaNO_2 or NaNO_3 enhanced the ion signals by two to fivefold.

ELECTRON ENERGY-DEPENDENT REGIOSELECTIVE LOSS OF CHLORIDE ANIONS FROM POLYCHLORODIBENZO-*p*-DIOXINS

Vadym D. Berkout, James A. Laramee and Max L. Deinzer
Department of Agricultural Chemistry and Environmental Health Sciences Center
Oregon State University, Corvallis, Oregon 97331-7301

Standard Electron Capture Negative Ion Mass Spectrometry (ECNIMS) is a sensitive and specific method for analysis of halogenated electrophilic compounds. But understanding the electron capture process and subsequent bond cleavage phenomenon is difficult due to complex gas-phase processes occurring in the ion source plasma. The Electron Monochromator / Mass Spectrometer system (EM/MS) eliminates the need for a buffer gas. This system is tunable to give just the right energy electrons to produce specific ions and because no buffer gas plasma is present artificial effects caused by ion-molecule reactions are eliminated (Laramee and Deinzer, 1994).

Mechanisms of electron capture and dissociative electron attachment were probed by examining a series of regiospecific chlorine-37 enriched polychlorodibenzo-*p*-dioxins congeners synthesized in house (Chang and Deinzer, 1990) with enrichments ranging from 74 to 96 atom percent. A gas chromatographic inlet was used to introduce the dioxins to the ion source via a DB-5 capillary column with splitless injection and $^{35}\text{Cl} / ^{37}\text{Cl}$ ion abundance ratios were recorded at a fixed electron energy. Regioselective loss of chlorine from the labeled position was calculated from the $^{35}\text{Cl} / ^{37}\text{Cl}$ ion abundance ratio and isotopic enrichment (Chang *et al.*, 1991). Comparative data were acquired on double-focusing JEOL DX-300 and Kratos MS-50 mass spectrometers under negative chemical ionization conditions using methane as buffer gas.

Chloride ion ejection occurs with an equal probability from any position for symmetrically substituted $2(^{37}\text{Cl})_3$ - and $1(^{37}\text{Cl})_4$ -dichlorodibenzo-*p*-dioxins when ionized by discrete energy electrons from the electron monochromator (Figure 1). These results clearly rule out any chlorine isotope effect under conditions of the EM/MS experiments. In the case of ECNIMS measurements the chlorine ion loss from the enriched positions ranged from 47 to 49%. These values are systematically less than 50% because the heavier ^{37}Cl isotope remains in the ion source about 1.5% longer than the ^{35}Cl isotope.

The energy of ionizing electrons has a decided influence on the regioselective chloride ion loss in the negative ion mode. For example chloride ion loss from position-1 of $1(^{37}\text{Cl})_2,3,4$ tetrachlorodioxin monotonically increases from 19% to 27.5% with increasing electron energy from 0.03 to 2.0 eV. The analogous dependence on electron energy for $1(^{37}\text{Cl})_3,3$ dichlorodioxin exhibits a minimum at an electron energy of about 1.4 eV.

The pentachloro- and hexachlorodioxins labeled at different positions provide a series for comparison (Figure 2). Chloride ion ejection from position-1 is highest in both dioxins at low energy and diminishes with increasing energy of ionizing electrons. Ejection of the chloride ion from position-2 is almost independent of electron energy. Chloride ion loss from position-3 in pentachlorodioxin and position-7 in hexachlorodioxin steadily rises with increasing electron energy. These results demonstrate that the most toxic - 2,3,7,8 tetrachlorodibenzo-*p*-dioxin is formed during the interaction of higher chlorinated dioxins with low energy (≤ 0.5 eV) electrons and loss of chlorine anion from different positions is randomized with increasing electron energy.

Negative ion resonances were measured by scanning electron energy and compared with semiempirical calculations using the PM3 Hamiltonian. Measured chloride anion resonances increase from 0.22 eV for hexachlorodioxin to 0.55 eV for dichlorodioxins and correlate with LUMO+4 orbital energies, which possess σ^* antibonding carbon-chlorine character. The molecular radical anion resonances (0.11 to 0.20 eV) correlate with LUMO+1 orbital energies.

Applications of Mass Peak Profiling from Selected-Ion Recording Data Using Probe Introduction

*Andrew H. Grange and William C. Brumley

USEPA, NERL, Characterization Research Division, PO Box 93478, Las Vegas, NV 89193-3478

Introduction. The CRD develops rapid screening techniques for targeted analytes including Aroclors (commercial PCB mixtures) and PAHs. Also of interest are new techniques to help identify compounds. Mass peak profiling from selected-ion recording data (MPPSIRD) acquired with a Fisons 70-250SE double focusing mass spectrometer using 10,000 to 20,000 resolution provides the high selectivity and sensitivity required for screening.^{1,2} Probe introduction of standard solutions and sample extracts were made to determine the utility of MPPSIRD for three rapid screening applications.

Identification and Quantification of Aroclors. Aroclors are often identified from patterns of chromatographic peaks of PCB isomers in an ECD chromatogram. When congener-specific analyses are performed using mass spectrometric detection, Aroclors can be identified from the summed responses for all congeners. Thus, chromatographic peak patterns and long analysis times are not necessary to identify Aroclors.

Two SIR descriptors monitored 74% of the mass range for the profile of the most abundant molecular ion for two sets of three congeners: MonoCBs, DiCBs, and TriCBs, or TetraCBs, PentaCBs, and HexaCBs. A mass increment of 10 ppm between m/z ratios was used with 15,000 resolution to ensure the partial profiles were well-centered in the observation windows. Different congener distributions were observed when each Aroclor (10 ng in 1 μ L of methylene chloride) was introduced by the probe, which was heated ballistically to 350°C. These differences permit identification of Aroclors 1016, 1221, 1232, 1242, 1248, 1254, and 1260 from probe introduction data acquired with both SIR descriptors.

A commercial analytical lab determined from peak areas for several PCB isomers in the ECD chromatogram that a sample extract contained 34% Aroclor 1254 and 66% Aroclor 1260. The PeCB-HxCB congener distribution observed with probe introduction was intermediate between Aroclors 1254 and 1260. Using a relative response factor (1.07) between Aroclors 1254 and 1260 determined from a 50:50 mixture and a mass balance equation, the extract was found to contain 51% Aroclor 1254 and 49% Aroclor 1260.

A third SIR descriptor was used to quantify Aroclor 1254. Partial profiles of the two most abundant congeners, PeCBs and HxCBs, and a carbon-labeled PeCB added as an internal standard were monitored. Triplicate data acquisitions were made for 1 μ L of standard solutions containing 0.01 to 1000 ng of Aroclor 1254 and 1 ng of ¹³C₁₂-PeCB. A useful calibration range of 5 orders of magnitude and linearity over 4 orders of magnitude were observed. The lab estimated that the Aroclor mixture contained 2800 ppb of Aroclors, and 1600 ppb was found by probe introduction. Because the lab quantification had a positive bias for Aroclor mixtures, the value from probe introduction was in reasonable agreement. Quantification against the pure Aroclors and a 50:50 mixture yielded similar results (1600 - 2000 ppb), since the responses of the Aroclors were similar.

Identification and quantification of Aroclors with probe introduction using MPPSIRD is feasible and provides several advantages over GC/HRMS analyses that require isomer separation: ~10-fold faster analysis time; 5-fold better precision due to an acquisition time of <1 min; a 5-10 times lower detection limit, because all isomers are monitored simultaneously; and extreme simplicity (no window-defining mixtures are used to set start and end times for several SIR descriptors, a single congener ratio and two exact masses replace retention time and ion ratio criteria for each isomer; only one internal standard is used; and maintenance of good chromatographic conditions is not required).

Confirmation of High Molecular Weight PAHs. PAHs with masses up to 278 Da are analyzed by EPA method 8270 using GC/MS. Higher-mass PAHs provide long retention times or do not elute as discrete chromatographic peaks. Probe introduction permits screening for higher-mass PAHs. Mass spectra for individual compounds are not observed, but an exact mass can be obtained for any ion observed in composite mass spectra. An average low-resolution mass spectrum was obtained for PAHs in a 1- μ L methylene chloride extract of a sample from a spent carbon electrode disposal site at an aluminum plant. The masses of the most abundant PAHs were greater than 278 Da, and Method 8270 would underestimate the level of PAHs present. The exact masses determined from full profiles plotted from data acquired at 20,000 resolution agreed to within 2.2 ppm of the correct masses (302.0939 to 552.1878 Da) for 16 PAHs. The largest mass PAH was not observed in the low-resolution mass spectra; its probable existence was inferred from the PAH distribution. Thus, MPPSIRD provided greater sensitivity at 20,000 resolution than the full scan mode at low resolution.

Although the exact masses provided evidence that the compounds were PAHs, other compositions containing O, N, P, or S atoms were possible based on these exact masses. Acquisition of M, M+1, and M+2 partial profiles did not provide data sufficient to exclude the other compositions, because other compounds (probably PAHs having two more H atoms) produced ions that interfered with the M+2 profiles. The sample's origin and the presence of lower-mass PAHs renders these other compositions improbable.

Determining Ionic Compositions for Components in a Complex Mixture. A methylene chloride extract of a black, viscous sample from a Superfund site was examined by GC/MS using MPPSIRD to determine elemental compositions for the molecular ion or other large mass ion for 47 components that provided chromatographic peaks. A three-step process was used to determine compositions. A survey of profiles at each nominal mass was made across a 1600-ppm mass range using 3,000 resolution. Two or three points across each profile provided an estimate of the exact mass for the most abundant analyte ion observed in the low-resolution mass spectrum. A better estimate of the exact mass was determined from the weighted average of several points near the apex of a full mass peak profile using data acquired at ~10,000 resolution across a mass range of 160 ppm. Finally, at 20,000 resolution, M, M+1, and M+2 partial profiles were plotted to obtain the exact masses of the three partial profiles and the abundances of the M+1 and M+2 partial profiles relative to the M partial profile. Five criteria compared these values with exact masses and relative abundance ranges calculated by a profile generation model³ to reject all incorrect compositions.

Probe introduction was used to determine compositions of 4 additional ions and to screen for 9 ions with compositions determined by GC introduction. In general, interferences from other components in the extract reduced the number of useful criteria. However, unique compositions based on fewer than five criteria were determined for the ions with masses less than 300 Da.

Conclusion. The high selectivity and sensitivity provided by MPPSIRD make rapid screening from the probe feasible for both qualitative and quantitative applications. Although chromatographic separation is still necessary for some analytes in complex mixtures to provide certain determination of the molecular ion's composition, probe screening with MPPSIRD is adequate to provide confirmation for the presence of target compounds without resorting to more complex analyses.

A SOLID SCINTILLATION CELL FOR METABOLITE CHARACTERIZATION BY MICROCOLUMN LC-RAM-MS-MS

*Schultz, Gary A. and Alexander IV, James N.

Rohm and Haas Company, 727 Norristown Rd Spring House, PA 19477

We developed an on-line microcolumn LC-RAM-MS-MS system using a solid scintillant for the detection of ^{14}C beta decays. Solid scintillation materials are non-destructive and convert nuclear beta decays into fluorescent photons which are detected by photomultiplier tubes operated in coincidence. Some challenges were designing a radioactive monitor (RAM) cell that does not increase the band broadening of the chromatographic peaks before entering the mass spectrometer and also provides sensitivity for the beta decays. We developed a 650 nl volume RAM cell for use with 0.25 mm i.d. packed microcolumns which can detect around 100 radioactive disintegrations per minute (dpm).

LC-RAM-MS-MS Microcolumn Close-up View of On-column RAM Cell

One advantage to using microcolumns for metabolite analyses is that the sample volume injected is proportional to the square of the column diameter. This means that a 0.25 mm id column requires $(4.6)/(0.25)^2 = 333$ times less sample injected for the same peak concentration on-column compared to a standard analytical column, i.e., coupling each of these chromatography systems to a mass spectrometer would give comparable MS data with 333 less sample using a 0.25 mm i.d. microcolumn.

Target spray on a crop is typically 20,000 dpm/ μg (20 dpm/ng) for the parent compound. A 1 ppm residue level in a tissue corresponds to 1 $\mu\text{g/g}$ tissue. A typical extraction uses 50-100 g of tissue. This corresponds to 50-100 μg or 1,000,000 to 2,000,000 dpm of metabolite if this radioactivity can be successfully isolated from its sample matrix. A sample submitted for MS

analysis at approximately 100 ppm would correspond to 2 dpm/nl (100 ng/ μl x 20 dpm/ng = 2000 dpm/ μl = 2 dpm/nl) and 60 nl injection corresponds to 120 dpm injected.

The energy window for the detector was adjusted to 5-156 keV since 90% of the electronic noise associated with RAM detectors occurs in the energy window of 0-4 keV. The energy associated with the decay of a ^{14}C atom occurs in an energy window from 0-156 keV with a maximum near 49 keV. By adjusting the energy window to 5-156 keV, the signal/background can be greatly increased without a significant decrease in the signal due to ^{14}C decays.

Band-broadening was minimized by incorporating the RAM cell within a 0.25 mm i.d. separation capillary. A 5 cm length of polyimide coating was removed approximately 3 cm from the end of a 60 cm fused silica capillary. This region was packed with 5-10 μm solid scintillant particles creating the "RAM Window" and then the remainder of the capillary was packed with 5 μm stationary phase particles. The exit of this LC-RAM column is coupled to a 50 μm i.d. fused silica capillary using a teflon sleeve (silanized glass wool frit) to couple to the mass spectrometer.

Band-Broadening Minimized!

The RAM sensitivity is increased by decreasing the size of the RAM cell, reducing quenching and thus increasing the detection of the photons produced by the radioactive decay events. Also, smaller scintillant particles have a greater efficiency of converting beta-decays into fluorescence events.

Identification of Photodegradation Products of DDT and Its Metabolites in Water

Jongki Hong¹, Jong-Shin Yoo¹, Hun-Young So¹, Seung-Yong Jung² and Kang-Jin Kim²

¹Mass Spectrometry Group, Korea Basic Science Institute, Taejeon, Korea

²Department of Chemistry, Korea University, Seoul, Korea

INTRODUCTION

As the production of DDT had been increased exponentially during 1940 - 1970s, it is obvious that the contamination of the environment is to be a major in environmental protection.

Numerous studies on the photochemical transformation of DDT in organic solvent have been reported. It is known that DDT in organic solvent is mainly converted by photolysis into DDD, DDE, DDMU and DCBP. Actually, as DDT is widely used as an insecticide, DDT and its photolytical products are consequently detected in aquatic environment. However, there is relative little information on the photolysis of DDT in water due to the lower water solubility. Therefore, it is important to study the phototransformation of DDT in water.

The object of this study was to examine the effects of a high pressure mercury lamp on the photodegradation of DDT in water. The photodegradation products of DDT were identified using GC-MS with EI, PCI and NCI. The reasonable photodegradation pathways were also proposed on the basis of products identified.

EXPERIMENT

DDT (5mg, 50 ppm) in 100 mL of water was irradiated for 5 - 10 min with a high pressure mercury lamp (Hanovia Photochemical Lamp, 1.2 KW). After irradiation, the DDT solution was extracted two times with 50 mL of dichloromethane. The extracts were passed through sodium sulfate column to remove trace water and evaporated under the nitrogen condition. In order to detect the hydroxylated metabolites, trimethylsilyl derivatization was adopted. To derivatize the hydroxyl group, MSTFA was added to concentrated solution. The solution was heated to 80°C for 15 min.

GC-MS data were collected on a Hewlett-Packard 5890 GC and JEOL SX-102A mass spectrometer with double focusing analyzer. A DB-5 (30 m x 0.25 mm i.d.) capillary column was programmed from 100°C held for 2 min to 300°C at 20°C/min. Sample were injected in splitless. Carrier gas was helium at 0.9 mL/min and inlet pressure was 10 psi. Injector temperature was 270°C.

Under EI conditions, ionization energy was 70 eV, ion source temperature was set 200°C and scan range was 50 - 500 amu. Under PCI and NCI conditions, methane was used as the reagent gas, ion source temperature and emission current were set 130°C and 200 uA, respectively. The instrument was tuned using methane gas; the target ions were m/z 17 and 29 at a ratio 1:1 with a source pressure of 10⁻⁴ torr.

RESULTS and DISCUSSION

It is reported that DDT readily decomposed to DDD, DDE, and DDMU under the UV irradiation. These compounds were identified by comparing retention times and mass spectra with those authentic standards and standard synthesized in our laboratory.

Due to the easy loss of -CCl₃ and -CHCl₂ from the saturated β -carbon position of DDT and DDD, respectively, their EI-mass spectra show weak intensity of the molecular ion cluster but consist almost exclusively of the m/z 235 ion cluster. In CI mode, (M+H)⁺ ion exhibited very weak but (M+H-Cl)⁺

and (M+H-phCl)⁺ ions appeared as the respective base peak for PCI mode. In NCI mode, M⁻ ion is absent mode whereas (M-HCl-Cl)⁻ and (M-Cl₂)⁻ ions are very abundant. For DDE and DDMU which contain a double bond between α - and β -carbons, EI-mass spectra showed abundant molecular ion cluster, (M-Cl)⁺ and (M-Cl₂)⁺ ion cluster as a base peak. In both PCI and NCI spectra of DDE and DDMU, these compounds exhibited abundant molecular ion while the abundance of (M+H-Cl)⁺ or (M-Cl)⁻ ions were of low intensity.

Several minor reductive products were also detected, they were tentatively identified as 4,4'-dichloromethane(M1), 2-(4-chlorophenyl),2'-phenyl-1,1'-dichloroethane(M2), 2,2'-bis(4-chlorophenyl),1-chloroethane(M3) and 3,6-dichloro-9-methylene, fluorene(M4). The retention time and mass spectrum of 4,4'-dichlorophenylmethane as tentatively assigned were identical to those of standard synthesized in our laboratory. Their mass spectra were considerably different according to the presence of double bond between α - and β -carbons in both EI and PCI mode. Unfortunately, satisfactory NCI spectra of these compounds could not obtain owing to their low concentration.

Oxidation was confirmed to be a minor photolytical decomposition route for DDT in water. In this study, five benzophenone compounds were detected from the photolysis of DDT and they were characterized by the molecular ion and m/z 139 formed by induced cleavage with charge initiation at oxygen of acyl-group. Thus the presence of m/z 139 ion diagnostically indicates that oxidation of DDT has taken place on the benzylic position.

Four hydroxylated degradation products were identified through the TMS derivatization. They were expected to be 4-chlorobenzoic acid, 4-chlorobenzhydrol, 4,4'-dichlorophenylmethanol, 2,4,4'-trichloro-phenylmethanol. They produced molecular ion and (M-15)⁺ ion in EI-mode. Their PCI mass spectra shown abundant protonated molecular ion and the base peak was formed by the loss of TMSOH molecule from the (M+H)⁺ ion.

CONCLUSION

The mass fragmentation patterns for DDT and its major products under EI, PCI and NCI mode are greatly influenced by the degree of unsaturation in α - and β -carbon chain or the presence of oxygen atom in α -carbon. The compounds with unsaturated carbon chain give simple spectra and produce strong abundant molecular ions whereas one with saturated carbon chain produce weak molecular ions and exhibit diverse fragmentation patterns. The compounds that have a ketone or hydroxyl group in α -carbon produce a significantly diagnostic ion at m/z 139 in both EI and PCI. Derivatization with MSTFA improves the gas chromatographic properties and this is useful for the identification of hydroxylated metabolites. The formation of OTMS derivatives affects the fragmentation patterns producing more characteristic ions. The observation of mass fragmentation patterns could help to clarify the structures of minor metabolites in photolysis of DDT in water. The transformation of DDT in aqueous environment would enable a better prediction on the basis of photodegradation of products identified.

**Analysis of Geosmin and 2-Methylisoborneol
by Isotope Dilution High Resolution Mass Spectrometry**

Vince Taguchi, Steve Jenkins, Dave Wang, J-P. Palmentier and Don Robinson
Ministry of Environment and Energy, Etobicoke, Ontario, Canada M9P 3V6

Introduction

Some taste and odour problems that have a natural origin occur seasonally in surface and drinking waters. Metabolites of actinomycetes and blue-green algae, geosmin (trans, -1,10-dimethyl-trans-9-decalol [CAS# 19700-21-1]) and 2-methylisoborneol (2-MIB)(1,2,7,7-tetramethyl-exo-bicyclo[2.2.1]heptan-2 ol [CAS# 2371-42-8]) have been identified as being responsible for imparting earthy, musty taste and odour qualities to water. Because human threshold odour concentrations for these compounds are 10 ng/L and 30 ng/L respectively, method detection limits for their analyses must be in the low ng/L range. The most widely used method for the analyses of geosmin and 2-MIB is the closed-loop stripping (CLS) method followed by GC-MS. The productivity of the CLS/GC-MS method was 2 samples/day and this was insufficient to meet the seasonal demands. Also, the CLS/GC-MS method with external standard quantitation could not compensate for decomposition of the analytes during storage. Korth et al (1991) reported that storage at 20°C for 21 days resulted in 0.1% geosmin and 74% 2-MIB recovered. At 5°C, the recoveries were 26% and 81% respectively. Addition of the isotopically-labelled analogues as early as possible/practical in the analytical train would compensate for any decomposition from that point. The method that was developed incorporated isotope dilution, analyte extraction/isolation with a granular adsorbent Ambersorb 572 and high resolution mass spectrometry.

Methods

A) *CLS/GC-MS.* The closed-loop stripping/GC-MS method utilized a 1 L sample equilibrated to 50°C over 0.5 hour. Air was recirculated through the sample for 2 hours and the components stripped from the matrix were trapped on an activated charcoal trap. Dichloromethane (DCM) was used to elute the geosmin and 2-MIB from the charcoal trap. The "hot and cold" technique described by Krasner et al (1983) was used to elute the analytes from the trap. Analysis by GC-(SIM)MS and quantitation (single point calibration) by external standard gave detection limits of 3 ng/L for both geosmin and 2-MIB.

B) *Ambersorb 572/GC-HRMS.* The 1 L sample was spiked with d₃-geosmin and d₃-2-MIB upon arrival at the laboratory and the sample was stored in a refrigerator at 4°C. A 1 L bottle containing a 0.5 L aliquot of the sample was used for the analysis. Alternatively, replicate analyses can be performed on a 1 L sample. A granular adsorbent, Ambersorb 572 [200mg (400 µL)], was added to the sample and the bottle was rolled at 50 rpm for 1 hour. The adsorbent was isolated by filtration and then air-dried for 1 hour. The Ambersorb 572 was transferred to a 2 mL autosampler vial and 400 µL DCM were added. The vial was capped and then placed in the autosampler tray. The instrumental analysis by GC-HRMS utilized the following ions: geosmin (m/z 112.0888), d₃-geosmin (m/z 115.1076), lockmass (m/z 118.9920); 2-MIB (m/z 150.1409), d₃-2-MIB (153.1597), lockmass (m/z 130.9920). Quantitation was done by multi-point calibration.

Results

To minimize the decomposition of geosmin and 2-MIB, the samples were stored on ice during shipment to the laboratory. Upon arrival at the lab, the 1 L sample bottles were spiked with d₃-geosmin and d₃-2-MIB and the samples were stored at 4°C. The use of the isotopically-labelled analogues compensated for any further decomposition of the analytes. However, their addition to the samples necessitated the use of HRMS. This is due to the common ion m/z 153 that is formed from [2-MIB - CH₃] and [d₃-2-MIB - H₂O]. The mass resolution required to resolve these ions was 4,811 and a resolution of 7,000 was used. The molecular ion at m/z 168 was not used because it is weak compared to m/z 150.

The sample preparation procedure has been simplified. With the CLS method, 2 samples, 1 procedure blank and 1 spiked control sample could be analyzed in 1 day. With the Ambersorb 572 method, 40 samples, 3 procedure blanks and 12 spiked control samples can be analyzed in 1 day. The use of a granular adsorbent allows the sample bottle to be rolled to effect the extraction and also allows facile isolation by filtration on filter paper. Elution of the analytes into DCM occurs in the autosampler vial. The granular nature of the Ambersorb 572 prevents clogging of the autosampler syringe needle. Because there is no sample cleanup, organics that are adsorbed onto the Ambersorb 572 and desorbed into DCM are in the final extract. To circumvent problems with chemical interferences, HRMS was used. To improve accuracy, a multi-point calibration was performed instead of a single point calibration.

Detection limits for the Ambersorb 572/GC-HRMS method were 3 ng/L for geosmin and 2 ng/L for 2-MIB. Accuracy was 5% for geosmin and 2% for 2-MIB. Precision was 8% for geosmin and 6% for 2-MIB. The CLS/GC-MS method had accuracies of 21% and 18% respectively, a precision of 15% for both and a detection limit of 3 ng/L for both analytes.

Comparative data between the 2 methods showed good correlations. The CLS method uses external standard quantitation and could be biased low if the recovery is low. The CLS method used LRMS and could be biased high if there are chemical interferences present.

Conclusions

The Ambersorb 572/GC-HRMS is more productive by a factor of 20. Turnaround time has been reduced to 48 hours. Replicate analyses can be performed on a 1 L sample. The isotope dilution technique compensates for analyte decomposition. Detection limits are comparable to the CLS/GC-MS method. Accuracy and precision have been improved.

MALDI-TOF OF LOW MOLECULAR WEIGHT ORGANIC ACIDS

J.A. Campbell, K.L. Wahl, S.C. Goheen, and W.P. Hess, Advanced Analytical Organic Methods Group, Pacific Northwest National Laboratory, Box 999, Richland, Washington 99352

Introduction

At the Hanford Site in southeastern part of Washington, there are 177 radioactive waste tanks containing various amounts of organic constituents such as ethylenediaminetetraacetic acid (EDTA), N-(2-hydroxyethyl)ethylenediaminetriacetic acid (HEDTA), and nitrilotriacetic acid (NTA). The structures are shown below:

The process involved in the analysis for chelating compounds and their degradation products involves leaching the radioactive waste sample with water, eluting through a cation exchange resin to reduce the radioactivity level, drying of the water fraction either by nitrogen blow down techniques or lyophilization, derivatization with boron trifluoride (BF₃/methanol), with subsequent analysis using mass spectrometry. The procedure is both time consuming and expensive. In addition, additional waste is produced during the derivatization process.

Matrix-assisted laser desorption/ionization time-of-flight (MALDI) mass spectrometry is frequently used to examine high molecular weight organic compounds such as peptides, nucleic acids, polymers, and microbes. Matrix assisted laser desorption mass spectrometry is an attractive technique for the analysis of low molecular weight organic acids known to be present in radioactive tank waste at the Hanford Site. Small sample sizes can be used and waste generation is minimal.

Experimental

Milli-Q water was used for all experiments; no solvents other than water were used for sample preparation. The matrix used was gentisic acid purchased from Sigma Chemical Company. Analytes were purchased either from Sigma, Aldrich, or Baker and were of the highest purity available. Gentisic acid was mixed fresh each day to a concentration of approximately 20-30 $\mu\text{mole}/\mu\text{L}$. Analytes were also mixed to the same concentration. Analyte and matrix were mixed 1:1 (V/V) in a small capped centrifuge tube, mixed by vortexing, and placed on a metal sample plate. Approximately 0.5 μL was spotted on the metal plate. The samples were allowed to air dry or were dried at room temperature in a drying chamber purchased from Kratos. The MALDI-TOF instrument used was the Concept II from Kratos.

Results and Discussion

The positive ion mass spectrum of HEDTA is shown in Figure 1, and Figure 2 is the negative ion mass spectrum of sodium nitrate.

Mass spectral data for many of the major components identified in actual tank waste have been obtained using MALDI. The advantages of MALDI include limited sample preparation, small sample size, and minimal waste production make it an attractive technique for the analysis of radioactive waste. Further studies will include analysis of mixtures of organic analytes and simulated wastes.

Selective Chemical Production of Limonene During the Pyrolysis of Scrap Tires

James E. Haworth, Eugene Phillips, Tim Burrell, and Curtis Hanson
University of Northern Iowa

Recycling of scrap tires has become an increasingly important environmental issue. In the United States alone, scrap tires generated has reached an amount of 2 million tons per year. Although these tires contain many useful and valuable products, approximately 70% are disposed of in landfill sites, open dumps, or are stockpiled. Pyrolysis permits a method of separating the hydrocarbon oils, activated carbon, and high grade steel. Although current methods of pyrolysis permit the production of hydrocarbons such as limonene, the low yield of valuable compounds limits the economics of the process. One material of interest that is produced in high quantities during the pyrolytic decomposition of tires is limonene. Limonene has many extremely fast-growing industrial applications. It is used in the formulation of industrial solvents, resins and adhesives and as a dispersing agent for pigments. It is also used as a feedstock for the production of fragrances and flavorings. Limonene is biodegradable, a natural solvent, environmentally safe with excellent solvency, rinseability and high wetting, penetrating and detergent properties. It has been used in a wide range of applications including water-based degreasers, natural lemon scented all-purpose cleaners, hand cleaners and replacements for chlorofluorocarbon solvents to clean electronic circuit boards.

Figure 1: A proposed mechanism of the depolymerization of polyisoprene rubber and the high and low energy mechanisms which take place during pyrolysis.

In order to evaluate the potential of scrap tire pyrolysis three different reactors were built. These reactors were used to thermally decompose scrap tire rubber and collect the liquids made from them. The first reactor built was initially used to investigate the possibility of modeling the pyrolysis process on the bench scale level. This reactor was also used to study the temperature effects on the pyrolysis process and to determine the different product ratios of those effects. The reactor was based on a preparative flash vacuum pyrolysis apparatus. A 30 gram piece of scrap tire was placed in a quartz pyrolysis tube and thermally decomposed in a Lindberg furnace. The temperatures ranged from 300-1000°C in order to determine the optimal pyrolysis temperature. The products were collected in a liquid nitrogen cold trap which was allowed to equilibrate to room temperature following product collection. Upon equilibration, the gaseous products were collected in a gas sampling bulb. Separate analysis of the liquid fraction and gaseous products was carried out using FT-ICR. Additional analysis of the liquid product fraction was performed using GC/MS. The products from this initial reactor were also used in the FT-ICR analysis.

The second reactor, built to study the effects of gas constriction during product formation, was made of a 12mm dia. by 90cm long copper tubing with 3mm dia. holes drilled in the furnace region, four holes at every

12mm interval. This tubing was surrounded by pyrex tubing with a diameter of 7cm and was 75cm long. The tire pieces used were predominately natural or polyisoprene rubber taken from the lower sidewalls of scrap automobile tires (approximately 12mm X 12mm and 6mm thick). These tire pieces were placed between the copper tubing and the pyrex wall in the region of the drilled holes. The heater was a Lindberg tube furnace. The temperature of the oven was brought up to 400°C before the reactor tube was placed into the oven. After 5 min. of thermal decomposition the reactor tube was removed. Two liquid samples were collected from this reactor. The liquid that was created inside of the copper tubing and the liquid that was created between the copper tubing and the pyrex glass wall.

A third bench scale reactor was constructed to optimize limonene production based on the proposed mechanism. The reactor consisted of an open heater coil located in a cooling jacket. The cooling jacket was initially cooled with liquid nitrogen to ensure all resulting products would be condensed for analysis. A vacuum environment was created using a Welch 1.5 Amp. vacuum pump to displace the atmosphere. Furthermore, the heater coil was insulated with Sanereisen ceramic paste to reduce any effects of the nichrome on the ensuing chemistry. The wire was wound in a spiral orientation with a 12mm dia., 3mm in between each wind and was approximately 12.5cm in length. The nichrome wire was hooked up to a Fisher variable 120V auto transformer(variac) and the temperature was monitored using a n/p thermocouple. Six 10 gram samples of scrap tires were loaded into the reactor (60-70 grams total) and temperature was brought up to approximately 250°C and from this point, the tires were allowed to decompose for 5 minutes. During this 5 minutes the temperature was ramped at a constant rate to approximately 425°C. After 5 minutes, the variac was turned off and the liquid was collected.

Modeling the chemistry of pyrolysis using Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR) indicates that two energy dependent reaction mechanisms exist. One being a radical cation mechanism and the other a low energy dimerization mechanism (Figure 1). Based on proposed mechanisms, a pyrolysis method that increases the amount of condensable limonene produced compared to conventional techniques has been demonstrated. It has been determined that the amount of limonene produced during pyrolysis can be increased by decreasing the reactor residence time of isoprene gas, which is produced during the thermal degradation of polyisoprene rubber. This reaction can be achieved by using a perforated vessel which permits rapid condensation to occur and therefore decreases the amount of soot and environmentally hazardous products produced. Using this approach the amount of Limonene produced has been increased from an average of 51% of the recovered liquid product to above 90% recovery (Figure 2).

Figure 2: A chromatogram obtained from the liquids collected from the open coil reactor.

The high limonene content of the oil fraction was associated with the decreased residence time of the isoprene gas in the high temperature areas of the oven during the thermal degradation of polyisoprene rubber. This was achieved by using the coiled heater reactor which permitted rapid condensation to occur and therefore allowed the isoprene gases to dimerize and form limonene. Furthermore, by allowing the above process to take place, the isoprene was not allowed to form radicals thereby forming the unwanted environmentally unfriendly soot products.

The ideas presented here illustrate a pyrolytic method that increases the amount of condensable limonene produced compared to conventional pyrolysis techniques of scrap tire carcasses. The high percentage of limonene in the oil fraction of the scrap tire vacuum pyrolysis will have a positive effect of the economics of the thermal decomposition process. This in turn makes the process of pyrolytic decomposition economically favorable.

Modeling PVC Pyrolysis Using Laser Desorption Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

Brian S. Glaser, James E. Haworth, and Curtiss D. Hanson
University of Northern Iowa

Introduction

Thermosets and thermoplastic production has been increasing at an average rate of 5% annually¹. The request for plastics is on the rise due to increasing demands for business machine housings, building and construction demands, and increasing automotive sales. The United States alone produced 75.3 billion pounds of plastics in 1994, a 9% increase over 1993¹. With new types of plastics being developed such as the new generation of polyolefins based on metallocene catalysts technology, new and innovative techniques for recycling of these plastics will also need to be developed. Thermoplastics can be remelted after it has been molded so it can be recycled by reinjection molding techniques. In contrast, thermoset plastics cannot be softened again or dissolved once molded, making reuse/recycling difficult if not impossible.

An innovative way to recycle thermoset plastics is through pyrolysis. Pyrolysis is thermal degradation of organic starting materials in the absence of oxygen. This can occur in either a vacuum or under an atmosphere absent of oxygen. The thermally degraded product can be collected and utilized as a liquid feedstock for subsequent cracking and fractionation by an oil refinery or if one product is produced in a high quantity it can be collected and distilled to remove any minor products. Since pyrolysis is based on thermal decomposition the products that are produced are dependent on the amount of thermal energy that is allowed into the system. So if the pyrolytic environment is changed the products that are formed will be different.

One instrument that allows the analysis of gas phase reactions and the ability to study the molecular ion and its fragments is Fourier transform ion cyclotron mass spectrometry. With the use of pulsed laser heating, samples can be subjected to a very large and rapid temperature increase which simulates pyrolytic conditions. When coupled with laser desorption, FT-ICR MS allows the study of reaction mechanisms during thermal decomposition.

Experimental

Samples used in this study consisted of poly(vinyl chloride) shredded into 8-10 mm pieces. The shredded PVC was then placed inside a quartz tube that was connected to a bench scale pyrolysis reactor. The system was evacuated to 1×10^{-5} torr utilizing a Welch Model 8905 vacuum pump. The PVC was heated by a Linneberg tube furnace oven to a temperature of 250°C to allow for the low temperature dehydrochlorination reaction to occur. The gaseous products were collected by a cold trap that was part of the pyrolysis apparatus. The cold trap was removed and the products were allowed to go back into the gas phase. The gaseous products were collected and analyzed on an IonSpec OMEGA 50 Fourier transform ion cyclotron resonance mass spectrometer with a high field Walker Scientific electromagnet held at 1.03 Tesla. Background pressures of 8.5×10^{-10} torr were maintained in the vacuum system analyzing chamber by a Balzer 330 liter/second turbo molecular pump backed by an Alcatel direct drive rouging pump. Gaseous products were set and maintained using a Vairan leak valve. Experimental pressures ranging from 2×10^{-7} - 3×10^{-7} torr in a 5 cubic centimeter analyzer cell were measured using a Bayard-Alpert type ionization gauge. The gaseous samples were continuously ionized by an electron beam at an electron energy of 60-70 eV. The filament current ranged from 1.0-1.4 microamps. Data was collected using the IonSpec 50 data system.

Following the low temperature dehydrochlorination the pyrolysis reactor was evacuated to remove any left over gaseous products that were formed from the initial thermal degradation. The resulting polymer residue was further reduced at a temperature of 750°C to allow for the high temperature degradation to occur. The gaseous products were collected and analyzed as previously described.

To analyze the reaction mechanism utilizing LD-FT-ICR MS the sample was attached to the solid insertion probe of the FT-ICR and inserted into the IonSpec OMEGA 50 FT-ICR for analysis. Background pressure was maintained at 6.9×10^{-9} torr. The sample was ionized by a Continuum Minilite Nd:YAG laser. The operating frequency of the laser was quadrupled to 266 nm with a pulse width of 4

nanoseconds. The repetition rate of the laser was controlled by the FT-ICR interface program at a maximum rate of 10 Hz. The energy of the laser output was 20 mJ with a peak power of 0.5 MW which results in thermal degradation/desorption and ionization to occur. The laser desorption ionization was triggered by the FT-ICR and the ions were detected following a 90 millisecond delay to permit stabilization of the desorbed ions and to maintain the maximum laser repetition rate.

Results and Discussion

Based on the spectrum obtained during pyrolysis at the low temperature dehydrochlorination reaction, the major product produced was HCl. The high temperature reaction underwent an aromatization with the major product being benzene. Shown in Figure 1 is the negative ion LD-FT-ICR MS of PVC. This spectrum illustrates both the dehydrochlorination reaction along with the aromatization reaction occur.

Figure 1
Negative Ion LD-FT-ICR MS Spectrum

The above results show the positive ion does not undergo gas phase reactions. The results of the negative ion suggest that the aromatization reaction occurs as a condensed phase reaction (Figure 2).

Figure 2
Aromatization reaction of PVC by LD-FT-ICR MS

Following the dehydrochlorination reaction the resulting polyene undergoes an aromatization reaction with benzene being the major product formed.

Differentiation of PAH Structural Isomers by Ion Molecule Reactions with Halogenated Reagent Gases

Andrew A. Mosi*, William R. Cullen and Guenter K. Eigendorf
University of British Columbia, Department of Chemistry, Vancouver, B.C.,
Canada, V6T 1Z1

Polycyclic aromatic hydrocarbons (PAHs) comprise a large class of compounds which exhibit isomer specific toxicity. Conventional GC/MS analysis of PAHs in environmental samples cannot differentiate between many structural isomers due to their identical mass spectra, close GC retention times and lack of analytical standards. This is notably the case for substituted compounds such as alkylated PAHs for which a multitude of isomers can exist.

The objective of this study is to differentiate structural isomers of PAHs using ion-molecule reactions with halogenated hydrocarbons (CH_3CHCl_2 , CCl_4 , CHCl_3 , CH_2Cl_2 , CH_3CHF_2 , CH_2F_2) in an ion trap mass spectrometer.

Isomeric differentiation among several structural isomers was achieved based upon their reaction with the reactive halogenated cations (R), produced during ionization of the halocarbons, followed by loss of HX ($\text{X} = \text{F}$ or Cl) to give adducts of the general formula $[\text{M} + \text{R} - \text{HX}]^+$. Using the haloethanes (CH_3CHCl_2 or CH_3CHF_2) some $[\text{M} + \text{R}]$ adduct was also produced.

When applied to the analysis of PAH contaminated sediments structural isomer differentiation was achieved for the two structural isomer pairs phenanthrene / anthracene and fluoranthene / pyrene and the corresponding C_1 and C_2 alkylated species by comparing the ion chromatograms for the molecular ion (M) and the $[\text{M} + \text{R} - \text{HX}]^+$ adduct ions as shown for CH_2Cl_2 (Figure 1). The proportion of two structural isomers in a coeluting cluster can be determined by comparing the ratios of the area of the molecular ion to that of the adduct ion.

Fig.1 Molecular (M) and adduct ion chromatograms for phenanthrene (Ph), anthracene (A), fluoranthene (F), and pyrene (Py) and C_1 and C_2 alkylated analogues.
 $\text{M}+13 = \text{M} + \text{CH}_2\text{Cl}^+ - \text{HCl}$, $\text{M}+47/49 = \text{M} + \text{CHCl}_2^+ - \text{HCl}$

Dechlorination Mechanisms of Selected PCB Isomers Containing Isotopically Enriched Chlorine Labels.

Robert T. O'Brien, Roger Guevremont, & K.W.M. Siu.
Chemical Metrology, Institute for National Measurement Standards,
National Research Council, Canada.
Montreal Road Campus, Ottawa, Ontario, Canada. K1A 0R6

The mass spectrum of a series of PCB congeners containing well defined isotopically enriched ^{37}Cl labels were collected after both electron impact and electron capture ionization. These spectra were analyzed to determine the extent of label involvement in the dechlorinations induced by this ionization and subsequent ion molecule reactions.

The electron impact spectra were collected on both a Varian Ion Trap and a VG ZAB HF mass spectrometer. The spectra typically contained ion clusters corresponding to $[\text{M}]^+$, $[\text{M}-\text{Cl}]^+$, $[\text{M}-2\text{Cl}]^+$, and $[\text{M}-3\text{Cl}]^+$. In the congeners containing at least one ortho chlorine on each ring the $[\text{M}-\text{Cl}]^+$ cluster was observed to be more significant and have less $[\text{M}-\text{HCl}]^+$ involvement than those isomers studied that did not. In these isomers with at least one ortho chlorine on each ring a greater than statistical loss of ^{37}Cl is observed in the formation of $[\text{M}-\text{Cl}]^+$. The observed loss of label indicates an exclusive loss of ortho chlorine in the formation of $[\text{M}-\text{Cl}]^+$. This and the fact that the percentage of label lost is correlated to the number of meta chlorine in the more chlorinated ring rather than the number of ortho chlorine indicates the formation of a chloronium ion. A table of some of the values obtained is presented below. (note: black balls indicate unlabeled chlorine, white balls ^{37}Cl and implicit hydrogens not indicated.)

Structure	Saturn % ^{37}Cl	ZAB % ^{37}Cl	Statistical % ^{37}Cl
 BZ 88	33%	36%	20%
 BZ 86	96%	100%	40%
 BZ 88	48%	47%	20%
 BZ 88	55%	45%	40%
 BZ 93	31%	35%	20%
 BZ 93	68%	72%	40%
 BZ 142	32%	40%	17%

The values for the $[\text{M}-2\text{Cl}]^+$ cluster produced very similar values for the possible dechlorination routes $[\text{M}-2\text{Cl}]^+$, $[\text{M}-^{37}\text{ClCl}]$, and $[\text{M}-2(^{37}\text{Cl})]$ in compounds that have one labeled chlorine on one ring and unlabeled chlorine on the other ring irregardless of the position of the label. A similar result was obtained for the isomers that have two labeled chlorine on one ring and unlabeled chlorine on the other ring although the values were different than the isomers with one label. This suggest that chlorine randomization is occurring and this is contained within each ring.

The electron capture induced dechlorination resulted in ions of the type $[\text{M}+\text{H}-\text{Cl}]^-$, $[\text{M}-\text{Cl}]^-$. These two reaction channels indicated significantly different regioselective loss of chlorine. It was demonstrated that this loss of chlorine could be effected by the ventilation rate even though the pressure and temperature were identical.

The reaction channel $[\text{M}+\text{O}-\text{Cl}]^-$ was also monitored and an exclusive loss of unlabelled chlorine from the isomers BZ 166, BZ 160, and BZ 142 was indicated. Section of the appropriate spectra demonstrating this is presented below.

A Fast GC/MS/MS Method to Quantitate Free Phytosterols

Jiu Ai

US Tobacco Manufacturing Company, Inc., 800 Harrison Street, Nashville, TN 37203

There are three major phytosterols in most of higher plants. They are β -sitosterol, campesterol and stigmasterol. The conventional GC/MS method to quantitate free phytosterols usually involves extracting sterols from the plant, cleaning the extract and derivatizing the hydroxyl group before GC injection. All those procedures take a lot of experimental work and may cause contamination. In this report, a new GC/MS/MS method is presented to quantitate free phytosterols in plants without sample cleaning and derivatization procedures. A short GC column is used to reduce the retention times of the un-derivatized free sterols. This GC process with shorter retentions and lower temperatures minimizes the risk of decomposition of less volatile free sterols in the GC column. A multiple selected reaction monitoring (SRM) MS/MS approach eliminates chemical background from the complex mixture of plant extracts and increases the sensitivity. It also resolves three phytosterols that are not separated well with a short GC column.

A 10 m long piece was cut off from a 30 m x 0.25 mm ID DB-5 column of J&W. The liquid film thickness of the column is 0.25 μ m. This piece of column was interfaced with a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer. The multiple SRM was set to scan campesterol (m/z 400⁺ to m/z 315⁺), sitosterol (m/z 414⁺ to m/z 329⁺) and stigmasterol (m/z 412⁺ to m/z 379⁺) alternately. The total ion current was filtered to three separate traces according to the three phytosterols. Figure 1 shows that three phytosterols which overlap while eluting from the short GC column are resolved through this MS/MS process.

Figure 1 Multiple SRM scan for phytosterols in tobacco

Figure 2 Calibration lines for stigmasterol and sitosterol

High purity β -sitosterol and stigmasterol were used to make the calibration solutions with cholestane and androstene-3,17-dione as internal standards. For campesterol, its quantity was calculated using the response factors of β -sitosterol since these two sterols had very similar fragmentation patterns. Figure 2 shows the calibration lines vs. either cholestane and androstene-3,17-dione. All calibration lines have correlation coefficients better than 0.99 at the sample injection range from 7.4 ng to 160 ng.

Phytosterols in 1994 TR Madole tobacco (both fire cured and air cured) were measured. 1.00 g of ground dry tobacco was extracted with 10.0 ml dichloromethane at room temperature in an ultrasonic bath for one hour. Before the extraction, cholestane and androstene-3,17-dione (0.30 mg each) were added to the tobacco as the internal standards. The extract was directly injected for quantitative measurements without any further treatment. At first, fire cure tobacco samples were spiked with known amounts of β -sitosterol and stigmasterol following a procedure of the standard addition method. Linear correspondences were obtained for both phytosterols with correlation coefficients better than 0.99. Table 1 lists measured concentrations compared with spiked concentrations and the recovery rate. The data show that this method generates reliable quantitative results. Table 2 lists three phytosterol concentrations in both air cured and fire cured tobacco measured with this fast GC/MS/MS method. The data were from four separately prepared samples. It shows that this method gives very reproducible results with relative standard deviations smaller than 10% for all three phytosterols in two different tobaccos. Fire cured tobacco contains significantly less β -sitosterol than air cured tobacco. The campesterol level is slightly lower in the fire cured tobacco. The concentration of stigmasterol in fire cured tobacco is at the same level as the air cured tobacco.

Table 1. Recovery of phytosterols spiked in fire cured TR Madole tobacco

β -Sitosterol (μ g/ml)	Spiked concentration	26.0	39.0	52.0
	Measured concentration	23.7	37.3	50.6
	Recovery Rate	91.2%	95.7%	97.4%
Stigmasterol (μ g/ml)	Spiked concentration	40.0	60.0	80.0
	Measured concentration	34.8	56.7	79.1
	Recovery Rate	87.0%	94.5%	98.9%

Table 2. Free phytosterols in tobacco

	Fire cured TR Madole		Air cured TR Madole	
	Concentration (ppm)	%RSD (n=6)	Concentration (ppm)	%RSD (n=4)
β -Sitosterol	128	9.2%	229	7.3%
Stigmasterol	335	3.9%	344	3.1%
Campesterol*	196	4.8%	224	7.2%

Volatile Organic Composition in Blueberry
Santford V. Overton and John J. Manura
Scientific Instrument Services, Ringoes, NJ 08551

Volatile and semi-volatile organic compounds present both in the sample matrix and in the headspace aroma exhibit a tremendous influence on the flavor/fragrance qualities of blueberries. There is a concern in the blueberry industry as to what constitutes the optimum conditions for harvesting blueberries so as to provide a consistent quality and flavor of blueberry to the consumer. Several investigations have reported that the concentrations of volatile constituents increased with the maturation of blueberries. The major volatiles of blueberries appear to be useful indices for determining maturity, and recently, the determination of flavor precursors and intermediates have become the target of flavor studies. To date, headspace GC analysis, cryofocusing techniques, and high resolution GC have been used for the analysis of blueberry volatiles from promising cultivars under development. However, static headspace techniques are limited in their detection and identification of many organic volatiles and especially semi-volatile organics. Other techniques are needed to profile a wider range of volatile and semi-volatile organics in blueberries and to identify the flavors, fragrances, off-flavors, off-odors and potential contaminants that may be present. The purpose of this investigation is to develop an analytical technique that could detect and identify a wide range of volatile and semi-volatile organic compounds in blueberry. For this study, volatile organic compounds are purged from blueberry samples followed by trapping on TenaxTMTA adsorbent resin using a dynamic purge and trap technique (P&T), and then chromatographed on two different columns to compare the volatile organics present. The adsorbent traps are subsequently analyzed by thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS).

The experiments were conducted using a Scientific Instrument Services model TD-3 Short Path Thermal Desorption System accessory connected to the injection port of an HP 5890 Series II GC and/or HP 5890 Series II GC with electronic pressure control interfaced to an HP 5971 Mass Selective Detector (MSD) and HP Engine Mass Spectrometer, respectively. The mass spectrometers were operated in the electron impact mode (EI) and scanned from 35 to 550 daltons during the GC run for the total ion chromatogram. The HP 5890 Series II GC contained a short 0.5 meter by 0.53 mm diameter fused silica precolumn attached to the injection port end of a 30 meter x 0.25 mm i.d. DB-5MS capillary column containing a 0.25 µm film thickness. The GC injection port was set to 260°C and a 10:1 split was used. A SGE BPX35 capillary column, 60 meters long by 0.22 mm i.d. x 0.25 µm film thickness was used in the GC oven with electronic pressure control. The GC injection port was set to 220°C and a splitless mode was used. The head of each column was maintained at -70°C using an S.I.S. Cryotrap model 951 during the desorption and extraction process and then ballistically heated to 200°C after which the oven was temperature programmed from 35°C (hold for 5 minutes) to 80°C at 10°C/min, then to 200°C at 4°C/min and finally to 260°C at a rate of 10°C/min.

Three varieties of blueberry (Jersey lowbush, Bluecrop lowbush & Rancocas lowbush) were analyzed by a dynamic P&T technique and chromatographed on both a 30 meter DB-5MS capillary column and a 60 meter BPX35 capillary column to compare and quantitate the volatile organics present. Approximately 100 grams of blueberry were homogenized for 3 minutes using a

Waring® commercial blender. Sample sizes of 10-11 grams of blueberry homogenate were then transferred into a 10 ml test tube and heated to 60°C for 45 minutes. Samples were sparged with high purity helium at 20 ml/min with an additional 25 ml/min dry purge using an S.I.S. Purge and Trap system. Volatile analytes were gas extracted and carried to a preconditioned 4.0 mm i.d. glass-lined stainless steel desorption tube packed with 200 mg of TenaxTMTA. The desorption tube with sample was then attached to the Short Path Thermal Desorption System and a syringe needle attached. The desorption tube was injected into the GC injection port at desorption block temperatures of 220°C for 5 minutes.

Three varieties of blueberry were analyzed to identify, compare and quantify the volatile organics present using both SGE's BPX35 and J&W's DB-5MS capillary columns, and from the data, determine the most sensitive method of analysis. The blueberries possessed numerous mono- and sesquiterpenoid compounds as well as numerous straight and branched chain hydrocarbons, aldehydes, alcohols, ketones and esters. Although they possess many common compounds, each blueberry variety had its own distinct fingerprint chromatograph. In addition, SGE's BPX35 capillary column provided better separation and resolution than J&W's DB-5MS capillary column with the identification of many more alcohol compounds. The blueberries were found to contain the flavor compound benzaldehyde which has an almond-like odor and the aliphatic compounds hexanal, heptanal and nonanal. It has been assumed that unsaturated fatty acids, primarily linoleic and linolenic acids, are the precursors of these aliphatic compounds and may contribute to the development of rancid flavor. The presence of the branched aldehydes 3-methyl-butylaldehyde and 2-methyl-butylaldehyde in each of the blueberries contribute to the fruity flavor notes as well as reflect the microbial quality of the blueberry. The predominant terpenes included 1,8-cineole and linalool with trace amounts of cymene, limonene, 1-α-terpineol, *trans*-caryophyllene and 3-carene. Citral which has a strong lemon odor was also identified in the Rancocas and Bluecrop varieties.

The major esters found in the blueberry fruit included ethyl acetate and 3-isopropyl-butyrate. It is generally considered that esters primarily contribute to the fruity and floral notes. SGE's BPX35 capillary column provided additional information to the volatile organic composition of blueberries with the identification of the alcohols 1-butanol, 1-pentanol, 1-hexanol, 2-ethyl-1-hexanol, 1-heptanol, 1-octanol and 1-nonanol which were not detected with J&W's DB-5MS column. The production of these alcohols may be characteristic of the fruit during maturation. Linalool oxide, an isomer of lilac alcohol, and tetrahydro-furfuryl-(2)-alcohol were identified in the Jersey and Rancocas varieties while the higher molecular weight compound decadienal was found in each of the varieties. This compound contributes to the flavor and aroma of the blueberries and is the result of fatty acid decomposition. The Jersey and Bluecrop varieties exhibited several furan derivatives which reflect the microbiological purity and storage conditions of the blueberries. The antioxidant butylated hydroxytoluene was detected in each of the blueberries and is probably derived from the packaging material during storage.

Rapid analysis of Volatile Flavor Compounds in Horticultural Produce Using SPME and GC/Time-of-Flight Mass Spectrometry

Jun Song¹, Ben D. Gardner², John F. Holland³, and Randolph M. Beaudry¹

¹Departments of Horticulture¹, Chemistry², and Biochemistry³,
Michigan State University, East Lansing, MI 48824

Presented at the 44th ASMS Conference on Mass Spectrometry and Allied Topics, May, 1996

The analysis of horticultural produce is an emerging field in which both flavor producing and malodorous compounds are detected from within a complex sample matrix. Both qualitative and quantitative information is desired. Conventional analysis methods such as purge and trap and GC/MS provide much of this information (Matthias et al., 1992; Song and Bangerth, 1994), but are both laborious and time consuming.

The seasonal nature of apple fruit requires that methods development for new protocols be worked out quickly and efficiently in order to meet research time 'windows' established by the commodity. Typical horticultural and biochemical research requires relatively large sample numbers (10's to 100's). Fruit aroma biosynthesis, especially in response to precursor feeding experiments, is dynamic, with short (minute) and long-term (hour) temporal components. Sampling must be repetitive and time intervals short. We require an analytical system with sufficient flexibility to work with both flow-through and low volume, sealed systems.

We proposed to substitute purge-and-trap with a solid phase micro-extraction (SPME) system (Supelco, Inc.), conventional GC with time-compressed GC, where peak widths are typically 0.2 to 0.5 seconds and full chromatographic separation is not always achieved, and conventional mass spectrometry with TOF MS (LECO FD-650, LECO Corp., St. Joseph, MI), where the spectral generation rate can exceed 200 spectra per second. Such rapid spectral generation permits analysis of compounds that have chromatographic peak widths of only a fraction of a second and are not fully chromatographically separated (Gardner et al., 1995).

Sampling. GC response versus vapor concentration of authentic compounds was linear (Fig. 1). The time required to saturate the fiber coating ranged from 2 min to > 24 min (Fig. 2). More lipophilic compounds took longer to saturate, but also accumulated to relatively greater levels (Fig. 2). The sorption coefficient varied as much as 40-fold for the volatiles tested (Butylacetate, ethyl-2-methylbutyrate, hexylacetate, butanol, hexanol and 6-methyl-5-heptene-2-one were 0.27, 3.25, 2.30, 0.17, 2.09 and 5.65 x 10⁵, respectively). Only slight evidence of matrix effects were encountered when complex volatile profiles, such as those of apple fruit, were used (Fig. 2). One to four min was considered a suitable sorption time. All the compounds detectable at 6 min were detected within this time range (Fig. 3).

Separation. Reducing column diameter, shortening the column and increasing temperature ramp rates reduced the chromatographic time to 1/10 that of conventional chromatography. Peak separation was acceptable (Fig. 3). Even with the conventional approach, some compounds still co-eluted (Fig. 4). Time-compressed chromatography created peaks widths as low as of 0.2 s, most were in the 0.5 to 1 s range and abundant analytes were in the 3 to 6 s range (Fig. 4).

Detection. Volatiles were identifiable and quantifiable in headspace concentrations as low as 1 ppb (data not shown). At this concentration, the amount of compound detected was approximately 0.2 to 5 picomoles (Table 1), which corresponds to approx. 20 to 100 pg. Due to the high spectral generation rate, compounds that partly co-eluted and whose elution times differed by as little as 0.2 s could be readily identified and quantified (Fig. 4). Spectra of authentic compounds typically had the highest probability of a match (i.e., 'first hit') for their respective spectra in the NIST mass spectral library.

CONCLUSIONS

The analysis system described here appears to be highly appropriate for aroma analyses. The speed of the system overcomes the primary limitation of SPME fiber (i.e., sample storage) and permits collection of pertinent biological data in real-time. Typical daily sample throughput was in the range of 40 to 50 samples and could be pushed to over 100. The factor now most limiting analytical speed is data handling (identification, quantification and reporting of detected compounds).

ANALYSIS OF POLYCYCLIC AROMATIC HYDROCARBONS IN SHELLFISH AND FISH BY SFE/Off-line GC/HRMS

Carl S. Alleyne, Victor Verigin and Brian T. Mori
Health Canada, Health Protection Branch
3155 Willingdon Green, Burnaby, BC V5G 4P2 Canada

Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a group of compounds composed of 2 or more fused aromatic rings. They are products of incomplete combustion. Several compounds of this group have been classified as probable or possible human carcinogens. Some literature reports suggest that food is the greatest source of human exposure to PAHs. Health Canada is currently undertaking an analytical program to provide up-to-date information on the levels of toxic PAHs in foods. This data will be used in the assessment of the potential health significance of exposure to PAHs.

Method

We have developed a sensitive analytical method to measure the levels of PAHs occurring in smoked and charcoal broiled seafoods. PAH detection limit is 50 pg/g (ppt) using only 1 gram of sample, while also allowing determination of the lipid content with the same extract. The samples analyzed by this method include commercially smoked fish and shellfish. They were comminuted with a Robot Coupe commercial food processor and stored at -4°C. The sample homogenate is mixed with an equal amount of Celite and thoroughly dispersed immediately before extraction.

A supercritical fluid extraction (SFE) sample thimble is filled with the matrix-Celite mixture (~2 g). A surrogate standard mixture containing four deuterated PAHs is then spiked in. The sample is extracted by SFE with CO₂ in a 4-stage dynamic extraction procedure using Hewlett-Packard 7680T extraction equipment and Hewlett-Packard 1050 modifier pump. Extraction #1 is carried out under relative mild conditions (CO₂ density, 0.35 g/mL; extraction temp, 40°C; time, 13.3 min; trap temp, 10°C) to extract out the lower molecular weight PAHs. In extraction #2, most of the remaining PAHs and lipid materials are extracted (CO₂ density, 0.95 g/mL; time, 35.8 min). The extracted material from each step collects on an ODS solid adsorbent trap and is desorbed into separate vials with n-hexane. Addition of 5% methanol modifier to the CO₂ in the 3rd step extracts out the residual traces of PAHs and lipid (time, 35.8 min; trap temp, 65°C). The final step is an extraction with CO₂ to remove all traces of methanol from the SFE system. This multi-step extraction procedure minimizes losses of the more volatile PAHs from the trap and also totally extracts out the lipids which are also determined in this procedure.

All the extracts are pooled together, and purified by HPLC on a normal phase silica column (Beckman Ultrasphere Si, 5µm, 250 x 4.6 mm id). PAHs and lipids are collected in separate fractions by gradient elution with hexane-dichloromethane (DCM)-isopropanol (IPA). During pre-injection and column equilibration stages, a pre-column (Merck silica gel 60, 70-230 mesh, 200 x 4.6 mm id) traps PAHs originating from the solvents by column switching with two 6-port valves. PAHs are eluted in a gradient from 100% hexane to hexane-DCM (85:15).

Lipid is backflushed off the column in a gradient from 100% DCM to DCM-IPA (50:50) and is collected in a pre-weighed flask. After conditioning the column back to 100% hexane in

the reverse direction, the column is equilibrated to the starting conditions and PAHs flushed out of the pre-column before the next sample injection. The lipid-containing fraction is concentrated to dryness by vacuum evaporation and the residue is weighed to determine the %lipid content of the sample.

The PAH-containing fraction is concentrated under vacuum and split into two aliquots. To analyze for PAHs >1 ppb, one aliquot is further concentrated to 1-2 mL, and quantitatively transferred to a GC autosampler vial. A mixture of deuterated PAH recovery standards (2.5 ng) is added just before GC/MS analysis. For PAHs in the range 0.05-2 ppb, the other aliquot is reduced to 50 µL, and 0.1 ng of the recovery standard mixture is added before GC/MS analysis.

GC analysis is carried out with a Hewlett-Packard 5890 Series II GC and a programmable on-column injector. A DB-5ms (60 m x 0.25 mm id x 0.25 µm film) capillary column is programmed as follows: 60°C hold 1 min, to 180°C at 20°C/min, to 250°C at 4°C/min, to 325°C at 10°C/min, final hold 13 min. The injector is ramped from 100°C to 320°C at 100°C/min, and held for 53 min.

The VG AutoSpec Q mass spectrometer was operated in selected ion monitoring EI+ mode and tuned to a resolution of 4000 using PFK. The source conditions are as follows: electron energy, 55 eV; accelerating voltage, 8kV; source temp, 275°C, trap current, 620 µA. Data acquisition was carried out in a 11- function SIM experiment. Two ions were monitored for each compound.

Results

The advantages of this method include the capacity to analyze for PAHs over a wide concentration range (0.05 to >500 ng/g) with a single extraction from only one gram of sample. Determination of lipid content is also integrated into the procedure.

This method has been applied to the analysis of PAHs in smoked shellfish and fish. They include canned and whole smoked fish (kipper, mackerel, whitefish, rainbow trout, chub, etc.), charbroiled shrimp, canned smoked oyster, mussel, and clam. Analytical results and estimated toxic PAH equivalents are summarized in the following Table.

Compound	TEF	Mean Concentration (ng/g)					
		Oyster	Mussel	Clam	Shrimp	Crab	Fish
Benzo[a]pyrene	1	3.7 (5.6)	2.8 (3.9)	6.9 (8.8)	0.57 (0.84)	<0.05	1.8 (2.7)
Dibenzo[ah]anthracene	1	0.35 (0.43)	0.41 (0.52)	0.67 (0.73)	0.02 (0.04)	<0.05	0.6 (1.7)
Benzo[a]anthracene	0.1	7.3 (10)	5.9 (8.0)	15 (16)	0.43 (0.55)	0.06	21 (59)
Benzo[b]fluoranthene	0.1	4.7 (4.2)	2.6 (8.0)	7.1 (8.6)	0.19 (0.30)	<0.05	1.4 (2.1)
Benzo[k]fluoranthene	0.1	1.8 (2.0)	1.1 (1.1)	2.9 (3.7)	0.10 (0.20)	<0.05	0.79 (1.2)
Indeno[1,2,3-cd]pyrene	0.1	2.0 (2.8)	1.9 (2.4)	3.9 (4.6)	0.07 (0.17)	<0.05	1.2 (1.9)
Number of Samples		19	13	3	10	2	10
TOTAL TEQ (ng/g)		5.6	4.4	10.5	0.67	0.01	4.8

Figures in *italics* are standard deviations. Crab is canned in water, not smoked.

TEF: Toxic Equivalence Factor, rel. to Benzo[a]pyrene. (Nesbet & LaGoy, *Reg. Toxicol. Pharmacol.* 1992; 16:290)
TEQ: Toxic PAH Equivalent

Conclusions

Commercially smoked shellfish and fish show a very wide range for PAHs, from non-detects (<0.05 ng/g) to >500 ng/g. The PAHs occurring in the highest concentrations include phenanthrene, acenaphthylene, fluorene, and pyrene. The levels of the most toxic PAHs are usually 1-2 orders of magnitude lower, but can sometimes be relatively high.

AN MS/MS INVESTIGATION OF ORGANIC SALTS.

Jia-shen Wang
Clairol Inc., Stamford, CT 06922

INTRODUCTION:

MS, with a solid probe as a sample inlet device is, undoubtedly, a simple and yet powerful technique. Compounds, especially salts, which are thermally unstable in the heating process may form degradation compounds and greatly reduce the structural elucidation capability of this technique. The usefulness of this technique, however, can be improved if the respective reactions are known. Here we would like to discuss the common thermal reactions of triphenylmethane salts. The model compounds shown here are Malachite green and pararosaniline.

EXPERIMENTAL:

In this study, all MS and MS/MS analyses were carried out using a Finnigan 7000 mass spectrometer equipped with a solid probe. The samples were obtained from Aldrich.

RESULTS AND DISCUSSION:

The EI mass spectrum of Malachite green oxalate is shown in Figures 1. By CI/MS, m/z 330, 316, and 225 were assigned to be the molecular ions. By MS/MS the respective fragment ions of these molecular ions were confirmed. The MS/MS spectra of 330, 316, and 225 ions are shown in Figures 1a, 1b, and 1c. The spectra 1a and 1b suggest that the main fragment ions of this type of triphenylmethane compounds are formed due to the cleavage of bonds of the center carbons. The molecular species of 330 was elucidated to be the leuco form of Malachite green. The presence of molecular species 316 is formed from an impurity similar to that of Malachite green. The molecular species of 225 is 4-dimethylaminobenzophenone, an impurity present in the original sample.

Figure 1. Mass Spect. of Malachite G.

Figure 1a. MS/MS Spect. of m/z 330

Figure 1b. MS/MS Spect. of m/z 316

Figure 1c. MS/MS of m/z 225

The EI mass spectrum of pararosaniline acetate is shown in Figures 2. By CI/MS, m/z 289, 287, and 212 ions were assigned to be the molecular ions. By MS/MS, the respective fragment ions of these molecular ions were confirmed and the structures were derived. The MS/MS spectra of 289 and 287 ions are shown in Figures 2a and 2b, respectively. 4,4'-Diaminobenzophenone (MW 212) is an impurity present in the original sample. The molecular species of 289 and 287 were elucidated to be the free base and leuco base of pararosaniline.

Figure 2. MS spect. of P-Rosa.

Figure 2a. MS/MS Spect. of m/z 289

CONCLUSION:

The MS characterization of triphenylmethane compounds is possible. The thermally stable molecular species of this type of compounds are the respective leuco base and/or free base. The formation of the leuco base is common to this type of compounds. The formation of the free base is limited to compounds with free amino groups.

IDENTIFICATION OF A PROCESS IMPURITY IN A PHARMACEUTICAL RAW MATERIAL

Donald F. Magin
Whitehall-Robins Healthcare
Pharmaceutical Research and Development
Sherwood Ave. Richmond, VA 23220

As part of regular testing, all raw materials used in research formulations are subject to several tests, including both assay and purity. During the routine testing of a batch of Pheniramine Maleate from a new supplier, the assay value was well within allowable specifications (>99.5%), but two minor impurities were noted during a TLC test (USP <466>, Ordinary Impurities Test). One of the compound was estimated to be less than 0.1%, but the other was estimated at 0.2% to 0.5%. Our Regulatory Division requires that any impurity present at greater than 0.2% be identified, and ascertained to be either a process impurity or a degradation product. Since Pheniramine (I) can be successfully chromatographed by GC, and we had a GC/MS system available, this was the method chosen to accomplish the identification. At the time we began this investigation, only EI was available; CI became available as the investigation progressed.

Initial GC results were confusing, because only one peak was evident, and the mass spectrum indicated that it was pheniramine. The impurity ascertained by TLC to be present at ~0.4% should have been visible in the gas chromatogram. Some of the impurity was scraped from the TLC plate and subjected to GC. It yielded a peak at exactly the same retention time as pheniramine. Its mass spectrum was completely different from pheniramine, although it shared many of the same mass peaks (see spectra). It became obvious that it was going to be difficult to identify this impurity using the resources available to us, if the only source was the impure batch of pheniramine.

After the application of some reasonable chemistry, and assuming a molecular weight of 188 based on the EI mass spectrum, a plausible structure was proposed (II). Attempts to find a commercial source for this compound led us to the Sigma-Aldrich Library of Rare Chemicals, which carry no guarantee of purity, although the identity of the major component has been determined. When it was co-injected with a spike of the known impurity (scraped from a TLC plate), two peaks were observed in the gas chromatogram. The first and major peak was the purchased compound, and the second, smaller peak was the impurity, but at a much higher amount than should have been there from the spike. The purchased material actually contained our unidentified compound as

an impurity at a level of ~15%. We now had a ready source of the impurity. (Fortune smiling the first time.)

At just this time, we obtained the ability to perform CI on our GC/MS, using NH_3 as a reagent gas (Fortune's second smile). This led to the conclusion that the impurity actually had a molecular weight of 259. Piecing all of this information together led us to propose a final structure for the impurity (III). When the supplier, who up to this point had been uncooperative, was confronted with our conclusion, it then provided us with an authentic sample of the identified compound, and acknowledged that it was likely a process impurity during the synthesis of the pheniramine, and should not be considered as a degradant.

Investigations of Fluorinated Ethylchloroformate Derivatives of Dipeptides Using Positive and Negative Chemical Ionization GC/MS

Ping Cao and Mehdi Moini
Department of Chemistry and Biochemistry,
University of Texas at Austin, Austin, Texas 78712

Recently, a complete mass spectrometric identification of the ethylchloroformate(ECF) derivatives of all protein and non-protein amino acids using both positive and negative chemical ionization modes has been reported by this lab [1,2]. In that work we used ECF + trifluoroethanol rather than ECF + ethanol [3] as a derivatizing agent. The work described here extends this derivatization technique to a broad range of dipeptides using positive and negative chemical ionization mass spectrometry. A wide range of dipeptides with different chemical properties (containing acidic and/or basic residues) were investigated. Application of this technique to a real world sample is demonstrated by analyzing a commonly used sugar substitute, "Equal" from NutraSweet, which is a methyl ester of aspartyl-phenylalanine.

Figure 1 illustrates the reconstructed ion chromatogram (RIC) of N-ethoxycarbonyl trifluoroethyl ester of the peptide mixture in the positive CI mode. Under the experimental conditions employed here, two derivatized dipeptides, Leu-Gly and Val-Asp, each gave two peaks; one with $[M+H]^+$ as the molecular ion and the other with $[M+H-HOC_2H_5]^+$ as the molecular ion corresponding to the loss of the HOC_2H_5 group from the $[M+1]^+$. Other derivatized dipeptides produced a single peak corresponding to $[M+H-HOC_2H_5]^+$.

Figure 1. Reconstructed ion chromatogram of N-ethoxycarbonyl trifluoroethyl ester of the peptide mixture in the positive CI mode.

The results of the mass spectrometric study of the ECF derivatives using trifluoroethanol in positive chemical ionization mode are tabulated in Table 1. Except for dipeptides that contain hydroxyl amino acids and Ala-Lys, all other dipeptides studied here show similar diagnostic ion peaks. The

diagnostic ions included: 1) $[M-45]^+$ corresponding to $[M+H-HOC_2H_5]^+$, 2) $[M-65]^+$ corresponding to $[M+H-HOC_2H_5-HF]^+$, 3) $[M-17]^+$ corresponding to $[M-HOC_2H_5+C_2H_5]^+$ and 4) $[M-5]^+$ corresponding to $[M-HOC_2H_5+C_3H_5]^+$.

For dipeptides with hydroxyl amino acids such as Val-Ser and Ala-Thr, GC/MS analysis showed different diagnostic ions including: $[M+H-H_2O]^+$, $[M+H-H_2O-HF]^+$, $[M-H_2O+C_2H_5]^+$, and $[M-H_2O+C_3H_5]^+$.

Ala-Lys (containing basic residue) showed a unique diagnostic ion $[M-130]^+$ which originates from the loss of $CH_3CH_2CH_2NHCOOC_2H_5$ from $[M+1]^+$.

The negative CI spectra showed that $[M-45+36]^-$ or $[M+35]^-$ is the base peak for all non-hydroxyl dipeptides. These arise from $[M-OC_2H_5+Cl]^-$ or $[M-H+Cl]^-$ ions formed from the loss of a proton from HCl adducts of the molecular ions under negative CI conditions. For dipeptides containing hydroxyl amino acids, $[M-18]^-$ peaks were the base peaks in the negative CI mode. These dipeptides did not give HCl adducts. Ala-Lys also gave a $[M-131]^-$ base peak with no HCl adducts.

Detection limits of the N-ethoxycarbonyl trifluoroethyl ester derivatives of dipeptides were studied using positive and negative CI modes. The results showed that most of the dipeptides can be detected at pmol levels in both positive and negative CI modes. The potential applications of this derivatization method are shown by the analysis of "Equal" (aspartame), the commercial sugar substitute which is a methyl ester of Aspartyl-Phenylalanine. Equal was dissolved in 0.1 M HCl to produce a 1 mg/ml solution. The reconstructed ion chromatogram of the derivatized "Equal" solution showed several peaks including aspartame, aspartic acid, phenylalanine, and dextrose as well as other constituents.

Table 1. Characteristic Ion Peaks in Positive CI Spectra of Derivatives of Dipeptides and Tripeptide Using Trifluoroethanol.

Dipeptide	Mw	Mw of the derivatized dipeptide	Diagnostic ion: $[M-45]^+$ or $[M-17]^+$
Val-leu	230	384	339
Leu-Ala	202	356	311
Leu-Phe	278	432	387
Leu-Gly	188	342	297
Met-Gly	206	360	315

Proflavine Derivatives for Mass Spectrometric Identification in Fish.

F. Aladar Bencsath, and Edward L.E. Jester
Food and Drug Administration, Gulf Coast Seafood Laboratory
P.O. Box 158, Dauphin Island, Alabama 36528, USA.

Proflavine is an effective antimicrobial agent with potential use in aquaculture for the prevention or treatment of infectious diseases in cultured fish. Its pharmacokinetics and metabolism in fish are being studied in our laboratory. Proflavine has low uptake in channel catfish, and therefore its identification is an analytical challenge. A detection limit of 5 ppm (= 10 ng in the injected volume of 2 µl) has been determined by continuous flow fast atom bombardment ionization mass spectrometry (CF FAB MS) in full scan mode, while the detection limit of the liquid chromatographic (LC) analysis with photometric detection at 454 nm was at the low ppb (< 10 ng/ml) level. In order to match the LC sensitivity with the MS, we attempted to improve the MS detection sensitivity for proflavine.

The sensitivity of the MS detection for proflavine was limited both by the background fluctuation and by the relatively low MS response of this highly polar compound. A less polar compound, e.g. the closely related acridine yellow G (a dimethylene homologue of proflavine) show four times higher response. Derivatization also shifts the analyte's mass to higher region where background fluctuation is less severe, even when injecting fish extracts. Therefore several derivatives of proflavine were prepared to reduce polarity and increase MS response.

Table 1. lists the reagents used and the expected derivative products.

We found the following:

Trifluoroacetylation with N-methyl-bis-trifluoroacetamide (MBTFA):acetonitrile mixture at 75°C was complete in 30 min, but the product was sensitive to hydrolysis. Acetylation with acetic acid anhydride in the presence of sodium acetate resulted in a more stable diacetylated compound. Its formation was slower which could easily be followed by MS. Dimethylformamide dimethylacetale reacted with both primary amino groups in warm methanol. The reaction was complete within an hour, and clean, simple spectrum was generated by sampling from the reaction mixture into the MS without cleanup. Phenylisothiocyanate (PITC) reacts slower; several hours needed for near completion. Although the spectrum was more complex, the analytically important m/z 480 molecular ion was well distanced from unrelated peaks.

Fluorenylmethylchloroformate (Fmoc chloride) seemed to react completely with proflavine in aqueous acetonitrile solution. The MS response of the derivative was, however, rather weak, probably caused by the large excess of reagent that formed the dominant methylene-fluorene ions m/z 178 and 179.

Transformation of proflavine with fluoroaromatic acylating agents were not fruitful: complex spectra were obtained even after incomplete reactions precluding identification. Silylation, however, progressed to completeness with N-methyl trimethylsilyl trifluoroacetamide (MSTFA). This reagent is an excellent solvent for proflavine even if diluted with acetonitrile, and

the reaction was complete at 75°C in a few minutes. A GC/MS attempt at 290°C with a 25m long capillary resulted in a very wide peak but with correct EI spectra, indicating that a shorter column with higher temperature will work.

The most useful results were obtained in the experiments with pentafluorobenzaldehyde (PFB). It reacts with proflavine in warm methanol forming the mono-pentafluorobenzal Schiff-base derivative. Both the positive and the negative desorption chemical ionization (DCI) spectra were simple, dominated by the appropriate molecular ion m/z 388 (MH⁺) and 377(M⁻), respectively. In the negative spectrum, M⁻ was the only intense peak. As one expects, the MS response with this electron capture CI mode was remarkably large: the insertion of 2 ng proflavine derivative still produced a distinguished molecular ion peak. We found that 50 ng PFB-proflavine derivative produces 48 times larger signal than does the same amount of underivatized proflavine in positive DCI mode.

MS/MS experiments with the molecular anion of PFB-proflavine yielded useful product ion spectra with two major fragments. This mode of operation will allow MS/MS confirmation of proflavine in fish, and increase confidence in the identification.

Table 1.

Reagents	Expected Derivatives
N-methyl-bis-trifluoroacetamide (MBTFA)	N,N'-bis-trifluoroacetyl proflavine
acetic acid anhydride	N,N'-diacetyl proflavine
pentafluoro benzoyl chloride	bis-PF-benzamido acridine
pentafluorophenylsulfonyl chloride	Pro-3,6-diphenylsulfonamide
pentafluorophenyl chloroformate	N,N'-bis-PF-phenoxy carbonyl proflavine
fluorenylmethyl chloroformate	N,N'-bis-Fmoc-proflavine
phenylisothiocyanate (PITC)	3,6-bis-phenylthioureido acridine
p-nitrobenzyl bromide	N,N'-di-p-nitrobenzyl proflavine
methyl-TMS-trifluoroacetamide	N,N'-bis-TMS-proflavine
dimethylformamide dimethylacetale	N,N'-bis-dimethylamino-
(DMF-DMA)	-methylene proflavine (Schiff base)
pentafluorobenzaldehyde (PFB)	N-pentafluorobenzal proflavine

New Silyl Derivatives for the Determination of Alcohols by GC/MS

Vladimir G. Zaikin, Michael Yu. Shmatko, Anzor I. Mikaya
Topchiev Institute of Petrochemical Synthesis, Moscow, Russia

Introduction: A wide variety of silyl derivatives are used for the determination of alcohols and acids by GC/MS. At the same time, there are number of potential simple silylating agents that could be used for this purpose. The spectra also provide additional structural information. Present investigation is devoted to the search of such agents. For the model study of straight-chain and branched primary and secondary aliphatic alcohols (C_3 - C_{12}), the following silylating agents have been tested: Methyl(trimethylene)silyl (MRMS), Methyl(tetramethylene)silyl (MEMS), Dimethyl(trimethylsilyl)silyl (DTSS) and Dimethyl(trimethylsilylmethyl)silyl (DTMS) chlorides.

MRMS
Chloride

MEMS
Chloride

DTSS
Chloride

DTMS
Chloride

Experimental: MEMS, DTSS and DTMS derivatives were readily prepared by addition of corresponding chloride to alcohol at 20°C and stirring for 5 min. Such a procedure can not be applied to MRMS chloride because of ease silacyclobutane ring opening under action of HCl evolved. In this case, to a solution of alcohol in n-pentane, quinoline was added followed by MRMS chloride and the mixture was stirred for 5 min.

All the alcohols were completely converted into MRMS, MEMS, DTSS and DTMS ethers by on-column silylation (both packed and capillary columns). In this case corresponding agent was introduced directly into injection port 5 s after the injection of alcohol. The volume ratio of an alcohol (or a mixture) and chloride 1:3 ensured quantitative silylation.

Results and Discussion: It is of importance that silacyclobutyl and silacyclopentyl derivatives display molecular ion peaks. For DTSS and DTMS derivatives the base peak appears at m/z 147 due to rearrangement process $[(CH_3)_2Si=O^+-Si(CH_3)_2]$. For all kinds of derivatives of secondary alcohols, the most characteristic fragmentation is due to cleavage of C-C bond in alpha position to silyloxy group which allows to locate a hydroxy group in initial alcohols.

It is of interest that silacyclobutyl ethers of straight-chain and branched alcohols differ mainly in relative intensities of the peaks at m/z 75 and ($M-43$). The ratio is higher for the isoalkanols ethers, whereas the opposite picture is observed for linear alcohol derivatives. The ease hydrogen migration from tertiary C atom of isoalkanols could be the reason of more favorable formation of an ion $[(CH_3)_2(OH)Si]^+$ (m/z 75).

The EI mass spectra of silacyclopentyl derivatives of isomeric linear and branched alcohols are also very different. The most important difference is due to the relative intensities of the peaks for $[M - C_2H_4 - C_3H_7]^+$ ions. The reason of such difference could be the anchimeric assistance that is realized in cation-radicals $[M - C_2H_4]^+$. In derivatives with branched alkyl chain, separated radical center in the $[M - C_2H_4]^+$ ion attacks the tertiary atoms which gives rise to more ease elimination of isopropyl radical.

The important feature of DTSS and DTMS ethers is the presence of the base peaks at m/z 147 the intensity of which (% TIC) appears to depend only slightly on the length and structure of alkyl chain. This fact could be successfully used for quantitative group determination of alcohols in mixtures with other non-derivatized compounds. Concerning the GC properties, it should be noted that all the derivatives are less mobile than corresponding TMS ethers.

Conclusion

- MRMS, MEMS, DTSS and DTMS chlorides are useful reagents for the conversion of alcohols into derivatives with mass spectra that reveal structural information.
- Silacyclobutyl and silacyclopentyl derivatives of straight-chain and branched alcohols show different mass spectra. This difference could be used for the determination of carbon skeleton of alcohols.
- Disilyl derivatives may be used for the quantitative determination of alcohols in mixtures with other non-derivatized compounds.

**University of Massachusetts-Lowell, Dept. of Chemistry, 1 University Ave., Lowell, MA 01854.

Various inorganic and organic chemical admixtures are typically added to concrete that either facilitate the mixing, transport, placing, and finishing of freshly mixed concrete, or improve the strength and durability of hardened concrete. General admixture classifications include: superplasticizers, set accelerators and retarders, air entraining agents, and corrosion inhibitors. The determination of admixtures in concrete is frequently needed to troubleshoot deviations from expected performance or verify the presence of critical, long term durability enhancing agents, i.e. corrosion inhibitors. The analyses can be especially difficult because of the presence of low levels (5-2000 ppm) of these additives in concrete. The current methods for the analyses of concrete admixtures rely on extensive extraction procedures followed by non-specific detection methods, and hence are laborious and time-consuming. We report here novel PY/GC/MS techniques for the analyses of a number of additives in hardened concrete, which are rapid, specific, and far less tedious.

We have developed a novel reactive pyrolysis-GC/MS method for the analysis of nitrite in hardened concrete. In this method, pulverized concrete powder containing calcium nitrite corrosion inhibitor is mixed with ammonium polyphosphate in a ratio of about 2:1. About 50 µg of the mixture is analyzed by PY/GC/MS at 800 °C. Under the reactive pyrolysis conditions, abundant N₂O is formed (Figure 1 and 2) from the nitrite present in the concrete, and is well separated from the air peak. In the absence of polyphosphate, nitrite in concrete produces NO but very little or no N₂O. NO, however, coelutes with air.

Naphthalenesulfonate formaldehyde condensates (NSFC), a typical concrete superplasticizer, was also successfully analyzed by PY-GC/MS directly in hardened concrete. At 600 °C, NSFC in concrete was found to produce abundant signal of naphthalene and methyl naphthalene (Figure 3). The peak areas of naphthalene were found to correlate linearly to the dosages of NSFC in hardened concrete (Figure 4), suggesting that the method can be used for quantitating NSFCs in hardened concrete.

Tall oil-based air entraining agents were also successfully characterized directly in hardened concrete by using an in-situ derivatization-PY/GC/MS method. The method includes: the addition of methanolic tetramethylammonium hydroxide (TMAH) to the pulverized concrete powder followed by the pyrolysis (600°C) of the mixture. Under the experimental conditions, the rosin and fatty acids in Tall oil were derivatized by TMAH to their methyl esters which were chromatographed easily. The pyrolytic conversion of rosin acids to phenanthrene represents an alternative method of determining this class of air entraining agents. Peak areas of phenanthrene were found linear with the increasing dosage of vinsol resin, a common air entraining agent for concrete.

For better accuracy and precision of the methods, we have interfaced a custom-made high-temperature oven that allows us to pyrolyze up to 2 grams of concrete powder at a time. The methods have been found to be very reproducible, rapid, specific, and exhibit sufficient sensitivity. Further works are in progress for the direct analyses of other admixtures in hardened concrete.

Off-line TMAH Thermochemolysis Applied to Structural Investigations of Lignin; *Minard, Robert; Dible, Scott; Sewell, Tara; Nanny, Mark, Hatcher, Pat; Departments of Chemistry and Fuel Science, Penn State University

Overview

Purpose: To develop a new method for analyzing polymeric materials such as lignin in wood and coal.

Method: "Off-line TMAH thermochemolysis" - Heating samples to 250°C with tetramethylammonium hydroxide in a sealed ampoule for 1/2 hour and analysis of products by GC and GC-MS

Results: Bond cleavage and in situ methylation produces a suite of products characteristic of the structure and extent of decomposition of the lignin. Quantitation is possible.

Background:

Thermal bond cleavage (pyrolysis) of polymeric materials at 600°C or higher produces a collection of low molecular weight products whose structures can be elucidated using GC-MS. Often, however, many of the pyrolysis products are too polar for gas chromatography and are difficult to detect. Challinor¹ has reported that pyrolysis in the presence of tetramethylammonium hydroxide (TMAH, (CH₃)₄N⁺OH⁻) leads to *in-situ*-methylation of these polar materials during pyrolysis, rendering them less polar and more volatile and thus more easily analyzed by GC. This "TMAH-pyrolysis" method has been applied to polymers¹, biopolymers^{2,3}, and humic materials^{4,5} and the products provide considerably more insight into the original macromolecular structure of these materials than pyrolysis alone. DeLeeuw and Bass³, have pointed out that this transformation is more likely a thermally-assisted chemical reaction or "thermochemolysis" and Hatcher and Clifford⁵, have shown that "TMAH-thermochemolysis" can be carried out at lower temperatures, 250-300°C. At these lower temperatures, the TMAH-thermochemolysis can be carried out off-line in sealed ampoules⁶. This new analytical procedure does not require the use of specialized pyrolysis equipment, can be run in batch mode, and provides quantitation since internal standards can be added.

Experimental Procedure:

The sample (~0.5 mg) was placed in a 14 cm by 8-10 mm o.d. diameter tube and 100uL of TMAH (25% in MeOH) added. The samples were placed in a vacuum dessicator, the air removed and the dessicator allowed to stand under static methanol vapor pressure overnight to let the TMAH soak into the sample. The remainder of the MeOH is removed with vacuum and the tube sealed under vacuum with a torch. The tubes are wrapped with aluminum foil and placed in a 250°C oven for 30 min. After cooling, the tubes are broken open, the contents thoroughly washed out with CH₂Cl₂ and the CH₂Cl₂ blown off. An eicosane standard solution (100 mL; 3.2 mg/mL in CH₂Cl₂) was added and the sample analyzed by GC-MS

Applications:

1. TMAH thermochemolysis/GC-MS characterization of lignin from different plant sources.

Figure 1 shows the TIC trace from GC-MS analysis of the TMAH thermochemolysis products of a wood sample from an alder tree. The structures of some of the more abundant products are shown. Examination of the current model of lignin structure shows that a great amount of structural information is represented in these products and that they arise largely by cleavage of the β-O-4 bond, the predominant linkage of lignin phenylpropane subunits of the *p*-hydroxyphenyl (P:4-methoxyphenyl), guaiacyl (G: 3,4-dimethoxy phenyl), or syringyl (S: 3,4,5-trimethoxyphenyl) types. Alder and other deciduous angiosperms have roughly equal amounts of the G and S type subunits. The complete methylation of all phenolic, hydroxylic, and carboxylic acid -OH groups, either present originally or formed in chemolysis, is observed (see structure G14, for example).

In comparison with alder, the TMAH thermochemolysis products of a gymnosperms yields essentially only the guaiacyl type products as shown in Figure 3 for red pine, tamarack, and white spruce. Non-woody plants are defined by a lignin which has a high proportion of P-type subunits.

Since the off-line method allows the introduction of an internal standard, the quantity of lignin can be determined and its proportion of the total organic matter (A) can be calculated. These values agree with those determined by other methods⁷.

2. TMAH thermochemolysis/GC-MS characterization of lignin in soils, sediments, dissolved organic matter, and coal.

Unlike other plant components, lignin is a fairly refractory material, very slow to biodegrade, and is, thus, the major source of organic material in dissolved organic matter (DOM) in ocean water, of organic matter deposited in soils and sediments, and, ultimately, of much of peat and coal. The lignin "signatures" of angiosperms, gymnosperms, and non-woody plants may be used to decide which of these different classes of plants was the source material for these highly transformed, no longer recognizable, lignin materials.

3. TMAH thermochemolysis/GC determination of lignin degradation in wood samples.

As lignin is subjected to chemical and/or enzymatic transformation over time, the ratio of guaiacyl or syringyl benzene carboxylic acids to the corresponding aldehydes was found to increase (Hedges et al.⁷). Our work shows TMAH method was a much more sensitive indicator of degradation⁸. The ratio of products G14+G15 to G6 (I) is also a good indicator of degradation⁹.

4. Off-line TMAH thermochemolysis/GC-MS analysis of other biomaterials such as cutin, protein, resins, carbohydrate, and hydrogen cyanide polymers.

GC/MS Chiral Analysis of Enantiomeric Drugs Amenable to GC Separation

T.A. Getek, A.G. Grill®, H. Tan, and S. Hariharan
Bioanalytical R&D, Forest Labs, 220 Sea Lane, Farmingdale, NY 11735
@Current Address: Pfizer, Groton, CT

Overview: The need for chiral bioassays are driven by pharmaceutical companies and the FDA to develop more potent drugs with less toxic side effects by selecting the appropriate enantiomer that gives the therapeutic response. The majority of chiral separations developed recently are based on HPLC or capillary electrophoresis (CE). For GC, it is known that certain chiral derivatizing reagents will cause a racemic compound to be separated via chiral center formation (1). An alternative GC chiral technique is to have a chiral stationary phase in the GC column (2). Similar to many HPLC and CE chiral methods, cyclodextrin can be used as a GC support. The first problem with cyclodextrin was the stability of the column due to the reactive hydroxyls that are present. In order to achieve better thermal stability, the -OH groups can be derivatized (3,4).

Experimental: GC/MS was performed with an HP5890/HP5989A system in the electron impact mode using selective ion monitoring (SIM). The GC column was a commercially available permethylated cyclodextrin type (0.25mm x 30m). Guard column (retention gap) was a 2.5 m section of deactivated fused silica (0.25mm id). Helium was at constant pressure at 23 psi.

Results and Discussion: The compound Drug P was examined in the SIM mode and the chromatogram of a neat solution can be seen in Figure 1. During elution of the drug, the GC was isothermal at 155°C with the "+" enantiomer eluting first. For quantitation the LOQ was 5 ng/mL for each enantiomer with a calibration range of 5 to 125 ng/mL. In order to achieve this LOQ, a splitless injection was necessary. In Figure 2, the d4-Drug P compound is seen. The corresponding d4-enantiomer was used to calculate the response ratio for quantitation. As expected, the d4-Drug P enantiomers elute slightly faster than the non-deuterated enantiomers. A chromatogram of Drug P extracted from plasma is seen in Figure 3. As noted in Figure 3, the "+" enantiomer is metabolized more rapidly than the "-" form as illustrated with the d4-Drug P internal standard. Extractions were also accomplished from cerebrospinal fluid (CSF) with results similar to the plasma extracted samples.

Conclusions: The rapid assay of enantiomeric compounds can be readily accomplished without derivatization provided the enantiomers are amenable to GC injection and separation. The simplicity and ease of this chiral GC/MS method makes it readily available for other compounds. The ruggedness and reproducibility of the bioassays with the permethylated cyclodextrin column is sufficient for hundreds of analyses to be performed.

Figure 1: The SIM chromatogram for Drug P shows the separation of the "+" and "-" enantiomers. The temperature ranges after injection increases rapidly to 155°C and during the majority of the analysis run time, the GC is isothermal at 155°C.

Figure 2: The internal standard (IS) used was d4-Drug P and the separation of the "+" and "-" enantiomers are seen. Each enantiomer was correlated to its appropriate IS peak and a response ratio calculated. As expected, the deuterated analog has a slightly shorter retention time.

Figure 3: The SIM chromatogram above shows a typical situation of metabolized Drug P extracted from plasma. It is noted that the "+" enantiomer is significantly less than the "-" enantiomer when compared to the IS. This shows the ease by which these enantiomers can be compared by GC/MS.

Study of Sesquiterpene Lactones Using Mass Spectrometry

J.A. Campbell and K.L. Wahl, Advanced Organic Analytical Methods Group, Pacific Northwest National Laboratory, Box 999, Richland, Washington 99352 and R.G. Kelsey, U.S. Department of Agriculture, Pacific Northwest Research Station, 3200 Jefferson Way, Corvallis, Oregon 97331

Introduction

More than 500 sesquiterpene lactones have been isolated and identified from many species of higher and lower plants over the past 20 years. Sesquiterpene lactones form one of the largest group of cytotoxic and anti-tumor family of compounds of plant origin. They have been known to cause allergic contact dermatitis in humans, poison livestock, and are insect feeding deterrents. One of the prerequisites for biological activity is the presence of a α -CH=C-C=O moiety as part of an ester, ketone or lactone.

Several sesquiterpene lactones, some of which are biologically active, have been analyzed using electron impact, positive ion chemical ionization, and fast atom bombardment mass spectrometry. As an example, tatridin-A (structure 1), an antifeedant for gypsy moth larvae, has been isolated from several different species of the genus *Artemisia* (sagebrush).

1 R, R' = H

2 R = Ac, R' = Ac

The structure of the acetate derivative (structure 2) was tentatively identified from X-ray data, but one of the acetate groups indicated severe disorder which produced a high R value (goodness of fit). Mass spectrometry was used to support the structure assignment.

Other sesquiterpene lactones including dihydroxyarbusculin-A and 1- β -hydroxysantonolide-C were analyzed using FAB/MS and FAB/MS/MS.

Experimental

A HP 5985 GC/MS was used for direct probe analysis under the following conditions:

Direct Probe 50° C-1 min.
50°-200° C at 10° C/min

Source Temperature- 200° C
Electron Energy - 70 eV
CI Reagent - Isobutane

A JEOL SX-102/SX-102 four sector, high resolution mass spectrometer was used for the FAB and FAB/MS/MS studies. The matrix used was glycerol. The scan range was 10-2000 with a scan speed of 30 sec and cycle time of 23.5 sec. The mass spectrometer was calibrated with ultramark.

Results and Discussion

Figures 1 is the electron impact and chemical ionization mass spectra of tatridin-A diacetate. The mass spectral results are consistent with the X-ray crystal structure. In addition, these results have resulted in being able to identify duplicate compounds isolated from diverse plant sources.

Several other natural products which show anti-tumor activity, dihydroarbusculin-A and 1- β -hydroxysantonolide-C were analyzed using FAB. Figures 2 and 3 are the FAB spectra of dihydroarbusculin-A and 1- β -hydroxysantonolide-C, respectively. In this particular set of compounds, the isomers can be differentiated. The FAB/MS/MS spectra, however, were identical.

Oxidation of diterpenoid *Pinaceae* resins in old master paintings

Klaas Jan van den Berg, Ivana Pastorova, Leo Spetter en Jaap J. Boon.
MOLART project, FOM Institute for Atomic and Molecular Physics, Kruislaan 407, 1098 SJ Amsterdam, The Netherlands. fax: 31-20-6684106. e-mail: kjvdb@amolf.nl, boon@macro2.AMOLF.NL.

Introduction

Many resins which have been commonly used in paintings originate from the conifer subfamily *Pinaceae*, such as colophony or rosin, common or Bordeaux turpentine (*Pinus*), Venice turpentine (*Larix*) and Strasbourg turpentine (*Abies*). These diterpenoid resins have been applied in virtually all parts of Old Master's paintings; as

- varnish (a thin film to protect the paint and deepen and add warmth to the colours)
- additive to paints (to change the properties of the paint, in e.g. glazes, lacquers)
- pigment/glaze (copper resinate)
- mordant (adhesive, e.g. for gold leaves)

In addition, resins may have been introduced during restoration as

- new varnish
- lining paste (wax/resin, for repairing and strengthening of the support)

The chemical composition and the degree of ageing of *Pinaceae* resins in Old Master's paintings is a result of the original biological composition, processing by the manufacturer and the artist and natural ageing in paint media depending on the presence of metal catalysts (pigments!) and light, pH and redox conditions.

Most prominent remainders of *Pinaceae* resins in Old Master's paintings are the relatively stable pimarane and abietane acids. The ageing of DTP resins is particularly a result of oxidation of diterpenoid acids such as abietic acid (AA) and dehydroabietic acid (DHA).

In the MOLART project, analysis methods for highly oxidised diterpenoid acids in very small (10 µg) and complex samples of paintings are developed. Since the state of oxidation of (a specific part of) a painting is related to the state of oxidation of its constituents, the abietane acids may serve as an indicator for the state of oxidation of a painting.

Scheme. Abietane acids in different stages of oxidation

Methods

For the analysis of aged diterpenoid resins in very small (10 mg) and complex samples of paintings, three methods have been compared:

- On-column GCMS; derivatisation with (TMS)diazomethane and BSTFA
- *in situ* thermally assisted methylation with TMAH with GCMS (Py-TMAH-GCMS)
- Direct Temperature-resolved MS (DTMS; fast fingerprinting of a broad range of volatile and polymeric constituents)

Results

The structures of diterpenoid acids in different stages of oxidation have been elucidated by their mass spectra. TMAH is found to react with 7-oxo compounds under formation of the methyl ether of the enol.

Derivatisation and mass spectrum of 15-OH-7-oxoDHA methylated with TMAH

Both on-column GCMS and Py-TMAH-GCMS are found to be good methods for the analysis of highly oxidised diterpenoid acids. Mass spectra of all five stages of oxidation can be obtained. The *in situ* thermally assisted method, however, is preferred because this method is fast and less sensitive to e.g. moisture. Moreover, additional pyrolysis provides information about a broader range of constituents of painting material.

The molecules of the diterpenoid abietane acids at different stages of oxidation and their fragments have discrete values. Comparative studies show that DTMS can be applied to assess the state of oxidation of resins in complex painting materials. Because with DTMS no separation on a molecular level is achieved, corrections for ^{13}C and additional matrix constituents must be made.

State of oxidation of the diterpenoid acid fraction in different (painting) samples as measured with Py-TMAH-GCMS, DTMS and DTMS with TMAH. With ^{13}C and background correction for DTMS

Sample	State of oxidation	(1:2:3:4:5)	
	Py-TMAH-GCMS	DTMS	DTMS w TMAH
000000	76:18:6:0:0	47:32:14:5:2	50:31:12:5:2
15-oxo-15-hydroxy-DHA	4:24:22:33:17	6:19:25:33:17	7:23:26:28:16
7-oxo-15-hydroxy-DHA	2:14:9:37:38	7:10:16:35:32	6:18:18:28:30

MOLART

MOLART (Molecular Aspects of Ageing in Art) is a 5-year Dutch joint project of art historians, conservators, chemists and physicists. The project is focussed on determination of the present condition of works of (painted) art produced from the 15th to the 20th century. Emphasis is put on molecular level studies using (spatially resolved) mass spectrometry, 2D-microscopy, infrared and Raman spectroscopy. Special attention is paid to indicators of ageing processes such as the degree of oxidation of terpenoids in resins, lipids and proteins. Part of the research program involves the development of a database of mass spectra from paintings using a variety of direct and hybrid mass spectrometric techniques.

A manuscript connected with these results is in preparation.

More results on highly oxidised diterpenoid acids in paintings will be published in the Proceedings of 11th Triennial Meeting of the ICOM Committee for Conservation, Edinburgh, 1-6 September 1996.

Study of the polymeric part of archaeological adhesives

Regert M.; Menu M.; Delacotte JM.; Houzé de l'Aulnoit A.; *Rolando C.

Ecole Normale Supérieure, Département de chimie, URA 1679 du CNRS, Processus d'Activation Moléculaire, 24 rue Lhomond, 75231 Paris cedex 05 (France)

Introduction

Among the organic residues discovered on prehistoric sites, adhesives are often well preserved and have been already studied by different authors. However, the works concerning these materials usually only deal with the solvent extractable part of the samples whereas the insoluble part, quite important and probably polymeric, did not retain the attention of the researchers.

It has been shown that birch bark tar was used during the Neolithic period (5500-2000 B.C.) in Europe. This identification was based on the presence of lupane biomarkers and degradation markers in the soluble part of archaeological samples analysed by gas chromatography coupled with mass spectrometry after derivatization.

In order to understand the adhesive properties and the composition of birch bark tar, we have tested different chemical methods able to break up the biopolymers.

Archaeological samples being very precious and conserved in low quantity, we first applied these methods to contemporary birch bark.

We present here a comparison of the results obtained after alkaline hydrolysis, thioacidolysis and action of metallic amides on contemporary birch bark.

Methods

Alkaline hydrolysis¹: 100 mg milled birch bark were stirred with 10 ml 0.5 M of KOH in ethanol/water (9:1, V/V) at 70°C for 1.5 h. One ml of the solution was then acidified with 0.25 M H₂SO₄ and extracted with ether. The organic fraction was washed with water, and concentrated.

Thioacidolysis²: 10 mg milled birch bark were added to 5 ml of a freshly prepared mixture of boron trifluoride etherate/dioxane/ethanethiol (7:62:31, V/V/V) and stirred at 100°C for 4 h. The solution was then neutralized with 0.4 M NaHCO₃ and extracted with CH₂Cl₂. The organic fraction was dried over Na₂SO₄ and concentrated.

Action of amides³: benzylamine (0.116 ml) was added dropwise on a solution of LiAlH₄ in anhydrous ether (0.21 ml). The solution was kept 30 mn at 25°C in order to synthesize the amide LiAl(NHCH₂φ)₄. 100 mg of milled birch bark were then added and the mixture stirred for one night. The reaction was quenched with 80 μl H₂O, 80 μl 10% NaOH and 240 μl H₂O. The precipitate, separated by filtration, was extracted with CH₂Cl₂. The organic fraction was then dried over MgSO₄ and concentrated.

Internal standard: cholesterol was used as internal standard

Derivatization: the solutions resulting of alkaline hydrolysis and thioacidolysis were methylated with freshly prepared diazomethane and then trimethylsilylated with BSTFA.

GC/MS analysis: sample analysis was performed with GC/MS instrument (Finnigan TSQ 46; GC Varian 9611) equipped with a (25m X 0.25mm) CP Sil 5CB (25μm) column from Chrompack using EI⁺ ionization.

Temperature program: 1 mn : 60°C ; 20°C/mn : 60 to 150°C ; 4°C/mn : 150 to 310°C , 310°C during 30mn.

Results

In order to compare the different methods of depolymerisation, we first present a chromatogram of a birch bark extract in CH₂Cl₂, after methylation and trimethylsilylation. The chromatogram shows the presence of the two main triterpenoids usually described lupeol TMS and betulin bis-TMS

- **Alkaline hydrolysis**: the chromatogram obtained after alkaline hydrolysis of birch bark can be separated in two regions¹: in the first one, corresponding to a retention time less than 38mn, a series of carboxylic diacids (C18-C22) containing some epoxy and hydroxy functional groups were identified. The second region of the chromatogram shows the presence of common triterpenoids from birch bark.

- **Thioacidolysis**: this method allowed us to liberate another terpenoid probably the monogynol A, usually described in the literature as a minor component of birch bark. This method was also efficient on an archaeological sample.

- **Action of amides**: this reaction allowed us to liberate lupeol and betulin as well as a set of not yet identified amides.

The different chemical treatments applied to birch bark allow to break different chemical bonds: alkaline hydrolysis and amides essentially break ester linkage whereas thioacidolysis mainly proceeds by cleavage of ether bonds. The liberation of carboxylic diacids by alkaline hydrolysis suggests the presence of esters of carboxylic diacids with alcoholic triterpenoids, possibly constitutive of a biopolyester in birch bark;

thioacidolysis liberates only another triterpenoid, indicating that the compounds involved in the ether linkages are essentially the same than those implicated in ester linkages;

the molecular peak of the amides resulting from the action of lithium aluminium benzylamide appears to be in the same mass range than the acids liberated by alkaline hydrolysis, further investigation will allow us to clarify their structure.

Conclusion and prospects

These results suggest that birch bark is partly made of biopolymers containing two kinds of monomers: carboxylic diacids on one hand, involved in ester linkages, triterpenoids of the lupane family containing hydroxy groups linked in the biopolymer by ester and ether linkages, on the other hand. So, the application of different methods of depolymerisation to birch bark allows to support the hypothesis of the participation of some triterpenoids in the structure of the biopolymers.

The next step of the work will be concentrated on the determination of each detected compound and their quantitation. Moreover, in order to precise the arrangement of the monomers in the biopolymer, which may be a three-dimensional one as it is often the case in plant tissues, we will apply a combination of the different methods of depolymerisation, these methods will be then applied to contemporary birch bark tar and to series of archaeological samples.

A GC/MS Study of Deuteration in Imines

Michael J. Lee¹, Ross Mabon², Andrew J. Organ³ and Catriona Thom³

¹ Analytical Sciences and ³ CASS, SmithKline Beecham Pharmaceuticals, New Frontiers Science Park (North), Third Avenue, Harlow, Essex, UK CM19 5AW

² University of Strathclyde, Department of Pure and Applied Chemistry, Thomas Graham Building, 295 Cathedral Street, Glasgow, UK, G1 1XL

Deuterium exchange, in conjunction with mass spectrometry, has been widely used to determine both the number and position of acidic protons thus aiding structural elucidation¹. We would like to report the application of ion trap GC/MS and GC/MS/MS to identify by-products in the synthesis of the tropane amine **I**, a structural moiety found in some compounds with anxiolytic activity. The investigation revealed the presence of a range of related imines with general structure **II**. These imino impurities exhibited unexpected deuterium incorporation behaviour when the GC/MS analyses were repeated using deuterated methanol. The level of deuterium incorporation was proposed as being a result of imine - enamine tautomerism and a range of related imines were synthesised to ascertain the scope of this observation

I

II

The initial deuteration experiment was carried out on the tropane amine feedstock and confirmed the presence of two exchangeable protons. The proposed presence of the acetone imine which, unexpectedly, gave rise to six exchangeables was investigated further by synthesising the imine and repeating the exchange experiment. The acetone imine was successfully synthesised and, indeed, six exchangeable protons were observed. This phenomenon was

observed again with the corresponding cyclohexyl imine where four protons exchanged. It was proposed that the phenomenon was due to base catalysed imine-enamine tautomerism which is analogous to the more widely known keto-enol tautomerism.

The exchangeable protons were proposed to be those α to the imine double bond. In order to confirm this an imine without α protons was synthesised. The benzyl imine showed no change between the GC/MS spectrum of the sample in methanol and that of the sample in d₄-methanol.

In order to compare the rate of deuterium exchange permitted by imine-enamine tautomerism directly to that permitted by keto-enol tautomerism an incomplete reaction mixture containing cyclohexanone, the tropane amine **I** and the cyclohexyl imine were dissolved in d₄-methanol and a GC/MS analysis carried out. The results show quite clearly that under these conditions all the α protons on the imine have exchanged whereas none have exchanged on the cyclohexanone.

Conclusions

- ◆ Complete deuterium exchange can be observed on the α carbon in imine systems under GC/MS conditions.
- ◆ The rate of exchange for a keto-enol system has been shown to be much slower than that for a similar imine-enamine tautomerism.
- ◆ A polar ('Wax') type GC phase remains sufficiently deuterated after a single injection of d₄-methanol to allow several deuteration experiments to be performed on non deuterated samples, precluding the need for prior deuteration of precious samples.
- ◆ Understanding the exchange characteristics of imine systems has allowed us to make several structural assignments of low level components solely on the basis of GC/MS analysis.

Methylamine in Methane: Improved CI Reagent Gas for Molecular Weight Determinations

James L. Little
Eastman Chemical Company
Kingsport, TN 37662-5150

A mixture of 3% methylamine in methane is a superior chemical ionization (CI) reagent gas for most classes of organic compounds that contain a heteroatom. It was found to yield improved molecular weight information and less fragmentation than is obtained with more traditional CI gases and gas mixtures. The methylamine/methane mix was evaluated with a variety of classes of organic compounds such as amines, alcohols, ketones, aldehydes, amides, trimethylsilyl ethers, trimethylsilyl esters, acetals, etc.

The dilution of the methylamine in methane has two advantages. The first is a significant increase in sensitivity when compared to employing pure methylamine. The analogous increase in sensitivity was noted [Ref. 1] in mixing 1% ammonia in methane. We tested the use of 1% ammonia in methane and did note some increased sensitivity. However, we seldom employ this mix because pure ammonia is easier to obtain, forms no carbon build-up in the source, and gives adequate sensitivity to characterize low-level impurities noted in EI GC/MS analyses.

The second advantage of employing 3% methylamine in methane is decreased regulator contamination. Regulators are rendered unusable in 1-2 months employing pure methylamine. A "scum" collects on the diaphragm and seat of the regulator. The dilution of the methylamine in methane eliminated this limitation.

As the proton affinity of the amine in a methane mixture is increased, the CI sensitivity significantly decreases. This is because the proton affinity is not in the range required for reaction with a wide variety of organic compounds [Ref. 2]. We evaluated both methylamine and dimethylamine as mixtures in methane. The dimethylamine yielded less fragmentation for many compounds, but its sensitivity was lower and its chemical noise higher than 3% methylamine in methane. The overall response for methylamine in ammonia including fragmentation was less sensitive than ammonia in methane. However, the actual response for the molecular ion adduct was often larger in compounds that showed significant fragmentation. Indeed in many cases the molecular ion adduct was infinitely larger since no molecular ion adduct was noted with ammonia in methane (see Figure 1).

Multispectral Identification of Oxidation Products of Glycols and Glycol Ethers

John Glass Green, Jen-Hsiang Kao and Thomas Ross Britt
The Dow Chemical Company
Louisiana Division R&D B-2503
Plaquemine, LA 70765-0400

During the course of a study of oxidation of propylene glycol methyl ether, dipropylene glycol and dipropylene glycol methyl ethers, it was observed that under certain conditions a series of new compounds was produced. The complementary information obtained from GC/MS and GC/FTIR proved essential in the characterization of the compounds.

The feed mixture for the oxidation consisted mainly of propylene glycol methyl ether, two isomers of dipropylene glycol methyl ether and isomers of dipropylene glycol. The effluent from the reactor consisted of five main compounds. The earliest eluting product was identified as methoxyacetone. This compound would be expected from the oxidation of the alcohol group in propylene glycol methyl ether. The mass spectrum matched the library spectrum of methoxyacetone well. The vapor phase infrared spectrum had a carbonyl at 1739 cm^{-1} . This value is about 15 cm^{-1} higher than measured for condensed phase spectra.

The molecular weights of the next two peaks in the effluent chromatogram indicated that they were the ketones derived from the two main isomers of dipropylene glycol methyl ether. These two isomers and their expected oxidation products are shown in the two equations below. The mass spectrum of compound (2) exhibits a strong ion at m/z 101. The mass spectrum of compound (3) exhibits a strong ion at m/z 59. This difference defines the position of the methyl group on the C-C bond between the methoxy group and the central oxygen. Scission of this bond results in the m/z 101 ion for (2) and the m/z 59 ion for (3).

The GC/FTIR spectra of these compounds have carbonyls at 1737 cm^{-1} and 1739 cm^{-1} . These values agree well with that measured for methoxyacetone. The ratios of the intensities of the C-O bands in these compounds to the carbonyl intensities are greater than the corresponding ratio for methoxyacetone. This is consistent with the presence of two ether linkages and only one carbonyl group.

The molecular weight of the fifth compound was found to be 130 da. This is consistent with the molecular weight of the double oxidation product of dipropylene glycol. The most abundant isomer of dipropylene glycol is the one with two secondary alcohols. The following reaction shows the oxidation of the sec, sec-dipropylene glycol isomer.

Although most of the features of the mass spectrum fit the proposed structure for (5), further support was sought in the IR spectrum. The vapor phase spectrum has a carbonyl at 1741 cm^{-1} . The features of the spectrum are very similar to those for the other ketones except for the C-H region near 3000 cm^{-1} , which should be different because of the absence of methoxy groups.

The fourth compound was found to have a molecular ion at m/z 112. This molecular weight cannot be explained in terms of oxidation of one of the primary feed components. The mass spectrum matched almost exactly the spectrum of dehydromevalonic lactone, an α,β -unsaturated six-membered lactone. The IR spectrum, however, clearly ruled this structure out because of the carbonyl frequency. Compound (5) has a carbonyl band at 1716 cm^{-1} . Unsaturated lactones have bands at much higher frequencies in the range of $1760\text{--}1770\text{ cm}^{-1}$. The carbonyl frequency fits an α,β -unsaturated cycloalkanone much better. The product of an intramolecular aldol condensation of (5) fits the proposed structure. The following equation shows the proposed structure (4).

This compound fits the infrared and mass spectra. The IR spectrum has a band at 1646 cm^{-1} that is consistent with a double bond. The mass spectrum shows a loss of formaldehyde to give m/z 82.

This investigation illustrates the value of using GC/MS and GC/FTIR data together to solve structural problems that either alone could not.

Negative Ion Chemical Ionization/Collisionally Activated Dissociation Studies of Some Substituted Phenol Pentafluorobenzoates (Part II)

M.-Y. Zhang*, N. Molinaro, J. Cantone, T. Cinque, K. Chan and S. Sisenwine
Wyeth-Ayerst Research, CN8000, Princeton, NJ 08543

Electron capture negative ion chemical ionization (ECNCI) mass spectrometry has been extensively used in the quantitative analyses of metabolites, trace impurities and degradation products due to its low detection limits. However, many compounds of interest are not inherently electrophoric and must be converted to a suitable volatile derivative. Pentafluorobenzoyl derivatization is one of the most popular EC derivative methods for ECNCIMS analysis. The occurrence of an interesting fragment ion at [M-64]⁻ in the ECI mass spectra of derivatized chlorophenols was observed by Trainor et al. in 1987¹. In our previous presentation², ECNCIMS combined with collisionally activated dissociation was employed to study the site specificity and the mechanism of this elimination process on some aryl pentafluorobenzoates. The results suggested that the [M-64]⁻ ion was formed by the loss of CO₂ and HF from the molecular anion, and the majority of [M-HF, -CO₂]⁻ was generated from the specific loss of the ortho-H atom on phenyl and deuterio-substituted phenyl pentafluorobenzoates. No [M-HF, -CO₂]⁻ ions were detected in the spectra of the pentafluorobenzoates of orth-methylphenols. [M-HF, -CO₂]⁻ was only detected in the spectra of derivatized meta- and para-methylphenols. In this studies, this elimination process was further elucidated using 3,5,6-d3-2,4-dimethylphenyl pentafluorobenzoate. In addition, the collisionally activated dissociation of molecular anions of the following chlorinated and methoxylated phenyl pentafluorobenzoates were also investigated.

1. R₂=R₄=CH₃, R₃=R₅=R₆=D
2. R₂=R₆=Cl, R₃=R₄=R₅=H
3. R₃=R₄=Cl, R₂=R₅=R₆=H
4. R₃=R₅=Cl, R₂=R₄=R₆=H
5. R₂=R₄=R₆=Cl, R₃=R₅=H
6. R₂=R₆=OCH₃, R₃=R₄=R₅=H
7. R₃=R₄=Cl, R₂=R₅=R₆=H
8. R₃=R₅=OCH₃, R₂=R₄=R₆=H

The occurrence of [M-HF, -CO₂]⁻ ion in the ECNCI/CAD spectra of meta- and para-methylphenyl pentafluorobenzoates, but absence of this ion in the ortho-methylated phenyl pentafluorobenzoates were reported in our previous presentation². The CAD spectrum of molecular anion of 3,5,6-d3-2,4-dimethylphenyl pentafluorobenzoate showed two interesting ions of [M-65]⁻ and [M-36]⁻. The ion [M-65]⁻ and [M-36]⁻ were formed by the loss of DF and CO₂, and by the loss of HF and CH₂D from M⁻, respectively. The results further confirmed our previous observation, in which the simultaneously or stepwise elimination of HF and CO₂ from molecular anion was only proceeded by the specific loss of the ortho-H atom on the derivatized meta- or para-methylphenols, and did not proceed by loss of the hydrogen on the methyl group. Our previous results also indicated that the majority of the [M-HF, -CH₃]⁻ from methylated phenyl pentafluorobenzoates was generated from the specific loss of the ortho-CH₃.

The M⁻ of phenyl and methylated phenyl pentafluorobenzoates formed from ECNCI were quite stable, and only a few low intensity fragment ions were observed upon CAD². However, upon chlorination, the product ion of B₁ was observed as the based peak in the CAD spectra of all chlorinated derivatives studied here. The [M-HF, -CO₂]⁻ ions were observed in the product ion spectra of 3,4-dichloro and 3,5-dichlorophenyl pentafluorobenzoates. No [M-HF, -CO₂]⁻ ions were observed in the product ion spectra of the molecular anions of 2,6-dichloro and 2,4,6-trichlorophenyl pentafluorobenzoates. The results demonstrated that the elimination of 64 amu (HF and CO₂) from M⁻ only proceeded by the specific loss of the ortho-H. The ion of [M-Cl, -CO₂]⁻ was only observed from 2,6-dichloro and 2,4,6-trichlorophenyl pentafluorobenzoates. The data suggested that this elimination was

formed by the specific loss of the ortho-Cl atom. The parent ion spectra of the [M-CO₂, -Cl]⁻ showed that the majority of this ion was formed from [M-Cl]⁻, suggesting the favorable loss of the ortho-Cl atom on the phenyl ring.

The [M-HF, -CO₂]⁻, [M-H₂F, -CO₂]⁻ and [M-HF, -OCH₃]⁻ ions were observed in the product ion spectra of all dimethoxylated phenyl pentafluorobenzoates studied here. The [M-HF, -CO₂]⁻ ion from the meta- and para-methoxylated derivatives were produced by the specific loss of ortho-H on the phenyl ring. However, the [M-HF, -CO₂]⁻ ion from ortho-methoxylated derivatives might produced by the loss of hydrogen on the ortho-methoxy group, and this ion might have structure with a six-member middle ring instead a four-member middle ring. The ion [M-HF, -CH₃]⁻ was a major product in the CAD spectra of 3,4- and 3,5-dimethoxyphenyl pentafluorobenzoates, and this ion was not observed in the CAD spectrum of 2,6-dimethoxyphenyl pentafluorobenzoates. One possible explanation was that the ortho-methoxy substituent on the aromatic ring might decrease the bond strength between the carbonyl group and oxygen. So, [B₁]⁻ was enhanced to be the most intensive product ion, and [M-HF, -CH₃]⁻ became too weak to be detected.

[M-HF, -CO₂]⁻ ion could be formed through a "tight complex"³ transition state, and [A₁]⁻ and [B₁]⁻ ions could be generated by a single bond cleavage through a "loose complex" transition state⁴. The collision energy effect on these two competing dissociation reactions were investigated at two different energy levels. The results indicated that at both collision energies, the dissociation through a "loose complex" transition state produced more product ions ([A₁]⁻ or [B₁]⁻) than that ([M-64]⁻) formed through a "tight complex" transition state. This phenomena was due to the steric requirement of forming a [M-64]⁻ ion⁴. For the formation of [A₁]⁻ or [B₁]⁻ ions, the dissociation can take place whenever sufficient energy accumulates. On the other hand, for the [M-64]⁻ formation, the energy requirements must be met at the same time that bonding distance for forming a new bond. However, when decreasing the collision energy, the ratio of [M-64]⁻/([A₁]⁻+ [B₁]⁻) was significantly increased. As indicated by F. McLafferty⁴, the amount of product ions formed through a "loose complex" are often more sensitive to the internal energy change than that through a "tight complex" in certain internal energy region. When decreasing the collision energy from 20 eV to 10 eV, the abundance of [A₁]⁻ and [B₁]⁻ decreased much faster than that of [M-64]⁻, so the ratio of [M-64]⁻/([A₁]⁻+ [B₁]⁻) increased. The substituents on the phenyl ring also effect the formation of these ions. The electron donation substituent, such as methyl group, enhanced the rearrangement-dissociation reaction; and the electron withdrawing substituent, such as chlorine group, enhanced the single bond cleavage reaction.

Heparin Sequencing by Chemical Depolymerization Combined with MALDI Analysis

Susan M. Wolf and Klaus Biemann, Department of Chemistry, MIT, Cambridge, MA, 02139-4307

Introduction. Heparin and heparan sulfate are highly sulfated linear polysaccharides composed of repeating units of 1-4 linked D-glucosamine and hexuronic acid residues. The anticoagulant activity of heparin has been linked to a specific ATIII-binding pentasaccharide sequence (1), and it has been postulated that a number of heparin's other important functions may also be attributable to the activity of a limited number of subsequences or perhaps even to single unique structures (2,3). We have developed a sequencing method which combines nitrous acid or free radical-mediated depolymerization of sulfated oligosaccharides with MALDI analysis of the resulting sequence-specific products. In all cases, products have been detected as their complexes with a basic peptide, (RG)₁₅, as previously described (4). It is anticipated that this approach will prove useful for the sensitive and reliable sequencing of biologically significant heparins.

Experimental. For nitrous acid depolymerization, an HNO₂ reagent solution was prepared by dissolving solid NaNO₂ in 0.5 M formic acid to a concentration of 2×10⁻³ M and allowing the solution to stand for ten minutes prior to use. 2 μL of this reagent solution were then combined with 2 μL of a 5-7 pmol/μL solution of sulfated oligosaccharide in water and the reaction was allowed to proceed at room temperature (21-22°C). At t = 0, 10 and 20 minutes, a 1 μL aliquot of the reaction mixture was removed and combined with 1 μL of a matrix solution (prepared by combining 8 μL of a saturated solution of caffeic acid in 30% ACN with 1 μL of 0.1 g/L (RG)₁₅). For Cu⁺/H₂O₂ depolymerization, 1 μL of 20 pmol/μL sulfated oligosaccharide was combined with 1 μL saturated CuCl in water and 1 μL 1% (v/v) H₂O₂ in water and the reaction mixture was heated to 48°C. At t=0, 15 and 30 minutes, a 1 μL aliquot of the reaction mixture was analyzed by MALDI using the thin film method of Xiang and Beavis (5). The matrix solution was prepared by combining 8 μL of a saturated solution of caffeic acid in 30% ACN 10 mM dibasic ammonium citrate with 1 μL of 0.1 g/L (RG)₁₅. All MALDI spectra were acquired in the linear mode using a PerSeptive Biosystems Voyager Elite reflectron time-of-flight instrument outfitted with a nitrogen 337 nm laser.

Results. When conducted at pH≤2, the nitrous acid reaction involves nitrosation of the N-sulfate group of D-glucosamine followed by glycosidic bond cleavage with concomitant conversion of the D-glucosamine to 2,5-anhydro-D-mannose (6). In the case of ISMS-3, which contains a repeating unit of Ido2S-GlcNS6S and an anhydromannitol "reducing terminus", the two expected tetrasaccharide deamination products differ by only 2 Daltons. A peak observed at Δ1076.6 Da, midway between the masses of these two products, indicates that both may be present (Figure 1b). In addition, peaks due to the expected "ring contraction" (RC) side products (6) are observed at 97 Da lower than the protonated complex. It has been found that the products of this reaction can be sampled directly by MALDI without further cleanup and without the need to reduce the anhydromannose residues to anhydromannitol. Disaccharide products, which do not complex as effectively with (RG)₁₅ as the larger more highly sulfated products, are not observed to any great extent. In the Cu⁺/H₂O₂ reaction, hydroxy radicals cleave heparin substrates to give products that retain the native heparin structure (7). Figure 1c shows the results obtained for the depolymerization of ISMS-3 by this method. The reaction conditions employed, optimized to allow for MALDI analysis of products at the low picomole level, represent a modification of the Cu⁺/ascorbate/H₂O₂ approach previously reported. To the best of our knowledge, the mechanism of this reaction has not been elucidated.

INTRODUCTION

In a recent review of the application of ms to the analysis of natural and synthetic sulfated oligosaccharides, results obtained with both FAB, ²⁵²Cf-PDMS, lonspray and MALDI were presented [1]. These techniques could all be used to characterize synthetic variants of the minimal pentasaccharide sequence of heparin, exerting antithrombin III mediated anti-Xa activity. It is now reported that both lonspray and MALDI are especially advantageous for the analysis of extreme complex synthetic oligosaccharides such as those with large number of sulfates and/or those with high molecular masses. These novel compounds are the result of the rational design of synthetic glycoconjugates with tailor-made coagulation factor inhibitory activity. They comprise a unique antithrombin III binding pentasaccharide domain linked via a linear spacer to a thrombin binding sulfated oligosaccharide [2]. In this report, lonspray and MALDI results obtained for the octadeca-sulfated deca-saccharide Org 36611 are presented.

RESULTS AND DISCUSSIONS

The flow injection lonspray analysis of highly sulfated synthetic oligosaccharides like Org 36611 is complicated by the presence of the sodium counterions and resulting spectra cannot be used to calculate molecular masses unambiguously. LC-MS desalting with a tetrapropylammonium formate ion pair (TPA) is only possible in combination with post-column membrane ion suppression and re-addition of TPA after the suppressor as was reported before [3]. Now we report flow injection analysis using a Dionex anion membrane suppressor combined with post-suppressor addition of NH₄OH. The lonspray(-) result obtained with Org 36611 (Fig. 1) shows that the molecular mass could be measured unambiguously (4145 Da) despite the presence of a series of adducts. Without NH₄OH addition a pronounced and repeated loss of SO₃ was observed in the lonspray(-) spectra.

Of these novel oligosaccharides also non-covalent complexes could be formed with basic oligopeptides, e.g. peptides with a high arginine content as in (RG)₁₀, according to a recently published MALDI procedure [4]. With this approach sodium is displaced completely as can be seen in Fig. 2. The MALDI(+) spectrum of Org 36611 shows a ternary cluster at m/z 8443.7 (Org 36611 with 2 icosapeptides) which corresponds with a molecular mass of 4142 Da.

A combination of MALDI and flow-injection lonspray ms is favoured for routine ms analysis of these novel, highly sulfated synthetic oligosaccharides as both ms techniques are highly complementary and these mass spectra can rapidly be obtained.

³Nihon PerSeptive Ltd., Minato-ku, Tokyo, Japan

We recently described a procedure for the derivatization of oligosaccharides with 4-aminobenzoic acid 2-(diethylamino)ethyl ester (ABDEAE) which can be detected at very low levels by ESI¹ or MALDI-MS². The ABDEAE-derivatized oligosaccharides showed a dramatic increase in molecular ion abundance over free oligosaccharides, as well as those derivatized with 2-aminopyridine (PA) and 4-aminobenzoic acid ethyl ester (ABEE). Sample clean-up is an important issue, since excess reagent in a reaction mixture used for chemical derivatizations often suppresses the ionization of the derivatized sugars. The ABDEAE derivatization involves reductive amination using a 1000-fold excess of the agent, ABDEAE/HCl. The ABDEAE derivative can be cleanly separated from the other reagents in the derivatization reaction by reversed-phase (RP) column, a procedure which allows the elution of the ABDEAE derivative in front of excess reagent.¹

In order to enhance the utility of the ABDEAE derivatization, a simple and rapid method for the purification of ABDEAE-derivatized oligosaccharides has been developed using normal-phase resin (Poros 20 NH, PerSeptive Biosystems) packed in the upper part of a 1.5 mL-Ultrafree-MC cartridge tube (Millipore). The method allows rapid removal of excess reagent and other non-sugar impurities from the reaction mixture by elution with acetonitrile. The procedure involves loading of the reaction mixture, dissolved in 75 % acetonitrile-water, elution of impurities with acetonitrile, and finally, elution of the oligosaccharide derivative with water, an aliquot of which can be used directly for MALDI-MS. (Fig. 1)

Figure 2 shows the reverse-phase (RP) HPLC profiles of a reaction mixture of maltohexaose after derivatization (top), an acetonitrile eluate from the resin, after loading the reaction mixture onto the cartridge tube (middle), and the water eluate from the resin (bottom). More than 95% of the excess reagent was eluted from the resin with acetonitrile, along with unknown non-sugar by-products. The derivatized oligosaccharide was recovered from the resin by elution with water in greater than 80% yield as estimated from the corresponding peak areas obtained at 310 nm. The results show that normal-phase resin such as Poros-20NH allows a rapid removal of the excess reagent from an ABDEAE-reaction mixture. Finally, the ABDEAE maltohexaose contained in the water-eluate was directly examined by MALDI-MS (Voyager-Elite, PerSeptive Biosystems) and could be detected at the 100 fmol level, although the sensitivity decreased by one order of magnitude in comparison with that obtained for the RP-HPLC-purified derivative². The most likely explanation for this is contamination by salts (largely NaCl) in the water eluate.

Introduction

Differentiation of oligosaccharide isomers by mass spectrometry is a challenging task and often requires preliminary steps of derivatization. Permethylation (PME) and peracetylation (PAC) are useful for production of significant fragment ions and for increase in sensitivity.¹ Used as a gas-to-solid phase method,¹ PAC requires minimal amounts of the substrates in order to produce derivatives that give rise to informative mass spectra. The specific objectives of this study are to differentiate trisaccharide isomers by LSIMS, MS/MS and MALDI-TOFMS and to compare the usefulness of PME and PAC for isomeric discrimination

Methodology

The compounds investigated in this study are the pairs of isomers 3- and 2'-fucosyllactose (3-fl, 2'-fl) and 6'- and 3'-sialyllactose (6'-sl, 3'-sl). PME was performed according to Larsson and co-workers.² For PAC, the gas-to-solid phase reaction method¹ was used. The amount of trisaccharide subjected to PAC varied between 500 pmol and 10 nmol. LSIMS experiments were conducted with a JEOL HX110/HX110 (E1B1-E2B2) tandem mass spectrometer, with Cs⁺ as the primary ion beam. For MS/MS experiments, 7 keV collisions were effected with helium in a cell located between E1B1 and E2B2. Linked scans of MS2 at constant B/E values were performed. MALDI-TOFMS spectra were obtained with a modified Vestec VT2000 (Perceptive Biosystems) linear system. A nitrogen laser (Laser Science Inc.) with radiation at 337 nm was used. The matrix used was 2,5-dihydroxy benzoic acid. The Hyperchem Molecular Visualization and Simulation software (Hypercube Inc.) was used for structure optimization. MM+ molecular mechanics force field and the Polak-Ribière parameters for geometry optimization yielded the structures discussed below.

Results

MALDI of the native compounds. Fucosyllactoses (fls) produced [M+Na]⁺, [M+K]⁺ ions and sialyllactoses (sls) gave rise to [M+Na]⁺, [M+K]⁺, [M-H+2Na]⁺ and [M-H+2K]⁺ ions. Although the two latter types of ions allowed for easy recognition of sialic acid, no differences were found between the spectra of isomers. **MALDI of the permethylated (PME) compounds.** Only [M+Na]⁺ and [M+K]⁺ ions were observed and the spectra of isomers were undistinguishable. **MALDI of the peracetylated (PAC) compounds.** The fl isomers produced [M+Na]⁺ and [M+K]⁺ ions and as in the case above, the spectra of isomers were undistinguishable. In the case of 3'- and 6'-sl, differences were observed and are shown in the spectrum of Figure 1. **LSIMS and MSIMS of the native compounds.** With the fl isomers, there were differences in the relative abundances of [M+H]⁺, B₂ vs. Z₂, C₂ ions. In the case of the sls, B₂ ions were more abundant for 3'-sl than 6'-sl. **LSIMS and MSIMS of the PME compounds.** The fl isomers gave rise to different spectra, notably with respect to B₁, B₂ and Y₂ ions. In the case of sls, the spectra of isomers were similar to each other. **LSIMS and MSIMS of the PAC compounds.** PAC fls yielded more mass spectral differences between isomers than the native and PME compounds. Discrimination was possible based on the relative abundances of [M+H]⁺, B₁ and B₂ ions and also on Z₁ ions, at m/z 559.2, which were observed in the spectra of 3'-fl only. The sl isomers produced ions with different m/z values for [M+H]⁺, [M+H]⁺ and B₂ due to lactonization of 3'-sl. The prime (') symbol refers to loss of a ROH residue; R = H for native compounds, R = CH₃ for PME compounds, and R = C(O)CH₃ for PAC compounds.

Discussion

Native sls. The Hyperchem-generated structures of ions protonated on N of sialic acid suggest that fewer H-bond interactions are possible for 3'-sl than 6'-sl between B₂-residues (Neu5NAc-Gal) and Glc, thus favoring B₂ fragmentations in the case of 3'-sl. More H-bonding seems to keep B₂-cleavages at a lesser rate.

PME fls. Hyperchem structures have been calculated for ions whose relative abundances are significantly different from one spectrum to the other (m/z 219.0, 393.1, 444.1). Energy differences between protonated molecular ions and fragment ions were evaluated, and no significant differences were found from one isomer to the other. Fragmentation mechanisms favoring production of B₁ fragments from rupture of C₁-O bonds are possibly involved.

PAC fls. 2'-fl produces abundant B₂ ions at m/z 561.2, while 3-fl produces Z₁ ions at m/z 559.2, emphasizing again that formation of fragment ions via cleavage of C₁-O bonds is favored. Most abundant ions are formed from these cleavages. C₄-O cleavages produce ions with lower abundance.

PAC sls. Hyperchem representations of the non-lactonized and lactonized forms of 6'-sl and 3'-sl suggest that lactonization increases strain on 6'-sl molecules by ca 20 kcal/mol more than in the case of 3'-sl. The results therefore are consistent with the spectra of Figures 1 and 2.

Conclusions

Where a very limited quantity of material is available, mass spectra of PME and PAC derivatives can potentially provide more structural information than those of native analogs. The nature of the information obtained is complementary from one type of derivative to the other. PAC is the most efficient method used in this study for discriminating between fl and sl isomers. The Hyperchem calculations were useful for the comparison of stabilities of lactonized vs. non-lactonized ions but gave very limited information on the processes linked to fragmentation.

Introduction

The rat kidney contains a large variety of sulfated glycosphingolipids in addition to the two well-known sulfated glycosphingolipids, galactosylceramide sulfate (SM4) and lactosylceramide sulfate (SM3). Since 1982, we have isolated seven novel sulfated glycosphingolipids belonging to the ganglio- and isoglobo-series core structures. In most cases, the content of the glycosphingolipid is low, and purification and complete characterization are cumbersome and time-consuming. The developments in mass spectrometry, as well as the availability of soft ionization like FAB and LSIMS, have made it possible to analyze underivatized glycoconjugates. We have explored the use of LSIMS and CID for the analysis of underivatized sulfated glycosphingolipids. We report that several homologous sulfated glycosphingolipids, when analyzed by CID, formed product ions that reflect structural differences in the position and number of sulfate esters.

Experimental

SM2a, SM2b, SB2 and SBla were purified from rat kidney and SMla was prepared by solvolysis of SBla. SMlb was isolated from mouse small intestine. LSIMS was carried out on a CONCEPT IH (Shimadzu/Kratos) in the negative ion mode with cesium gun (14KV). The matrices used were triethanolamine and 3-nitrobenzyl alcohol. The B/E constant linked scan spectra were obtained after CID with air. The negative LSIMS were also run on a TSQ 70 (Finnigan MAT) equipped with a cesium gun (20KV). Low energy CID was performed with a 10eV collision energy and 1.5mTorr of Ar.

Results and discussion

In the negative LSIMS, each mono-sulfated glycosphingolipid gave abundant $[M-H]^-$ ions and each bis-sulfated glycosphingolipid gave abundant $[M+Na-2H]^-$ ions as well as the hydrogen sulfate anion $[HOSO_3]^-$. In high energy CID of the deprotonated molecule, only ions containing a sulfate ester were clearly observed (Fig.1). When a sulfate was present on the non-reducing terminal saccharide residue, a series of ions corresponding to sulfated

mono- to tetra-saccharides, resulting from sequential cleavage of glycosidic bonds, was observed. If the sulfate was attached to an internal hexose of the sugar chain, the product ions corresponding to the non-sulfated, non-reducing terminal residue were absent. In contrast, the low energy CID resulted in extremely simple spectra that contained only one or two major product ions characterized each sulfated glycosphingolipid (Fig.2). These results provided clear information on the overall sugar and ceramide compositions, and allowed saccharide structures differing in location and number of sulfate esters to be distinguished.

Fig. 1. The region of high energy CID spectra containing the saccharide product ions for three sulfated glycolipids of gangliotetraose core with their respective CID schemes. The deprotonated molecules formed by LSIMS, $[M-H]^-$ 1435 for SMla (A), $[M-H]^-$ 1451 for SMlb (B) and $[M+Na-2H]^-$ 1537 for SBla (C), were selected as the precursor ions. The product ions at m/z 680 (A and B) and 782 (C) were produced by the cleavage of the glucose ring linked to the ceramide.

Fig. 2. Low energy CID product ion spectra of (A) SMla, (B) SMlb, and (C) SBla. The precursor ions are $[M-H]^-$ at m/z 1435 for SMla (A) and 1451 for SMlb (B), and $[M+SO_3H]^-$ at m/z 1435 for SBla (C).

Highly sensitive structure analysis of oligosaccharides

Yingming Zhao, Jun Qin, Brian T. Chait

The Rockefeller University, 1230 York Avenue, New York, NY 10021

During positive ion MALDI, a sample molecule containing basic groups ionized relatively efficiently by protonation reactions. Neutral and acidic oligosaccharides lack basic groups and are usually ionized with lower efficiency by alkali metal cationization (when small amount of salts are present). The resulting low sensitivity of oligosaccharides limits the application of the MALDI for structure analysis of oligosaccharides. A variety of derivatization methods for oligosaccharides have been developed to increase the sensitivity of mass spectrometric analysis. Most of these methods use reductive amination, a procedure involving formation of a covalent linkage by the reduction of a Schiff adduct between a primary amine and an acyclic aldehyde form of the oligosaccharide. The derivatization can provide a basic moiety for protonization during ionization.

Here, we report a new method for derivatization of oligosaccharides in which a bulky, readily ionized basic aminoxy acetyl peptide is conjugated to the sugar. The resulting glycoconjugates were found 50-1000 times more sensitive than underivatized oligosaccharide in MALDI-TOF MS. For the 15 oligosaccharides that we have analyzed using our new derivatization procedure, sensitivities were found to be in the 2-10 fmol range. The reaction yield is determined to be about 95% by HPLC.

There are several approaches available for sequence analysis of oligosaccharides. One of the most commonly applied involves sequential removal of monosaccharide residues from oligosaccharides using arrays of exoglycosidases with known specificities. Here we demonstrate this strategy to be highly effective and sensitive when used to determine the structures of oligosaccharide that have been derivatized by our new method.

Sensitivity Enhancement after derivatization

Carbohydrates	A1	A2F	LSTa	NA2FB
Underivatized (fmol)	600	3000	10000	100-300
Derivatized (fmol)	10	10	10	2
Signal Enhancement (fold)	60	300	1000	50-150

FABMS (LSIMS), ESIMS and CID-MS/MS, as Guiding Tools in Glycoconjugate Synthesis

Introduction

A series of glycopeptides were synthesized to study epitopes of certain proteoglycans¹⁾. Products were analyzed by NMR and mass spectrometry (MS). The latter analytical method was, at least in this particular case, more efficient at confirming structures and the completion of deprotection of final products. GlcA-Gal-Gal-Xyl, a common O-glycosyl sugar unit of proteoglycans, was synthesized and coupled with a tetrapeptide GSGE for preparation of the O-glycosylated carbohydrate-peptide region. Simple glycopeptides Xyl-(GSGE) and Gal-Gal-Xyl-Ser with sugar-chain analogs were also prepared and used to verify fragmentational hypothesis for more complex glycopeptides.

Samples and Methods

Samples synthesized and studied here are shown in Fig. 1, where 1 and 2 are tetra- and monosaccharide-tetrapeptide while 3~7 are series of oligosaccharide-serine analogs. FAB (LSIMS) and ESI mass spectra were obtained using a triple stage quadrupole mass spectrometer (ThermoQuest TSQ 700). For the FAB(LSIMS) measurements the primary beam was xenon (cesium ion for LSIMS) at 8 kV, and the collision gas was argon at 20-30 eV at 0.15 Pa. Glycerol and triethanolamine were used as the matrix for the positive-ion and negative-ion mode, respectively. In the ESI measurements, the samples were dissolved in methanol or methanol/water, and the potential difference was -4 and 3 kV for the positive-ion and negative-ion mode, respectively. CID-MS/MS measurements were taken in the same way as the FAB(LSIMS) spectra.

Results and Discussion

1. Usefulness of CID-MS/MS to check completion of deprotection

A tetrasaccharide-tetrapeptide GlcA-Gal-Gal-Xyl-(GSGE) conforms the core structure of serine-linked cell-surface proteoglycans, and believed to participate in a variety of biological processes. In an intention to study the role of such proteoglycans, glycopeptides covalently bound to serine were synthesized and characterized by spectral methods. Thus synthesized tetrasaccharide-tetrapeptide GlcA-Gal-Gal-Xyl-(GSGE) (1), which was apparently deprotected according to NMR analysis, showed $[M + 84 + Na]^+$ at m/z 1087 in addition to the expected $[M + Na]^+$ at m/z 1003 with the respective protonated ions on the (+)FAB mass spectrum, where "M" stands for the exact molecular weight of the free acid. A similar set of ions 84Da apart were detected in the negative ion mode as well. The (+)FAB CID-MS/MS spectrum of $[M + 84 + H]^+$ at m/z 1065 showed similar series of reducing side sequence ions down to the Pen-tetrapeptide at which point the interval to the next lower ion was 84Da larger than the normal pentose residue, suggesting the presence of extra substituent(s) in this moiety. Product ions representing the tetrapeptide and constituent amino acids were the same as for the normal product. The mass increment of 84Da was also observed in the lower analog "Xyl"-tetrapeptide (2). This 84Da may be accounted for by either two acetyl groups or one pivaloyl group of unremoved protective groups,

however, the former possibility was ruled out by the fact that (-)ESI CID-MS/MS of [(Xyl-tetrapeptide) + 84 - H]⁻ showed a loss of 100Da, which coincides with a 2,2-dimethyl- β -lactone derived from the pivaloyloxy unit. After careful reexamination of deprotection conditions, the 84Da increment in the molecular weight of xylosyltetrapeptide disappeared. Thus, MS was a sensitive means to examine completion of deprotection.

2. Sequence information of the sugar chain by CID-MS/MS

Starting from elimination of GlcA, down to the sodiated tetrapeptide, the (+)FAB CID-MS/MS of $[M + Na]^+$ showed a series of Y ions, thus verifying the tetrasaccharide structure. The presence of a product ion at m/z 479 signifies that the sugar directly linked to the peptide is xylose.

3. Analyses of oligosaccharide-serine analogs (3~7)

A sequence of five synthetic oligosaccharide-monoserines (3~7) showed consecutively heavier molecular weights by LSIMS. In particular, their positive CID-MS/MS spectra yielded abundant fragment ions indicating the serine residue. Conversely, negative CID-MS/MS spectra showed almost exclusively fragment ions of the nonreducing end of the saccharide chain. The CID-MS/MS spectra also showed the expected sequences of oligosaccharides, indicating that the attachment site of serine is xylose because of the presence of Xyl-Ser fragment ion. Furthermore, a difference was observed in the relative ion intensity in the LSIMS CID-MS/MS spectra between compounds 5 and 6, in which the non-reducing terminal disaccharide is α - and β - linked, respectively. However, distinguishing epimers such as compounds 6 and 7 (GalNAc α - vs. GlcNAc α -) at the nonreducing end is presently not feasible.

Structural Analysis of Chromophore Labeled Disaccharides by Liquid Chromatography/Mass Spectrometry

D. T. Li and G. R. Her

Department of Chemistry, National Taiwan University, Taipei, Taiwan, R. O. C.

It has been recognized that mass spectrometry may be used as universal and sensitive detectors for high performance liquid chromatography, but it is only recently that LC/MS is considered a routine technique mainly due to the development of powerful LC/MS interfaces such as ESI and APCI. HPLC has been a fundamental tool for the separation and recovery of carbohydrates. In the present study, disaccharides were labeled with ABEE(p-amino benzyl ethyl ester) and then analyzed by HPLC/ESIMS with in source CID. The merits of this approach in the structural analysis of disaccharides including glycosidic linkage, anomeric configuration, and monosaccharide composition are discussed.

Disaccharide were labeled at the reducing end with ABEE by amination rather than reductive amination because it was found that the maintaining of a close ring structure was crucial to the determination of glycosidic linkage by CID. Many ring cleavage ions were observed and these ions provided unambiguous assignment of the linkage as shown in Fig. 1. and table 1. The analysis of four ABEE labeled glucose disaccharides by LC/MS is shown in Fig. 2. Two anomers were produced for each disaccharide, thus a total of eight peaks were observed. Ions at m/z 368, 260, 263, 236 which represented 1-2, 1-3, 1-4, and 1-6 linked disaccharides were selected for the construction of mass chromatograms. The similarity between total ion current (Fig. 2b) and UV trace (Fig. 2a) suggested that the interface had little effect to the resolution of HPLC.

The relative abundance of fragment ions appeared to be sensitive to anomeric configurations. The m/z 221 ion was the base peak for 1-6 α linked disaccharides whereas the m/z 179 ion was the base peak for β linked disaccharide. Similar phenomena was observed for 1-4 linked disaccharides, the m/z 221 ion was the base peak for α linked disaccharides, while the most abundant peak was the m/z 248 ion for β linked disaccharides.

Difference in fragment ion intensity was observed for disaccharides of same linkage, same anomeric configuration but different monosaccharide composition. Unfortunately, we were unable to draw any conclusion because of the lack of many disaccharide standards. Consequently, in order to make a complete structural assignment, the retention time (or relative retention time) is needed along with the information provided by in source CID.

STABILISATION OF OLIGOSACCHARIDES CONTAINING SIALIC ACIDS FOR EXAMINATION BY MALDI

Andrew K. Powell and David J. Harvey,

Oxford Glycobiology Institute, Department of Biochemistry, South Parks Road, Oxford, OX1 3QU, UK.

Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry of sialylated sugars and gangliosides is normally accompanied by loss of sialic acid, particularly when α -cyano-4-hydroxycinnamic acid is used as the matrix. In addition, the signal is split as the result of both positive and, to a greater extent, negative ion formation, leading to weak spectra, particularly in the positive ion mode. In order to stabilise the sialic acid moieties under MALDI conditions and to convert all of the signal into the positive ion mode where it could be recorded with that of the neutral oligosaccharides obtained from mixtures, a method for converting them into methyl esters has been developed. This technique proved to be superior to permethylation as the reaction was quantitative, avoided the need to remove sodium salts and only produced a mass increment of 14 mass units for each sialic acid present. Derivatives possessed the additional advantage that multiple peaks produced by alkali salt formation, were absent

The acidic oligosaccharides (10 pmole - 200 pmole), obtained from glycoproteins by hydrazinyolysis, were first converted into their sodium salts by the use of an AG-50 ion exchange resin and were then reacted for 2 hours with methyl iodide in dry dimethylsulphoxide. After removal of the methyl iodide by evaporation, the sample was dried onto the mass spectrometer target with the matrix [2,5-dihydroxybenzoic acid (2,5-DHB) or α -cyano-4-hydroxybenzoic acid]. Samples were examined with a Micromass AutoSpec magnetic sector mass spectrometer fitted with an LSI nitrogen laser and an array detector, and with a Thermo Bioanalysis LaserMAT linear time-of-flight instrument.

Methyl ester formation from the free acid required 48 hours for completion whereas preparation from the sodium salt was essentially complete within 2 hours. The reaction appeared quantitative and produced strong positive ions $[(MNa)]^+$ from all compounds examined. Negligible loss of sialic acid was observed where, in the absence of methylation, quantitative sialic acid loss occurred. Fig. 1 shows the MALDI mass spectrum of human serum transferrin before (top) and after (bottom) methylation. Minor peaks in the lower spectrum are due to in-source glycosidic fragmentation and provide considerable information of the detailed oligosaccharide structure.

Fig. 2 shows a similar pair of spectra from sugars from bovine fetuin. Major peaks are from the carbohydrates shown with the profile corresponding closely to those obtained by other techniques. Minor peaks are produced by in-source fragments.

The ganglioside G_{D1a} , containing two sialic acids also gave an abundant molecular ion, even with α -cyano-4-hydroxy-cinnamic acid as the matrix. The method was also used to profile the range of fucosylated monosialo-biantennary oligosaccharides from the human parotid gland.

Figure 1. - Positive ion MALDI mass spectrum of the disialo-biantennary oligosaccharides (200 pmole) from transferrin recorded with the magnetic sector instrument from 2,5-DHB. (a) Before methylation (b) after methyl ester formation. Key to monosaccharide residues in the structures - $\square$ = galactose, $\circ$ = mannose, $\blacksquare$ = N-acetylglucosamine (GlcNAc), $\blacklozenge$ = sialic acid.

Figure 2. - Positive ion MALDI mass spectrum of the di-, tri- and tetra sialo-oligosaccharides (total 200 pmole) from the bovine fetuin recorded with the magnetic sector instrument from 2,5-DHB (a) before methylation (b) as methyl esters. Symbols are as shown in Fig. 1.

Analysis of Complex Sugars in Synthesis

George R. Dubay*, John Debenham, Robert Rodebaugh, and Bertram Fraser-Reid, Department of Chemistry, Duke University, Durham, NC, 27708-0347

Leguminous root nodules are the largest sole source of nitrogen fixation in the world. In these bacteria a series of lipooligosaccharide nodule factors are secreted that stimulate the plant to begin root nodule formation. To study the mechanism of action of these key oligosaccharides, a large synthetic program here at Duke focuses on developing general methods for the preparation of oligosaccharides and these nodule factors, in particular. Synthetic strategies require the use of bulky aromatic functional groups to control reactivity of the hydroxyls and amines present. Coupling of the sugars requires specific reaction at the sites of oligomerization which can be strongly affected by adjacent amines and their derivatives. NMR is normally used to characterize di- and trisaccharides, but as the synthesis progresses and the complexity of the oligosaccharides increase, characterization using NMR becomes ambiguous even for some trisaccharides. In addition, the NMR spectra of small saccharides are difficult to interpret when rotomers are present.

Alternatively, TLC is frequently used to qualitatively evaluate the success and purity of reaction mixtures in oligosaccharide synthesis. Yet, the TLC was also ambiguous in many cases studied here because it is ineffective in separating the very large compounds. As the synthesis progresses, the utility of TLC to provide separation of mixtures becomes very limited. The value of TLC for characterization is very low since it does not have any molecular information. Thus, some other form of characterization is required.

Mass spectrometry has been used extensively for the analysis of oligosaccharides by a variety of techniques⁽¹⁾. Yet, most of this work is done on naturally occurring compounds or their simple derivatives which are generally quite polar. The derivatives are permethylated, peracetylated, or attached with cationizing metals or other reagents to improve the quality of the spectra. All these compounds are readily soluble in polar solvents such as alcohols, water, or mixtures which could include DMSO. This aids in the analysis significantly. The synthetic procedures used here require very bulky and nonpolar groups which make the oligosaccharides very insoluble in polar solvents. Thus, these compounds were found to be less amenable to techniques such as electrospray where their low solubility in polar solvents prevented routine analysis. In addition, mass spectrometry analysis with cationizing metals was found to decrease ion intensities on all compounds. Ion currents were so low those without phthaloyl derivatives were not observable with attached metal ions.

To characterize the heavily protected oligosaccharides being prepared here, FAB-MS in the positive and negative ion modes was found to be very useful. The reaction products of disaccharides through pentasaccharides yield useful spectra with all the hydroxyls protected and molecular weights above 2200 daltons. Positive or negative ion FAB-MS for heavily protected compounds is our preference since it was successful for all compounds in this study. FAB-MS is easy to perform, sensitive, and allows use of nonpolar solvents which are necessary to dissolve the very highly protected and lipo-containing sugars being prepared in this project.

To determine the success of protection, deprotection, and coupling reactions, our goal was first to provide rapid analysis with high sensitivity, second to analyze reaction mixtures, third to determine the accurate mass of these sugars, and fourth to avoid multiple reactions in ion formation which make spectra very difficult to interpret. Since NMR and TLC are incapable of determining the success of many reactions, mass spectrometry became our major tool for evaluating the results of a reaction. Sensitivity is of particular importance since some synthetic procedures are done on solid supports where only picomole amounts of these compounds are present. We have successfully used FAB-MS to identify picomolar quantities of the oligosaccharides after release from the surface of the support. This demonstrates the high sensitivity available using this approach.

Key procedures developed here to protect amines use phthaloyl and tetrachlorophthaloyl derivatives. Phthaloyl containing polysaccharides are not easily characterized for they undergo both proton addition and proton abstraction in the mass spectrometer under standard conditions for positive ion FAB spectra. Yet, when a small amount of lithium acetate solution is added, the $(M+Li)^+$ ion is observed in the mass spectrometer as the most abundant high mass ion. Thus, lithium addition is specifically useful for a these derivatives. When the tetrachlorophthaloyl(TCP) group was present, the lithium addition was not needed. The TCP containing compounds in negative FAB yield very strong ions for the M^- cluster ions and isotope patterns which are characteristic halogens present in the reaction products. This is found to be observed for all TCP compounds analyzed to date including those with other halogens on the molecule.

Sensitivity is particularly important to this study when performing reactions on the surface of solid supports. Oligosaccharides are bound at picomole levels on the surface of a solid support for reaction and then released. At these low concentrations analysis by NMR or other techniques is too insensitive to have any chance of identifying the analyte of interest. The FAB-MS yields significant ions for the oligosaccharides we have investigated at masses as high as 1600 daltons. This is extremely useful to the synthetic program for it allows rapid evaluation of the progress of the work which is not available from any other technique.

Elemental analysis of large oligosaccharides is very difficult for the solid will frequently contain some residual solvent that was used during the purification. This causes the determination of C, H, and N by combustion analysis to be inaccurate. We have found that using FAB and PEG mixtures of the appropriate mass distribution that the accurate mass measurement can yield the elemental composition within 5 ppm on most compounds we have studied. This is the only way currently available for the analysis for many of these compounds.

In summary, we are using FAB-MS to routinely analyze oligosaccharides in the molecular weight range from 400-2400 daltons. This work provides a rapid method which allows us to determine the synthetic success of a reaction, a determination of the relative complexity of a reaction mixture, and the accurate mass of isolated products.

A complex reaction mixture analyzed by positive ion FAB/MS Spectra clearly indicates incomplete reaction

Electrospray Ionization and Collision Induced Dissociation of
Oligosaccharides in the Negative Mode

Ye, S., Reinhold, Vernon., Costello, Catherine., and Bruce Reinhold

Mass Spectrometry Resource
Boston University Medical School
80 East Concord Street
Boston, MA 02118

Negatively charged ions can be generated from almost every type of oligosaccharide using electrospray ionization. For those containing carboxylic acid, sulfate or phosphate groups, negative ions are generated primarily by deprotonation. For oligosaccharides containing neutral or weakly basic groups (e.g. N-acetyl), ionization can occur by either deprotonation or anion adduction (e.g. Cl^- , SO_4^{2-}). Electrospray ionization of maltoheptaose is examined with respect to sensitivity, clustering and ionization mode. Fragmentation pathways by low energy collision of anionic species contrasts markedly with what is observed by proton or metal ion adduction in the positive mode. Linkage specific fragments, previously reported for deprotonated disaccharides by electrospray ionization and low energy collision [1], are also observed with anion adducted ions. The product ions of anion adducted oligosaccharides in large do not retain the anion, hence the CID (collision induced-dissociation) spectra of doubly deprotonated, doubly chloride adducted or singly sulfate adducted samples are essentially the same. Identification of various structural details by tandem MS in the negative mode is discussed for a range of structures including neutral oligosaccharides (disaccharides, maltoheptaose), oligosaccharides with weakly basic groups (LNT, LNFP-II) and acidic oligosaccharides (rhizobium octasaccharide). The important role of a free reducing end in the fragmentation pathways is also considered by examining the alditol of maltoheptaose and a cyclic glucose oligomer.

MULTIPLE NEUTRAL ALKALI HALIDE ATTACHMENTS ONTO OLIGOSACCHARIDES IN ELECTROSPRAY IONIZATION MASS SPECTROMETRY

André M. Striegel,¹ Judy D. Timpa,² Piotr Piotrowiak,¹ and Richard B. Cole^{1*}

¹Department of Chemistry, University of New Orleans, New Orleans, LA 70148 USA

²Late of USDA, ARS, Southern Regional Research Center, New Orleans, LA 70179 USA

Oligosaccharides perform essential functions in a variety of biological and agricultural processes. Recent approaches to characterization of these molecules by mass spectrometry have utilized mainly soft-ionization methods such as electrospray (ES) and thermospray (TS), as well as fast atom bombardment (FAB). The behavior of a series of maltooligosaccharides with α -(1 $\rightarrow$ 4) linkages, maltose (G_2) through maltoheptaose (G_7), under ES conditions has been investigated here. The oligosaccharides were dissolved in *N,N*-dimethylacetamide containing lithium chloride (DMAC/LiCl), prior to analysis by ESMS. A highly unusual feature, evident in all mass spectra obtained using this solvent system, was the presence of multiple "neutral" salt attachments onto lithium adducts of the sugars. Resultant ions took the form of $[G_x + Li + nLiCl]^+$ (Figure 1), and $[2G_x + Li + nLiCl]^+$, where G_x represents the oligosaccharide molecule G comprised of x α -glucose oligomers, $2G_x$ represents a non-covalently bound sugar dimer, and n may reach values as high as eight. The neutral attachments were observed to the highest extent with LiCl, and to a lesser extent with LiBr, but not at all with LiF, NaCl, KCl, or CsCl. Due to the exceptional stability of LiF, the lithium adduct ion was not observed in solutions containing oligosaccharides mixed with this salt.

MNDO (modified neglect of differential overlap) semi-empirical computer modeling was performed to optimize the geometry of the Li^+ cation with respect to the maltose molecule (G_2). Relative stabilities, based on calculated heats of formation (ΔH_f), indicate that coordination of lithium to maltose seems to be trivalent in nature. Moreover, no single conformation of overwhelming relative stability was found (i.e., coordination may be ring-bridging, but not necessarily). This proposed trivalent coordination contrasts with the previously postulated tetravalent attachment of lithium to other disaccharides such as gentiobiose, lactose, and laminarbiose.

The lack of $[Li(LiCl)_n]^+$ salt clusters in ES mass spectra of DMAC/LiCl solutions in the presence or absence of dissolved oligosaccharides, as well as the observation of neutral LiCl attachments in the spectra of both maltoheptaose and β -cyclodextrin (the cyclic analog of maltoheptaose), are considered as evidence against the presence of LiCl salt clusters, and against the possibility of direct oligosaccharide attachment onto different size salt clusters.

Figure 1. Electrospray mass spectra of 0.3 mM solutions of: a) maltose (G_2); b) maltotriose (G_3); and c) maltoheptaose (G_7); each in *N,N*-dimethylacetamide containing 0.01% lithium chloride.

IDENTIFICATION AND ANALYSIS OF FLAVONOIDS FROM HOPS (*HUMULUS LUPULUS*) BY HPLC-APCI-MS-MS

Jan. F. Stevens, Hoon-Joo Kim and Max L. Deinzer
Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331

In our studies of flavonoids from *Humulus lupulus* L., we have explored the utility of HPLC-APCI-MS-MS for the identification of flavonoids from the female hop cones which are used for beer brewing. Over the past decade, the use of thermospray [1], FAB [2,3,4], LSI [5], MALDI [6] and electrospray [6] in MS of flavonoids have appeared in the literature. This is the first report of the application of the APCI (atmospheric pressure chemical ionisation) source in the mass spectrometric analysis of flavonoids. Three types of flavonoids are known from hops: (1) prenylated flavonoids located in the resin, (2) flavonol glycosides and (3) proanthocyanidins, also referred to as condensed tannins. We have focused our work on the first two monomeric flavonoid types. Knowledge of the flavonoid chemistry of hops is a prerequisite for studies of the natural resistance of this agricultural crop to herbivore pests and pathogens, and for studies of the impact of flavonoids on the flavour and stability of beers. Flavonoids constitute a class of plant polyphenolics with a variety of physiological and ecological functions, of which the attraction of pollinators and herbivore feeding deterrence are well-known.

Mass spectra were recorded on a PE Sciex API III+ triple quadrupole mass spectrometer. Microbore HPLC separations were achieved on a 1 x 250 mm 5µm RP-18 column with solvent gradients from H₂O-HCOOH (99:1) to MeCN. Hop resin flavonoids were separated from other resinous constituents by Sephadex LH-20 column chromatography. An aliquot of the purified mixture of flavonoids was analysed by LC-MS in the positive ion (PI) and the negative ion (NI) mode. In the NI mode, post-column adjustment of the pH was not necessary and therefore omitted. Seven prenylflavonoids were identified by the combination of MS, UV and NMR (Fig 1; compounds 2, 3, 6 and 7 have not been reported from hops before). Loss of the prenyl substituent is the main fragmentation pathway in PI-APCI-MS. This fragmentation type can be used to distinguish between 6-prenylflavones and their 8-prenyl isomers since prenyl loss from the 6-position occurs at an orifice voltage of 55V but not from the 8-position. On collisional activation, prenyl cleavage takes place regardless of the position of the prenyl group. Subsequent retro Diels-Alder (RDA) fission gives rise to an intense A-ring derived ion (Fig. 2). Because chalcones readily isomerise into their corresponding flavanones, distinction between both flavonoid types is not possible. Fortunately, they are distinguishable by (on-line) UV spectroscopy. In contrast to prenyl loss in PI-APCI-CAD mass fragmentation, the prenyl substituent remains intact on NI collisional activation. Instead, the pseudomolecular ion undergoes RDA fission leaving the negative charge on A and B-ring fragments.

Glycosides of flavonols and related phenolics from hops show prominent [MH]⁺ and protonated aglycone (Y₀⁺) ions in their PI-APCI mass spectra. O-Diglycosides also give Y₁⁺ ions arising from loss of the terminal sugar unit followed by hydrogen rearrangement. Malonylated glycosides yield additional [MH-CO₂]⁺ ions as a result of loss of carbon dioxide from the malonic acid residue. (Fig. 3). As the flavonoid glycosides from hops are exclusively derived from two flavonols, kaempferol and quercetin, precursor ion scanning offers a specific method for the detection of each of the glycoside series. Tandem mass spectrometry proved also useful for the identification of the aglycone part of glycosides in plant extracts. To this end, the Y₀⁺ ions were collisionally activated at higher voltage, typically 30V. In flavonol glycosides, the CAD mass spectrum of the Y₀⁺ ion shows RDA fragments and ions arising from loss of H₂O and CO molecules. So far, we have identified six flavonol glycosides in hops, i.e. the rutinosides, glucosides and malonylglucosides of kaempferol and quercetin. The malonyl glucosides have not been reported from hops before.

Fig. 1. LC-APCI-MS (Q1) profile of purified hop resin flavonoids recorded in the positive ion mode. Xanthohumol is the principal flavonoids of hops.

Fig 2 Positive ion APCI-CAD mass spectrum of 3'-geranyl-2',4',6',4-tetrahydroxychalcone.

Fig. 3. Positive ion LC-APCI mass spectrum of quercetin-3-malonylglucoside recorded in the precursor ion scan mode (Daughter = Y₀⁺ ion at m/z 303).

MALDI MS Investigations of Complex Oligosaccharides from Human Milk

A. Pfenninger, U. Bahr, M. Karas*

Div. of Instrum. Analyt. Chemistry, JWGoethe University,
Theodor-Stern-Kai 7, 60590 Frankfurt, Germany

B. Stahl, B. Finke, G. Sawatzki

MILUPA GmbH&Co KG, Research Int.; 61381 Friedrichsdorf, Germany

Neutral and acidic oligosaccharides isolated from human milk have been investigated using MALDI MS; large-size neutral OS have been detected extending beyond 8 kDa in mass with a highly variable stoichiometry (1). The analysis of the acidic fraction was aggravated by the occurrence of metastable fragmentation resulting in substantial loss of sialic acid as well as of fucose residues. Whereas this fragmentation occurs essentially in a metastable time frame - and would therefore only affect reflectron TOF measurements - experiments for a test sample (Disialo-Lacto-N-tetraose) proved that with enhanced laser fluence this fragmentation is occurring on a shorter time scale and becomes "prompt" and is therefore also showing up in linear TOF analysis. Therefore an investigation was started addressing the important parameters affecting this fragmentation and the following were selected for inspection: the nature of the quasimolecular ion, role of matrix and matrix additives, the initial extraction field strength. Even though the fragmentation which prominently occurs by loss of sialic acids appears to be straightforward, some focus was given to develop a simple and unified fragmentation scheme accounting for the observed phenomena.

For TOF mass analysis a PerSeptive Voyager RP was used. Metastable fragmentation was identified and attributed by selecting a precursor ion, mass assignment and identification was done by one PSD measurement, but all further results were obtained in the normal reflector mode without using the PSD routine. 2,5-DHB was used as a matrix with and without the addition of hydroxyisquinoline (HIC), water was used as a solvent without any addition of cations. Experiment were done in positive ion mode, because negative-ion mass spectra are obscured by metastable fragmentation, especially because the neutral sugar originating from the loss of sialic acids is not observed.

The first observation was that all the different quasimolecular ions of the disialylated test sample (MH^+ , $(M+Na)^+$, $(M-H+2Na)^+$, $(M-2H+3Na)^+$) exhibited a different fragmentation pattern. The fact that in general a contribution of neighbouring quasimolecular ion is found can only to some extent be attributed to a limited resolution of the precursor ion selector and the very high relative intensities of the strongly fragmenting precursor ions. Based on these measurement a very simple fragmentation scheme is deduced which exclusively regards the loss of 291, the

incremental sialic acid. This implicitly means that the triply sodiated species does not fragment from its own, but has to switch to the doubly sodiated channel in a first step. This would suggest a chemical-equilibrium like interchange of the quasimolecular ions existing in the initial ion-neutral plume by exchange of sodium against protons presumably by collisions with reactive matrix species. The existence of such an equilibrium is further substantiated by the observed mass spectra. In most cases all quasimolecular ions showed up irrespective which ion was selected - but, as pointed out, very different fragmentation patterns were obtained. Moreover, reduced ion-extraction field strength, which results in a reduced fragmentation degree in the case of sialylated glycopeptides and -proteins, has the opposite effect in the case of sialo-oligosaccharides, which is further promoted by increasing the laser fluence. This can be rationalized within the equilibrium model by an increase either in the effective reaction time or in the density of the emitted ion/neutral cloud. On the other hand the use of HIC as a matrix additive does not result in significant differences in the metastable fragmentation behaviour.

These observations may give some guideline for future experiments. It may be suggested that a higher ion stability which would be desirable for molecular mass mapping purposes is achieved in a different matrix system lacking the strong protonation ability which is very useful for peptide and protein analysis and thus defining a successful matrix. On the other hand, the latter matrices may be further used and optimized for structural analyses based on the PSD methodology.

Characterization of a *Haemophilus* Carbohydrate Epitope Expressed as a Chimeric LPS in *Escherichia coli*

Bradford W. Gibson, Nancy Phillips, Jeffrey Engstrom, and Michael A. Apicella

Department of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143 and Department of Microbiology, University of Iowa, Iowa City, Iowa 52242

Haemophilus influenzae is a pathogenic bacteria that is known to express an array of complex surface glycolipids (or lipooligosaccharides, LOS) that mediate aspects of the disease process such as cell adhesion, cell invasion and immune evasion. The appearance of these carbohydrates as part of the surface LOS molecules is regulated by a number of different gene clusters. One such gene cluster has been isolated as a large DNA fragment and incorporated into a plasmid, pGEM3Zf+, and its DNA sequence revealed the presence of a number of open reading frames that likely encode proteins and enzymes required for aspects of lipooligosaccharide biosynthesis. In an attempt to understand the function of these genes, we have transformed several mutant *E. coli* strains, which make a small truncated lipopolysaccharide (LPS) containing only a core oligosaccharide, with *Haemophilus* DNA-containing plasmids constructed from the original pGEM3Zf+ plasmid. Subsequent mass spectrometric and immunochemical analyses of the LPS from these transformed *E. coli* have shown that they now make larger LPS which can also be recognized by monoclonal antibodies to the original *Haemophilus* LOS. Therefore, these transformed *E. coli* strains make true chimeric LPS molecules.

One of the difficulties in the characterization of these new chimeric LPS is the complexity of their oligosaccharide components and their larger masses ($MW \geq 2,000$), which makes sequencing difficult by high-energy tandem LSIMS on a four sector instrument, a method we have used successfully in previous studies for LPS-derived oligosaccharides with masses less than 1600-1800 Da. Therefore, in this study we have departed from our initial LSIMS-based strategy and are now using both ESI and MALDI techniques to obtain molecular weights, relative molecular ion abundances, and sequence data of this complex set of LPS-glycoforms. Two crucial concerns we had in carrying out this work were our ability to determine relative LOS amounts and to assign branching patterns of the oligosaccharides in an unambiguous manner, as we did not know how these novel chimeric LPS molecules would be constructed.

ESI-MS of the oligosaccharide pools from the wild type *E. coli* called pGEM and two variants pGEMLOS-5 and pGEMLOS-4 revealed the extent of the heterogeneity underlying LOS biosynthesis (Figure 1). Additions of small oligosaccharide components onto the pGEM LPS core structure were evident in the shifts to higher mass peaks in the pGEMLOS-5 and pGEMLOS-4 oligosaccharide spectra. A minimum of two hexose and two N-acetylhexosamine units were added onto the 4Hep4Hex1KDO core and pGEMLOS-4 carried an additional Hex or HexNAc residue. Composition analysis showed these monosaccharides to be GlcNAc and Gal. In studies to determine if MALDI-TOF under post source decay conditions can be used to assign oligosaccharide structures, a single major dephosphorylated oligosaccharide from *Salmonella typhimurium* Ra LPS ($M_{\text{exact}} = 1665.54$ Da) was analyzed in positive mode to form a singly sodiated species, $(M+Na)^+$ at 1688.5, and gave numerous fragments throughout the mass range that could be correlated with the expected Ra-oligosaccharide structure. We are currently evaluating positive-ion PSD, therefore, for the sequencing of the pGEM oligosaccharides, both as their sodiated adducts, as well as with other cations such as calcium.

Acknowledgments: Financial support was provided by NIH (AI24616). We also acknowledge support for the UCSF Mass Spectrometry Facility (RR01614), and are grateful to Dr. Arnie Falick for helpful suggestions and PerSeptive Biosystems for access to their Voyager Elite MALDI-TOF instrument.

Fig. 1. Negative ion electrospray mass spectra of the oligosaccharide mixtures from pGEM, pGEMLOS-5 and pGEMLOS-4. The heterogeneity is evident in the complexity of all three spectra, although some of this is due to the formation of both doubly and triply charged ions. The increase in mass due to the addition of oligosaccharide units onto the pGEM core structure is seen by the shift to higher mass regions in the spectra for pGEMLOS-5 and pGEMLOS-4. Species B represents the core structure of 4Hex4Hep3Phos1KDO and the extended glycoform appears as Species E, with two galactose and two glucosamine residues apparently being added to an acceptor. Species carrying an additional hexose or hexosamine are also seen in the pGEMLOS-4 spectrum.

N-GLYCAN STRUCTURE OF A SMALL PROTEOGLYCAN DECORIN

Yoshinao Wada, Yoshiko Nakayama and Jianguo Gu

Department of Molecular Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health (BOSHI), 840 Murodo-cho, Izumi, Osaka 590-02, Japan.

Introduction

A fluorescence-labeling, pyridylation, is an excellent derivatization for separating oligosaccharides by HPLC with high sensitivity. A combination of reverse-phase and amide-adsorption chromatography makes it possible to identify more than 100 kinds of different oligosaccharides. We have previously reported ESI-MS of pyridylaminated (PA) sugar chains (Biol. Mass Spectrom. 23:212, 1994). Herein we incorporate MALDI-TOF-MS into the pyridylation-based methodology and characterize the heterogeneity of the N-glycan structure in decorin, a small proteoglycan with 36 kDa core protein and a single glycosaminoglycan chain. This protein has three potential sites of N-glycosylation.

Experimental

Sample Preparation:

Decorin was prepared from bovine tendon. Whole protein was treated with hydrazine and pyridylaminated. Resulting PA-sugar chains were separated from other small degradation products by gel filtration. For the analysis of oligosaccharides of glycopeptides, Endo-Lys-C digest of carboxymethylated decorin was separated by reverse-phase LC, and the glycosylated peptides were collected. Glycopeptides were then analyzed by MALDI-TOF-MS, or subjected to hydrazinolysis and pyridylation.

HPLC of PA oligosaccharides:

PA sugar chains were separated by an ODS column under ammonium acetate buffer pH 4.0 with a gradient of n-butanol and detected by fluorescence (Ex.320 nm and Em.400 nm).

Mass Spectrometry:

MALDI-TOF mass spectra were acquired with a Finnigan Vision 2000 instrument (nitrogen laser, 337 nm). Targets were loaded with 0.3 μ l of sample matrix and the same volume of sample (1 pmol/ μ l in water or water/acetonitrile/TFA=70/30/0.1). In most cases, DHBs, a 9:1 mixture of solutions of 2,5-dihydroxybenzoic acid (DHB, 10 mg/ml) and 2-hydroxy-5-methoxybenzoic acid (HMD, 10 mg/ml), gave a good result for both PA oligosaccharides and glycopeptides.

Results

More than fifty kinds of PA oligosaccharides, which can be separated each other by reverse-phase and amide-adsorption HPLC, are now available. Reverse-phase chromatogram of PA sugar chains from whole decorin molecule is shown (right figure). Peak intensity correlates with the abundance of the molecule.

High-mannose type structures I and II, and complex type ones VI-IX were easily

Conclusion

Based on a high sensitive HPLC method for separating more than a hundred kinds of PA oligosaccharides, MALDI-TOF-MS is a good auxiliary technique to delineate structural heterogeneity of N-glycosylation.

determined by HPLC and MS (off-line).

We then focused on the peaks III, IV and V. MALDI-TOF-MS determined their molecular weight 1677.6, 1661.5 and 1499.6, respectively. MALDI-TOF mass spectrum of peak III is presented (left figure).

Subsequently, we performed exoglycosidase digestion followed by reverse-phase HPLC. Oligosaccharide III was susceptible to β -galactosidase digestion, and the resulting sugar was identical to IV. Both IV and V were susceptible to α -fucosidase and β -N-acetylhexosaminidase. These results, in together, suggested hybrid type structures (left scheme). The structures were finally confirmed by proton NMR.

Similar analyses carried out on the separated glycopeptides identified uneven distribution of these heterogeneous structures among three N-glycosylation sites (bottom figure).

A concentration of 0.4 pmol/ μ l of PA oligosaccharides was definitely sufficient for MALDI-TOF-MS in this study.

DETECTION OF A NON-COVALENT OLIGOSACCHARIDE ANTIGEN-ANTIBODY COMPLEX BY ESI MASS SPECTROMETRY

Abstract:

The molecular basis of protein antigen recognition by antibody molecules has been explored in numerous studies of immune responses to model antigens using physicochemical and immunochemical approaches. Recombinant antigen-binding (Fab) and variable (Fv) fragments are accessible through expression in bacterial systems. In this contribution electrospray mass spectrometry has been applied to study binding of a Salmonella lipopolysaccharide O-antigens to natural and recombinant antibody proteins. A single chain Salmonella antibody variable domain Fv protein, expressed in *Escherichia coli*, and a Salmonella Fab antibody fragment from a mouse monoclonal antibody were shown to undergo a clustering process with a hexadecasaccharide containing four repeating tetrasaccharide hapten units. The stoichiometry of the carbohydrate/protein complex was determined directly from the mass shift of the multicharged protein molecular ions in (+)ESI-MS.

The specificity of the carbohydrate antigen/antibody complex formation was investigated using substrates with alternate carbohydrate and protein structures. Immune response to Salmonella lipopolysaccharide antigen is dominated by epitopes involving 3,6-dideoxyhexoses. Using ESI-MS approach it can be demonstrated, that the change of stereochemistry at C-2 and C-4 in the 3,6-dideoxyhexose unit (tyvelose instead of abequose) abolishes the clustering process with the same antibody protein. If Shigella antibody protein component was incubated with the hexadecasaccharide Salmonella O-antigen, no clustering took place.

In this study the potentials of the mass spectrometric approach for analysis of carbohydrate antigen complexes with their respective antibody proteins are shown.

Strategy:

1. step: components
2. step: clustering
3. step: declustering
4. step: controls

Proteins:

Fv (single chain) antibody fusion protein Salmonella MW = 26276.8 Da

Fab antibody fragment Salmonella MW = 46853.1 Da

Fab antibody fragment Shigella MW = 48281.3 Da

Fig. (+)ESI mass spectra (a) from the single chain Salmonella antibody Fv fragment in 5 mM ammonium acetate (aq.); (b) the same protein after addition of hexadecasaccharide at the concentration of 10 pM/μl and (c) the same protein after addition of hexadecasaccharide antigen at the concentration of 20 pM/μl. A and B are the antibody and antigen/protein antibody complex, respectively. The numbers indicate the charge state. The calculated m/z values for A are 2190.7, 2389.8, 2628.7 and 2920.7 and for B 2609.8 and 2870.7.

METHYLATION ANALYSIS OF OLIGOSACCHARIDES REVISITED:

C/MS/MS OF PERMETHYLATED ETHYL-GLYCOSIDES

INTRODUCTION

Methylation analysis, which includes permethylation, hydrolysis, reduction, acetylation and GC/MS characterization of the resulting partially methylated alditol acetates, has a long tradition in carbohydrate chemistry. An alternative, simplified protocol was developed in which the oligosaccharides were permethylated, ethanolyzed and the resulting partially methylated ethyl-glycosides were deuteriomethylated prior to GC/MS/MS analysis. This approach presents the advantages of cleaving all types of sugar residues in one single step and of avoiding degradation of labile monosaccharides.

RESULTS AND DISCUSSION

The mass spectrometric analysis of the permethylated ethyl-glycosides was carried out in the chemical ionization mode using C_4H_{10} or $CH_4:N_2O$ (75/25) as reactant gas.

Under these conditions the protonated molecular ions decompose to a very large extent to yield fragment ions at m/z 219 ($[M+H-EtOH]^+$; B_1 ion) and m/z 187 ($B_1 - MeOH$). The B_1 ions of permethylated ethyl-glycosides selectively O- CD_3 labeled in position 2, 3, 4 or 6 were subjected to MS/MS analysis on a triple quadrupole instrument (precursor ion: m/z 222, collision energy: 5 eV). The resulting MS/MS spectra allowed immediate differentiation of 3- and 4-deuteriomethylated products from those labeled in position 2 or 6 (see Figure). In addition, the MS/MS analysis of the fragment at m/z 190 allowed clear distinction of all four types of substitution (2, 3, 4 and 6). In a first approximation, the fragmentation patterns are independent of the nature of the hexose residues (Glc, Gal or Man).

Furthermore, the systematic study of all possible di- and tri-substituted isomers showed that the fragmentation patterns observed were in very good agreement with those predicted from the data of the singly labeled products. This means that this method is a valuable alternative for the interglycosidic linkages analysis of oligosaccharides.

This approach was applied to the structure analysis of uronic acid containing oligosaccharides produced by the bacterium *Alteromonas* sp. and to glycans derived from glycoproteins. In the former case, uronic acid residues were first converted into hexopyranosides- d_2 by reduction of their methyl esters.

REDUCING END ANOMERIC CONFIGURATION OF Gal(β 1→4)GlcNAc-P-NITROPHENOL DERIVATIVES BY INCREMENTED COLLISION ENERGY ON AN ESI TRIPLE QUADRUPOLE

R. Singh¹, Betty Zhu², and R. Laine²

¹Department of Drug Metabolism, Central Research Division, Pfizer Inc, Groton, CT 06340

²Department of Biochemistry, Louisiana State University, Baton Rouge, LA 70803

OVERVIEW

Tandem mass spectrometry using ESI and low energy collision was used to discriminate between anomeric configurations of the aglycon on disaccharide-*p*-nitrophenol glycosides, and between thio- & oxy-*p*-glycosides.

Incremented collision offsets of 0 to (-)100 Volts in the collision cell of a TSO7000 Finnigan were plotted vs. daughter/parent ratio in a graph we term "Incremented Low Collision Energy Plot" (ILCEP).

Results may lead to nanomole MS methods for anomeric configuration of oligosaccharides.

INTRODUCTION

ESI-MS-QD-MS was used to discriminate among anomeric pairs of disaccharide glycosides and thio glycosides. The anomeric *p*-nitrophenol glycosides of 2-deoxy-2-acetamido-D-glucose (GlcNAc) were used as a receptor substrates for bovine milk (β4 galactosyl transferase) producing 3 novel compounds as follows:

- Galactosyl(β1→4)GlcNAc(β1→O)-*p*-nitrophenol
- Galactosyl(β1→4)GlcNAc(α1→O)-*p*-nitrophenol
- Galactosyl(β1→4)GlcNAc(β1→S)-*p*-nitrophenol

"Incremented Low Collision Energy Plot" (ILCEP), which depicts collision offsets on the abscissa vs. daughter to parent ratio on the ordinate^{1,2} were used to analyze anomeric pairs A and B, and the β-thioglycoside, β-oxyglycoside pair A and C.

In previous work on linkage position of oligosaccharides from our lab, rotational mobility of the glycosidic bond was related to the absorptive of the glycoconjugate collision energy^{2,3} using the ILCEP plot. It was our hypothesis that anomeric pairs should also be discernible by ILCEP, and we examined this approach using ESI, also applied to distinguish energy absorptive differences between β-oxyglycosides and β-thioglycosides.

METHOD

Sample solutions of 0.02 μg/μl in 1:1 water:methanol were infused at 50 μl/min into a Finnigan-MAT ESI source on a TSO7000 mass spectrometer. Collision cell pressure (Argon) was set at 2.5 mTorr to correspond with threshold fragmentation of Compound A. Capillary temperature was 200°C, capillary spray voltage 2.5 kV, spray current of 0.15 μAmp. Sheath gas (helium) pressure was 80 psi and auxiliary gas (helium) pressure 0.8 l/min. Resulting API pressure was 640 mTorr. Collision offset was incremented from 0 to (-)70 Volts to produce the ILCEP plots.

RESULTS

Compound B [Gal(β1→4)GlcNAc(α1→O)-*p*-nitrophenol], at a (-)10 Volts collision offset gave only the [MNA]⁺ ion at m/z 527 while compound A, its Gal(β1→4)GlcNAc(β1→O)-*p*-nitrophenol counterpart yielded 18.5% of fragment ion at m/z 286 (the disaccharide fragment ion)(Figure 1). The collision gas pressure was set to give threshold fragmentation with compound B cation. At a collision offset of (-)25 volts under the same collision gas pressure compound A was completely fragmented with the base peak at m/z 286, whereas compound B retained the molecular ion as the base peak at m/z 527 (Figure 2).

Incremented Low Collision Energy Plots for α and β Anomers

Gal(β1→4)GlcNAc(α1→O)-*p* NP

Incremented Low Collision Energy Plots for α and β Anomers

Gal(β1→4)GlcNAc(β1→O)-*p* NP

Gal(β1→4)GlcNAc(β1→O)-*p* NP

Gal(β1→4)GlcNAc(β1→S)-*p* NP

CONCLUSIONS

The β-anomeric *p*-nitrophenyl disaccharide cation was more fragile to collision induced fragmentation than its α-anomeric counterpart as measured by the plotted curves shown in Figure 3.

Preliminary information suggests that besides discriminating among terminal¹ and internal² collision Energy Plots (ILCEP),³ using nanomolar quantities, may be useful in assessing anomeric configuration.

The β-anomeric *p*-nitrophenyl disaccharide oxyglycoside cation was more fragile to collision induced fragmentation than its β-anomeric thioglycoside counterpart as measured by the curve shown in Figure 4.

Energy differences between thioglycoside and oxyglycoside cations of the otherwise identical compound may be discerned using ILCEP.

INTRODUCTION

Carnitine transports coenzyme A activated acyl groups across cell membranes.¹ Regular monitoring of carnitine concentrations is of clinical importance in the care of preterm infants and dialysis patients. Metabolic disorders have been associated with abnormally high ratios of acyl to free carnitine in the blood.² Since there are data to indicate a link between metabolic disorders and sudden infant death syndrome,³ routine screening of all infants could decrease the infant mortality rate. A method for the determination of free and acylcarnitine concentrations by GC/MS/MS using methane chemical ionization has been under investigation in this laboratory.⁴

Carnitines are derivatized to form N-t-butyldimethylsilyl (TBDMS) esters prior to analysis. The TBDMS esters of carnitine are quaternary ammonium compounds. Demethylation of the derivatized carnitine compounds, due to the thermal instability of the quaternary ammonium group, has been reported to occur in the injection port of the chromatograph.⁵

Free carnitine, with two hydroxyl sites for derivatization, can form both singly and doubly derivatized species. Additionally, injection port demethylation of the doubly derivatized free carnitine can occur by two pathways, resulting in two GC peaks. Since, the presence of multiple species would prevent accurate quantitation of free carnitine, the effects of temperature and concentration on the demethylation reactions were studied.

EXPERIMENTAL

All experiments were performed on a Finnigan MAT TSQ70 triple quadrupole mass spectrometer equipped with an octopolar collision cell in place of the second quadrupole, Q2. Samples were introduced into the ion source from a Varian 3400 gas chromatograph (GC) via a heated transfer line. The column employed for this study was a 30m, 0.25 mm i.d. open tubular DB5-MS temperature programmed from 140°C (one minute hold time) to 290°C at 20°C/min. The reagent gas was methane. The samples were derivatized by silylation to form N-t-butyldimethylsilyl (TBDMS) derivatives prior to analysis.

RESULTS

At very high concentrations, both singly and doubly derivatized free carnitine species are observed. Fortunately, at physiological concentrations, the singly derivatized species is not detected. The dominance of the doubly derivatized species at low concentrations may be attributed to a large excess of derivatizing reagent driving the reaction equilibrium.

The unique structure of the doubly derivatized free carnitine provides two pathways for demethylation to occur. The methyl group can leave directly from the nitrogen to yield the expected $[M+H]^+$ ion at m/z 376 (FIGURE 1a); however, demethylation can also occur by an intramolecular ring formation mechanism to yield an ion at m/z 318 (proposed structure shown in FIGURE 1b). The daughter spectrum of m/z 318 is shown in FIGURE 2. The unique daughter ion at m/z 147 (proposed structure shown in FIGURE 1c) supports the proposed ring structure. All other daughter ions are those characteristic of all demethylated TBDMS carnitine esters. At high concentrations of free carnitine both the m/z 376 and 318 ions were observed.

Experiments were performed to study the effects of concentration and injection port temperature on the relative abundance of the m/z 376 and m/z 318 ions. Data were collected for single-stage,

daughter, and selected reaction monitoring modes of operation. The overall signal increased as a function of the injection port temperature, with the relative percentage of m/z 376 exhibiting an inversely proportional relationship to the injection port temperature. The relative percent of m/z 376 was directly proportional to the analyte concentration. This effect suggests that the reaction is surfaced-induced. In the SRM mode, the relative percent m/z 376 was consistently less than two percent for all temperatures and concentrations examined.

CONCLUSIONS

Two pathways have been identified for the injection port demethylation of doubly derivatized free carnitine, with structures identified for both simple and intramolecular ring formation demethylation products. The relative abundance of the non-ring demethylated doubly derivatized free carnitine (m/z 376) was inversely dependent on the injection port temperature and directly dependent on the concentration of free carnitine analyzed. The intramolecular ring formation demethylation reaction dominated under the assay conditions, allowing quantitative determination of free carnitine in blood and plasma.

DEVELOPMENT OF STRATEGIES FOR LIPID A CHARACTERIZATION BY METHODS OF MASS SPECTROMETRY

Lipopolysaccharides (LPS) are a major constituent of the cell wall of gram-negative bacteria and are composed of a polysaccharide chain and a Lipid A moiety. Studies of biosynthesis and pharmacological activities of Lipid A, the active component of LPS, require complete understanding of its covalent chemistry. The structure of non-toxic diphosphoryl Lipid A from *R. sphaeroides* (Rs DPLA), a potent endotoxin inhibitor, has been reported a number of years ago [1]. The validity of the proposed structure has been recently disputed in the literature, based on the comparison of the natural product with the synthetic material [2]. In the present work, we have subjected this disputed structure to scrupulous mass spectral analysis, which has confirmed the originally proposed structure.

Molecular weight measurements of the three fractions of Rs DPLA have been performed by LSIMS (on a Concept IH two-sector mass spectrometer, Kratos Analytical, Manchester, UK) and by MALDI (on the KOMPACT III MALDI/TOF MS, Kratos Analytical, Manchester, UK and on the home-built quadrupole ion trap mass spectrometer [3]). There is a very good correlation between the measured molecular weights and the ones calculated based on the proposed structures [1].

Table 1. Molecular Weights of $[M + Na]^+$ ions of Rs DPLA.

fraction #	1 (a)	2 (b & c)	3 (d)
LSIMS (monoiso)	1576.6	1578.8	1580.5
MALDI/ITMS (monoiso)	1576.9	1579.2	N/A
MALDI/refTOF (average)	1578.5	1580.1	1582.4
calculated MW (monoiso)	1576.9	1579.0	1581.0
calculated MW (average)	1577.9	1579.9	1582.0

Figure 1. Proposed structures [1] of RsDPLA. $R_2' = \Delta^7\text{-C}_{14}$ (a,c), C_{14} (b,d); $R_4 = 3\text{KC}_{14}$ (a,b), C_{14}OH (c,d).

Figure 2. LSIMS (a) and MALDI/IT (b) spectra of Rs DPLA (fraction 2).

Figure 3. The high-energy CID spectrum of $[M + Na]^+$ ion (Rs DPLA, fraction 2)

The splits in the oxonium ion peak and the $^{0.4}\text{A}_2\text{Na}^+$ ion peak (Figure 2) suggest that two isomers of Rs DPLA are present in fraction 2. This hypothesis is further supported by the results of high energy CID experiments (Figure 3) performed on the $[M + Na]^+$ ions. The major fragments arise from the loss of one or both phosphate groups, and/or ester-linked hydroxy fatty acyl groups C_{10}OH . Both oxonium and $^{0.4}\text{A}_2 + \text{Na}^+$ fragment ions are present in the spectrum. Several internal fragments are present in the low-mass region of the spectrum. The fragmentation patterns for fractions 1 and 3 are also consistent with the earlier reported structures [1].

INVESTIGATION OF THE PRODUCTION OF cADPR AND cGDPR BY ADP-RIBOSYL CYCLASE USING ELECTROSPRAY IONIZATION LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY (ESI/LC/MS)

Bethanne M. Warrack*, Mark E. Hail, David W. Green and Paulina Wang
Bristol-Myers Squibb Pharmaceutical Research Institute
P.O. Box 4000, Princeton, NJ 08543-4000

Cyclic ADP-ribose (cADPR) has been identified as a mediator of intracellular calcium release via a mechanism independent of the inositol phosphate pathway (1). Since microsomal calcium release is believed to play a significant role in the cellular physiology of myocardial ischemia, we want to identify and characterize the proteins that interact with cADPR in cardiac tissue. The production of cADPR from nicotinamide adenine dinucleotide (NAD⁺) is catalyzed by the enzyme ADP-ribosyl cyclase (2). Three isoforms of this enzyme have been isolated from the sea snail *Aplysia californica*, where the abundance of the enzyme makes it a model system. It has been more difficult to identify and characterize the enzyme in cardiac tissue, primarily because NAD⁺ is readily converted to ADP-ribose (ADPR) with little, if any, cADPR accumulating. However, the guanine analogue of NAD⁺, NGD⁺, has been used as a substrate to demonstrate cyclase activity in rabbit heart membranes through the production of cGDPR, which presumably is hydrolyzed to GDPR more slowly than cADPR is to ADPR (3).

Here we describe the results of characterization efforts using a combination of infusion ESI and LC/MS techniques for the detection of cADPR, cGDPR, and the enzyme *Aplysia* cyclase. ESI/MS and ESI/MS/MS were used to confirm the presence of cADPR from rat heart and cGDPR from rabbit heart membranes incubated with NGD⁺. Fractions were provided in 0.25M ammonium formate, and diluted 1:1 with water prior to analysis. cADPR was detected in the mass spectrum with signal:noise 4:1; however, the product ion spectrum clearly confirmed the presence of cADPR or cGDPR in the fraction. The fragmentation observed is shown in Figure 1.

ESI/LC/MS was used to elucidate the origins of three isoforms of the enzyme (*Aplysia* cyclase) having the same apparent MW (29 kDa) by SDS-PAGE analysis and similar kinetic properties. These samples were isolated using an ion exchange chromatography purification procedure. Four fractions from the purification were subjected to ESI/LC/MS profiling. Each sample was expected to contain ~1 µg (30 pmoles) of protein in 50 µL. The samples were injected onto a protein trap (1 mm x 10 mm PLRP-s 4000 Å) and washed with 100 µL 98/2 H₂O/ACN/0.05% TFA prior to injection on the 0.5 mm x 50 mm PLRP-s 4000 Å HPLC column. Mobile phase composition was A=96/2/2 H₂O/ACN/acetic acid; B=73/15/10/2 ACN/n-propanol/ H₂O/acetic acid. Gradient elution from 20%- 95%B in 22 minutes was used. The flow rate was 20 µL/min. After analysis by ESI/LC/MS (see Figure 2 and Table 1), these isoforms, initially thought to be due to phosphorylation, appeared to be the result of C-terminal processing. These data highlight the utility of ESI/MS for the study of enzymatic processes involving both small and large molecules.

A HPLC-Bioassay PSD-MALDI Stratega for the Identification of Vasoactive Compounds

U. Bahr, M. Karas*, T. Russ

*Div. of Instrum. Analyt. Chemistry, JWGoethe University,
Theodor-Stern-Kai 7, 60590 Frankfurt, Germany*

J. Lou, H. Schlüter

Universitätsklinik Marienhospital, Nephrologisches Labor, 44625 Herne, Germany

Since diadenosine phosphates (AP5A and AP6A), isolated from human platelets have recently been identified to exhibit hormone-like blood pressure rising vasoactivity (1), the question was addressed whether these or related compounds may be present and active in other tissues, too. Thus, in the present study myocardial tissue (porcine) was inspected for the occurrence of diadenosine phosphates and other vasopressor substances

For this purpose the following strategy was applied: Vasoactive fractions were isolated from homogenized and deproteinized myocardial tissue after lyophilization by a dedicated HPLC scheme (several RP-, affinity-, and anion exchange chromatography steps). Vasoactivity was identified by UV-spectrometry testing for the presence of adenosine and by a bioassay, i.e. with a perfused isolated rat kidney. Finally, MALDI mass spectrometry was applied, a) for compound identification by molecular mass determination and b) for the confirmation of the structure by PSD fragment ion analysis.

For MALDI mass spectrometry a PerSeptive Voyager RP was used in positive reflector mode either for molecular mass analysis or in the PSD mode for fragment ion analysis of selected precursor ions. 3-HPA was used as a matrix in demineralized water at a concentration of 40 mg/ml, purification from salt contamination was accomplished by using ammonium-loaded cation exchange beads. For a more uniform crystallization and thus reduction of spot-to-spot intensity fluctuations an addition of β -octylglucoside proved to be useful.

Molecular mass determination yielded a mass of 757 Da for the MH^+ -ion which agrees well with the mass expected for AP3A. The PSD data of the protonated precursor ion exhibits a characteristic fragmentation pattern which is indicative for the supposed structure, AP3A (see Figure). In order to further confirm the structural analysis a AP3A reference sample was

investigated, which yielded an identical fragmentation pattern.

From the occurrence of AP3A in myocardial tissue, AP5A and AP6A in human platelets and of coenzyme A glutathione disulfide in adrenal gland, it is suggested that AP3A and related substances may be present in a broad range of different tissue and may be involved in other regulatory functions as well. Thus, the search for related substances and efforts towards a more detailed understanding of their physiological activity remain subjects for further investigations.

Trace detection of muramic acid, a bacterial chemical marker, in human body fluids.

D. Harrelson, K. Fox, A. Fox* and M. Krahmer*.

Dept. Microbiol. & Immunol. Univ. South Carolina Sch. of Med, Columbia, SC 29208.

This is the first report to employ gas chromatography-tandem mass spectrometry (GC-MS-MS) to study trace levels of muramic acid (Mur, or indeed any other microbial chemical) in a mammalian tissue or body fluid. Mur (3-O-lactyl glucosamine) is unique to the bacterial cell wall peptidoglycan (PG) but is not synthesized by mammalian enzyme systems. Mur thus serves as a chemical marker for the presence of PG. Unfortunately, the levels of PG (even in grossly infected mammalian tissues and body fluids) are so tiny that it has been extremely difficult to provide categorical proof of its presence. What little information is available is confusing and contradictory. This confusion has been primarily due to the use of non-mass spectrometric based detection methods.

It has been highly controversial as to whether Mur is present in normal tissues or body fluids. Clearly if Mur is present in "aseptic" tissues this raises the important question as to its origin. Mur has not been shown to be synthesized by mammals nor to be a structural component of any mammalian molecule. It is possible that Mur could be taken up from the gut or through the respiratory tract in "normal" animals but this remains unproven. If Mur is present at substantial levels in aseptic tissues this also negates the use of Mur as a marker for studying the presence of PG in infection. At the tiny levels that Mur has been reported to be present in mammalian tissues and body fluids it is absolutely essential to have unequivocal identification of Mur.

In the past, mass spectrometry studies of Mur have been limited to GC-MS. In order to increase sensitivity, selected ion monitoring was used. Only in those cases where high levels of Mur were present was it possible to obtain a mass spectrum. For example, in a 1980 report using GC-MS we noted the Mur peak (isolated by GC) found in spleens of rats previously injected with bacterial cell walls (70 µg/g wet weight of tissue) had an identical spectrum to that of standard Mur. Mur was detected at levels of 1 µg/g in joint tissue. However, at the low levels of Mur present in joints categorical identification provided by the mass spectrum was not possible. However, no peak was seen at the retention time of Mur in normal tissues used as negative controls.

In our current work, using a triple quadrupole instrument, multiple reaction monitoring was used to lower detection limits by removing extraneous peaks. Most importantly, using a GC ion trap MS-MS "absolute" identification of Mur (by daughter spectrum) in human joint fluids at trace levels was achieved.

Thirty three septic and aseptic human joint fluids were kindly provided by Bertil Christensson MD, PhD, University of Lund, School of Medicine. Mur was released from synovial fluids by hydrolysis in sulfuric acid and converted to an alditol acetate. Analyses were performed in multiple reaction monitoring mode by GC-MS-MS: VG Quattro triple quadrupole with Fison's 8000 GC series equipped with autosampler and a polar SP-2330 capillary column. Daughter spectra were obtained on a second GC-MS-MS: a GCQ ion trap MS with a Finnigan GC equipped with an autosampler and a non-polar DB-5MS column.

Mur was readily detected after GC separation in septic fluids using MS-MS as a highly selective

chromatographic detector. Mur was found to be eliminated over a period of several days *in vivo*. At the retention time for Mur, daughter mass spectra of peaks in synovial fluids were identical to standard Mur. Identification was at 1000 fold lower levels than in previous GC-MS identifications. The exquisite specificity of "daughter spectra" for trace identification of Mur is the gold standard for judging all past or future studies. Mur is not present in uninfected body fluids. Mur was not detected in 11 aseptic fluids. As expected, an additional synovial fluid from a patient with a fungal septic arthritis was negative for Mur. It is well established the fungi do not contain Mur.

In conclusion, use of GC-MS-MS allowed definitive identification of Mur in human synovial fluids at trace levels. There is a real need for further study of normal and infected animal and human tissues to determine precisely when Mur is present and at what levels. This could greatly help our understanding of the pathogenesis of sepsis as well as a number of diseases of unknown etiology where bacterial peptidoglycan is suspected to play a role.

Daughter mass spectra (A) Mur Pure (B) Mur (30 ng/ml) present in human joint fluid.

Determination of EDTA in Human Plasma by Ion Spray SRM-CE/MS

Robin L. Sheppard and Jack Henion, Analytical Toxicology, Diagnostic Laboratory, Cornell University, 927 Warren Drive, Ithaca, NY 14850

Capillary electrophoresis/mass spectrometry is still considered by some to be a non-routine analytical technique. While there are increasing applications of CE/MS appearing in the literature, there are few that quantitatively determine analytes in biological matrices in a routine manner. In this work, we will attempt to show that CE/MS can indeed be a rugged technique for the determination of low level analytes in complex matrices.

The analytical problem that we have selected is the determination of ethylenediamine-tetraacetic acid (EDTA) in human blood. While EDTA is a common additive to foodstuffs as a preservative or as a means of adding trace metals important for nutrition, we know of no published modern analytical method for determining the actual levels of EDTA nominally present in the human body. Another important use of EDTA is as an anti-coagulant for the preservation of blood samples. It was recently demonstrated in a prominent court case that a method for determining the relative concentration difference between EDTA-preserved blood and non-preserved blood can be forensically important.

There are several published CE/UV methods which demonstrate the utility of CE for the separation of EDTA and its metal chelates. However, some of the chelates are not detectable by UV absorbance. In addition, none of the methods were used for biological samples where the UV detection would most likely suffer from matrix interference without extensive sample clean-up. Therefore, we are working to develop a method that uses CE/MS with minimal sample preparation for the determination of EDTA at low levels in human blood.

This work was performed using both a Hewlett-Packard 3DCE instrument and an ATI Unicam Crystal CE Model 310 instrument. Mass spectrometry was performed on a PE-Sciex API 300 triple quadrupole instrument using selected reaction monitoring (SRM). The CE/MS interface is the self-aligning liquid junction with ion spray device developed in this laboratory. Sample preparation was automated on a Gilson ASPEC instrument using Ansys SPEC strong anion exchange extraction discs. The CE/MS method involves the complexation of EDTA with nickel and separation on a Supelco CElect Amine capillary with a pH 4 formate buffer. This strategy increases the method sensitivity by maximizing the ion current signal into a limited number of analyte peaks.

It was found that the lowest concentration samples could be analyzed by using relatively long duration (60s) electrokinetic injection. However, for this strategy to be applied to biological samples, the sample matrix must be cleaned-up to reduce the levels of the major ionic species. Therefore, a solid-phase extraction method was developed using strong anion exchange extraction discs (Figure 1). The most important step was to find an appropriate elution solvent that would not interfere with the electrokinetic injection. A mixture containing bromothymol blue in 50 mM trifluoroacetic acid was found to be suitable. The bromothymol blue is a higher molecular weight sulfonated compound which acts to displace the Ni-EDTA from the extraction disc. Because it has a high mass/charge ratio, it migrates more slowly than Ni-EDTA in the CE separation, and therefore has minimal interference on the electrokinetic injection. The trifluoroacetic acid lowers the pH to where the Ni-EDTA is most likely uncomplexed to form the free acid and Ni^{2+} cation. In the subsequent solvent evaporation of the sample eluate, the TFA is removed by evaporation. The Ni-EDTA is re-formed when the sample is reconstituted in dilute

ammonium hydroxide. The sample is then re-evaporated to remove excess ammonia and is then reconstituted in water.

For Ni-EDTA standards in water, this CE/MS/MS method provides a lower level of detection of 10 nmol/l (3.5 ng/ml) with good linearity over the broad concentration range of 10 nM - 60 μM (Figure 2). This approaches the best detection limit in the literature at 1 ng/ml in water which is obtained by sample derivatization GC/MS. In plasma extracts, the CE/MS/MS method has a lower level of detection of 100 nmol/l (35 ng/ml) as shown in Figure 3. There are no known literature reports of detecting EDTA in a biological matrix.

Our analyses of real human plasma samples have revealed no EDTA in heparin-preserved plasma. This is in contrast to the high levels of EDTA found in EDTA-preserved plasma. These results are shown in Figure 4.

We are grateful to Hewlett-Packard and ATI Unicam for their generous loans of CE instruments, PE-Sciex for partial funding and providing the API 300, Monsanto for their generous loan of the Gilson ASPEC instrument, and Supelco for providing some of the amine-coated capillaries. Thanks are due to the entire Henion research group, especially Tim Wachs and Melissa Anderson. R.S. would like to thank Xerox Corporation for this unique educational opportunity.

⁴Bionetics Corporation, NCTR, Jefferson, AR

Pyrolysis mass spectrometry (PyMS) with computerized pattern recognition (PRec) has been used for chemotaxonomy of bacteria. Its advantages include potential automated operation and rapidity of analysis, only 1 minute per analysis on an automated PyMS instrument. Reproducibility of PyMS spectra is essential, because typically, by PyMS, there are no signature ions for bacterial samples. The purposes of this work were (A) to evaluate the effect on reproducibility of variations in ① total sample mass introduced, ② Pyrolysis-wire sample coating consistency, and ③ synchronization between the beginning of pyrolysate introduction to the MS ion source and the quadrupole m/z scan timing; and (B) to remedy or ameliorate those factors which introduce variability into the resulting mass spectra.

To distinguish the effect of coating inconsistency from sample mass differences, a device capable of producing, by electrodeposition, many identically coated pyrolysis wires was designed. It not only identified significant troublesome factors but also enabled their control.

The device can handle up to 96 samples. The 8 × 12 matrix of electrodeposition wells was based on a Teflon cell culture plate (Berghof/America, Concord, CA). For the anode a 2 cm length of 0.25" o.d. stainless steel tubing was inserted into each well. The pyrolysis wire to be coated became the cathode. After filling each well with 0.25 mL of bacterial suspension, the device was capped with a second Teflon culture plate in which were located female electrical pins for positioning and electrically contacting each pyrolysis wire.

Procedure: A 20 hour culture of the non-pathogenic bacterium *Pseudomonas mendocina* was sampled from a standard soy agar plate. Enough cells were harvested so that, when mixed in de-ionized water in a 3 mL Pyrex vial, the suspension showed turbidity. 0.25 mL aliquots of this suspension filled several wells in the electrodeposition device. The device's cap was re-positioned, and a Curie point wire (510 °C) was inserted into each filled well. 18 VDC was applied for 15 minutes to the wires. The cap was then lifted and the wires were air dried.

After drying, each wire was sheathed in a protective glass capillary. This was mounted on the end of a probe and inserted into the vacuum lock. After 60 s of vacuum drying, the capillary was pushed into the pyrolyzer. After 15 s, MS acquisition over the range m/z 30 to 300 was started. 12 s later, pyrolysis was initiated for 5 s. Spectra averaged from the 9 or 10 scans acquired during pyrolysis were collected for pattern recognition using the RESolve PRec software program (Colorado School of Mines, Golden, CO).

Experimental Design: To assess the importance of sample mass, the portion of wire coated with bacteria was nipped to varying lengths of 1, 0.5, and 0.1 cm, representing bacterial masses of ~100, 50, and 10 ng, respectively. Replicate analyses at each mass were made, spectra were averaged. These data were then combined into a PRec file for comparison.

To assess the importance of sample smoothness, spectra of 9 electrodeposited samples were compared to those of 9 manually applied samples. (In the second case, bacteria were spread on the wire using a spatula, like buttering bread.)

To discover whether lack of scan/sample introduction synchronization was an important source of spectral variation, 10 identical electrodeposited samples were compared: 4 spectra in which pyrolysate introduction coincided with the beginning of a scan were combined with 6 in which the pyrolysate first entered the ion source at various other positions in the m/z scan.

Pattern Recognition: Data pretreatment steps included: ① normalization to total ion intensity (to compensate for analytical mass variations), ② autoscaling each ion intensity to a mean of zero and units of standard deviation (to increase the contribution of lower intensity ions), and ③ Fisher weighting (to increase the contribution of ions responsible for differentiating classes relative to those in which ion intensities varied randomly within classes).

Pattern Recognition consisted of calculating as many as 30 Principal Components of Variation (PCs), Canonical Variates (CVs), and non-orthogonal graphical rotation (autospin or AS) vectors. In the demonstration described below, cross-validation of sample identifications was conducted using the AS vectors. Two-D projections of sample locations in CV factor space were plotted to assess similarity between groups, reproducibility of the categorization process.

Results: The 2-D projections showed that all three factors, if not controlled, greatly exaggerate PyMS spectral variability. A strategy for controlling these effects was devised.

Demonstration: A test problem was set up to classify five different species using electrodeposition to ensure sample smoothness and mass consistency plus a change in the scans used to define the average spectrum. The first pyrolysate scan from each average was omitted, only the 9 later scans during which time pyrolysate influx decreased slowly were used. **Figure 1** is a 2-D projection in the plane of the first 2 CVs based on the first 12 PCs (91% of the sample variance). It shows factor spatial locations for: *Escherichia coli* (C), a hot spring *Bacillus* sp. (B), and three bacteria from the genus *Pseudomonas*: *P. aeruginosa* (A), *P. mendocina* (M), and *P. putida* (P). The symbols (0) are for *P. mendocina* samples run as unknowns. Classification of the 31 samples by AS vectors cross-validate with 97% correct.

Figure 1

Conclusion: Use of electrodeposition for sample application and an altered scan averaging procedure gave excellent results: i.e. 97% species-level classification, for the tested bacteria.

Identification of Flavonoids in Wine and Grape Products Implicated in Vasorelaxation Effects

D. Fries¹, R. O'Malley¹, P. Jantzen², D. Fitzpatrick³

¹ Department of Chemistry, University of South Florida, Tampa, FL

² Department of Pharmacology and Therapeutics, University of South Florida, Tampa FL

Introduction

Wine, primarily red wine, has been identified in several studies as having manifold physiological functions and effects. Wine consumption has been reported as having impact on platelet aggregation, blood lipid changes, and antioxidative activity. Concurrently, much media attention has been directed towards the studies of the so-called French Paradox which suggests that liberal French consumption of red wine products protects against coronary heart disease, in spite of consumption of saturated fatty acids, apparently by lowering cholesterol levels or preventing abnormal blood clots. Further investigation by Fitzpatrick et al.,¹ into the physiological effects of wine has revealed an endothelium-dependent vasorelaxing activity on precontracted rat aorta in vitro by components in wine and other grape products. The specific compound contributing towards the effect was not identified in the study. The purpose of this study is to use multiple mass spectrometric methodologies in order to identify the liquid chromatographic isolated component showing potent vasodilation.

Experimental Methods

All experiments were performed on a Fisons 70-SE double focusing magnetic sector mass spectrometer. The chemical ionization mass spectrometry (CI) data were collected in the positive ion mode while the liquid secondary ion mass spectrometry (LSIMS) data were collected in both positive and negative ion conditions. The isolated solid mass submitted was first divided into portions for use in each MS experiment. The first portion was quickly screened using a solid's probe on the sector instrument. The data collected was used as a rough estimate of the type and/or class of compounds and as a determinant for the subsequent experiments. The reagent gas used in the CI experiments was isobutane at a stable pressure of 5×10^{-6} mbar. All LSIMS experiments employed a glycerol matrix in conjunction with samples that were either unaltered, acidified (HCOOH , pH=3.00) or baseified ($\text{KOH}/\text{NH}_4\text{OH}$, pH=10.00). Controls of the matrix as unaltered, acid affected or base affected were accomplished also. The primary ions used for desorption was an 8 KeV xenon atom beam.

Results and Discussion

Wine has been studied extensively, yet knowledge of the polyphenolic, anthocyaninic and procyaninic compositions and distributions is far from complete. In addition the behavior of glycosidic moieties and their interaction in the ongoing chemical evolution of a maturing wine is not well understood. Historically, *vitis vinifera*, has been shown to contain a single glycoside; glucoside. However, non *vitis vinifera* grapes such as *vitis labrusca* and grapes from hybrid rootstocks show under paper chromatographic separations, the evidence of both mono- and diglycosides. In fact this differential is used as a test to discern *vinifera* from other hybrid rootstocks. Figures 1 shows CIMS data and indicates glycosides and diglycosides in the material. The

thermal probe, and both negative and positive LSIMS show peaks that appear to arise from procyanidin precursors. LC-ES-MS/MS is most likely better suited for acquiring the higher molecular weight, fragile signal of the procyanidin polymers. The composite information from the various techniques indicate that a likely candidate for the vasorelaxation response is a procyanidin, polymeric flavonoid, with association with mono and di glycosides. The sugars help to stabilize and greatly solubilize the aggregate so that the 3-D complex may be viewed as a hydrophobic interior with a sugar shell further solvated by another shell of water molecules

Analysis Of Porphyrins In Biological Material By Mass Spectrometry.

Russell M. Jones*, John H. Lamb, Jin-Li Luo and Chang Kee Lim

MRC Toxicology Unit, Hodgkin Building, University of Leicester, PO Box 138, Lancaster Road,
Leicester, LE1 9HN, UK.

Introduction

Measurement of the levels and types of porphyrins accumulating in biological material is an important approach in the diagnosis of the porphyrias, a category of disease where abnormalities in the haem biosynthesis pathway are seen. Each porphyria produces a characteristic pattern of porphyrin intermediates, providing a unique "finger print"¹. The existing analytical techniques used for the diagnosis of the disease are useful but time consuming. Traditionally the method of choice has been reverse phase HPLC², which allows a detailed study of the porphyrin content of the urine, provided authentic standards are available, but information on unknown intermediates is limited.

Porphyrins have been previously studied using Electron ionisation (EI)³ and Chemical ionisation (CI)^{4,5}, with side chain fragmentation being seen. For the analysis of these thermally labile compounds intact, one of the soft ionisation mass spectrometry methods is required. We describe the application of both Fast atom bombardment (FAB) and Laser desorption/ionisation time-of-flight (LDI-TOF) mass spectrometry⁶, to provide rapid characterisation of porphyrias, and information on the structure of unknown porphyrin intermediates.

Experimental

LDI-TOF MS. Mass spectra were determined on a VG TOF SPEC mass spectrometer (VG Organic, UK) fitted with an ultraviolet nitrogen laser (337 nm, 4 ns). The ions formed were accelerated using a static voltage of 23,500 V. All mass spectra were acquired in positive ion mode, averaged from multiple laser pulses, over the range m/z 1 to 1500.

FAB MS. Mass spectra were determined on a VG 70-SEQ mass spectrometer of the geometry of EBqQ, where q is an r.f. only quadrupole collision cell. MS spectra were acquired in positive ion mode, over the mass range of m/z 1350 to 50. MS/MS product ion spectra were acquired in MCA mode over the range of m/z 40 to 1000, with argon used as collision gas.

Sample Preparation. Porphyrins from urine samples of patients suffering from a variety of porphyria were derivatised to their respective methyl esters by treatment with 10% sulphuric acid in methanol, at 37°C for 2 hrs. The resulting porphyrin methyl esters were extracted into chloroform. Samples (2 µl) were analysed, by LDI-TOF MS without added matrix and FAB MS using *p*-nitrobenzyl alcohol as matrix.

Results

The porphyrin methyl esters derived from the urine of patients suffering from various porphyria, have

been analysed by LDI-TOF and FAB MS and the resulting profiles compared to u.v. absorbance profiles of normal phase HPLC on silica. The ion profiles for both MS techniques compare favourably with the corresponding profiles obtained from HPLC¹. The major ions observed correspond to the [M+H]⁺ of the methyl esters of uroporphyrin (m/z 943), heptacarboxylic acid porphyrin (m/z 885), hexacarboxylic acid porphyrin (m/z 827), pentacarboxylic acid porphyrin (m/z 769) and coproporphyrin (m/z 711). Satellite ions corresponding to 14 Da lower than the major porphyrin ions could also be seen, due to either partial hydrolysis of the ester or incomplete esterification of the porphyrin free acid. With normal phase HPLC on silica these partially esterified compounds are not detected, as they are retained on the column.

FAB MS/MS analysis of uroporphyrin octamethyl ester showed the major route of fragmentation is by loss of the side chain substituents from the porphyrin nucleus. In a similar analysis of an unknown metabolite (m/z 959) formed in congenital erythropoietic porphyria (CEP), an additional product ion at m/z 942, corresponding to a loss of 17 Da was detected. This indicates the loss of a hydroxyl group, suggesting that the unknown metabolite is hydroxylated-uroporphyrin.

Conclusions

Porphyrin profiles consistent with the characteristic "finger print" profiles seen with HPLC, have been obtained by both MS techniques with little, if any, fragmentation. LDI-TOF MS provides a very rapid method for the analysis of mixtures of porphyrin methyl esters, without the need for "classical" matrices. FAB MS also produces a characteristic porphyrin profile, but in addition FAB MS/MS provides important structural information assisting in the characterisation of unknown porphyrin intermediates.

Both FAB MS and LDI-TOF MS are suitable techniques for the rapid profiling of porphyrins and characterisation of unknown intermediates. The ability to profile the porphyrin content of the urine allows rapid diagnosis of porphyrias, and highlights potential application of these methods in the clinical field.

Acknowledgements

We would like to thank VG Organic, UK for the kind loan of the VG TOF SPEC mass spectrometer.

EC-LC-ESI MS: Electrochemistry combined with Liquid Chromatography and Electrospray Ionization Mass Spectrometry.

Lubomyr Baczynskyj

Structural, Analytical and Medicinal Chem.

Pharmacia and Upjohn, Inc., Kalamazoo, MI

Introduction.

The combination of an electrochemical cell with LC/MS

is a relatively simple but effective method to study oxidation/reduction processes occurring in solution. Electrochemical oxidation of organic compounds and the formation of potential metabolic products that might occur in nature has been suggested previously. In those studies a Thermospray LC/MS system was used (1). More recently reports of the direct coupling of electrochemical cells with an electrospray ionization (ESI) source have been published (2,3). In the present study we present the results of combining an electrochemical cell (EC) with an LC-ESI MS system.

Delavirdine (I) is a member of the new antiretroviral class called nonnucleoside reverse transcriptase inhibitors (NNRTIs) for the treatment of HIV-1 infections. It is synergistic in blocking viral growth in combination with other classes of antiretrovirals used to treat HIV-1 infections or AIDS. The metabolism of delavirdine mesylate has been studied in dog, human, monkey, mouse, rabbit and rat. Monohydroxylation of the pyridine ring at three different positions is a major metabolic path. Some of these metabolites are conjugates (glucuronides and sulfates).

The study of the electrochemical oxidation of this drug candidate was undertaken in order to evaluate the potential of the combined EC-LC-ESI MS instrumentation and to compare the oxidation products with those obtained in living systems.

Methods.

EC-LC-ESI MS: The electrochemical cell (EC) was a porous graphite electrode, part of the ESA Coulochem II Electrochemical Detection System. The voltages applied to the cell could be varied from 0 mV to 2000 mV in 1 mV increments.

A Varian Vista 5500 LC system equipped with a UV detector was used. The electrochemical cell was inserted between the 20 μ L Rheodyne 7010 injection valve and the Waters Symmetry C8 (4.6x250 mm) reverse phase column. For most experiments the LC was run isocratically (30/70 MeOH/H₂O containing 1% ammonium acetate) unless indicated otherwise. The flow rate was 0.5 mL/min. The effluent from the LC column was split ca. 1/4 going to the ESI source of a Finnigan MAT 900S high resolution mass spectrometer. The rest was diverted to the UV detector.

The mass range scanned was m/z 125 to 1500 at 2.4 sec. intervals. ESI mass spectra were recorded under normal conditions using the Finnigan MAT data system.

Results and Discussion.

The Electrospray Ionization (ESI) mass spectrum of delavirdine using the setup described in the experimental with no voltage applied to the EC cell consists of two major ions, the pseudomolecular ions (M+H) at m/z 457 and (2M+H) ion at m/z 913.

To obtain a rapid survey of the products formed in the electrochemical cell, the voltages were increased from 400 mV to 2000 mV in increments of 200 mV. Four major LC peaks were apparent. The ESI mass spectrum of the first LC peak shows two major components having (M+H) at m/z 470 and 483.

From these experiments it is clear that as the starting material (delavirdine, which appears under the LC peak 2 and 3) is consumed in the EC cell, the concentrations of the products formed by electrochemical means increase with the increase in the EC cell voltage. In addition to the starting material the LC peaks 2 and 3 correspond to a product having a (M+H) ion at m/z 165. The concentration of the material corresponding to this ion increases when the EC cell voltage is above 1000 mV to the detriment of other products. At 2000 mV it is by far the most abundant material.

A slow gradient LC-ESI MS run of a mixture generated in the EC cell at a voltage of 1000 mV shows three regions where LC peaks appear. The first region encompasses compounds of retention time between 4'35" and 6'45" and at least seven components can be detected. The pseudomolecular ions of the major components in this region ranged from m/z 165 to 616. A few of them could be rationalized. Thus the pseudomolecular ion at m/z 471 could be due to oxidation of one of the -CH₂- group to a -CO- of the piperazine. Further studies of this complex mixture by MS/MS and high resolution MS will be required.

The LC peaks in regions 15'50" and 18'40" are less complicated. The LC peak at 15'50" contains one component of (M+H) at m/z 487. The (M+H) ion is 30 mass units heavier than the starting material and is thought to be a product of double oxidation - hydroxylation on the pyridine ring and oxidation of a -CH₂- to a -CO-.

The other LC peak at 18'40" contains two components showing (M+H) ions at m/z 633 and 691. Since both of these compounds are considerably larger than the starting material (MW 456) they must be products of a radical reaction with delavirdine. The structure of these products is unknown. Note that in the ESI mass spectra of the last three components in addition to the (M+H) ions, (M+Na) and (M+K) ions are also present. When a search of the pseudomolecular ion of the starting material was undertaken, it appeared at a retention time of 12'20". This shows that under these conditions (EC cell voltage 1000 mV) nearly all the delavirdine is consumed.

Conclusions.

In this study we have applied an electrochemical cell in combination with liquid chromatography-electrospray ionization mass spectrometry to study the reaction products of organic compounds. Delavirdine was chosen as a test compound.

These preliminary studies indicated that nearly all of the starting material (delavirdine) is consumed when the EC voltage reaches 1000 mV. However many products formed in the EC cell elute together under the isocratic LC conditions.

A gradient LC-ESI MS showed that a large number of components are formed. High resolution MS and MS/MS will be required to identify all of these.

MASS SPECTROMETRY OF 3,4- AND 3,5-DICAFFEOLQUINIC ACIDS AND RELATED ANALOGS

Petra Miketova, Karl H. Schram, Barbara N. Timmermann, Yong-Long Liu, and Susanne Valcic
Department of Pharmacology/Toxicology, College of Pharmacy, University of Arizona, Tucson, AZ 85721

Recent biological testing results indicate that quinic acid derivatives may possess considerable activity as agents for the treatment of HIV infections (1,2). Our interest is focused specifically on the 3,4- (1) and 3,5-dicaffeoylquinic acid (2) (DCQA) analogs, compounds isolated in these laboratories which show very promising anti-HIV activity as their peracetate derivatives, 3 and 4 respectively (see Table 1 below).

1, 3,4-DCQA, R=H
3, 3,4-DCQA-Ac, R=Acetate

2, 3,5-DCQA, R=H
4, 3,5-DCQA-Ac, R=Acetate

Only one report has appeared in the literature (3) describing the use of mass spectrometry for the characterization of dicaffeoylquinic acids. In an effort to develop mass spectrometric methods for the identification of the DCQAs and related analogs which may be contained in extracts of *Baccharis* species, we have examined the mass spectral behavior of the free target compounds and their TMS and peracetylated derivatives using EI, CI, FAB and ESI. The objective of this work was, thus, to provide a "survey" method for crude or semicrude plant extracts for DCQAs and related analogs. Differentiation of the 3,4- from the 3,5-dicaffeoylquinic acid isomer by mass spectrometry was also desirable because of potential differences in biological activity. Finally, methods for the chromatographic separation and mass spectral identification of the isomers and components of the derivatization mixture were developed to insure the purity of the compounds submitted for antiviral testing.

The results of this survey of the mass spectral analysis of the 3,4- and 3,5-dicaffeoylquinic acids, their TMS derivatives and the peracetate derivatives may be summarized as follows:

Electron ionization: No useful data is available from the EI (probe) analysis of the free compounds since significant ions above m/z 200 are not observed. Analysis of the TMS derivatives of 1 and 2 provided good molecular weight information, although a mixture of TMS derivatives was observed and the spectra were essentially identical so no differentiation of the isomers was possible. Analysis of 3 and 4 showed the presence of only 4 acetate groups, whereas, 6 are expected and the spectra were very weak above m/z 300. While slight differences were observed in some ion intensities, these differences were not deemed significant enough to pursue.

Chemical ionization: The CI results were complimentary to the EI analyses, i.e., no useful data was obtained in the analysis of 1, 2; their TMS derivatives were useful in establishing MW but not in distinguishing the isomers. No useful data was obtained in the CI analysis of the acetate derivatives.

Fast Atom Bombardment: A number of different matrices were tried for the analysis of 1 and 2, with a 1:1 mixture of glycerol/MeOH providing only a weak MH^+ ion which could be related to these compounds; no fragments arising from the MH^+ ions were observed. FAB analysis of the TMS derivative in diglyme provided a simple spectrum with peaks representing MH^+ , $[MH-Caf]^+$ and Caf^+ ions being observed, but the isomers could not be differentiated.

In contrast to the results of the FAB analysis of the free compounds or their TMS derivatives are the results of the analysis (NBA) of the acetylated derivatives where a considerable amount of MW and isomer information is available. The presence of ions for the Ac4, Ac5 and Ac6 derivatives indicates a mixture of acetates is formed during isolation of 3 and 4. (Which of the derivatives provides the greatest antiHIV activity is currently being investigated.) In addition, ions representing loss of water from each of the MH^+ ions of the 3,5-DCQA acetates clearly differentiates this isomer from the 3,4-DCQA analogs (see Figure 1). MIKES analysis of the MH^+ ion at m/z 769 shows the unambiguous loss of water from the 3,5-isomer, but not from the 3,4-isomer. Thus, FAB mass spectrometry of the acetylated derivatives 3 and 4 allows differentiation of the 3,4- from the 3,5-DCQA and the presence of a mixture of acetate derivatives is clearly indicated.

ESI: Of all of the techniques examined, ESI provided unambiguous MW information on the free compounds 1 and 2; however, the isomers could not be differentiated because of the similarity of the spectra. Similar to the FAB spectra of 3 and 4, the loss of water was observed from the MH^+ ion (m/z 769) of the 3,5-isomer, but little indication of this loss is evident in the spectrum of the 3,4-isomer.

Conclusions: FAB MS of the acetate derivatives of DCQAs provides sufficient information to a) determine the MW of the compounds b) distinguish the 3,4- from the 3,5-isomers and c) determine the extent of acetylation of the parent compounds 1 and 2. This information should be used in conjunction with purification of the individual components of the mixture for obtaining new antiviral testing data. ESI complements the FAB information and, in addition, should provide an effective method for the analysis of mixtures containing DCQAs and their analogs obtained from natural sources when coupled with LC/MS and LC/MS/MS systems.

**A new enantioselective GC-MS method for the determination of
Milnacipran and two of its metabolites in human plasma**

C. Puozzo, Institut de Recherche Pierre Fabre, Castres, France

U. Agvaz, M. Zick, B. Schmid and K. Michaelis, L.A.B. GmbH, Neu-Ulm, Germany

Milnacipran (F2207) is a new non tricyclic antidepressant drug. Three metabolites, originating from N-dealkylation and hydroxylation of the aromatic ring have been identified in humans and animals. For the development of the drug, a sensitive analytical method, able to separate and measure the optical isomers of Milnacipran and its metabolites in human plasma was needed. For this, a method, based on GC-MS, involving a chiral phase capillary column to separate the derivatized enantiomers, was developed. MS analysis was performed on a VG TRIO-2 quadrupole system using the CI source.

By coupling two different types of enantioselective capillary columns, we were able to separate the enantiomers of Milnacipran and the metabolites F2941 and F2800 in one chromatographic run. The isolation of the analytes and internal standards from the biological matrix was carried out by liquid/liquid extraction using ethylacetate and a 1M solution of disodiumhydrogen phosphate.

Milnacipran and two of its metabolites

GC-MS chromatogram of milnacipran and its metabolites F2800 and F2941

The described assay for milnacipran and its metabolites F2800 and F2941 is

- selective, sensitive and robust
- requires relatively simple sample preparation
- is linear for all S(-) and R(+) enantiomers in the range 0.123 - 10 ng/mL
- shows excellent accuracy and precision

IDENTIFICATION OF DEGRADATION PRODUCTS AND TRACE CONTAMINANTS OF MYCOPHENOLIC ACID MOFETIL BY LC-MS

*Lustig, David A.; Hooijmaaijer, Elvira; Leaf, Brian; Austin, Steven
Roche Bioscience
Palo Alto, CA

INTRODUCTION

Mycophenolate mofetil (RS-61443), the ethyl morpholino ester of mycophenolic acid (MPA), has been shown to be an effective immunosuppressant and is currently being used to prevent acute renal transplant rejection. Mass spectrometry has been used as a key tool for the analysis of this compound during many stages of the drug discovery and development process. This work examines the use of LC-MS for the structural determination of: 1) reaction by-products formed during the synthesis of RS-61443; 2) degradation products of RS-61443 under stressed conditions; 3) contaminants found in the formulated drug product.

EXPERIMENTAL

LC-MS was performed on a Finnigan triple stage quadrupole mass spectrometer with a variety of ionization sources including thermospray, electrospray and atmospheric pressure chemical ionization (APCI). Tandem mass spectrometry was accomplished by collision induced dissociation using argon gas at collision energies typically between -20 eV and -30 eV (E_{lab}).

The tandem mass spectra of RS-61443, MPA and related analogs were studied extensively for use as model compounds to aid in the structural elucidation of the reaction by-products, degradation products and formulation contaminants. Much structural information can be found in the MS-MS spectra of these compounds because fragments are formed which are characteristic of both the acid/ester and aromatic moieties.

Specifically, in RS-61443 the fragment at 114 amu indicates the presence of the ethyl morpholino ester. Likewise, the MS-MS spectra of hydrolysis products lack 114 amu but contain fragments characteristic of the carboxylic acid including the successive losses of H_2O and CO (303, 285 and 275 amu for MPA)

Two key fragments of RS-61443 and MPA are indicative of the hexasubstituted benzene moiety: 195 and 207 amu for the phenyl and benzyl ions, respectively. Any shift in this pair of fragments indicates modification. For example, the O des-methyl fermentation by-product exhibits ions at 181 and 193 amu rather than 195 and 207 amu.

RESULTS

Reaction By-Products: LC-MS and LC MS-MS were performed on a sample of the mother liquor of a batch of RS-61443 chemical substance. It was found that most of the related by-products were ethyl morpholino esters of variants of MPA; the variants are likely formed as mutations of the microbial process that produces the MPA. Variations in the length of the alkyl chain were observed, as were de-methylations (O-des methyl and aryl-des-methyl). Fewer by-products corresponded to derivatives of ethyl-morpholino alcohol. The lactone of MPA was also observed.

Degradation Products: RS-61443 was subjected to degradation in solution under stressed conditions (high and low pH, addition of hydrogen peroxide, heat and UV light). Similar degradation products were observed for all of the conditions, although additional oxidation products, such as the N-oxide, were unique to the hydrogen peroxide solutions. The observed degradation products include the lactone of MPA, a hydroxy lactone of MPA, the formation of a five member ring with the phenol and the alkyl chain of MPA, and the lactone of that product.

Formulation Contaminants: LC-MS was used to identify a trace contaminant in a preliminary I.V. formulation of RS-61443. The contaminant was identified as the sorbitol ester of MPA. This was subsequently confirmed by NMR and was consistent with the presence of sorbitol in the formulation.

CONCLUSION

LC-MS has proved to be a valuable tool for the drug discovery and development process for Mycophenolate mofetil (RS-61443). It has allowed for the identification of reaction by-products, degradation products and formulation contaminants at trace levels in complex matrices. It is important to identify these compound to ensure the safety of the drug in humans.

Application of Ionspray Ionization for Quantitation of Guaifenesin. *Winslow, L.D.; Schorno, Karl S., Kansas City Analytical Services, Inc. Shawnee, Kansas.

Guaifenesin is a common expectorant found in many over-the-counter cough and cold preparations. Well established methods for its analysis are currently in use employing such techniques as liquid/liquid extraction followed by HPLC, GC, or GC/MS analysis. LC/MS is a preferable technique that would provide a rapid, sensitive quantitative method. An added advantage of LC/MS over the GC or GC/MS techniques would be that derivatization would not be required. Initial steps in developing an analytical method call for the collection of mass spectral data for the reference compounds used in the assay. It has been theorized that guaifenesin will form an ammonium complex in solution and therefore be a good candidate for atmospheric pressure ionization. The ammonium complex would likely form in the region of the propanediol due to the structural proximity of the alcoholic oxygens and the fact that the aliphatic chain is free to rotate in space.

Solutions of guaifenesin, mephednesin, and 3-phenoxy-1,2-propanediol were infused into the ionspray interface of a PE/SCIEX API III+ mass spectrometer with interesting results. Separate primary solutions of each compound (100 µg/mL) were prepared in methanol. From these primaries, individual scanning solutions were made by diluting (1:100) into a mobile phase solution (90% Acetonitrile/10% 120 mM Ammonium Acetate). For the flow injection analysis, the guaifenesin scanning solution was used, as well as serial dilutions of the scanning solution at concentrations of 100 ng/mL, 10 ng/mL and 1 ng/mL.

The infusion analysis was carried out by drawing up 1 mL of scanning solution into the syringe. The syringe was then fixed in the syringe pump and conditions were set to deliver the solution at a rate of ~5 µL/min into the ionspray interface of the mass spectrometer. All spectra were acquired as 10 scans in MCA mode. The product ion scans were produced from argon collision induced dissociation ($CGT \approx 2.25 \times 10^{14}$ atoms/cm²).

The flow injection analysis was carried out by placing aliquots of each concentration level of the guaifenesin solutions into separate vials. The vials were then placed in the auto sampler. Duplicate 10 µL injections were made into the flow-stream (at 40 µL/min). Multiple reaction monitoring was used to monitor the decomposition of m/z 199 → m/z 125. The dwell time was 200 ms.

As expected, guaifenesin yielded a spectrum showing extensive complex formation. The base peak is m/z 199 ($[M + H]^+$). It can also be seen that complexes exist for $[M + Na]^+$ (m/z 221), $[M + K]^+$ (m/z 237), and $[M + NH_4]^+$ (m/z 216). There is also evidence of premature CID even with a moderate orifice voltage setting. This can be seen by comparing precursor ion scans to product ion scans.

Mephednesin and 3-phenoxy-1,2-propanediol showed unusual spectra. The

presence of a molecular ion is atypical for atmospheric pressure ionization spectra. However, m/z 182 is present, though not the base peak. The spectrum for 3-phenoxy-1,2-propanediol is even more unusual in that the nearest to a molecular ion that was found was a m/z 167 ($[M - H]^+$) which theoretically should not exist. In both spectra, there was no evidence of complex formation with a low orifice voltage setting. There is, however, some evidence of premature CID occurring at this low setting. Later spectra also show evidence that the unusual precursor scans may be produced from some type of solvent complexing.

The product ion spectra obtained from guaifenesin follow expected results which are corroborated by comparison to a reference spectrum. The product ion spectra acquired under the same conditions for all complex ions appearing in the precursor scan show the same general pattern, except there is a tendency toward less fragmentation for the higher mass complexes. The product ion scan for mephednesin shows very little fragmentation and does not compare favorably with a reference spectrum. The product ion spectrum for 3-phenoxy-1,2-propanediol does exhibit more fragmentation than the mephednesin. However, when compared to a reference spectrum, the lower mass fragments do not necessarily follow the typical pattern for these type of compounds. A possible ionization scheme for the spectrum produced from argon collision induced dissociation of guaifenesin is proposed.

The spectra for guaifenesin show relatively good intensities for the ions present. This indicates a high degree of ionization efficiency and transmission down the ion path. Therefore, sensitivity experiments were performed for this compound only. The absolute amounts of drug injected was 10, 100, 1000, and 10000 pg. Due to dead volume in the LC system and the relatively slow flow rate, the peaks are wide. With the development of appropriate chromatographic conditions, the peak shape would be more narrow and sharper.

Based on the spectra obtained and comparison to reference spectra, initial ionization under atmospheric pressure conditions and further ionization via argon CID is dependent on the presence of *o*- ring oxygens rather than on the alcoholic oxygens in the propanediol as originally hypothesized. Guaifenesin is well suited for analysis by LC/MS/MS provided that adequate preparation and chromatographic conditions can be established. However, further searching is required to find a suitable internal standard. More experiments could be carried out using compounds containing *o*- oxygens, such as guaifetolin (3-(*o*-ethoxyphenoxy)-1,2-propanediol), which would support or refute the assertion that ionization is dependent on the planar *o*- oxygens. Experiments using various forms of isotope-labeled guaifenesin could also be carried out. These experiments would also help to elucidate the actual mechanisms by which the ions form. Compounds like guaifetolin or deuterated guaifenesin would be likely candidates to serve as an internal standard provided a suitable source is available.

MASS SPECTROMETRIC ANALYSIS OF TAXOL AND ANALOGUES

Christopher A. Emond, Rajina Naidu and Guenter K. Eigendorf*
University of British Columbia, Department of Chemistry, Vancouver, B.C.,
Canada, V6T 1Z1

INTRODUCTION

The biological activity of taxol and related compounds has stimulated many research activities in natural products chemistry. Associated with this have been developments of analytical procedures, including mass spectrometric techniques¹⁻⁵. The latter focus mainly on detection of known compounds (taxol, baccatin etc.) in extracts from cell cultures. We have developed a protocol that not only permits detection of these known materials but also enables structural elucidation of other components present in cell cultures.

EXPERIMENTAL

A Kratos Concept IIHQ EBqQ hybrid mass spectrometer was used for all experiments. Low resolution data were obtained at $R=1,300$ and accurate mass measurements at $R=10,000$. $\pm$ LSIMS spectra were run with a CsI gun (12KV, source 8KV) using different matrixes and $\pm$ DCI data were obtained with *i*-butane, methane and ammonia in low and high resolution mode. MSMS experiments were carried out using He, N₂, Ar and Xe for CID studies in the 10-300 eV range. Precursor ions were selected in low or high resolution mode.

RESULTS

Pos. DCI with ammonia was found to be the best ionization method for low resolution measurements giving strong $M+NH_3H$ signals for taxol (Fig. 1), baccatin III, cephalomannine etc.. In high resolution a mixture of ammonia and methane was used as reagent gas⁶.

Under these DCI conditions a detection limit of $<10\text{ng}$ ($S/N=10:1$, scan window m/z 500-950) was observed in low res. for taxol and 10-desacetyl baccatin. In high res. mode the detection limit was $<25\text{ng}$ ($S/N=10:1$, scan window 1000ppm). Selection of target ions in high res. mode for CID enables analysis of impure LC fractions or even crude extracts, provided the target compound is present in suitable concentration.

CID experiments in DCI/NH₃ provided informative product ion spectra with Argon at 30-70eV.

Using above conditions baccatin III and other compounds could be identified in LC fractions isolated from a cell extract.

The structure of a synthetic material was established as 14-hydroxy-10-desacetyl baccatin III.

Structural Elucidation of New Polyether Antibiotic by Tandem Mass Spectrometry

Young Hwan Kim^{1,2}, Jong Shin Yoo¹ and Myung Soo Kim²

¹Mass Spectrometry Group, Korea Basic Science Institute, Taejeon, Korea

²Department of Chemistry, Seoul National University, Seoul, Korea

Introduction : The polyether antibiotics, also called polyether ionophores, are a well-known important class of antibiotics in veterinary medicine. Their chemical structures are characterized by the presence of a terminal carboxylic acid group and several cyclic ether units. Fast atom bombardment tandem mass spectrometry (FAB MS/MS) has provided important structural information for compounds which have repetitive similar structural moieties. Characteristic fragmentation patterns have been observed for natural polycyclic ethers in negative-ion FAB tandem mass spectra. We have isolated nigericin, abierixin and a new polyether antibiotic from a *Streptomyces* spp. In this study we examined the fragmentation patterns of nigericin and abierixin by FAB-MS and FAB MS/MS techniques in both positive and negative ion modes and applied the knowledge of their fragmentation patterns to the structure elucidation of the new polyether antibiotic.

Experimental : The residue extracted from culture media of a soil microorganism was column-chromatographed with silica gel, Sephadex LH-20 and preparative TLC to obtain nigericin, abierixin and a new polyether compound. FAB MS and MS/MS spectra were taken with JMS-HX110A/110A tandem mass spectrometer of E₁B₁E₂B₂ configuration with a JMS-DA9000 data system. Collision-induced dissociation (CID) of the precursor ions selected with MS-1 occurred in the collision cell floated at 3.0 kV (or -3.0 kV) in both positive and negative ion modes, respectively. The collision gas, argon, was introduced into the collision chamber at a pressure sufficient to reduce the precursor ion signal by 70%.

Results and Discussion : The negative-ion FAB mass spectra of nigericin and abierixin show abundant [M-H]⁻ at m/z 723 and less intense sodium-containing [M+Na-2H]⁻ at m/z 745. Since a negative charge is located at the terminal carboxylate group in their [M-H]⁻ ions, the charge-remote fragmentation in their negative-ion FAB MS/MS spectra produces CID product ions which are characteristic for cyclic ether structures. Since abierixin has a cyclic ether ring-opened chain structure at its carboxylic terminal, the intense product ions at m/z 169, 139, 125 and 111 are produced by 1, 4-elimination mechanisms of the charge-remote fragmentation (see Fig. 1 and 2). The positive-ion CID spectrum of [M+Na]⁺ of abierixin in Fig. 3 show complex fragmentation pattern due to the well-known rigid cyclic conformation of Na⁺ adduct. We can group the product ions into two types, Type-A and Type-F, on the basis of whether a charge site is on the left-hand side or on the right-hand side of the cleaved bond (or bonds) as illustrated in Fig. 3. The two fragmentation patterns are complementary to each other.

The FAB MS/MS spectra of a new polyether antibiotic obtained in the negative and positive ion modes (Fig. 4) show spectral patterns similar to those of abierixin. The product ion peaks above m/z 300 in Fig. 4(a) which are produced from the decomposition of C, D, E, and F ring units appear at 14 mass unit less than their counterparts in the abierixin spectrum. Type-F series ion peaks in Fig. 4(b) derived from openings of B, C, D, E, and F ring units in the positive-ion CID spectrum are also observed at 14 mass unit less than their counterparts in the abierixin spectrum. Hence, the new polyether antibiotic was identified to be O-

demethylabierixin in which the methoxy group of six-membered ether ring in abierixin was replaced by the hydroxy group.

Structural Elucidation of C-Glucosyl Chromones from *Aloe barbadensis* Miller

Susan T. Weintraub, Mohammad Salman, Robert F. Williams, John A. Hutter, Neera Satsangi, Robert T. Streeper and William B. Stavinocha

Departments of Biochemistry, Research Imaging Center and Pharmacology
The University of Texas Health Science Center at San Antonio

Aloe vera plants have been utilized for hundreds of years in home remedies for burns and for treatment of a variety of conditions in traditional medicine. There is also widespread use of aloe vera in cosmetics and skin lotions. In view of the large body of anecdotal evidence attesting to the efficacy of preparations derived from these succulent plants, we initiated a search for the anti-inflammatory components of a species of Aloe grown in the lower Rio Grande Valley of Texas, *Aloe barbadensis*. After determining that lyophilized Aloe was able to reduce experimentally-induced inflammation in an *in vivo* mouse model,¹ individual components were then isolated and screened for potential biological activity. The most promising candidate (1) was selected for further study.

1 eluted as a single peak with a retention time of 27 min by analytical reversed-phase HPLC using a mobile phase of 50% aqueous MeOH. It was recovered as an off-white solid with a melting point of 138–139 °C. The UV spectrum of 1 in MeOH exhibited four principal absorption maxima (log ϵ), 220 nm (4.74), 246 nm (4.60), 254 nm (4.66), and 284 nm (4.74). The electron impact ionization mass spectrum (Figure 1) suggested that the molecular weight of 1 was 540 Da. From the peak at m/z 410 ($[M - 130]^+$) and the ions at m/z 77, 103, 131 and 147, we speculated that a cinnamoyl substituent was present in the molecule. To investigate this possibility, 1 was treated with methanolic HCl. The predicted formation of methyl cinnamate was confirmed by EI/MS and by agreement of the HPLC retention time of the product with that of authentic methyl cinnamate. By EI/MS analysis, the molecular weight of the deacylated product (2) was found to be 410 Da.

Acetylation of 1 and 2 was accomplished by treatment at room temperature overnight with a mixture of pyridine and acetic anhydride (1:1, v/v). The products were analyzed by electrospray ionization MS by infusion in 70% aqueous MeOH/0.5 mM NaOAc.

The ESI mass spectra were characterized by intense peaks at m/z 731 and 643, respectively, consistent with the addition of four acetyl groups and a sodium ion to 1 and five acetyl groups plus a sodium for 2. These results confirmed that hydrolysis of 1 led to the appearance of an additional hydroxyl group on 2 and suggested the possibility of a sugar substituent to account for the relatively large number of hydroxyls on the molecule. However, treatment of 1 with strong acid failed to release the putative sugar.

In order to gain insight into the structure of 1, a comparison was made with the mass spectra of known major constituents of Aloe. It was found that there were obvious similarities between the EI mass spectral fragmentation of aloesin and the EIMS patterns for 1 and 2. In particular, the intense ion at m/z 261 ($[M - 133]^+$) in the spectrum of aloesin proved to be characteristic for a C-glycosyl substituent and gave us

the clues needed to interpret the ion at m/z 277 in the spectra of 1 and 2. Moreover, the ion at m/z 179 in the spectrum of aloesin, formed in part by the loss of 82 mass units through a retro-Diels-Alder reaction,² provided insight into the nature of the side chain on the chromone ring of 1 and 2 through the corresponding ion at m/z 193 in the spectra of 1 and 2.

From our acetylation experiments, it was known that 2 contained the same number of hydroxyl groups as aloesin, but the presence of a phenolic moiety was ruled out from the lack of pH-dependence of the UV spectrum of 2. On the basis of this evidence, 2 was tentatively identified as 8-C-D-glucopyranosyl-2-[2-hydroxy]propyl-7-methoxy-5-methyl-chromone, and 1 as the corresponding 8-C-D-[2-O-(*E*-cinnamoyl)]-glucopyranosyl analog. The results of ¹H and ¹³C nmr analysis of 1 further confirmed the identification of this previously unreported component of *A. barbadensis*.

We subsequently discovered that a research group in Italy had isolated a similar compound, aloeresin D (3), from Kenya aloe (*A. ferox* Miller).^{3,4} From a comparison of the EI mass spectra, we found that the fragmentation of 1 was identical to that of aloeresin D for the chromone portion of the molecule. In contrast, the fragment ions attributable to the acyl substituent on the sugar were 16 mass units lower than the *p*-coumaroyl fragments in 3, consistent with the presence of a cinnamoyl moiety in 1. On the basis of UV, ¹H and ¹³C NMR and MS analyses of 2, it was, further, revealed that the same chromone was released by alkaline hydrolysis of 1 as was reported for aloeresin D. A detailed examination of 1 by ¹H and ¹³C NMR and comparison with the spectra of aloeresin D have led to the assignment of a 8 C-glucosyl moiety at position 8 of the chromone nucleus and substitution of an (*E*)-cinnamoyl group at carbon-2 of the sugar residue. In view of the structural similarities between 1 and 3, an *R* configuration has been assigned to carbon 10 of 1. However, lack of sufficient quantities of purified 1 has prevented the determination of absolute configuration at this time. The chirality at C-10 will be fully investigated in the future when more material becomes available.

Assessment of the topical anti-inflammatory activity of highly purified 1 was then made. We found that a dose of 200 μ g/ear of 1 afforded anti-inflammatory activity that was comparable to 200 μ g of hydrocortisone at 6 hr after treatment; there was diminished residual activity of 1 at 24 hr. Of particular importance is the fact that there was no reduction in thymus weight caused by treatment with 1 for any of the doses tested while 200 μ g/ear of hydrocortisone resulted in a 50% decrease in thymus weight. These results support the efficacy and safety of aloe vera as a topical anti-inflammatory agent and indicate that the cinnamoyl-C-glucosyl-chromone described in this presentation may be a significant contributor to the biological activity of *A. barbadensis*.

Analysis of Bile Acids by LC/ESI/MS/MS Using a Benchtop Quadrupole Ion Trap

Jonathan L. Josephs*, Matthew J. Sweeney, David C. Gale and Mark Sanders

Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Introduction: Bile acids are the polar derivatives of cholesterol. These compounds are highly effective detergents because they contain both polar and nonpolar regions. They are the major constituents of bile and their role is to solubilize dietary lipids. The effective increase in the surface area of the lipids has two consequences: It promotes their hydrolysis by lipases and facilitates their absorption by the intestine. Increased serum levels in fasting or postprandial state is considered a specific indicator of liver disease. A decreased level indicates bile acid malabsorption, possibly due to ileal dysfunction. Bile acids are present as the native acids and as glycine and taurine conjugates.

Presented here is a liquid chromatography/electrospray mass spectrometry (LC/ESI/MS) method using a benchtop quadrupole ion trap mass spectrometer for the analysis of bile acids and their conjugates. The bile acids and their conjugates are separated on a reverse phase chromatography column and detected by negative ion electrospray ionization. Both LC/MS and LC/MS/MS data are obtained in a single chromatographic run by running the experiment in a data dependent mode, where detection of a peak in MS mode triggers the instrument to acquire a product ion spectrum of the detected precursor ion on the following scan.

Method: Sample Preparation: Pure bile acid and bile acid conjugate standards (Sigma Chemical Co., St. Louis, MO) were dissolved in methanol/water at the 1 µg/µl level, combination and dilution gave a mixture of standards at the 100 ng/ul level. 10 µl injections of this standard were made onto the HPLC column. Animal bile was obtained as lyophilized solid (Sigma Chemical Co., St. Louis, MO) and dissolved in water at the 1 µg/µl level. 10 µl injections of this standard were made onto the HPLC column.

HPLC Conditions: LC separations were performed on a 4.6x100 mm YMC ODS-AQ column with a gradient of 75% A at 0 min, to 45% A over 2 min, to 15% A over 18 min, hold 15% A for 5 min, where A is 10 mM ammonium acetate B is methanol. Flow rate was 1ml/min.

Ion Trap Mass Spectrometer Conditions: Mass spectrometry data was recorded with a Finnigan MAT LCQ™ equipped with the Finnigan Electrospray Source: For negative ion, 1ml/min LC flow the conditions were: Capillary temp 275°C, needle voltage -3.5 KV, sheath gas 80 psi, auxiliary gas flow 40 units.

Conclusions: Negative ion electrospray ionization coupled with reverse phase liquid chromatography provides a convenient method for the separation and detection of bile acids and their conjugates. Data dependent LC/MS and LC/MS/MS 'on the fly' enables the collection of both full scan MS and full scan MS/MS spectra in a single run. The ability to clearly differentiate between different species by bile acid analysis indicates that similar analysis of human bile should be of value in the diagnosis of disease states.

The Identification and Characterisation of Bile Acids by LC/Electrospray/MS/MS

Introduction

Bile acids are synthesised in the liver from cholesterol, conjugated with either glycine or taurine and secreted into bile which is stored in the gallbladder. When food is taken, bile acids are admitted into the duodenum where they act as a detergent and form micelles with the products of pancreatic lipolysis. Bile acids form molecular aggregates with the more polar constituents in the system such as triglycerides. In turn, these mixed micelles then solubilise the less polar dietary compounds by incorporating them into their molecular structure. A number of hepato-biliary disorders may result in a change in the composition of bile, preventing the formation of micelles so that the absorption of nonpolar dietary constituents is practically non-existent. Thus the clinical analysis of biliary, serum or urinary bile acids and their conjugates can give valuable information in the diagnosis of disorders of bile acid metabolism. In addition, bile acid analysis will also give vital information for the understanding of the biochemical mechanisms involved in cholestasis and liver rejection episodes after liver transplantation. In this work, the characterisation of bile acids has been carried out using reverse phase LC with detection by electrospray-MS/MS. This method has been chosen in preference to previously used methods, such as LC-UV and GC-MS, as it is not limited by the sensitivity and specificity restrictions found with UV detection and the time-consuming sample preparation for GC analysis of bile acid conjugates is not required. When performing clinical analyses a rapid sample screening process is required and to this end constant neutral loss experiments have been used as a generic detection method for bile acids. Further experiments have been carried out to investigate the use of product ion spectra libraries to confirm the identity of bile acids and bile acid conjugates.

Methods

The HPLC was carried out using a HP1090 liquid chromatograph (Hewlett Packard, Palo Alto, CA) with a 250 x 10mm, RP300, 7µm (ABI) column using the following mobile phase conditions: A: water + 0.05% TFA, B: acetonitrile + 0.05% TFA; gradient 5%-80%B in 30 minutes, 90%B at 40 minutes at a flow rate of 50µL/minute.

The mass spectrometry was carried out using a Quattro II triple quadrupole mass spectrometer (Micromass UK Ltd, Altrincham, Cheshire, UK) in electrospray mode. All MS/MS was carried out with an argon collision gas pressure of 3×10^{-3} mbar. Product ion scans were acquired from the $[M+H]^+$ ions with a collision energy of 25eV. Neutral loss scans were acquired at collision energies of 15eV for the loss of 36 and 18eV for the loss of 54.

Standards of the following bile acids were obtained from Sigma Chemical Company: cholic acid (C), hyocholic acid (HC), deoxycholic acid (DC), chenodeoxycholic acid (CDC), glycodeoxycholic acid (GDC), glycochenodeoxycholic acid (GCDC), taurodeoxycholic acid (TDC), taurochenodeoxycholic acid (TCDC), glycocholic acid (GC) and taurocholic acid (TC). Human bile samples were supplied by Hôpital Sainte-Justine, Montréal. One sample was diluted by a factor of 10 in water with no prior extraction or clean up. Another sample was analysed as a 1000 fold dilution in water spiked at 2µM level with 5 of the bile acids (GDC, GCDC, GC, TDC and TCDC).

Results

The chromatography described allowed the separation of bile acid isomers which is useful for the constant

neutral loss analysis, but vital for library searching product ion spectra. Initial investigations of the analysis of the diluted bile sample spiked at the 2µM level with bile acids showed that the method was suitable for the screening of bile acids at the expected physiological levels. Solutions of the bile acid standards were infused directly into the electrospray source to create a library of product ion spectra from the $(M+H)^+$ ions. Examination of the product ion spectra of bile acid isomers suggested that there were sufficient differences between the spectra to allow a library searching algorithm to recognise them. The ability to differentiate isomers by library searching was tested by analysing the spiked dilute bile sample by LC/MS/MS. It was found that it was possible to library search the product ion spectra to give the correct search result. In each case the correct isomer was identified as the best fit by the search and, as may be expected, the other isomer was found as the second hit with a much poorer fit. The x10 diluted (unspiked) bile sample was analysed under the same conditions. GC, TC, TCDC, TDC, GCDC and GDC were detected by neutral loss and confirmed by product ion analyses and library searching. Figure 1 shows the library search result for TCDC and TDC.

Figure 1 : Library search result for TCDC in human bile

Conclusions

LC-ES/MS/MS was found to be suitable for the analysis of bile acids in bile. The samples could be rapidly screened for bile acids using constant neutral loss of 36 and 54 and confirmation of the presence of compounds found from screening was achieved by product ion analysis with library searching of product ion spectra. The product ion spectra of bile acid isomers showed sufficient differences to allow differentiation by library searching. Initial results suggest that analyses may be carried out on diluted bile with no sample extraction necessary.

POINT MUTATION DETECTION BY LASER DESORPTION MASS SPECTROMETRY

I. Introduction

Although laser desorption mass spectrometry still can not be used for routine DNA sequencing, it can be applied to fast DNA analysis in disease diagnosis. With the invention of polymerase chain reaction (PCR), a selected region of genomic DNA can be amplified for analysis. Chen and his co-workers^[1] recently demonstrated the detection of the most common mutation ($\Delta F508$ deletion) for the cystic fibrosis gene by laser desorption mass spectrometry from 30 patient samples. Lubman and his co-workers^[2] have demonstrated the feasibility of using MALDI to detect other mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene as well.

A point mutation in a single base pair can be associated with the pathogenesis of inherited or acquired diseases. The G551D mutation in the CFTR gene involves a G $\rightarrow$ A mutation at nucleotide 1784, which results in a Gly $\rightarrow$ Asp substitution at amino acid 551.^[3] G551D is one of the several mutations of the CFTR gene present in 1-3% of the mutant CFTR alleles in most European populations.^[4] In this work, we present two different approaches to the detection of the G551D point mutation in the cystic fibrosis gene. The strategy is to amplify the desired region of DNA template by PCR using two primers of different sizes which overlap one single base at the site of a point mutation. If the two primers based on the normal sequence match the target DNA sequence a normal PCR product will be produced. However, if the alternately sized primers that match the mutant sequence, a PCR product of mutant DNA segment will be produced. Thus the mass spectrometer can be used to identify patients that are homozygous normal, heterozygous for a mutation or homozygous abnormal at a mutation site.

Another approach to identify similar mutations is the use of sequence specific restriction enzymes which respond to changes in the DNA sequence such as that described previously by Lubman and coworkers. Mass spectrometry is used to detect the length of the restriction fragments generated by digestion of a PCR generated target fragment.

II. Experimental

Some of the experiments in this work were conducted with a home-made linear time-of-flight mass spectrometer. A Nd:YAG laser with third harmonic generation was used for laser desorption and ionization. The details of this instrument have been described previously.^[5] Other experimental results are from a Voyager II instrument from PerSeptive Biosystems, Inc. A N_2 laser was used for laser ablation of samples. The sample plate can hold as many as 100 samples. The ion energy is typically fixed at 28125 eV. The laser energy was measured by an external power meter (GenTec). A central guiding wire was used to deflect small matrix ions to prevent the possible saturation of the detector. The vacuum of the time-of-flight chamber was typically at 1×10^{-7} Torr. The ions were detected by a microchannel plate. Electronic signals were then digitized by a digital scope (Tektronix 520), which was controlled by a PC computer.

III. Results and Discussion

Our first attempt to use this method involved a synthetic ssDNA as a template. The chosen template was a simulation of a fragment of the p53 gene, which is of critical importance in several cancer syndromes.

Upstream and downstream primers are overlapped at the base which may mutate. If the template is normal, PCR will proceed. The size of amplified DNA product should be 38 bp. Experimental result clearly indicated the production of a 38 bp DNA PCR product. The length of the template used was 60 mer ssDNA.

When primers were changed to those with the 3' end base not complimentary to the normal template, no PCR products were observed by laser desorption mass spectrometry. Two sets of oligonucleotide primers were designed to sequence specifically the amplified G551D mutation. The oligos were complimentary to 19 bases on either side of the mutations site.

When only normal sequences are present, the normal primer pair should produce the expected 37 bp PCR product while the mutant primers should not produce any significant product under these conditions. Similarly, when template with both normal and mutant sequences are present, the expected 37 and 46 bp PCR products should be produced.

A template DNA was produced as described above and analyzed before and after digestion with Hinc II by MALDI. The 114 bp fragment and the 60 and 54 bp fragments were detected in the digested heterozygote template DNA, while only the 60 and 54 bp products were detected in the normal samples.

In conclusion, we have demonstrated two different successful methods to use MALDI for CF patient sample detection. With the progress of mass spectrometry and its high potential for fast DNA analysis, we expect that MALDI will become an important clinical tool for molecular diagnosis in the near future.

DNA Sequencing by Laser Induced Fragmentation in MALDI-TOFMS

Y. F. Zhu, N. I. Taranenko, S. L. Allman, and C. H. Chen
Health Sciences Research Division, Oak Ridge National Laboratory,
Oak Ridge, Tennessee 37831-6378 USA

Up to now, sequencing DNA has required the implementation of either the Sanger or Maxam-Gilbert method to produce DNA ladder products. DNA fragments generated by this method are subsequently separated and their sizes identified by gel electrophoresis. A more efficient method would be to obtain the DNA sequence information from mass spectroscopy of fragmentation patterns resulting from controlled dissociation. The successful implementation of such a method would eliminate both of the time consuming steps of DNA ladder product preparation and gel electrophoresis. The approach of fragment generation and mass analysis have been studied by several techniques. The results in those investigations implied that the selected bond cleavage is needed for obtaining the sequence information of DNA. The technique of MALDI-TOF mass spectrometry seems to provide the best environment for this selected bond cleavage process. In this work, we present the MALDI results of DNA sequencing by fragmentation method.

The MALDI experiments were conducted in a linear time-of-flight mass spectrometer (PerSeptive Biosystems - Voyager) which was equipped with a pulsed nitrogen laser (337 nm) as the desorption/ionization source. The signals of negative DNA ions were digitized by a digital oscilloscope (Tektronix 520A), from which waveforms were downloaded to an IBM-PC compatible computer. Synthetic oligodeoxynucleotides (Operon Technologies, Inc.) used in this work were purified by HPLC after desalting. The MALDI spectra of these oligodeoxynucleotides using a matrix of 3-HPA and ammonium tartrate give no detectable signal of failure sequence product. This indicates that the DNA sample is highly purified. The selective fragmentation of DNA was discovered in several matrices. Based on experimental results, we discovered the following effects in the aspect of the fragmentation of DNA in MALDI mass spectrometry. 1). The ammonium citrate (or other ammonium salts) not only serves as an adduct suppression but also as an ionization reagent. Upon the addition of ammonium citrate, there will be no DNA signal for these protein matrices (such as 4-HCCA, sinapinic acid, 3,4-dihydroxycinnamic acid, etc.). The DNA was ionized through protonation or deprotonation mechanism by ammonium citrate (ionization component) under the laser ablation. The matrix material like 4-HCCA only serves as a light absorber (absorption component). The only requirement for the absorption component is the cocrystallization with ammonium citrate. Since the selection of absorption component is broad, this two-component matrix provides the possibility of selective bond weakening through the interaction with different matrix crystal ("solvent effect"). 2). Using these two-component matrices, the selective bond cleavage for the fragmentation of DNA in MALDI-TOF mass spectrometry becomes possible. Figure 1 shows the MALDI fragmentation pattern of a 15-mer DNA sample with the sequence of 5'-CACATACGATTAGG-3' using 2-amino, 4-florobenzoic acid + ammonium citrate as matrix. Two series of fragments have been resolved. The first one is due to the cleavage of O-C bond at 5' position. The second one is due to the cleavage of P-O bond at 3' position. These series are labeled in Figure 1 to provide the sequence information of this DNA sample. 3). At relatively high laser fluence, the fragmentation at the 3' position P-O bond is dominant.

However, these fragment peaks strongly depend on the type of base near cleavage position. Figure 2 shows the MALDI spectra of the same DNA sample under a high laser fluence. The intensity of second series fragments were greatly enhanced while the intensity of first series fragments disappeared. Among these fragments, the cleavage at C-G position gives the strongest intensity. The cleavages at other positions such as A-T, C-A, and A-C also give relatively strong intensity. Trace a in Figure 2 is the MALDI spectra using 3-HPA + ammonium tartrate as matrix. There was no fragmentation in this case, and its double charged DNA is stable. 4). The fragmentation effects have been observed in several other matrices.

The fragmentation pattern resolved in the two component matrix can be used to obtain sequence information for small synthetic DNA. The base dependent fragmentation effect observed in this case may be used in obtaining sequence information for relatively large DNA and in the study of DNA interaction with other molecules.

Recently, many genetic alterations that cause variable hereditary or sporadic diseases have been identified and thus the detection methods of such alterations are becoming more and more important in these years for the practical diagnostic purpose. A powerful technique for directly amplifying short segments of the genome, polymerase chain reaction (PCR) was developed by Mullis and his colleague in 1987. PCR amplifies the number of copies of a target DNA sequence by $>10^6$ times. Various analysis of trace DNA have been able to be performed by using PCR. The gel electrophoresis based methods are widely used so far to analyze the base sequence of DNA, however, those are not sufficient in the resolution. Recent progress of electrospray ionization technique in the mass spectrometry field has enabled us to measure the accurate mass of biopolymers such as protein, sugar, and nucleic acid. Synthetic oligonucleotides of about 100 bases length are thought to be measurable now. We report here, the detection of PCR products amplified from human DNA by ESI-MS and its application to the genetic diagnosis picking up the human gene mutations including the base deletion and even the one base substitution.

Adenomatous polyposis coli (APC) gene fragment of about 50 base pairs (bp) whose relative molecular mass (Mr) was approximately 15,000 was amplified from normal human blood DNA by PCR. The products were digested with EcoRI restriction enzyme to liberate 3' end adducts (Figure 1) and purified by phenol/chloroform extraction, ammonium acetate addition, ethanol precipitation and ultrafiltration to remove sodium ions from phosphoric acid backbone of the DNAs. The ESI-MS spectra showed two groups of mass peaks which were assigned to the sense and antisense strand of the PCR amplified DNA fragments (Figure 2A). The molecular mass of the products was determined with an accuracy of about 0.005% (1).

The APC gene PCR products were also obtained from a familial adenomatous polyposis (FAP) patient whose one DNA allele was affected by a five base deletion mutation. ESI-MS spectra of the PCR products showed four groups of peaks which were assigned to the sense and antisense fragment of the normal and mutant allele DNA with expected molecular mass and high accuracy (Figure 2B).

One base substitution has been also detected by ESI-MS on the PCR products which was amplified from human mutated collagen gene (COL1A2) of osteogenesis imperfecta patient. ESI-MS spectra of the PCR products also showed four groups of peaks which were assigned to the sense and antisense PCR fragment of the normal and mutant allele DNA that differ in only one base kind, with expected molecular mass and the high accuracy (Figure 3)

MASS SPECTROMETRY AND SITE-SPECIFIC SYNTHESIS OF MODIFIED OLIGODEOXYNUCLEOTIDES

Charles R. Iden, Department of Pharmacological Sciences,
State University of New York at Stony Brook, Stony Brook, NY 11794-3400

This laboratory has developed strategies and procedures for the incorporation of modified deoxynucleotides site-specifically into synthetic DNA oligomers. We have approximately sixteen deoxynucleotide modifications which exist as the phosphoramidites and can be used in automated DNA synthesis. The structures range from models of the abasic site (tetrahydrofuran), nucleobase oxidation products (8-oxo-dG, 8-oxo-dA, 5-hydroxymethyl-dU) and exocyclic molecules (1,N²-propano-dG, 3,N⁴-etheno-dC, 3,N⁴-ethano-dC) to molecules containing a carbasugar modification or a thiophosphate linkage. Initially, mass spectrometry played only a minor role in the synthetic program since fast atom bombardment (FAB) was generally limited to oligomers smaller than decamers. Nevertheless, negative ion FAB/MS produced both a molecular ion and fragment ions from which the sequence of the modified deoxynucleotide could be ascertained. New ionization techniques such as electrospray ionization and matrix assisted laser desorption ionization have revolutionized the analysis of oligodeoxynucleotides. Accurate molecular masses can be determined easily; however, the lack of fragmentation is restrictive since the sequence can no longer be determined without access to MS/MS techniques.

EXPERIMENTAL

Oligodeoxynucleotide Synthesis

Oligonucleotides were synthesized on an Applied Biosystems Model 394 DNA/RNA synthesizer using the phosphoramidite chemistry. All reagents were obtained from Applied Biosystems (Foster City, CA). The phosphoramidite for 3, N⁴-etheno-dC was prepared by the method of Zhang, *et al.* (1). After synthesis, oligomers were deprotected and removed from the CPG support by treatment with 28% ammonia at 55°C for 16 h, and the 5'-DMT-protected oligomer was purified by reverse phase HPLC on a semipreparative RP-1 column. After lyophilization of the solvents, the dimethoxytrityl group was removed with acetic acid; the oligomer may be rechromatographed a second time using slightly different solvent conditions.

Electrospray Mass Spectrometry

Mass analysis was performed on a Fisons TRIO-2000 quadrupole mass spectrometer system. Samples were diluted to 200 µL/OD with 60% acetonitrile/water and spiked to approximately 1% triethylamine just prior to injection into the electrospray source. The source was supplied with a flow of 60% acetonitrile/water at a rate of 12 µL/min from a Harvard syringe pump. Nitrogen was used as a drying gas (250 L/hr) and also as the nebulization gas (15 L/hr). The instrument was operated in the negative ion spray mode with the high voltage set to -3.3 kV and the source temperature at 70°C. The sampling cone was fixed at -54V and lenses were adjusted to maximize transmission. The data system acquired signal over a *m/z* range of 200-1500 at 8 sec/scan with a 0.06 step. Approximately 8 scans were collected in the multi channel averaging (MCA) mode, baseline adjusted, and digitally filtered to produce a spectrum.

RESULTS AND DISCUSSION

After incorporation into a growing oligomer, a modified deoxynucleotide is exposed to a large number of chemicals during each subsequent deoxynucleotide addition. Synthesis reagents may react with the modified nucleotide causing a change in the chemical structure, and this could have disastrous consequences for

experiments examining the mutational spectrum of the modification. Electrospray ionization mass spectra have proved invaluable in maintaining quality control of modified oligomers. Accurate spectra can be generated from the 5'-dimethoxytrityl-protected oligomer directly upon release from the support by ammonia or on the fully purified oligomer after dual pass HPLC purification. Quantities of oligomer used (10 pg) are insignificant when compared to a full scale synthesis, and mass accuracy of 0.01% can generally be obtained. MS/MS analysis of multiply charged molecular ions from ESI yields sufficient product ions to determine sequence for many oligomers. Electrospray ionization mass spectra have also been used to resolve problems in the synthesis of modified oligomers. Figure 1 shows the HPLC chromatogram of the 5'-DMT-protected product from a synthesis incorporating 3, N⁴-etheno-2'-deoxycytidine into an 8-mer, 5'-TGTXTCTA-3'. Two DMT products were found from this synthesis, and both were collected as pure fractions from the HPLC. ESI/MS analysis was used to identify the products: peak A (Figure 2a), the desired octamer in protected form (MW 2702.6 Da); peak B (Figure 2b), a mixture of two substances, the 5'-end of the oligomer with a terminal phosphate (5'-TGT-p; MW 1256.8 Da) and a similar portion of the oligomer with a phosphate and a modified ribose moiety at the 3'-end (5'-TGT-p-dR-NH₂; MW 1372.9 Da).

MASS SPECTROMETRIC ANALYSIS OF MORPHOLINO PHOSPHORODIAMIDATE OLIGOMERS

Robert M. Hudziak¹, Doreen L. Weller¹, Dwight D. Weller¹, Elisabeth Barofsky², and Douglas F. Barofsky². ¹AntiVirals Inc., 4575 SW Research Way, Suite 200, Corvallis, Oregon 97333. ²Department of Agricultural Chemistry (ALS 1007) and Environmental Health Sciences Center, Oregon State University, Corvallis, Oregon 97330.

INTRODUCTION. The optimal solution to the problem of stability of antisense agents in biological systems is the adoption of an inherently stable backbone structure which is resistant to cellular hydrolases. Morpholino oligomers with phosphorodiamidate linkages (MO-PDA) are a new structural type with excellent promise for antisense applications.¹ They are derived from readily available ribonucleosides and have been shown to outperform classical nucleic acid analogs in both efficacy and specificity of inhibition of translation in cell free systems. In order to further assess the suitability of MO-PDA as therapeutic agents, we have examined their stability in the presence of enzymes representative of the common cellular hydrolases.

EXPERIMENTAL. A Morpholino phosphorodiamidate oligomer with the sequence 5'-GGU GGU UCC UUC UCA GUC GGA CUG G-3' (25-mer) was synthesized by methods described elsewhere.¹ Quantitation of the oligomer was performed by UV-spectroscopy using absorbance values determined for oligoribonucleotides.² The oligomer possesses a 5'-acetylpiperazine group, is unsubstituted on the 3' terminus, and has dimethylaminophosphoryl intersubunit linkages (Figure 1a).

The 25-mer was treated with phosphoric acid, 11 different nucleases, 2 different proteases, an esterase, and serum (Table 1), and the reaction mixtures directly analyzed by MALDI-TOF mass spectrometry. The activities of the enzymes were chosen to represent a broad range of hydrolytic specificities, and many are among the most active of their type. One half of the enzymes tested are of mammalian origin and therefore relevant to possible therapeutic use of Morpholino oligomers. The activity of each of the reagents was assessed in control experiments with the natural substrate for each enzyme using one-half the number of units used with the Morpholino oligomers. In all cases the control substrate was found to be completely degraded.

RESULTS AND CONCLUSIONS. The cleavage fragments observed in the mass spectrum resulting from 2 hours of acid hydrolysis (Table 2) can be resolved into a 5' series that correlates with 5'-acetylpiperazine, 3'-H species (Figure 1b) and a 3' series that correlates with 5'-monophosphate, 3'-H species (Figure 1c). Cleavage for 24 hours gives products resulting from secondary degradation of initial reaction products. These results demonstrate that MALDI mass spectrometric analysis can provide a rapid, sensitive, and accurate assay for backbone cleavage in Morpholino oligomers.

The 25-mer was completely resistant to the 14 different hydrolases and serum. All mass spectra appeared essentially identical to that of the untreated oligomer and that shown for serum. The resistance undoubtedly arises from the unusual nature of the linkage, whose natural occurrence is rare. The excellent resistance of the Morpholino phosphorodiamidates to enzymatic attack indicates their suitability for use in vivo.

Interactions between metal ions and nucleic acids are of immense biological importance. Many metal ions such as Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Fe^{2+} , Ni^{2+} and Cu^{2+} are present in the cell and known to bind to deoxyribonucleic acid (DNA). These metal ions have been implicated in vital biological processes involving DNA and its component parts such as DNA replication/transcription processes and metabolic reactions. A knowledge of the binding characteristics of metal-nucleic acid complexes may also explain the toxic behaviour of certain metal complexes and the mutagenic and carcinogenic behaviour of others. An investigation of metal ion-nucleoside complex formation in solution is a natural starting point in this area of research and can provide information on the intrinsic cation binding tendencies and the properties of these complexes when more complex real situations are considered.

Metal ion interactions with nucleic acids and nucleosides have been studied extensively with all the available NMR techniques and by Raman spectroscopy. However, no studies have been reported using ESI-MS to monitor metal ion-nucleoside binding. ESI-MS is a well suited technique to study solution formed ionic complexes. ESI-MS provides unambiguous identification of singly and multiply-charged metal-ion complexes in solution formed upon reaction of metal ions with the nucleosides (M). The detection of such complexes cannot be achieved by other MS techniques and the data obtained for these systems with other techniques such as Raman and NMR are often difficult to interpret. In this work, the reactions of adenosine, guanosine, cytidine, thymidine, uridine and their corresponding bases with alkali, alkaline earth and transition metal salts are studied. Gas phase collision activated dissociation (CAD) was performed to complement the ESI-MS data.

The experiments were carried out on a VG-Quattro tandem MS equipped with an ESI source; +ve ion mode, ESI source at 80°C, cone and skimmer set at 20V. Solutions were introduced to the ESI by flow injection, 1:1 $\text{H}_2\text{O}/\text{MeOH}$ was the carrier solvent pumped at 10 $\mu\text{L}/\text{min}$. The test solutions (100 μM) were made-up in the same solvent and equimolar amounts of the nucleoside and the selected metal cations were used. No buffers were added and no adjustments were made to the pH. For the CAD experiments Ar was used as the collision gas at 4×10^{-4} mbar, 17eV collision energy.

Alkaline Earth Metals. The ESI-MS mass spectrum for uridine/ CaCl_2 is shown in Figure 1 and the three characteristic major metal ion-nucleoside ion series are tabulated in Table 1. The multiply-charged ions M_nZ^{2+} , $n=1-4$, are seen in ESI for all nucleosides studied. The enhancement of these species over $(\text{M}_n\text{-H})\text{Z}^+$ and $\text{M}_n(\text{ZX})^+$ in ESI-MS shows the co-ordination of the metal provided by more than one molecules is favored over single nucleoside binding. The formation of these complexes can not be detected by LSIMS and have not been identified by NMR for uridine, adenosine and guanosine (Marzilli, L.G. et al. J. Am. Chem. Soc., 104, 461, 1982). Theoretical calculations involving divalent metal cations and the nucleobases suggest similar strength interactions with adenosine and guanosine at the N6/N7 positions and O6/N7 positions, respectively. Also observed for nucleoside/alkaline earth metal systems in ESI is formation of $(\text{M}_n\text{-H})\text{Z}^+$, $n=0-1$, occurring through substitution of a proton by the metal ion. CAD of the M_3Ca^{2+} species resulted in different spectra for adenosine and guanosine, see Figure 2.

There was no proton substitution observed with guanosine possibly because there is no proton in the proposed binding position O6/N7. These adducts ($n=0-1$) are also seen in ESI of all nucleosides except guanosine and 3-methyluridine where the M_nZ^{2+} are present but $(\text{M}_n\text{-H})\text{Z}^+$ are not observed.

Transition Metals. For the transition metal ions the multiply-charged complexes M_nZ^{2+} are also observed in ESI. In Table 1 are also tabulated all the major ion series observed by ESI-MS for the nucleosides and the divalent transition metal ions. Interestingly, adducts up to $n=4$ are observed with guanosine while M_nZ^{2+} adducts are not observed for adenosine, cytidine and thymidine. This strongly suggests that the site of metal ion attachment for adenosine and cytidine differs between the alkaline earth and the transition metal ions. Both $(\text{M}_n\text{-H})\text{Z}^+$ and $\text{M}_n(\text{ZX})^+$ adduct formation are seen in ESI-MS for all nucleosides studied except 1-methylguanosine. This suggests that in the guanosine-metal ion experiments the proton substitution is occurring at the N1 position. For $\text{Z}=\text{Cu}$, an additional feature in the ESI mass spectra is the presence of peaks incorporating Cu^+ . Reduction of Cu^{2+} is a facile process and is expected to occur at the needle/solution interface.

[†]Department of Drug Metabolism and Pharmacokinetics, Hoffmann-La Roche, Inc., Nutley, NJ 07110

5-Fluorouracil (5-FU), uracil-tegafur (UFT), and leucovorin have been used in cancer chemotherapy for years. A number of analytical methods for the determination of 5-FU and its analogs in biological matrices have been reported during the last two decades. Gas chromatography-mass spectrometry (GC/MS) is the most widely used instrumental technique, because GC/MS methods are one to two orders of magnitude more sensitive than those reported for high-performance liquid chromatography (HPLC). 5-FU and its analogs are very polar molecules, so derivatizations are usually involved in the GC/MS methods. API LC/MS/MS techniques would appear to be a preferred approach for the quantitative determination of 5-FU and the other three test articles.

Three LC/MS/MS quantitative analytical methods were developed to meet the high sensitivity and specificity required for the analysis of human plasma samples for 5-fluorouracil, uracil, tegafur and leucovorin, respectively. The first method was developed for 5-FU and uracil using positive ion atmospheric pressure chemical ionization LC/MS/MS. Derivatization of 5-FU and uracil with 4-bromomethyl-7-methoxy-coumarin (BMC) provided excellent sensitivity for the quantitation of both compounds. This method provided lower level of quantitation (LOQ) of 0.5 and 2.5 ng/mL for 5-FU and uracil with the use of 0.5 mL of human plasma (Figure 1). 5-Chlorouracil (5-CIU) and uracil-¹⁵N₂ were used as the internal standards at 100 ng/mL level for 5-FU and uracil, respectively. The upper level of quantitation (ULQ) were 200 ng/mL for 5-FU and 1000 ng/mL for uracil. A simple protein precipitation with aqueous trichloroacetic acid (TCA) was performed followed by evaporation to dryness. The dry residues were treated with the derivatizing reagents containing BMC at ambient temperature. Chromatography was performed on a 4.6 x 150 mm BetasilTM C18 column using gradient elution with acetonitrile and 10 mM ammonium acetate (pH 4.5) at 1 mL/min in 4.5 min.

The second and the third methods were developed for tegafur and leucovorin, respectively. A simple solid-phase extraction (SPE) using Bond ElutTM C18 cartridges was used for both methods. The

reconstituted extracts were separately analyzed by TurboIonSprayTM LC/MS/MS operated in the negative ion mode. For tegafur, a 2 x 100 mm BetasilTM C18 column was used with isocratic elution with acetonitrile and ammonium acetate buffer. (+)-5-Fluorodeoxyuridine (5-FDU) was used as the internal standard at 100 ng/mL level for tegafur. A 2 x 150 mm BetasilTM C18 column was used for leucovorin using isocratic elution with 5 mM ammonium acetate in methanol and aqueous 5 mM ammonium acetate. Methotrexate was used as the internal standard at 100 ng/mL level for leucovorin. For both tegafur and leucovorin, the LOQ was 10 ng/mL based on 1 mL aliquots of human plasma (Figures 2-3). The calibration curves were linear from 10 ng/mL to 500 ng/mL for both compounds using weighted (1/x) least squares regression.

R.J. Parker and J.M. Strong
Food and Drug Administration, Laurel, MD 20708

Introduction

We have previously reported on pentafluorobenzyl chloroformate (PFBCF) as a reagent for the facile derivatization of amino acids (AA's) and alcohols, with detection by electron capture negative ion mass spectrometry (ECNI) [1,2].

Currently, we have been investigating the application of PFBCF derivatization to several molecules of biological importance, including methyl phenidate (Ritalin®), tryptophan, cysteine and homocysteine. In addition, we have studied analyte steric effects on the mechanism of the derivatization.

Ritalin has received considerable attention in relation to its use in the treatment of hyperactivity in children, as well its more recent use as a drug of abuse. In collaboration with the FDA, we investigated the application of PFBCF derivatization of Ritalin and its major metabolite, α -phenyl-2-piperidineacetic acid (ritalinic acid, RiTA).

The chromatographic and ECNI mass spectral properties of the PFBCF derivatives of tryptophan, cysteine and homocysteine were also investigated.

Experimental

Pentafluorobenzyl chloroformate (PFBCF): PFBCF is now commercially available (SynQuest Laboratories, Alachua, FL, USA, (904) 462-0788). The reagent was used without further purification. It is supplied in sealed ampules and is transferred to screw-cap vials as needed. Sealed ampules or screw-cap vials are stored at -20°C.

AA, Ritalin and Ritalinic Acid Derivatization: A 10 μ L aliquot of an AA or Ritalin or RiTA solution in 0.1M HCl, was added to 100 μ L of H₂O / ethanol / pyridine, 60/30/10, v/v/v, or H₂O / pyridine, 90/10, v/v and vortexed. PFBCF (10 μ L, neat) was then added and the solution vortexed for 30 sec. Toluene (30 μ L) was added, the phases separated by freezing in Dry Ice, and an aliquot of the upper liquid phase transferred to an autosampler vial for GC/MS analysis.

Rat or Mouse Plasma Analysis: Animals were dosed by addition of Ritalin to feed at levels of 250, 500 or 1000 ppm and plasma samples taken at 1, 8, 15, 22 and 27 days. Ritalin undergoes hydrolysis under the conditions used for PFBCF analysis. Therefore, Ritalin and the major metabolite, ritalinic acid, were analyzed separately. Ritalin in plasma (0.1mL) was extracted with hexane and derivatized with heptafluorobutyric anhydride and analyzed by GC/MS in EI mode.

The aqueous phase, containing ritalinic acid, was protein precipitated by addition of 0.75 mL acetone. The sample was then centrifuged, and the supernatant lyophilized. The lyophilized sample was diluted to 0.1mL with H₂O and 10 μ L pyridine added followed by 10 μ L PFBCF and then vortexed. Toluene (0.5 mL) was added, the phases separated by freezing in Dry Ice, and the upper organic phase transferred to an autosampler vial for analysis. Diclofenac and Carprofen were used as internal standards and added to plasma samples (5 μ g/mL) prior to initial extraction.

GC/MS Conditions: Standards data were collected on either a HP-5989 mass spectrometer interfaced with a HP-5890 GC or a Finnigan TSQ-70 interfaced with a Varian 3400 GC. The ion source temperature was 150°C. Full scan data was recorded from m/z 100 to 750. Methane was used as buffer gas for all ECNI experiments. Plasma samples were analyzed on a HP-5988, with an ion source temperature of 150°C. Selected ion monitoring

(SIM) experiments on the 5988 monitored the following ions, Ritalinic acid (m/z 295, 315, 442), Carprofen (m/z 228, 272) and Diclofenac (m/z 258, 294).

GC separations were performed on a DB-5MS, 12 m x 0.18 mm id x 0.18 μ m film thickness (HP-5988 and TSQ-70 mass spectrometers) or DB-17, 15 m x 0.25 mm, 0.25 μ m film thickness (HP-5989). A typical oven ramp profile was 70°C to 150°C at 30°/min, 150°C to 250°C at 10°/min and 250°C to 300°C at 30°/min with a 3 min hold at 300°C. Injection was splitless at 250°C. All injections were 1 μ L.

Results and Discussion

Ritalin hydrolyzed under the conditions used for PFBCF derivatization and was analyzed separately from its major metabolite, ritalinic acid (see Experimental). The metabolite gave the *l*-RiTA-OPFB derivative as the predominate product (Fig. 1), even in the presence of ethanol.

FIG 1: ECNI mass spectrum of the PFBCF derivative of ritalinic acid.

This steric dependence of the derivatization suggests that CO₂ loss is preferred relative to nucleophilic attack by ethanol. This aqueous conversion to the PFB ester by decarboxylation allowed for the facile detection of ritalinic acid in rat and mouse plasma at biological levels.

The competition between nucleophilic attack and decarboxylation was further investigated with tryptophan. Under reaction conditions with ethanol present, both the *l*-Trp-OEt and *l*-Trp-OPFB are formed. By eliminating ethanol from the reaction mixture, the *l*-Trp-OPFB can be formed exclusively and its ECNI mass spectrum is dominated by m/z 427, [M-181].

Cysteine and homocysteine formed the expected *l*-(N,S)-(H)Cys-OEt derivatives at room temperature under aqueous conditions. The mass spectra of the derivatives were dominated by ions resulting from fragmentation at the sulfur as well as loss of HF.

To date we have used PFBCF for the derivatization of amines, carboxylic acids, thiols and alcohols. While our efforts have been centered on amino acids, PFBCF derivatization can be potentially applied to any molecule containing any or all of these functional groups. Detection by ECNI mass spectrometry then allows for extremely sensitive and specific analysis of the resulting products from complex matrices.

Simultaneous Determination of alpha- and beta-Propylene Glycol Methyl Ethers and 2-Methoxypropionic Acid in Rabbit Blood by GC/NCI/MS

Debra A. McNett, Steven C. Hansen, Michael J. Bartels, The Dow Chemical Company
H&ES Analytical Chemistry Laboratory, 1803 Building, Midland, MI 48674

INTRODUCTION Propylene glycol ethers, like other glycol ethers, are commonly utilized as solvents for products such as paints, inks and cleaning formulations due to their miscibility with water and a wide variety of organic solvents. Components in products such as these require toxicological testing prior to and while being marketed. Propylene glycol methyl ether (PGME) is one such glycol ether which exists as two isomers. The major isomer present at > 98% is α -PGME, a secondary alcohol, and the minor isomer (< 2%) is β -PGME, a primary alcohol. The β -PGME isomer can be oxidized to the alkoxy acid, 2-methoxypropionic acid (MPA) through the hepatic alcohol/aldehyde dehydrogenase system.¹ In order to describe the uptake, metabolism, and disposition of PGME in laboratory animals, analytical methods must be attained for all three of these compounds in blood. Classical methodology requires separate sample preparation and separate analysis for the PGME isomers and MPA. This separate analysis requires twice as much sample, analysis time and instrument time. In order to overcome this sample and time constraint, a new sensitive and selective method has been developed for all three analytes simultaneously with detection limits of 5 ppb for both MPA and β -PGME and 50 ppb for α -PGME in rabbit blood. The stable isotope (deuterium) tri-labeled analogs of the PGME isomers and MPA were employed as internal standards in this method. The procedure involves simultaneous derivatization of MPA to the pentafluorobenzyl ester and the PGME isomers to their corresponding pentafluorobenzoyl esters followed by extraction of all three analytes into toluene. The derivatized analytes are then analyzed by gas chromatography with negative-ion chemical ionization/mass spectrometry in a single run. Quantitation of α - and β -PGME and MPA was performed by selected ion monitoring of [M]⁻ for the PGME isomers and [M-CH₂C₆F₅]⁻ for MPA.

SAMPLE PREPARATION Rabbit blood samples (approximately 250 mg) are weighed into glass vials and combined with 750 μ L (weighed) of ion-pairing agent (0.3 N NaOH solution containing 0.5 to 0.9 μ g/mL of D3 internal standards of MPA and α - and β -PGME, and 0.1 M tetrabutylammonium hydrogen sulfate) and mixed well. The samples are then derivatized by adding 4 μ L of pentafluorobenzoyl chloride (for the PGME isomers) and 60 μ L of pentafluorobenzyl bromide (for MPA) followed by mixing while heating (46°C) for 20 minutes. The derivatized analytes are extracted into 1 mL of toluene by vortexing while heating (46°C) for 20 minutes. The organic layer is separated by centrifugation and transferred to new vials and analyzed by GC/NCI/MS.

ANALYTICAL CONDITIONS Quantitation of MPA, α - and β -PGME in rabbit blood extracts was performed with a Finnigan MAT SSQ-710 GC-MS system (San Jose, California) interfaced to a Hewlett-Packard 5890 Series II gas chromatograph (Palo Alto, California). The derivatized extracts were injected (2 μ L) in the splitless mode at 1 minute with an injection port temperature of 280°C. Separation was performed using a fused silica capillary column coated with 1.0 μ m film bonded phase of Durabond-1701 (30 meter x 0.32 mm i.d.; J & W Scientific, Folsom, CA). Helium was the carrier gas at a head pressure of 15 psi. The column temperature was initially held at 75°C for 1 minute, increased at 10°C/minute to 200°C followed by a final ramp to 250°C at 30°C/minute. The mass spectrometer was operated in the negative chemical ionization mode using methane as a reagent gas at a pressure of 9 torr. The source temperature was held at 150°C. Quantitation of α - and β -PGME and MPA was performed by selected ion monitoring of [M]⁻ for the PGME isomers and [M-CH₂C₆F₅]⁻ for MPA. Ions m/z 103, 106, 284, and 287 were monitored for MPA, D3-MPA, α - and β -PGME and D3- α - and D3- β -PGME, respectively. Scan time was 0.075 seconds for each ion.

Figure 1. Chromatogram of a rabbit blood standard containing MPA, D3-MPA, α -PGME, D3- α -PGME, β -PGME and D3- β -PGME

RESULTS Duplicate standards prepared in control rabbit blood demonstrated excellent linearity by GC/NCI/MS over ranges of 5-1000 ng/g for MPA and β -PGME and 50-1000 ng/g for α -PGME. Using a power curve plot of the data for each analyte (concentration versus peak area ratio), the correlation (r^2) was 0.9995, 0.9999, and 0.9995 for MPA, α -PGME, and β -PGME, respectively. The precision of the method was determined by preparing triplicate spikes in rabbit blood. For all analytes the coefficient of variation was generally less than 10% and did not exceed 15% at any concentration. Inter-day precision of this method was investigated using fortified samples prepared with rabbit blood. Sets of matrix standards and blood samples fortified with MPA, α -PGME, and β -PGME were prepared on 5 different days. Single samples were prepared each day within the concentration ranges. The mean relative recovery of the fortified samples compared to matrix standards of the same day was determined along with the coefficient of variation of this recovery across all analyses at each concentration level. The coefficient of variation across all concentration levels for MPA, α -PGME, and β -PGME were 4-11%, 7%, and 4-13%, respectively.

CONCLUSIONS A sensitive and selective GC-MS method has been developed to simultaneously derivatize and analyze for MPA, α - and β -PGME in rabbit blood. This method results in lower costs per sample by reducing the sample size, sample preparation time and instrument time due to the fact that all three analytes are derivatized and extracted in the same reaction.

Summary- The goal of this work was to develop a universal high capacity non GLP bioanalytical screen to provide initial relative pharmacokinetic and bioavailability data to help refine the Drug Candidate selection process from Combinatorial Chemical libraries. A new strategy using LC/MS technology and the mouse *in vivo* model has been developed that is capable of producing relative pharmacokinetic and bioavailability results for two new compounds per week.

Mouse Model- The mouse *in vivo* model was used because it is a common pharmacologic model and, at a body weight of 25 grams, requires much less test compound than larger animal models (rat and dog). The study was designed to obtain both oral and intravenous plasma concentration profile data to provide an estimate of absolute bioavailability. Oral and intravenous plasma concentration profiles were obtained using 12 mice dosed at 50 mg/kg and 10 mg/kg, respectively. A single 1.0-mL sacrifice blood sample was drawn via cardiac puncture from two mice at six time points up to six hours post dose. The blood was anticoagulated with EDTA to obtain plasma for Drug Candidate analysis.

Sample Preparation- To each 100 µL plasma sample, 25 µL of internal standard solution (containing an analog of the Drug Candidate at a concentration of 1-2 µg/mL in 66% methanol/water) was added. Precipitation of the plasma proteins was accomplished by the addition of 200 µL of methanol followed by vortex mixing. The sample was centrifuged at ~2000Xg for 10 minutes and ~200 µL of the supernatant was passed through a 0.45 µm filter. As much as 75 µL of the resulting filtrate was injected onto the LC/MS system. In two cases, samples from two rats receiving different Drug Candidates were pooled and the samples analyzed simultaneously.

Standard Curves- The mouse plasma standard curve ranged from 1 ng/mL to 10,000 ng/mL. The calibration samples were prepared in singlicate by adding small aliquots of various dilutions of methanolic stock solutions directly to 100 µL of drug-free mouse plasma.

Liquid Chromatography- In order to obtain optimal ESI sensitivity, high organic strength mobile phases were required. The use of high organic strength mobile phases with this class of polar compounds required a very retentive stationary phase such as C18. See Figure 1 for an example of a mass selected chromatogram containing two Drug Candidate analytes and one internal standard.

Mass Spectrometry- Selected Ion Monitoring of the protonated molecular ion [M+H]⁺ of each Drug Candidate was used. The same internal standard was used for each analyte. Typical MS conditions are shown in Table 1. The Universal LC/MS setup is displayed graphically in Figure 2.

Results- Concentrations of Drug Candidate in plasma were determined by interpolation of the daily standard curve. The standard curves were typically nonlinear over the 4-orders of magnitude studied. The calibration curve was fit to a power function of the form $Y = a + bX^c$, where Y is the area ratio, a is the slope, b is the intercept and c is the exponent. A weighting factor of $1/X^2$ was used for all standard curves. See Figure 3 for a typical standard curve and power function parameters. See Figure 4 for a comparison plasma concentration profiles for two Drug Candidates. On a typical work week, relative pharmacokinetic and bioavailability data were generated for 2 new Drug Candidates.

The plasma concentration profile data were further reduced to produce an area under the curve from post dose time = 0 to time = τ , the last measurable time point ($AUC_{0 \rightarrow \tau}$). These values are compared in Table 2. The ratio of dose-normalized oral $AUC_{0 \rightarrow \tau}$ to the intravenous $AUC_{0 \rightarrow \tau}$ provides an estimate of absolute bioavailability. Estimates of elimination half-life were not obtained due to the paucity of data and parallel group experimental design.

Conclusions- LC/MS in a non GLP environment offers the benefits of nearly universal applicability, fast method development, high sensitivity, good specificity and high throughput. The mouse *in vivo* model can be used to distinguish between Drug Candidates of the same structural class on the basis of relative pharmacokinetics and bioavailability using only milligram quantities.

Future Work- We are developing strategies to triple the number of new assays per week using the same resources. The expected 2 to 3-fold loss of sensitivity with simultaneous measurement of multiple analytes is not considered an obstacle to success. We are, however, concerned that concomitant dosing of mice using "cocktails" of 3-6 compounds may improve the *in vivo* screening throughput but drug interactions may obscure the results. Lack of sufficient solubility will limit the total dose in a Drug Candidate "cocktail".

Quantitative Drug Metabolism Studies Using Liquid Chromatography/ Chemical Reaction Interface Mass Spectrometry (LC/ CRIMS) and LC/ Electrospray Tandem Mass Spectrometry (LC/ ESI MS/ MS). Feng-Yin Hsieh¹, Charles A. Goldthwaite, Jr.¹, Suresh Yeola¹, Ajai Chaudhary¹, Brian J. Nobes¹, Robert F. Mayo¹, Lewis J. Klunk² and Ian A. Blair^{1,2}. Departments of ¹Pharmacology and ²Chemistry, Vanderbilt University, Nashville, TN 37232; ³Bristol-Myers Squibb Co., Pharmaceutical Research Institute, Wallingford, CT 06492.

Tracer experiments based upon isotopic substitution have long played a significant role in drug metabolism studies. Although these methodologies often employ radioisotopes, an attractive alternate approach utilizes stable isotopes such as ¹³C and ¹⁵N as tracers in isotopic substitution experiments. Chemical reaction interface mass spectrometry (CRIMS) is a powerful technique that can be coupled on-line with liquid chromatography for selectively detecting and quantifying stable isotope labeled compounds such as drugs, metabolites and xenobiotics. CRIMS involves the combustion and subsequent atomization of analytes within a microwave-induced plasma oven and oxidation of the resulting species via an oxidation gas such as SO₂ (Figure 1). This generates an array of low molecular weight gaseous species corresponding to stable oxidation products which are detected by a quadrupole mass spectrometer using the selected ion monitoring (SIM) mode (i.e. m/z 31 for ¹⁵NO and m/z 45 for ¹³CO₂). Thus, quantitation of analytes becomes possible regardless of the structure of the original compound. However, CRIMS is a destructive technique, and structural characterization of analytes must be completed using a complimentary on-line LC compatible technique such as LC/electrospray ionization tandem mass spectrometry (LC/ESI MS/MS).

The CRIMS system was coupled with HPLC via a Vestec Model B Universal particle beam interface. [¹⁵N/¹⁴C] BMS 180048 *in vitro* metabolites were selected as a model system to evaluate the technique. Rat liver slice and S9 fraction extracts were analyzed using the LC/CRIMS system following dosing of the animals with [¹⁵N/¹⁴C] BMS 180048. Minimal sample cleanup was required, and ¹⁵N labeled species were selectively detected using the response in the m/z 31 channel. [¹⁵N] buspirone was used as the internal standard, and metabolites were chromatographed by a Zorbax Rx-C₈ (4.6 mm x 150 mm, 5 μ m) column operated at 0.5 mL/min using a methanol/water solvent system. A post-column addition of 0.7 mL/min methanol was employed to ensure uniform thermospray nebulization within the particle beam interface. The accuracy of LC/CRIMS for quantitation was evaluated by comparing the results with those obtained from LC/radiomatic detection. Metabolite structures were then characterized using LC/ESI MS/MS.

Fifteen [¹⁵N] BMS 180048 *in vitro* metabolites were detected and quantified using these methodologies, thus demonstrating that LC/CRIMS has particular application for metabolism studies as a stable-isotope sensitive and compound-independent detection tool. Figure 2 represents the LC/CRIMS chromatogram for a [¹⁵N₂] BMS 180048 liver slice incubation as monitored in the m/z 31 channel. Excellent correlation was obtained between the LC/CRIMS technique and LC/radiomatic detection, although the CRIMS system provided superior resolution. In combination with LC/ESI MS/MS, LC/CRIMS provides a powerful technique for the complete quantitation and structural characterization of newly discovered metabolites. Supported by Bristol-Myers Squibb.

LC/MS Quantitation with Electrospray Ionization

Rong Zhang, Alan E. Schoen, Clay S. Campbell
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Internal standards are often used in quantitative LC/MS and LC/MS/MS assays to compensate for non-quantitative operations in sample preparation. They also compensate for instrumental non-linearities such as the response of the analyte in an electrospray ionization or atmospheric pressure chemical ionization source.

The elution of a large peak may deplete the charge available to ionize a smaller peak because of charge competition in the ionization process. This does not affect area ratio calculations when an analyte peak exactly coelutes with the internal standard because the ionization efficiency for both internal standard and analyte peaks are identical. The sum of the chromatographic peak areas for the analyte and internal standard as a function of total concentration fits an exponential equation of the form:

$$AreaCounts = k(1 - e^{-(c/\alpha)})$$

where *AreaCounts* is the area of the chromatographic peak, *k* is a scaling factor related to system gain, *c* is the total sample concentration (internal standard plus analyte), and *alpha* is the exponential response of the ionization process.

The terms *k* = 818907 and *alpha* = 616 are calculated from a fit to a typical data set. Taking the first derivative of the derived curve at zero analyte concentration gives the non-saturated response function for the ESI source. The ideal response, 1329*c*, occurs if charge depletion does not occur in the API source as analyte concentration increases. The response factor (RF) is the ratio of actual to ideal and is a function of the amount.

$$ResponseFactor = \frac{616(1 - e^{-0.00162296c})}{c}$$

When analyte and internal standard peaks elute with slightly different retention times, as is typically the case, the ionization efficiency for the two peaks may vary during their elution. The peak shape of the smaller peak will depend on the retention time difference as illustrated in figure 1. When charge depletion occurs and the internal standard peak does not coelute with the analyte peak, the area ratio between analyte peak area and the internal standard peak will depend on the retention time difference. The simulation shows that as the difference in peak elution times increases, the area ratio decreases.

The resulting calibration curve, shown in figure 2, is not linear because the effect of charge depletion varies with analyte concentration. The theoretically-predicted calibration curve rolls off as concentration increases. Forcing a linear fit to a fundamentally non-linear process provides less quantitative accuracy than can be obtained by using a fit to a mathematical model which properly describes the phenomenon. A more complex equation with an exponential term is superior to a quadratic fit or a linear fit.

The relative standard deviation (RSD) for an area ratio depends upon, and is limited by, the RSD for the internal standard due to propagation of errors.

$$RSD_{AreaRatio} = RSD_{Std} + RSD_{Analyte}$$

The effect of a low internal standard concentration causes accentuated scatter at high analyte concentrations. The minimum RSD is determined by the low ion count in the internal standard peak. A higher internal standard concentration provides better statistics as shown in table 1 and in Figure 3. Note that this assay has no evidence of charge depletion, providing a linear response over 3 orders of magnitude.

Int Std Conc.	RSD @ 12 pg	RSD @ 25 ng
431 pg	15 %	5.0 %
1.7 ng	6.6 %	1.3%

John Newton, Debra Buhrman, Regina Burton, Brian Folk, Piper Price, Danlin Wu,
Sanof-Winthrop, Malvern, PA

Introduction

Recent technological advances in atmospheric pressure ionization (API) are revolutionizing the quantitation of pharmaceutical products. LC-MS/MS provides the selectivity and sensitivity sufficient to quantitate many compounds at levels below 100 pg/ml in biological matrices.

The goal of this study was to investigate assay performance differences across different types of LC-MS/MS instruments. Assay performance across the different platforms was evaluated using an assay for SR 27417, a platelet activating factor receptor antagonist. This assay which utilizes a deuterated internal standard, employs a liquid/liquid extraction for sample cleanup and covers a concentration range of 10 to 1000 pg/ml based on a sample volume of 1 ml of human plasma. Within-day and between day precision and accuracy for SR 27417 in human plasma was evaluated over the full calibration range on all platforms. The platforms evaluated for this study were the Finnigan TSQ 7000 and the Sciex API III Plus quadrupole mass spectrometers and the Finnigan LCQ quadrupole ion trap mass spectrometer.

Results

The SR 27417 validation results are summarized below.

	Within Day		Between Day	
	%CV	M%D	%CV	M%D
LCQ	< 14 %	< 16 %	< 8 %	< 13 %
TSQ	< 6 %	< 5 %	< 9 %	< 5 %
APIIII	< 7 %	< 6 %	< 16 %	< 13 %

Conclusion

- The precision and accuracy result obtained by the LCQ at 25 pg/ml level was similar to those obtained by the TSQ 7000 at 5 pg/ml and the API III Plus at 50 pg/ml levels.
- The LCQ quadrupole ion trap mass spectrometer was determined to be a very capable quantitation platform for the SR 27417 assay at MQL between 10 - 25 pg/ml.

AUTOMATED SOLID PHASE EXTRACTION IN THE "96 WELL" MICROTITRE PLATE FORMAT FOR HIGH THROUGHPUT BIOANALYSIS USING LC-MS-MS

Robert A. Biddlecombe, Anne E. Jones and Stephen Pleasance
GLAXOWELLCOME, Group Development Operations, BioMet, International Bioanalysis, Langley Court, Beckenham, Kent, BR3 3BS, U.K.

Introduction

The automation of sample preparation for bioanalysis has primarily been driven by the analytical run time. The run times of conventional HPLC, with for example UV detection (8-25 min), have proved well suited to automating sample preparation in a sequential "on-line" mode, e.g. the Gilson ASPEC system. Unfortunately, the fast analysis times possible with LC-MS-MS (1-3 min per injection) have posed problems for this type of sequential automation, i.e. sample preparation becomes the rate limiting step. In addition, dedicating one type of sample preparation system on-line with an expensive mass spectrometer can cause scheduling problems in a high throughput laboratory dealing with multiple methods/projects. While continuing to work with manufacturers to reduce cycle times of existing automated sequential sample preparation systems for LC-MS-MS, our initial approach to circumvent the problem of sample preparation being the rate limiting step has been to separate sample preparation and analysis and focus on optimising the former for automated, high throughput batch processing.

The majority of chromatographic based bioanalytical methods in our laboratory employ solid phase extraction (SPE) for sample preparation. The technique being well established, with numerous manufacturers providing a wide range of phases for many applications, and it is also more suited to automation than other extraction techniques. Although there are several systems for automated sequential processing by SPE, the development of batch processing has been limited essentially to variations in the design of the vacuum manifold. More recently, Kaye *et al.* at Pfizer have reported a novel "micro preparation SPE system" [1]. This system consists essentially of 96 SPE cartridges bundled together and mounted into a "block" with the dimensions of a standard 96 well microtitre plate. The system has been patented and is now produced commercially as the MicroLute™ system by Porvair Filtronics U.K. The present work describes our experiences in the application of this technology for automated high throughput bioanalysis using LC-MS-MS [2]

The MicroLute™ System

The MicroLute™ system consists of a polypropylene block, the dimensions of a standard microtitre plate, containing 96 tubes into which conventional SPE material is packed on top of a filter. Currently, packing beds of 50 mg or 15 mg are routinely used. The block can be fitted with strips of column extenders to allow larger solvent volumes to be used with the 50 mg packings. A schematic of the block is presented opposite. The MicroLute™ blocks are mounted on a specially designed vacuum manifold (Porvair) and the drain tubes channel the final extract into a 96 well collection plate which can be either a standard microtitre plate or a deep well version for larger elution volumes (Porvair).

The MultiPROBE RSP

Although manual 8 channel pipettes may be used with the blocks, in our laboratory all liquid handling, including dilution of samples, the addition of ISTD etc, is carried out using a Packard MultiPROBE 104 robotic sample processor (RSP). The operator has only to place the source rack, containing the samples, standards and/or controls together with reagent reservoirs onto the RSP bed. The MultiPROBE software enables control of a vacuum system, allowing automation of all steps (e.g. condition, load, wash), except the placement of a collection plate in the manifold prior to the final elution step. The Multiprobe typically takes 20-50 min to process 96 samples depending on the SPE procedure. This compares very favourably with the time taken to prepare 60 samples by manual pipetting, using individual SPE cartridges and conventional vacuum manifolds, and also with the time required to prepare the same 60 samples by for example a Gilson ASPEC operating in batch mode. The collection plates are transferred to an autosampler modified to accept the 96 well format. Initially, a Jasco AS-950 autosampler which had been modified to accept a single plate was used. This has been supplanted by a Gilson 233 XL autosampler which has the capacity to load up to 6 collection plates (576 injections) and has an open design well suited to further automation.

For the majority of LC-MS-MS methods used in our laboratory where the analysis time is less than 3 mins, it has been possible to exploit the full potential of the Gilson autosampler and analyse up to 6 plates in unattended operation. Indeed, in a recent study supported by a method with a run time of 2.2 minutes, it was possible to analyse 800 clinical samples in under 48 hours of continuous operation.

We are currently working to refine and further automate the process. The modification of the vacuum manifold, to allow the collection plate to be placed under the MicroLute™ block for the final elution step without manual intervention, has been the first priority.

The MicroLute™ approach to automated SPE has proved to be a very successful alternative to both manual and sequential "on-line" extraction, offering a 5 fold decrease in sample preparation times and therefore being more compatible with the fast analysis times possible with LC-MS-MS. Indeed, the potential of this technology is such that the analysis is again becoming the rate limiting step. The fact that the analyst has minimal manual pipetting, and no longer has to handle, cap, label, etc. individual vials and/or cartridges is a significant advantage of this system.

QUANTITATIVE DETERMINATION OF RPR 102681 IN HUMAN AND MONKEY PLASMA USING ION SPRAY LC/MS/MS

Henry Y. Wu,¹ Daniel Mulvana,¹ Mary T. Gilbert²
and Jack D. Henion,

¹ Advanced BioAnalytical Services, Inc., 15 Catherwood Rd., Ithaca, NY 14850

² Rhône-Poulenc Rorer Pharmaceuticals, 500 Arcola Rd., P.O. Box 1200, Collegeville, PA 19426

A simple, fast, sensitive and specific analytical method was developed and validated to quantitate RPR 102681 in human and monkey plasma. This method employs a solid-phase extraction procedure to isolate RPR 102681 and the internal standard, RPR 72820, from the biological matrices. The overall recovery of RPR 102681 was 87.7% (%RSD = 3.74) from human plasma and 88.9% (%RSD = 6.50) from monkey plasma. Reconstituted extracts were analyzed by ion spray liquid chromatography/tandem mass spectrometry (LC/MS/MS) in the selected reaction monitoring mode. Chromatography was performed on a 2 x 100 mm BetasilTM C18 column using isocratic elution with acetonitrile and ammonium acetate buffer.

The chemical interference from plasma was minimized by the combination of HPLC and MS/MS. No interference by endogenous substances from drug-free plasma was observed. The assay has a limit of quantitation (LOQ) of 0.4 ng/mL for RPR 102681 in human plasma (Figure 1) and 2 ng/mL for RPR 102681 in monkey plasma based on 0.5 mL and 0.1 mL aliquots of plasma, respectively. For the validation of the method in monkey plasma, monkey plasma quality control (QC) samples were diluted five-fold with human plasma, and calibration standards prepared in human plasma were used. The assay has an upper limit of quantitation (ULQ) of 250 ng/mL for RPR 102681 in human plasma and 1250 ng/mL for RPR 102681 in monkey plasma, respectively. The standard curves ranged from 0.4 ng/mL to 250 ng/mL for RPR 102681 in human plasma (Figure 2). The internal standard (RPR 72820) concentration was 100 ng/mL of plasma. The standard curves are linear if a ULQ of 100 ng/mL is used. Statistical results showed that the current method provides acceptable precision and accuracy with a ULQ of 100 ng/mL using weighted ($1/y^2$) least squares regression.

The inter-assay precision (RSD) for any level of calibration standards did not exceed 5% for RPR 102681 in human plasma validation analyses and 7% for RPR 102681 in monkey plasma validation analyses. The intra-assay precision (RSD) for any QC level was within 5% in human

plasma and 13% in monkey plasma. The inter-assay precision (RSD) for any QC level was within 3% in human plasma and 5% in monkey plasma. The inter-assay accuracy (DEV) for any calibration standard level was within 5% in human plasma validation analyses and 4% in monkey plasma validation analyses. The intra-assay accuracy (DEV) for any QC level was within 9% in human plasma and 11% in monkey plasma. The inter-assay accuracy (DEV) for any QC level was within 6% in human plasma and 9% in monkey plasma. RPR 102681 and RPR 72820 were stable in acetonitrile for 24 hours at ambient temperature, and 44 days (for RPR 102681) and 68 days (for RPR 72820) at -20°C. RPR 102681 was found to be stable in plasma for 24 hr and in the reconstitution buffer for 24 hr at ambient temperature. RPR 102681 was also found to be stable in human plasma for 35 days and in monkey plasma for 30 days at -70 °C. RPR 102681 was shown to be stable after 3 freeze/thaw cycles in plasma and to be stable up to 6 days as dry extracts at -20°C.

LC/MS/MS Determination of Bisphosphonates

Melissa Anderson* and Jack Henion

Cornell University, Analytical Toxicology, 927 Warren Drive, Ithaca, NY 14850

Introduction

Bisphosphonates are synthetic compounds that are taken up preferentially by the skeleton and suppress osteoclast-mediated bone resorption. In spite of the several methods described for this class of compounds, few analytical methods have described the determination of bisphosphonates in biological fluids at low concentrations. Because phosphonic acids cannot be analyzed readily with GC because of their low volatility and polar nature, HPLC would be the preferred separation technique for these compounds. Previous HPLC methods have utilized different detection techniques including electrochemical, fluorescence, and ultra-violet; however, these techniques do not offer the same sensitivity and/or specificity needed for the quantitative determination of this compound in urine as ion spray tandem mass spectrometry.

Experimental

Isocratic conditions using an eluent of 1% Acetic Acid in water with a 1 x 100 mm column (Keystone Scientific Deltabond Cyano) combined with MS/MS in the selected reaction monitoring (SRM) mode provided an elution time of approximately two minutes for these compounds. A longer retention time would be preferred to allow interference peaks to elute before the analyte. This was accomplished using an eluent of 45% acetonitrile and 55% 10 mM tetrabutylammonium hydroxide 5 mM ammonium acetate with a 1 x 150 mm PRP-1 column (Keystone Scientific). Unfortunately, this ion pairing reagent caused a significant decrease in the mass sensitivity by SRM-LC/MS. The self-aligning composite liquid junction/ion spray interface adapted to the Sciex TAGA 6000E triple quadrupole upgraded to an API III (operated at 3.6 kV in negative ion mode) received 50 μ L/min from the column effluent with no post-column split and 50 μ L/min from the makeup liquid (10 mM ammonium acetate in acetonitrile).

Solid-phase extraction was used to isolate CGP 42446 and the internal standard, CGP 44393, from water and urine. The water samples were directly applied to Ansys SPEC Plus 3 mL NH₂ (aminopropyl) disk, and the urine samples (0.5 mL) were diluted with 2.5 mL of water and then applied to the disks. The disks were conditioned with methanol and then water, the sample applied, and the analyte eluted with 25 mM ammonium citrate--25 mM ammonium phosphate (dibasic) (1:1). The extraction procedure has been automated using the Gilson ASPEC system. This extraction technique provides percent recoveries of 60% at mid nanogram levels in water and < 20 percent recovery in urine. We are continuing method development to improve the recovery of these compounds from urine.

Results and Discussion

Calibration standards were prepared in duplicate by adding aliquots of CGP 42446 and CGP 44393, the internal standard, to 2 mL of deionized water. The concentrations of the standard in the calibration curve were 200, 500, 800, 2000, and 5000 ng/mL. The concentration of the internal standard was 1000 ng/mL. Three quality control (QC) samples: 400, 700, and 3000 ng/mL were analyzed.

Using solid-phase extraction, the lower level of quantitation (LLQ) of CGP 42446 in water is 200 ng/mL with a linear response up to at least 5000 ng/mL (Figure 2). The accuracy from QC samples was <10% for each QC level.

The sensitivity of the bisphosphonates was enhanced by adding a makeup solvent using the self-aligning composite liquid junction/ion spray. The optimum makeup solvent was determined by LC/MS using various amounts of organic solvent. The makeup solvent chosen was 50% acetonitrile which showed a significant increase in response.

CE/MS-Ion Trap Determination of Bisphosphonates

Gloria A. Bach, Jack Henion, Analytical Toxicology, Cornell University, 927 Warren Drive, Ithaca, NY 14850

Introduction

We have initiated studies for the quantitative determination of important calcium replacement bisphosphonate compounds using CE/MS. Preliminary LC/MS experiments with the parent compounds proved unsatisfactory due to their very polar nature and insolubility in organic solvents. Considerable difficulties were encountered under HPLC conditions with limited retention behavior and precipitation of the target compounds in the HPLC injector and associated hardware. Preliminary off-line CE/UV analysis using the Supelco CElect-Amine coated CE capillary appeared promising. We therefore initiated studies to explore the analytical utility of CE/MS for the qualitative and quantitative determination of bisphosphonate compounds. A modified Varian Saturn II ion trap system was used with an ion spray CE/MS interface operated in the sheath-flow mode. Analytical standards dissolved in water were loaded using a Beckman P/ACE 2050 capillary electrophoresis instrument.

Experimental - Capillary Electrophoresis / Mass Spectrometry

A Beckman Model P/ACE 2050 system was kindly supplied by Beckman Instruments, Inc. (Palo Alto, CA). The commercial instrument was slightly modified in that both the safety lock between the capillary ends and the temperature controlling system were bypassed. In addition, 100 mbar of pressure was added to the inlet during electrophoresis which sped the electrophoretic analysis. The ion spray interface used in this study was constructed in house.¹ The sheath liquid used was 5 mM Ammonium Formate in 90% Isopropyl Alcohol, 10% H₂O, and was delivered at 12 μ L/min by a Harvard Apparatus syringe pump. The capillary electrophoretic separation was carried out in the negative ion mode by applying -28 KV to the anode while -2.5 KV was applied to the cathode via the ion spray interface. Sample injection was made at the anode end in the electrokinetic mode for 12 seconds during which a voltage of -10 KV was applied to the anode. The nebulising gas was turned off during injections to avoid siphoning of analyte and introduction of air bubbles. The optimal CE buffer was found to be 40 mM Ammonium Formate, pH 3.5, and separation was achieved using the Supelco CElect-Amine coated capillary of length 85 cm, 50 μ i.d., and 190 μ o.d. The injection quantity was determined by the mobility of the analyte during injection

according to the equation $q = \pi r^2 c l \frac{t_{inj}}{t_{mig}}$. r is the inner radius of the capillary, c

is the concentration of the solute, l is the length of the capillary, and t_{inj} and t_{mig} are the duration of injection and the time required for the analyte to migrate the length of the capillary.

Results and discussion

Calibration curves were made for the 3 bisphosphonates in the injected mixture.

Standard concentrations on the curve were at the 2, 4, 8, 12, 16, and 20 picogram levels. 6 injections of QC standards were made at the 3 and 14 picogram levels to test the accuracy and precision of the calibration. We found the scatter in the points on the calibration curve to be high, especially at the higher concentrations. We believe this may possibly be due to the bisphosphonates sticking to the surfaces of the ion sprayer tip and the capillary. This phenomenon is currently under study in our laboratory. Shown below is a representative electropherogram and mass spectra of the 3 compounds and internal standard at the 20 pg. level. Mass spectra were taken in the full-scan negative ion mode from m/z 155 to m/z 550. Work in progress includes identifying the factors involved in CE/MS reproducibility, in an effort to make the technique useful for quantitative work.

LC/MS/MS Determination of Carnitine and Acetylcarnitine in Human Plasma and Urine.

Steve Lowes¹, Herbert Birnboeck² and Jack D. Henion¹

1. Advanced BioAnalytical Services, Inc., 15 Catherwood Road, Ithaca, NY 14850

2. F. Hoffmann-La Roche Ltd., Basel, Switzerland

Introduction

Carnitine and its O-acyl esters (acylcarnitines) play an important role in the metabolism of fatty acids. Detection of endogenous carnitine esters in biological fluids can be used for the diagnosis of a number of metabolic disorders. It is this latter feature which has led to the development of a wide variety of analytical methods for the determination of carnitine and acylcarnitines in biological matrices.

We have recently developed an LC/MS/MS method for the determination of D-3 and D-6 carnitine and D-3 and D-6 acetylcarnitine in human plasma and urine using D-9 carnitine and D-9 acetylcarnitine as internal standards. The objective was to be able to study the metabolism of non-endogenous acetylcarnitine through co-administration of D-6 acetylcarnitine. The goal was to quantitatively determine the target deuterated compounds in human plasma and urine at levels down to 0.15 and 0.01 nmol/mL, respectively.

Experimental

The sample preparation procedure for the analytes in plasma employed a simple protein precipitation step followed by drying the filtrate and reconstituting the carnitine compounds in methanol. Urine samples were treated analogously without the protein precipitation. The extracts were analyzed by LC/MS/MS using a PE/SCIEX API III^{Plus} and an API 300 triple quadrupole mass spectrometers operated in the Turbo IonSprayTM, positive ion mode. Chromatography was performed using a Shimadzu LC-10AD binary gradient system, a 2.1 x 100 mm C18 HPLC column and an acetonitrile/heptafluorobutyric acid gradient.

Results and Discussion

Combining a reversed-phase chromatographic separation with the sensitivity and selectivity of MS/MS, allowed detection of the deuterated carnitine and acetylcarnitine at the sub nmol/mL level for both plasma and urine. Figure 1 shows the SRM chromatograms obtained for a spiked human plasma extract at the experimentally determined lower level of quantitation (LLQ) of 0.01 nmol/mL. An upper level of quantitation (ULQ) was studied at 10 nmol/mL. For plasma samples, linearity of instrument response versus analyte concentration was observed for each of the carnitine compounds (Table 1).

The same analyte concentration range was studied for spiked human urine samples. All analytes except D-3 carnitine produced the same LLQ as plasma, 0.01 nmol/mL. An increased background signal for D-3 carnitine raised the LLQ to 0.05 nmol/mL. For urine

samples, instrument response versus analyte concentration demonstrated a quadratic curve fit for each compound.

Figure 1. SRM Chromatograms from a LLQ Standard Plasma Extract at 0.01 nmol/mL

	HUMAN PLASMA				HUMAN URINE		
	LLQ* (nmol/mL)	ULQ** (nmol/mL)	Fitting Model/ Weighting Factor	Correlation Coefficient	LLQ* (nmol/mL)	ULQ** (nmol/mL)	Fitting Model / Weighting Factor
D-3 Carnitine	0.01	10.00	Linear / 1/y	0.997	0.05	10.00	Quadratic / 1
D-6 Carnitine	0.01	10.00	Linear / 1/y	0.998	0.01	10.00	Quadratic / 1
D-3 Acetylcarnitine	0.01	10.00	Linear / 1/y	0.998	0.01	10.00	Quadratic / 1
D-6 Acetylcarnitine	0.01	10.00	Linear / 1/y	0.998	0.01	10.00	Quadratic / 1

Table 1. Results Summary Table

Conclusions

A sensitive, specific, accurate and reproducible analytical method for the quantitation of deuterated analogs of carnitine and acetylcarnitine in human plasma and urine was developed. Reproducible quantitative results were obtained over an analyte concentration range of 0.01 to 10 nmol/mL (except D-3 carnitine : 0.05 to 10 nmol/mL). The method allows the analysis of up to 11 samples per hour.

Analysis of Transcellular Metabolites of Arachidonic acid by LC/API/MS

Vinod K. Arora¹, Carlos O. Garner², John R. Falck³ and Ian A. Blair^{1,2}. Departments of Pharmacology¹, Chemistry², Vanderbilt University School of Medicine, Nashville, TN 37232 and School of Biomedical Sciences, UT Southwestern Medical Center at Dallas, 5323 Harry Hines Blvd, Dallas, Texas 75235³.

Cytochrome P-450 (CYP) has been shown to catalyze the oxidative metabolism of arachidonic acid to epoxyeicosatrienoic acid (EETs) and $\omega/\omega-1$ alcohols (19- and 20-hydroxy arachidonic acid). There is growing interest in defining the biological significance of this pathway due to the overlapping biological activities of these metabolites. It is becoming increasingly evident that this activity can be mediated by other enzymes involved in eicosanoid metabolism such as cyclooxygenase (COX) and lipoxygenase (LOX). Biotransformation of cyclooxygenase and lipoxygenase metabolites of arachidonic acid by CYP has long been recognized. However, recently attention has become focussed upon the possible bioactivation of CYP metabolites by COX and LOX. There is compelling evidence suggesting that COX plays a key role in the biological activity of several CYP metabolites. It is proposed that this is due to the transcellular metabolism of CYP arachidonic acid metabolites by COX and that this process is important in determining the observed biological activity of the metabolites.

CYP epoxigenase yields four regioisomeric monoepoxyeicosatrienoic acids ($\pm 5,6$; $\pm 8,9$; $\pm 11,12$ and $\pm 14,15$ EETs). During experiments designed to examine the effects of 8,9-EET on human platelet aggregation, it was found to be extensively metabolized. We have shown that incubation of 8,9-EET with purified COX (derived from purified ram-seminal vesicles); 8(R),9(S) EET was metabolized to 11(R)- and 15- hydroxy regioisomers, whereas 8(S),9(R) formed exclusively the 11(R)-hydroxy isomer, suggesting COX to be enantioselective. During *in vitro* studies designed to mimic biological milieu, these COX derived HEETs were further metabolized via epoxide hydrolase to their corresponding triol products. The epoxide hydrolase derived triol and diol products of 11-HEET and 8,9-EET were characterized by LC/API/MS.

Due to the instability of these compounds to autoxidation and thermal decomposition, liquid chromatography tandem mass spectrometry was employed in the study of these metabolites.

Liquid chromatography was conducted using a Hewlett-Packard 1090 series liquid chromatograph equipped with a Zorbax Rx-C8 column (2.1 mm x 150 mm, 5 μ m) interfaced with a Finnigan TSQ 7000 triple quadrupole mass spectrometer (operating with an API source). A linear gradient was employed over 50 min after the injection at which the initial solvent composition was 50 % A : 50 % B, and the final composition was 10 % A : 90 % B. This solvent composition was maintained for the next 5 min. Additionally, a 10 min post time period was employed to allow the column to equilibrate at these conditions. Solvent A was 5 mM aqueous ammonium acetate containing 0.05 % acetic acid and solvent B was 5 mM ammonium acetate in a mixture of methanol/water 9/1 containing 0.05 % acetic acid.

The API ion source was used in the negative mode for the free acids with a needle voltage of -4.5 kV and was operated in the positive mode for the methyl ester with a needle voltage of +4.5 kV. Nitrogen was used as the sheath gas and auxiliary gas, to assist in nebulization. The capillary was heated to 200 °C to provide optimal desolvation. The mass spectrometer parameters were optimized to obtain maximum sensitivity without sacrificing unit resolution. MS/MS conditions were optimized for each metabolite to obtain maximum structural information. Figure 1, shows the MS of a mixture containing 8,9-EET (m/z 319.4), 11(R)8,9-HEET (m/z 335.4), and their corresponding diol (m/z 337.4) and triol (m/z 353.4) metabolites respectively.

Fig. 1 : API MS of a mixture containing 8,9-EET (EET); 8,9-epoxy-11- hydroxyeicosatrienoic acid (HEET); 8,9-dihydroxyeicosatrienoic acid (DIOL) and 8,9,11-trihydroxyeicosatrienoic acid (TRIOL)

Quantitative determination of Mevinolinic acid by HPLC-negative ion ESI/MS/MS
R.E Calaf, M.Carrascal, E.Gelpi and J.Abián. Department of Medical Bioanalysis, IIBB-CSIC, Jordi Girona 18-26,08034-Barcelona, Spain

INTRODUCTION Lovastatin belongs to a family of recently introduced antihypercholesterolemic drugs which are potent inhibitors of HMG-CoA reductase, the rate controlling enzyme in cholesterol synthesis. The drug is hydrolyzed in vivo to mevinolinic acid (MVA), the active dihydroxyacid form which is structurally similar to HMG-CoA. Analytical methods for pharmacokinetic studies of this drug are based on elaborated and time consuming GC-MS procedures involving various derivatization methods. The detection limits reported in these studies are 0.2-0.1 ng/ml in human plasma (ref.1,2). Some authors have already compared the application of the new ESI methods for related compounds, highlighting their efficiency relative to other LC-MS techniques (ref.3)

Herein, we report an HPLC-ESI/MS/MS analytical method for the quantification of MVA which is fast, simple and more sensitive than reported GC-MS methods.

EXPERIMENTAL 100µl of the internal standard (metilmevinolinic acid, MMVA) were added to 1ml of spiked human plasma. The sample was then loaded onto a SEP-PAK (Bond Elut C8, 200mg) solid phase extraction cartridge and mevinolinic acid and its internal standard were eluted with methanol.

The two extracted compounds were separated under gradient conditions in less than 8 minutes on an HPLC column (1x100 mm ODS). Eluent A was MeOH:H₂O with 0.1% of acetic acid (2:1) and eluent B was MeOH. The gradient started at 30% B and increased to 80% B in 0.1 min. where it was held for 5.9 min. The column was connected to the Electrospray interface of a Finnigan TSQ 700 Mass Spectrometer operated in the negative ion mode.

The analyte and its internal standard were baseline resolved. Quantification was achieved in the precursor ion mode by monitoring m/z 421 (MVA), m/z 435 (MMVA), and the shared product ion at m/z 319. The collision energy was set at 20eV and the argon gas pressure was 1.8-2.0 mTorr.

RESULTS The negative ESI mass spectra of mevinolinic acid and its internal standard show (M-H)⁻ ions at m/z 421 (MVA) and m/z 435 (MMVA) as well as a characteristic common ion at m/z 319. MS/MS spectra of product ions from both compounds are shown in Fig. 2.

HPLC/MS in SIM mode was the method first used (Fig. 1a), but on account of the interferences masking the signal of the acid due to the complexity of the matrix (major peaks at the wrong retention times), we decided to apply a MS/MS method which made it possible to achieve a higher specificity of analysis, as illustrated in Fig. 1b, where specific responses are shown at the expected retention times.

Examples of the chromatograms used for the calculation of the calibration curves and detection limits are shown in Fig. 3. Calibration curves, interassay and intraassay analysis and stability studies were performed in order to establish a method fast, sensitive and selective enough for the analysis of MVA. Fig. 4 illustrates three calibration plots obtained in different days. The response is linear within the working range (50pg to 10ng/ml) and the detection limit was set at 50pg/ml plasma.

Quantitative Analysis of Steroids in Complex Matrices by LC/MS/MS on an Ion Trap

Jack Cunniff, Philip Tiller, Adrian Land, Michael Wakefield and Tom Vasconcellos
Finnigan MAT, San Jose, CA, 95134

Introduction

Pharmacokinetic studies carried out on potential drug compounds are often performed using triple stage quadrupole mass spectrometers. The reason for this is the facility with which single reaction monitoring (SRM) can reduce and often eliminate background interferences derived from the complex matrices these studies necessarily use.

With the introduction of the LCQ a great deal of interest has been shown, in particular, relating to the ability of the modern ion trap to perform quantitative analysis of specific components within a biological matrix such as plasma or urine. The reason for this interest is that in the past ion traps have not been able to address the main issues that determine whether an assay is reliable and therefore useful, namely

- 1) Do you have sufficient precision
- 2) Do you obtain a straight calibration curve
- 3) Do you have sufficient dynamic range
- 4) Do you have low detection limits
- 5) Can you obtain quantitative data using complex matrices
- 6) Can you quantitate in the presence of co-eluters

Experimental Methods

All experiments used an LCQ ion trap mass spectrometer (Finnigan MAT, San Jose, CA) operated in the **full-scan MS/MS** mode. An APCI probe was operated at 475°C with a heated capillary temperature of 150°C. An HP 1050 HPLC and autosampler delivered an isocratic mobile phase of 60:40 MeOH/Water + .5% acetic acid at a flow rate of 500 μ L/min through a 4.6 X 33 mm Supelcosil LC-18-DB column.

Untreated human plasma was extracted in 1 mL aliquots using SPEC•PLUS™•3ML•C8 extraction column (ANSYS, Inc., Irvine, CA). The extraction disc was conditioned by saturating with 0.2 mL of methanol for 1 minute. One milliliter of plasma was aspirated (<5 in. Hg) through the column. The disc was washed with 0.5 mL of 0.1 M NaOH followed by 0.75 mL of 20% methanol in distilled water. The disc was dried by vacuum for 5 minutes. One milliliter of ethyl acetate was aspirated (<5 in. Hg) through the disc into collection tubes. The eluate was evaporated to dryness under nitrogen at 40°C, spiked with appropriate level of steroids, and then reconstituted with 200 μ L of mobile phase; 100 μ L of which were injected into the mass spectrometer.

Results

A series of 10 μ L injections were made from a single vial containing 500 pg/ μ L of both Testosterone and Testosterone-d3 over a ten hour time period. Thus 5 ng of both components were injected on-column. This was an unattended over-night run acquiring full scan MS/MS data from which the %RSD was determined to be 5.7%.

A calibration curve for Budesonide with Budesonide-d8 as the internal standard was generated, in triplicate, over 3 orders of magnitude. The lowest standard was at a level of 40 pg and the most concentrated was at a level of 40 ng. The R^2 obtained was 0.9961.

A calibration curve was generated for Testosterone and Hydrocortisone using Testosterone-d3 (98% pure) and Hydrocortisone-d3 (95% pure) as internal standards. The target compounds were spiked into a human plasma extract at levels between 94 pg/mL and 12088 pg/mL, with the internal standards at a level of 10,000 pg/mL.

This curve was analyzed five times in succession over a period of 5 hours. The calibration curves for Hydrocortisone and Testosterone afforded R^2 values of 0.9934 and 0.9986 respectively.

Conclusion

The purpose of these experiments was to determine whether the LCQ is able to meet the 6 main criteria listed in the introduction.

All three experiments demonstrate that the LCQ affords the precision necessary to generate useful quantitative data.

Both the second and third experiments afforded linear calibration curves with acceptable r^2 values.

The second experiment was carried-out over 3 orders of magnitude demonstrating the desired dynamic range.

The detection limits observed in the second experiment were 40 pg.

Both the second and third experiment used internal standards that co-eluted demonstrating that co-elution was not a barrier to obtaining quantitative data.

The third experiment demonstrated that a complex matrix was not a hindrance to obtaining linear calibration data.

Acknowledgment

We would like to thank Gail Mueller and Dennis Blevins of Ansys Inc. for providing the human plasma extract used for this report.

ESTABLISHING COLLISION-INDUCED DISSOCIATION PATHWAYS OF PTAD-VITAMIN D₃ DERIVATIVES FOR METABOLIC STUDIES OF EB 1089

Andrew S. Weiskopf¹, Jack Cunniff², Paul Vouras¹

1) The Barnett Institute, Northeastern University, Boston, MA 02115

2) Finnigan MAT, San Jose, CA 95134.

Mass spectrometry, and LC-MS/MS in particular, has provided a sensitive and specific means to study the metabolism of vitamin D₃ analogue drugs. Metabolite-selective derivatizations can be performed with a dienophilic reagent, 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD), which complexes the C5-C6:C10-C19 cisoid diene A-ring system common to most vitamin D₃ structures. The principal advantage of this derivatization is that most all 1-hydroxylated D₃ metabolites yield a common fragment ion of m/z 314 upon collision-induced dissociation in ESI-MS/MS, allowing for their facile identification by parent scanning and trace detection by multiple reaction monitoring.^{1,2}

Fig. 1 Structures of EB 1089 and PTAD

EB 1089 AND PTAD DERIVATIZATION: EB 1089, a breast cancer therapeutic, is structurally unique among the well-known D₃ analogues in that it contains a second diene system on the side-chain, and therefore presents a second site for derivatization by PTAD. Using ESI-MS/MS on the VG Quattro Mass Spectrometer, a comparison of EB 1089-PTAD standards against derivatives synthesized in-lab has found that reaction at the side-chain site is greatly favored over the traditional A-ring derivatization. CID of the side-chain derivative, EB 1485, results in a fragment ion at m/z 296, which initially suggested that the reaction somehow produced a dehydrated form of the familiar m/z 314 ion. However, derivatizations performed on a EB 1089 analogue, MCW-068-Y-EE (1-CH₂OH instead of 1-OH), have shown that while the m/z 314 ion shifts upwards 14 mass units to 328, the m/z 296 does not, indicating that the "side-chain 296" and the "A-ring 314" are two structurally independent ion fragments.

FRAGMENT ION STRUCTURES BY MS²: Ion trap MS was performed on the Finnigan LC-Q in both ESI and APCI. MS³ of the side-chain derivative (630→296→, Figure 2a) has revealed a loss of 119 at m/z 177. This loss of 119 is characteristic of PTAD derivative fragmentation, and has been identified as -C₆H₅NCO, thus, the "side-chain 296" does contain the PTAD moiety. A number of other ions in the MS³ spectrum have been assigned structures consistent with losses of varying portions of PTAD: 204 -C₆H₅NH, 149 -C₆H₅N(CO)₂, and 121 -PTAD. The probable mechanism of formation for the "side-chain 296" fragment is cleavage of the C20-C22 bond on the side-chain and subsequent loss of the 25-OH, yielding the structure shown in Figure 3.

Previously, it was postulated that formation of the "A-ring 314" ion involved loss of the PTAD from the molecule by a retro Diels-Alder mechanism. However, MS⁴ experiments on EB 1483, the A-ring PTAD derivative of EB 1089 (612→314→296→, Figure 2b) also show a facile loss of 119. This result suggests that the PTAD is fully intact on the ion, and is not lost in the formation of m/z 314. We now propose an alternative mechanism which entails the cleavage of the C6-C7 bond and loss of the C-D ring portion; the remaining A-ring and PTAD moieties yield an ion of m/z 314 (Figure 3).

Figure 2a: MS³ of EB 1485, 630→296→

Figure 2b: MS⁴ of EB 1483, 612→314→296→

CONCLUSIONS: The implications of these results must now be considered before proceeding with analysis of EB 1089 metabolites by LC-MS/MS. The preferentially formed derivative (side-chain) yields the m/z 296 ion, but if metabolism of EB 1089 occurs primarily at the distal region of the side-chain as currently believed,³ fragmentation will yield ions shifted upwards from 296, depending on the type of metabolic alteration. In this manner, potential sites of EB 1089 metabolism can be identified by metabolite-specific ion fragments, using simple, preliminary MS/MS experiments long before intensive structural characterization need be performed by trimethylsilylation and EI-MS.

Fig. 3 Proposed structures of fragment ions.

QUANTITATIVE DETERMINATION OF A NEW ESTROGEN IN HUMAN SERUM USING NCI-GC/MS/MS

M. BRUDNY-KLÖPPEL, A. BAUMANN, C. MADETZKI & W. KUHNZ
Research Laboratories, SCHERING AG, D-13342 Berlin, Germany

Introduction

14,17 α -Ethano-1,3,5(10)-estratriene-3,17 β -diol (ZK 115194) and 14,17 α -ethano-1,3,5(10)-estratriene-3,16 α ,17 β -triol (ZK136295) are new estrogenic compounds developed and investigated as possible alternatives to ethinylestradiol (EE2) to be used in oral contraception. The aim of the present clinical phase I study was to determine the absolute bioavailability of both substances in comparison to the reference compound ethinylestradiol. Serum concentrations of EE2 and ZK136295 were determined radioimmunologically with validated methods. In contrast to ZK136295 the RIA of ZK115194 indicates cross reactivity with metabolites of the drug in human serum samples. Therefore, a specific and sensitive GC/MS/MS-method had to be developed and validated in the concentration range from 1 pg/ml to 1000 pg/ml. In the following, the results obtained with ZK 115194 are presented.

Experimental

The drug and the internal standard (1 ng EE2) were isolated from the female human serum by liquid-liquid-extraction with 2.5 ml diethylether for 30 minutes in a Heidolph®rotor at room temperature. Thereafter, phases were separated by centrifugation at 2400 g and the ether layer subjected to evaporation by a gentle stream of nitrogen. The dry serum extracts were dissolved in 50 μ l heptane and derivatized with heptafluorobutyrylimidazole at 70 °C for 30 minutes. Sample separation was obtained by a gas chromatograph HP 5890 Serie II equipped with a CTC autosampler and a 25 m HP1 fused silica column (0.22 mm i.d., 0.33 μ m film). Helium was used as carrier gas with a head pressure of 20 p.s.i. and a flow rate of 40 ml/min. The injector as well as the transfer line temperature were set at 330 °C. The temperature program applied, kept the start temperature at 150 °C for 6 minutes. Thereafter, temperature was increased at a rate of 20 °C/min to 325 °C and was kept at this final value for 5 minutes to condition the column. Samples were analyzed with a mass spectrometer TSQ 700 from Finnigan operated in NCI-SRM mode. Methane was used as reactant and argon as collision gas. The mass spectra of the HFB-derivatives of ZK 115194 and EE2 obtained in negative chemical ionization (NCI) mode were characterized by signals at m/z 670 and m/z 668, respectively, the quasi molecular ions formed by the loss of hydrofluoric acid (HF) from the molecular ions. The collision of argon with these quasi molecular ions resulted in the cleavage of the ether bonds, thus the HFB-residue (m/z 197) could be detected in the negative mode. Data were recorded from 12 to 16 minutes post injection with the third quadrupole operated at m/z 197. Until a retention time of about 14 minutes the first quadrupole was set to 668 amu, the mass of quasi molecular ion of EE2. Thereafter, it was switched to 670 amu, corresponding to the quasi molecular ion of ZK 115194.

Results and Discussion

The standard curve was linear in the range of 1 to 1000 pg/ml. The quality of the assay was assessed by quality control samples included in each sample batch. Each quality control was analyzed in triplicate. The mean results are presented in Table 1. The lower limit of detection was established to be 10 pg/ml with a precision of 16.2 %.

After i.v.-administration of 60 μ g ZK 115194, the drug was rapidly distributed in the body. The terminal half-life was calculated by non-compartmental analysis to be 28.7 ± 9.6 h (Figure 1). The total serum clearance and volume of distribution were calculated to be 5.5 ± 3.0 ml·min⁻¹·kg⁻¹ and 464 ± 209 l, respectively. Following single oral administration of 240 μ g ZK 115194, the substance was rapidly absorbed reaching its mean peak serum level after 1.4 hours (Figure 2). The absolute bioavailability was calculated to be 33 ± 19 %. Postmaximum drug levels declined biphasically with a mean terminal disposition half-life of 33.2 ± 11.4 h. After single oral administration of 240 μ g ZK 115194, t_{max} and $t_{1/2}$ values were similar as observed for the same EE2-dose.

These results demonstrate the usefulness of the above method as a substitutive for the radioimmunoassay in case of cross reactivity etc..

Identification of 5-(N-acetylcystein-yl)-2-Ene Valproic Acid (5-NAC-2-ene VPA) as a Urinary Metabolite of the Antiepileptic Drug VPA in Rats and Humans. Evidence for the Formation of Reactive Species. Sashi V. Gopaul¹, Wei Tang¹, Kevin Farrell², Abdul Mutlib¹, Frank Abbott¹, Faculties of Pharmaceutical Sciences¹ and Medicine², University of British Columbia, Vancouver, B.C., Canada V6T 1Z3.

Valproic acid (VPA) is a broad spectrum antiepileptic agent with a fatty acid structure. The use of VPA is limited by the reported incidences of hepatotoxicity, believed to be mediated through metabolic activation (1). Hepatotoxic metabolites in rats include 4-ene VPA and (E)-2,4-diene VPA which are activated in vivo to reactive species (2,3). Evidence for reactive species formation was obtained when the urinary N-acetylcysteine (NAC) conjugate of (E)-2,4-diene VPA, i.e. 5-NAC-3-ene VPA was identified.

Urine samples from rats treated with 4-ene VPA (200 mg/kg, i.p. injection) and samples from patients were extracted and derivatized. The putative metabolite was analyzed as the corresponding pentafluorobenzyl (PFB) ester by GC/MS under NICI mode using either a DB101 column or a DB1701 column (30 m x 0.32 mm, 0.25 μ m). The GC/MS was an HP 5890 GC interfaced to an HP 5989A mass spectrometer. The GC oven temperature was programmed: 50-150°C at 20°C/min, hold for 5 min, then 150-300°C and hold for 10 min. The carrier gas was helium at a head pressure of 10 psi. The ion source temperature was at 200°C. The ionization energy for the NICI analysis was 120 eV at a source pressure of 1 torr using methane as a reagent gas.

The PFB derivative of 5-NAC-2-ene VPA eluted at 19.79 min on a DB101 column (Fig. 1) and at 30.88 on a DB1701 column. The mass spectrum of the PFB derivative showed the single characteristic [M-181]⁺ fragment corresponding to m/z 482. Comparison of GC retention times on both columns of different polarity and MS spectra generated for the putative NAC metabolite with that of the authentic reference compound made available by chemical synthesis confirmed the presence of urinary 5-NAC-2-ene VPA in rats treated with 4-ene VPA and in patients on VPA therapy (Fig. 2).

Our finding of this conjugate is consistent with observations in rats where 5-GS-2-ene VPA, in principle the precursor of NAC-2-ene VPA was detected as the biliary metabolite in rats treated with 4-ene VPA (4). Quantitatively, 5-NAC-2-ene VPA was found at concentrations ranging from 0.70-18 μ g/ml in seven patients and the isomer 5-NAC-3-ene VPA was found at a concentration of 0.19-5.8 μ g/ml. By measuring the urinary excretion of NAC conjugates of (E)-2,4-diene VPA, one may be able to determine the degree of exposure of to the toxic reactive metabolite in patients on VPA therapy.

Pharmacokinetics and Tissue Distribution of (E,Z)-2,3'-Diene VPA in the Rat Brain

Janice L. Moshenko*, Steven Ma and Frank S. Abbott, Faculty of Pharmaceutical Sciences, 2146 East Mall, University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3

Valproic Acid (VPA), a commonly used anticonvulsant, causes teratogenicity and a potentially fatal hepatotoxicity. The development of structural pharmacologically-active analogues of VPA without the harmful side effects is of great interest in our laboratory. A serum metabolite of valproic acid (VPA), (E,Z)-2,3'-diene VPA, is being investigated for its equivalent anticonvulsant potency to VPA and for its potential to be a less toxic alternative to VPA therapy. A desired attribute of anticonvulsant therapy is that the drug persists in brain tissue for an extended period of time, thus prolonging its pharmacological activity. The objectives of this study were to utilize a GC-MSD assay to determine (E,Z)-2,3'-diene VPA levels in brain tissue to determine whether the diene is selective or persistent in specific brain regions of rats over time.

After i.p. administration of 150 mg/kg (E,Z)-2,3'-diene VPA to male Sprague-Dawley rats, serum and brain tissues were collected at designated time points over a 12 h period. The whole brain was quickly removed, dissected into 11 brain sections, and each homogenized. For the assay of drug in serum and brain tissue, samples were extracted using ethyl acetate, the solvent volume reduced under nitrogen, and derivatized using MTBSTFA by heating at 60°C for 60 min. One μ L aliquots were injected into the gas chromatograph (HP 5890 series II) equipped with a mass selective detector (HP 5971A) and a DB-1701 fused silica column (30 m X 0.25 mm, 0.25 μ m). GC conditions were as follows: injector temp: 250°C; detector: 270°C; oven: 80-100°C (10°C/min), 100-130°C (2°C/min) and 130-260°C (30°C/min); helium head pressure 10 psi. The mass spectrometer operated under EI conditions (70 eV) at a source temperature of 275°C. Emission current was 300 μ A. Figure 1 represents the EI-GCMSD spectrum of (E,Z)-2,3'-diene VPA. The $[M-57]^+$ ion was used to quantitate the diene. Ions for the parent drug and the internal standard (m/z 197 and 206, respectively) were monitored using selected ion monitoring. Standard curves of (E,Z)-2,3'-diene VPA/ $[^2H_7]$ -2-ene VPA area ratio vs. concentration of (E,Z)-2,3'-diene VPA were prepared using peak area ratios from chromatograms for both serum and brain (Fig. 2).

Similar absorption and elimination patterns were observed for each brain region which included a secondary concentration peak at 4-6 h which was attributed to enterohepatic cycling. (E,Z)-2,3'-Diene VPA regional distribution was approximately uniform as the C_{max} values and kinetic profiles of each brain region were similar to that obtained for whole brain. Peak regional brain concentrations for (E,Z)-2,3'-diene VPA ranged from 38.7 to 55.4 μ g/g and were obtained within 22.5 min. The brain:serum ratios were relatively low (0.12-0.17) at C_{max} but an increase in the brain:serum ratios at 12 h was observed for 10 of 11 brain regions, the largest ratios observed in the substantia nigra (0.33), inferior colliculus (0.99), and superior colliculus (0.35). The apparent selectivity for brain tissue by the diene at such low concentrations is unlikely to contribute to prolonged anticonvulsant action.

This research was funded by Berlex Biosciences, PMAC-Health Research Foundation of Canada, and a grant from the Medical Research Council of Canada.

Low Level Determination of a Novel 4-azasteroid and its Carboxylic Acid Metabolite in Human Plasma and Semen Using Liquid Chromatography with Atmospheric Pressure Chemical Ionization Tandem Mass Spectrometry, C. M. Chavez-Eng, M. L. Constanzer, B. K. Matuszewski, Merck Research Laboratories, West Point, Pennsylvania 19486, USA and J. Carlin, D. Graham, Merck Research Laboratories, Rahway, New Jersey 07065-0900, USA

4,7 β -dimethyl-4aza-5 α -cholestan-3-one **I** is a potent type 1 5 α - reductase inhibitor. Sensitive, specific and separate assays have been developed and validated for the analysis of **I** and its carboxylic acid metabolite **II** in human semen and plasma using high performance liquid chromatography (HPLC) with tandem mass spectrometric (MS-MS) detection. The analytes **I** and **II** with their respective internal standards **III** and **IV** were extracted from biological matrix using separate liquid-liquid extractions. The organic extract was evaporated to dryness, the residue was reconstituted in mobile phase and injected into the HPLC system.

The chromatographic conditions for **I** were a MetaChem Inertsil C-8 50 x 4.6 mm 5 μ m analytical column heated to 60°C with a mobile phase consisting of a 90:10 mixture of acetonitrile:water containing 10mM ammonium acetate and 0.1% formic acid pumped at 1.0 mL per minute, yielding retention times for **I** and **III** of 2.7 and 2.4 minutes, respectively. Due to the presence of metabolites in post-dose plasma samples interfering with the quantification of **II**, chromatographic separation of **II** from metabolites was required. The chromatographic conditions for **II** were a Keystone Scientific C-8 BDS 150 x 4.6 mm 5 μ m with a mobile phase consisting of a 75:25 mixture of acetonitrile:water containing 10mM ammonium acetate and 0.1% formic acid pumped at 1.0 mL per minute, yielding retention times of 5.5 and 2.5 for **II** and **IV**, respectively.

The MS-MS detection was performed on a PE Sciex API III Plus tandem mass spectrometer using the heated nebulizer probe. The positive product ion mass spectra of the protonated molecular ions (M+H)⁺ at m/z = 416 and 404 for **I** and **II**, respectively, indicated the presence of a fragment ion at m/z = 114 for both analytes. Monitoring these parent - product ion combinations in the MRM mode, after chromatographic separation, gave standard curves in plasma which were linear in the concentration range of 0.2 to 200 ng/mL for **I** and **II** with correlation coefficients greater than 0.99 and coefficients of variation less than 15% for replicate analysis at all concentrations within the standard curve range. For the semen assay the linear range of **I** was 0.2 to 50 ng/mL. These assays were applied to support clinical studies with **I**.

Comparing TOF-SIMS with Laser Desorption/Photoionization for Surface Analysis*

Jennifer L. Trevor,^{1,2} Luke Hanley,² Michael J. Pellin,¹ and Keith R. Lykke¹

¹Materials Science and Chemistry Divisions, Argonne National Laboratory, Argonne, IL 60439

²University of Illinois at Chicago, Chicago, IL 00607

TOF-SIMS has become the standard mass spectrometric tool for the molecular analysis of polymeric, organic, and biological surfaces.¹ However, variations in desorption yields, ionization efficiencies, and ion-induced damage of adsorbates still present significant difficulties in the analysis of TOF-SIMS data. Laser desorption combined with photoionization may provide a significant improvement over TOF-SIMS, but little data has been collected comparing the relative efficacy of these processes. When such comparisons have been done, they usually have not been supported by independent surface analysis.

An instrument exists that has the capability of utilizing both methods of analysis and the potential for imaging of these surfaces. The Chicago-Argonne resonance ionization spectrometer for microanalysis (CHARISMA) is a reflectron time-of-flight mass spectrometer (TOF) that is configured for secondary ion and neutral mass spectrometry using either ion beam bombardment or laser ablation for sample desorption.² A Schwarzschild all-reflecting microscope that enables in situ laser microanalysis with a lateral resolution below 1 μm has been incorporated into the instrument, which allows for easy sample viewing and imaging. The instrument has a mass resolution of $m/\Delta m > 2000$.

We have studied biotin and biotin conjugated self-assembled monolayers (SAMs) adsorbed onto gold as a model system to compare TOF-SIMS with laser desorption/photoionization as a method for biological surface analysis. Surface coverages were monitored independently by high-resolution spectroscopy for chemical analysis (ESCA). Projection lithography³ with a Schwarzschild microscope and UV radiation was performed on a masked biotin-SAM. The sample was then rinsed with water and etched in an aqua regia solution ($\text{HCl}:\text{HNO}_3:\text{H}_2\text{O}$) to expose the underlying Cr adhesion layer and form a positive photopattern. The photopattern was then analyzed by both SIMS and laser SNMS to validate the utility of both techniques for this system. N_2 laser desorption was used in combination with 193 nm laser photoionization to probe the photopattern. Although the microscope resolution is diffraction wavelength limited, for this photopattern we used a grid with bar lengths on the order of 10 μm magnified to ensure that the correct region of the pattern was sampled with the laser. A signature mass fragment for biotin was seen in both SIMS and SNMS. This is an important result for laser SNMS, because it validates the utility of the technique for biological surface analysis.

ReO₄⁻ Surface Bombardment in SIMS: Disappearance Cross Sections and Desorption Mechanism

G. S. Groenewold, A. K. Gianotto, J. E. Olson, J. C. Ingram, A. D. Appelhans, D. A. Dahl, J. E. Delmore. Idaho National Engineering Laboratory Idaho Falls, ID 83415-2208

The detection of adsorbed organic compounds on silicate surfaces has been an area of active research in our laboratory. Molecules such as tributyl phosphate,¹ cyclohexylamine,² and organosulfides³ have been effectively detected on mineral surfaces using secondary ion mass spectrometry (SIMS). The instrumentation utilizes a ReO₄⁻ (perrhenate) primary ion beam,⁴ and pulsed secondary ion extraction;⁵ together, these two technologies serve to effectively manage sample surface charging, and facilitate efficient desorption of analyte ions. These attributes have greatly facilitated the analysis of naturally occurring samples including rocks and soil samples.

The purpose of the present study is to gain understanding of the behavior of secondary adsorbate ions originating from silicate surfaces, as a function of ReO₄⁻ dose. A widely accepted tenet of static SIMS is that at low doses (i.e., $< 1 \times 10^{13}$ ions/cm²), any one position on the surface of the sample is impacted only once, and the resulting secondary ion mass spectrum represents the unadulterated surface. Conversely, above a dose of 1×10^{13} , the spectrum is representative of the altered surface. However, for organic adsorbates on solid surfaces, changes in the secondary ion mass spectrum caused by primary ion bombardment, can be observed at smaller doses. Spectral alteration due to primary ion bombardment was also observed for tetraalkylammonium ions sputtered from gelatin matrices.⁶

To gain a more quantitative understanding of this phenomenon, a soil sample on which one monolayer of cyclohexylamine-d₁₁ (CHA-d₁₁) was deposited, was bombarded with ReO₄⁻, and the abundance of [CHA-d₁₁+H]⁺ (I) was monitored as a function of dose. When $\ln(I/I_0)$ was plotted versus dose, a curve was generated (Figure 1), which indicated that the decay of [CHA-d₁₁+H]⁺ was not a first order process relative to CHA concentration. σ values were estimated using linear portions of the curves observed at low ($< 1 \times 10^{12}$ ions/cm²) and high ($> 5 \times 10^{13}$) dose. The σ values were 290 Å² at low dose, and 160 Å² at higher doses. A second experiment was conducted in which the soil was exposed to a lower concentration of CHA-d₁₁ (approximately 0.3 monolayer). The apparent σ calculated for this experiment was 160 Å² over all dose regimes (0 to 5×10^{13} ions/cm²), which is in agreement with the high dose value observed for the one monolayer experiment. The result suggests that CHA-d₁₁ facilitates its own desorption. This can occur when the surface concentration is high (one monolayer, low dose), but does not occur when the surface concentration is low (one monolayer, high dose, and 0.3 monolayer, independent of dose). An alternative explanation for the phenomenon is the existence of two types of adsorption sites, which strongly and weakly bind CHA-d₁₁. In this scenario, the weakly

bound CHA-d₁₁ are removed quickly (larger σ), the strongly bound CHA-d₁₁ are removed more slowly (smaller σ).

Fig 1 Plot of $\ln(I/I_0)$ vs primary ion dose for [M+H]⁺ of cyclohexyl amine-d₁₁ on soil

The disappearance of tetrapropylammonium (TPN⁺) from a glass surface was also studied as a function of primary ion dose. As in the case of CHA-d₁₁, the disappearance was not exponential (Figure 2): the abundance of TPN⁺ decreased much more rapidly

at doses $< 1 \times 10^{13}$ ions/cm² than at higher doses ($< 5 \times 10^{13}$). σ was estimated at 680 Å² for the low dose regime, and 320 Å² at higher doses. The latter value is in good agreement with σ for TPN⁺ sputtered from gelatin using 20 keV Ga⁺.⁶ The higher σ observed at low dose may be due to desorption which is assisted by other adsorbate molecules. This explanation is supported by an experiment in which the primary ion bombardment was stopped after 2.5×10^{13} ions/cm², the target was exposed to air, and then bombardment was restarted. This action caused the intensity of TPN⁺, and its rate of disappearance, to increase significantly. We attribute this observation to the enhancement of the rate of sputtering by adventitious adsorbates: the adsorbates serve to transfer energy from the point of primary ion impact, to the point of secondary ion desorption. This conclusion is consistent with the observation that the apparent σ measured at low dose is independent of molecular size: a σ of 720 Å² was measured for tetrahexyl ammonium at doses $< 1 \times 10^{13}$ ions/cm². It implies that the overlying organic adsorbates are more efficient at transferring energy to the nascent secondary ion than is the underlying silicate. Two recent studies have also suggested that neighboring adsorbates assist in the formation of secondary ions.⁷

These observations have important implications on the analytical application of static SIMS to environmental analyses. The rapid rate of decay for adsorbate molecules on silicate surfaces dictates that the most sensitive analyses will be conducted during the initial bombardment, even under "static" SIMS conditions, which are conventionally correspond to a dose less than 1×10^{13} ions/cm². We note that the abundance of TPN⁺ decreases by 6% over the first 9×10^{11} ions/cm², and by 50% over the first 9×10^{12} ions/cm².

MALDI of Size Selected Microparticles

Bashir A Mansoori* and Murray V Johnston Department of Chemistry and Biochemistry
Anthony S Wexler, Department of Mechanical Engineering
University of Delaware,
Newark, DE 19716

Matrix-assisted laser desorption/ionization (MALDI) is widely used for molecular weight determination of natural and synthetic macromolecules. Quantitation of the analyte based upon the MALDI signal intensity, however, is impeded by poor reproducibility. The signal intensity is strongly affected by sample morphology, laser irradiance and analyte concentration. We present here a method to control many of the variables associated with sample morphology by studying aerosol particles and performing MALDI on-the-fly, so that the analyte dependence of signal intensity can be quantitatively assessed.

Monodisperse aerosol droplets containing matrix, analyte, and solvent are generated with a vibrating orifice aerosol generator and entrained in a dry stream of air. Solvent evaporation occurs within 2-3 seconds. The dried particles are drawn from atmospheric pressure directly into the source region of a reflecting field time-of-flight mass spectrometer. Individual particles are then detected by light scattering and analyzed on-the-fly by MALDI. The particle size and composition are systematically varied using both liquid, 3-nitrobenzyl alcohol (NBA), and solid, 2,5-dihydroxybenzoic acid (DHB), matrices.

Calibration plots for leucine enkephalin (LE) and gramicidin S (GS) in NBA and DHB show that the analyte signal intensity at first increases with increasing analyte-to-matrix mole ratio and then levels off. This dependence is interpreted on the basis of analyte surface activity and can be fit to the modified adsorption isotherm equation.

$$I = I_{\max} \left(\frac{bm}{1+bm} \right) \quad (1)$$

where I is the analyte signal intensity in MALDI spectrum, $I_{\max}$ is the analyte signal intensity with unit surface coverage, m is mole ratio of LE to NBA, and $b = K\gamma/\gamma_s$ where K is equilibrium constant, γ is the solute activity coefficient and γ_s is solvent activity coefficient.

Quenching effects are observed when two different peptides are present in the same particle. Figure 1 shows a plot of signal intensity versus analyte to matrix mole ratio. The LE/GS mole ratio is held constant at 1:7. The $(M+Na)^+$ peak area of GS at first increases with increasing mole ratio and then levels off. This plot follows equation 1. The LE plot is different and shows signal suppression. The $(M+Na)^+$ peak area of LE initially increases with increasing mole ratio and then decreases. This dependence suggests a competition between LE and GS for surface adsorption. As the mole ratio increases, GS occupies a greater fraction of the total surface area and displaces adsorbed LE. As the GS coverage approaches one monolayer, the LE surface coverage and signal intensity go to zero. The plot follows the equation:

$$I_{LE} = I_{LE, \max} \left\{ \frac{b_{LE}m_{LE}}{1+b_{LE}m_{LE}} \right\} \left\{ 1 - \frac{b_{GS}m_{GS}}{1+b_{GS}m_{GS}} \right\} \quad (2)$$

where I , b and m are the same as in equation 1. The first term in parenthesis represents the increasing surface coverage with increasing m_{LE} while the second term represents the decreasing number of available surface sites for LE as m_{GS} increases. Figure 2 shows a plot of GS signal intensity vs GS-to-DHB mole ratio. In this experiment, the LE-to-DHB mole ratio is held constant

at 2×10^{-3} . The GS signal intensity at first increases and then levels off with increasing mole ratio. This plot also follows equation 1. The LE signal intensity decreases as the GS to DHB mole ratio increases and the LE signal vanishes when the GS to DHB mole ratio exceeds 8×10^{-3} . By analogy to equation 1 and 2, the LE signal intensity plot following the equation

$$I_{LE} = I_{LE, \max} \left\{ \frac{b_{GS}m_{GS}}{1+b_{GS}m_{GS}} \right\} \quad (3)$$

where the term in parenthesis represents the decreasing number of available surface sites for LE as the m_{GS} increases.

CHEMICAL AND PHYSICAL PROCESSES IN AEROSOL MALDI

Lin He, Gang Wei, and Kermit K. Murray

Department of Chemistry
Emory University, Atlanta, GA 30322

In aerosol MALDI, a solution of matrix and analyte is sprayed directly into a TOF mass spectrometer and ionized by 355 nm pulsed laser radiation.¹ This method represents a new and unique perspective from which to study the fundamentals of the MALDI process. First, the sample is continuously renewed therefore the effects of sample depletion, spot to spot, and sample to sample signal variation are not a significant factor. Second, because aerosol particles are directly ionized, substrate effects are not present as they may be in conventional MALDI using a solids probe. Third, mass spectra can be obtained over a wide range of laser pulse energies, typically more than two orders of magnitude, facilitating pulse energy dependence studies. We have begun series of studies to elucidate fundamental chemical and physical processes that occur in aerosol MALDI.

Figure 1 shows a mass spectrum of bradykinin obtained on the Emory aerosol MALDI reflectron TOF apparatus.² The mass spectrum is an average of 1000 laser shots and a boxcar average of order ten has been performed on the data. The laser pulse energy was 120 mJ and the mass resolution is $m/\Delta m = 270$. The $[M+H]^+$ peak is the prominent high mass peak. The broad peak corresponding to post source decay is labeled PSD in the mass spectrum.

Figure 1. Aerosol MALDI reflectron TOF mass spectrum of bradykinin.

An expanded region of the bradykinin mass spectrum is shown in Figure 2 (The data set is identical to that of Figure 1). The peak immediately to the left of the bradykinin $[M+H]^+$ peak corresponds to the PSD loss of NH_3 from bradykinin. Evidence for assignment of this peak to PSD loss of NH_3 is that the apparent mass of this peak shifts with respect to the $[M+H]^+$ peak as the reflectron voltage is changed. The broad peak corresponding to low mass PSD fragments appears near m/z 550, although it should be noted that the mass calibration does not apply to PSD formed ions. The peak labeled $[M+F+H]^+$ is believed to be an adduct of bradykinin and trifluoroacetic acid used to acidify the aerosol solution. The peak does not appear in mass spectra obtained with solutions acidified with acetic acid, although no acetic acid adduct is observed.

A notable feature of the mass spectrum in Figure 2 is that it contains peaks associated with ions undergoing fragmentation prior to acceleration and mass separation, fragmentation that is "prompt" with respect to the total ion flight time. The peptide prompt fragmentation peaks are labelled following published convention and appear at m/z values within ± 1 u of peaks observed in fast

atom bombardment and PSD mass spectra. Prompt ion source fragmentation is not typically observed in conventional MALDI mass spectra, although delayed fragmentation can be observed in PSD or with delayed ion extraction. The mass measurement accuracy for the prompt fragment peaks is $< 0.1\%$ and the peak widths range from 70 to 300 ns fwhm, corresponding to mass resolution of between 200 and 350. The time for the formation of the prompt fragment ions can be no greater than the widths of the associated spectral peaks, thus fragmentation is occurring on a time scale of less than 100 ns. Additional support for the prompt fragmentation assignment is that several of the prompt fragment ion peaks appear at a shorter flight time than the unresolved PSD peak, which cannot occur for PSD formed ions. Also, the prompt fragmentation peaks maintain the same m/z value at different reflectron voltage settings, whereas the PSD ion peaks shift in observed mass (requiring a separate mass calibration). There is the possibility for fragmentation due to aerosol heating in the drying tube, however, mass spectra contain the same fragment peaks over a range of drying tube temperatures.

Figure 2. Mass spectrum of bradykinin showing peaks resulting from prompt fragmentation. The broad peak labeled PSD results from unresolved post source decay fragment ions.

Prompt fragmentation has been observed for the peptides bradykinin and angiotensin II and for vitamin B₁₂. The general results from these studies are that the prompt fragmentation occurs on a time scale of approximately 100 ns and is not strongly pulse energy dependent. There are some indications that the PSD fragmentation does vary as a function of laser pulse energy and aerosol source conditions. With the current nebulizer configuration, however, specific aerosol conditions can be difficult to reproduce. The prompt fragmentation can be matrix dependent, especially in the case of the vitamin B₁₂ molecule. Studies are underway to further investigate the effects of matrix, laser pulse energy, wavelength, extraction delay and other parameters on peptide fragmentation in aerosol MALDI.

Several instrument improvements are planned that could help aerosol MALDI become a viable method for structural analysis of peptides. The addition of a reflectron to the Emory aerosol AMALDI apparatus has already resulted in an improvement in mass resolution of a factor of ten over a linear TOF.² Another necessary improvement is in sample consumption: most of the continuously nebulized sample is wasted in the current instrument configuration. The implementation of single aerosol generation and ionization can improve ionization efficiency and potentially reduce sample consumption to the fmol level or lower. Single aerosol MALDI also opens up the possibility of correlation of mass spectral features to aerosol size and composition.

Effects of Ammonium Salts as Co-matrices for the Analysis of Oligonucleotides by Matrix Assisted Laser Desorption Ionization Mass Spectrometry

S-W. Cheng and Dominic T-W. Chan*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong.

Since the revolution brought by matrix assisted laser desorption ionization mass spectrometry (MALDI-MS) for detecting high mass biomolecules,¹ large expectation has been raised of applying the technique to DNA sequencing.² However, with increasing size of oligonucleotides, the signals fall off rapidly. This imposes strong limitation on the application of MALDI-MS for DNA sequencing. The search for new and better matrices which offer "softer" MALDI processes leading to cooler analyte ions, is one of the approaches to overcome this problem.³⁻⁵

In attempt to construct improved matrix materials, fourteen ammonium salts^{6,7} have been tested as co-matrices for the MALDI analysis on a number of DNA homopolymers: phosphorylated d(T)₈, d(A)₄ and d(C)₄ and non-phosphorylated d(G)₄, using 2-amino-5-nitropyridine (ANP), 2,5-dihydroxybenzoic acid (DHB) and 3-hydroxypicolinic acid (HPA) matrices.

In the present study, both cations and anions of the ammonium salts were found to play critical roles in the desorption / ionization of the oligonucleotides under typical MALDI conditions. The effect of ammonium salts was highly matrix dependent. In combination with ANP, almost all tested salts impose enhancements on the MALDI signals of the oligonucleotides. However, in DHB or HPA system, enhancement or suppression was found, depending on the nature of the ammonium additives. In comparison with the results obtained using the corresponding isomorphous potassium salts as co-matrices, it is postulated that NH₄⁺ serves to eliminate the alkali metal adducts as well as provide cooling that is important in stabilizing the oligonucleotides in the MALDI process. Besides, the ammonium salts might influence the solid state interaction between the matrix and DNA molecule. Although the effect of ammonium salts has been found to vary with the combinations between matrix and analyte, it was observed that salts of strong acids, especially ammonium fluoride generally impose prominent enhancements in the mass spectrometric response of oligonucleotides.

The introduction of suitable ammonium co-matrices widens the list of useful matrices for the MALDI-MS analysis of DNA. Examples are the ANP / NH₄F and the HPA / NH₄F systems. The use of improved matrix materials is a large step forward in the application of MALDI-MS for DNA sequencing.

Frozen Solution Matrices for MALDI Time-of-Flight Mass Spectrometry of DNA Oligomers

Joanna M. Hunter, Hua Lin, and Christopher H. Becker
Molecular Physics Laboratory, SRI International, Menlo Park, CA 94025

Matrix-assisted laser desorption/ionization (MALDI) in conjunction with time-of-flight mass spectrometry is an effective technique for analysis of DNA oligomers. However, with increasing oligomer length, mass resolution degrades as the effects of metastable decay, adduct formation, and ion kinetic energy spreads become increasingly dominant. Attempts to reduce these factors have focused on an investigation of matrices that are liquids at room temperature. The presence of high vapor pressure molecules introduces an alternative pathway for dissipation of excess energy absorbed by the sample during the desorption laser pulse. Previous studies have demonstrated that laser desorption from frozen water matrices can produce oligonucleotide and protein cation mass spectra that are largely free of fragmentation and matrix adducts.^{1,2}

Typical samples contain 0.1-10 pmoles of single-stranded mixed-base oligonucleotides (up to 65 nucleotides in length) in 0.5 μ l of matrix solution. Frozen films were prepared by pipetting the sample solution onto silicon substrates and then dipping into liquid nitrogen. Homogeneous films obtained by this method are approximately 3 mm in diameter and 100 μ m thick. The mass spectrometer sample stage is cooled to approximately 170 K using liquid nitrogen, cold enough to maintain a low vapor pressure thin film of the frozen matrix solution. Desorption laser wavelengths of either 266 or 355 nm were employed.

A list of some of the photoabsorbing substituted phenols that were examined is given in Table 1. Oligonucleotide signals were observed for several of these additives frozen in solvents such as acetonitrile, water, and methanol, but the best solvent system was found to be 1:1 (volume) methanol:water. Relative intensities of 36-mer positive ion signals obtained from frozen methanol/water solution matrices are also tabulated. In general, negative ion intensities were comparable to positive ion intensities. The 3-hydroxypicolinic acid (3-HPA), currently the best room-temperature solid matrix for DNA,³ and other commonly used carboxylic acid matrices do not work as well in frozen matrix solution. Spectra of proteins such as cytochrome *c* and insulin were also collected from several of these frozen matrices, although the spectral quality was lower than that obtained from room-temperature matrices.

Mass spectra of oligonucleotides embedded in several of these frozen solution matrices exhibit lower amounts of base-loss fragmentation than spectra from the equivalent room temperature solid matrices. The example illustrated in Figure 1 was obtained using 2,4-dihydroxyacetophenone as the photoabsorber. The threshold laser fluence required for desorption/ionization from the frozen solution matrix is approximately 50% higher than for the room-temperature crystalline matrix. Note, however, that the fragmentation observed in the spectrum obtained from the crystal matrix is significantly reduced in the spectrum obtained from the frozen matrix. When this frozen solution sample is warmed in vacuum to evaporate the solvent, the fragmentation returns to the spectrum. This is clear evidence that the solvent molecules contribute to lowering the oligonucleotide internal energy and decreasing the degree of fragmentation, possibly through enhanced collisional-cooling or lowering of the energetics required for MALDI. The reduction in fragmentation is an extremely reproducible effect.

Application of Time-Lag-focusing(TLF) Method in the Improvement of Mass Resolution for the detection of Small DNA Oligomers using Linear MALDI TOF-MS Spectrometry

Yongdong Zhu, Jian Bai, Xiaoli Liang, Jannavi R. Srinivasan, David M.Lubman,
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109

INTRODUCTION MALDI/MS has been considered as a potential replacement of gel electrophoresis for ultra-fast DNA sequence analysis. It has been outlined that there are three principal requirements for fast DNA sequencing by MALDI/MS: detection of DNA fragments larger than 300 nucleotides, adequate sensitivity for the detection of PCR products(in femtomole range), sufficient mass resolution for the separation of adjacent oligomers. According to previous studies, the first two requirements have been met. The major obstacle remaining is the relatively poor mass resolution of TOF mass spectrometer. The major contribution to the peak broadening in MALDI/TOF-MS is the initial kinetic energy distribution of the ions. In this study, the Time-Lag-Focusing (TLF) method was used to compensate for the kinetic energy distribution of the ions initiated in the ion source. In this method, a short time delay is inserted between the laser ionization and ion extraction events. During this short period of time, the ions which are initially moving faster will move further to the second extraction grid and will sense less extraction potential than the ions which are initially moving slower. By adjusting the delay time and extraction potential, all ions with the same mass/charge ratio can be made to reach the detector at the same time.

EXPERIMENTAL linear TOF mass spectrometer was used for detection and 355 nm laser radiation for LD/I. DNA oligomers were synthetic ss-DNA oligomers and were used directly without further purification. 3-HPA was used as matrix and nitrocellulose was the substrate in all the experiments.

RESULTS AND DISCUSSION In this study, a fixed pulse potential of 3 kV was employed and a pulse delay time of up to 10 μ s was studied. The results show that dramatic improvement of mass resolution was obtained(from 500 to 1000), up to 100 times compared to those observed using continuous extraction experiments on DNA oligomers up to 28 nucleotides. As figure 6 shows, mass resolution for small oligomers should be sufficiently high for rapid MALDI/MS DNA sequence analysis. The delay time is proportional to the mass of the DNA oligomers, where the larger the mass of the DNA, the longer the delay time needed. The study also shows that the resolution of a certain m/z DNA fragment is not extremely sensitive to the delay time, where comparable resolution can be obtained within a relatively large range(a few μ s)

of delay times. This makes it possible to detect DNA mixtures having large mass distributions at high resolution for every component. Counter-ion adduct peaks were also resolved so that we can study the effects of matrix and substrates on the elimination of counter-ions in DNA samples.

Capillary Electrophoresis Combined with Matrix-assisted Laser Desorption Ionization Mass Spectrometry; Continuous Sample Deposition on a Matrix-precoated Membrane Target

Haiying Zhang and Richard M. Caprioli
University of Texas Medical School, 6431 Fannin, Houston, Texas 77030

The combination of capillary electrophoresis (CE) and mass spectrometry (MS) provides an effective technique for the analysis of femtomole/attomole amounts of proteins and peptides. A considerable amount of work has been published using electrospray mass spectrometry for on-line coupling to capillary electrophoresis. Matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS) is a second technique that has the capability for coupling to CE because of its high sensitivity, ease of use, and compatibility as an effective off-line method. The first report describing the off-line coupling of CE with MALDI MS appeared in 1992 [1], and subsequently, several other investigators reported several types of interfaces for off-line fraction collection [2,3]. The effective coupling of the ground electrode with the target for techniques using repetitive sample spotting, while maintaining the separation efficiency of CE, remains problematic. Improper coupling can produce a "memory effect" [4], and to help reduce this effect, either a sheath flow or a high electroosmotic flow rate is utilized. However, one consequence of this is that the sensitivity of MALDI MS is compromised. Other problems involve difficulties in addition of MALDI matrix to the collected effluent, and the separation resolution lost in collecting discrete sample drops of the CE effluent.

In the current work, we describe the off-line coupling of CE and MALDI MS by continuous effluent deposition on a matrix-precoated cellulose membrane [3] which is then used as the MALDI MS target. A membrane target, precoated with MALDI matrix, was used for the continuous deposition of effluent exiting from a CE device. A sample track was produced by linear movement of the target during the electrophoretic separation and this track was subsequently analyzed by MALDI MS (Figure 1). The technique is effective for peptides and small proteins up to about 25,000 daltons, having limits of detection ($S/N > 3$) of about 50 attomoles for neurotensin (Figure 2) and 250 attomoles for cytochrome c. The electrophoretic separation achieved from the membrane target as measured by theoretical plate numbers from the mass spectrometric data was greater than 90% of that achieved by on-line UV detection (Figure 3). Non-volatile buffers such as 10–50 mM phosphate can also be used in the electrophoresis process and directly deposited on the membrane. The use of post-source decay techniques is shown for peptides in the CE sample track in order to obtain sequence verification. The effectiveness of this method of integration of CE and MALDI MS has been demonstrated with both peptide and protein mixtures and with the analysis of a tryptic digest of a protein.

Probe Surfaces for Desorption of Bioactive Arrays Tethered with Photolytic Devices

Jesus Ching¹, Kamen I. Voivodov^{1,2}, and T. William Hutchens¹

¹University of California, 110 FSTB, Davis, CA 95616 and ²Molecular Analytical Systems, Inc., 2121 Sage Road, Suite 280, Houston, TX 77056

The process known as surface-enhanced laser desorption/ionization (SELDI) and referred to often as affinity mass spectrometry (1,2), was introduced in 1993 in our laboratory. SELDI is based upon use of new probe material compositions and/or defined surface chemistries. In one category of SELDI process identified as SEAC (surface-enhanced affinity capture), chemically-defined and biologically-defined affinity capture devices are covalently bound directly to modified probe surfaces. Only the captured target biomolecules, docked on the probe surface through *noncovalent* molecular recognition events, are selectively desorbed by laser irradiation.

Our laboratory presented for the first time (at '94 Colorado Asilomar conference & '95 Atlanta ASMS conference), the *covalent attachment* of target biopolymers to both inorganic and polymeric probe surfaces with tether chemistries enabling single pulses of laser irradiation to initiate subsequent *uncoupling and desorption/ionization* of the covalently bound biomolecules (3-6).

We have pursued further development of solid-phase as well as solution-state bioconjugate chemistries for the investigation of biopolymer structure. This category of SELDI technology has been called SEPAR (surface-enhanced photolabile attachment and release).

A modular construction strategy was adopted for construction of probe surfaces for SEPAR. Three separate tether-probe device components are designed to extend outward from polymeric-based and/or silica-based probe surfaces (Fig. 1). These three SEPAR components include (1) a variable length spacer arm, (2) a photolytic component located at different positions within this spacer arm, and (3) a zero-length bioconjugate component at the end of the spacer arm for covalent macromolecule attachment (4). The components within each device were intended to function collectively to accomplish several specific objectives. They must first act as a tether to covalently bind the target molecule at some defined distance from the probe surface. Second, after attachment, the photolytic component within the tether must remain an extremely efficient light-dependent triggering device for release of the tethered biomolecules. Finally, for specific applications upon laser-induced uncoupling, a defined portion of the tether ("tail") must be photochemically stable and remain covalently attached to the biomolecule as a probe.

SEPAR technology may be accomplished with surface chemistries constructed to allow laser-induced macromolecular uncoupling/desorption with or without reporter tails depend upon application needs. This capability should accommodate a variety of specific purposes and applications: 1) Ability to identify *chemical and structural determinants of important molecular recognition events* is improved through covalent tethering approaches as an alternative approach to *chemical-based cleavage and separation strategies* now typified by solid-phase combinatorial library screening. 2) A covalent docking approach also increases greatly the overall sensitivity and efficiency of both chemical and enzymatic digestion methods for the elucidation of biopolymer structure *in situ* (e.g., *protein sequence and post-translational modifications*). 3) The ability to covalently anchor a target biopolymer through not just one, but several, attachment sites enables enzymatic cleavage of the anchored biopolymer between attachment sites. This process facilitates subsequent structural evaluations, including *elucidation of internal*

sequence. 4) SEPAR is also a tool to evaluate *relative alterations in biopolymer size/shape or surface architecture ("footprint")*. The light-dependent introduction of one or more well-defined chemical reporter groups (i.e., "tails") to the target biomolecule resulting from its laser-induced departure from the surface may allow biopolymer conformations or "footprints" to be probed. 5) The SEPAR process can be utilized to evaluate *solid-phase photochemical reaction mechanisms and products*, for a wide variety of small and large molecules, including not only proteins but also oligonucleotides, polysaccharides, and synthetic polymers.

Figure 1: Modular design of polymeric photolabile tether-probe device. A photolytic component (1) is placed at different relative positions (indicated by dotted arrows) within a variable length spacer arm (2) terminating with a bioconjugation component (3) for covalent attachment through specific sites on the target biomolecule surface. This device is designed so that laser irradiation induces a photolytic event that triggers uncoupling of the tethered biomolecule in a manner that leaves the dissociated biopolymer with one or more reporter tails.

The Use of Membranes/Films Coated Membranes/Films in MALDI MS
 Bai, J., Liu, Y.-H., Liang, X., Zhu, Y., Cain, T. C., Srinivasan, J. R., Lubman, D. M.
 Dept. of Chemistry, The University of Michigan
 Ann Arbor MI-48109

Abstract: One of the essential steps in MALDI MS analysis of biomolecules is the preparation of samples for the experiment. Biological molecules obtained from traditional preparation procedures are difficult to retrieve due to their low concentrations and the presence of buffers and salts. The use of membranes and films as concentration and purification devices for MALDI/MS analysis of biomolecules is reported. Key applications of membranes and coated membranes in combination with MALDI MS analysis for DNA screening and detection of polymorphisms are also demonstrated

Introducti : The MALDI MS technique has become a very powerful tool for the analysis of biological molecules. Since its introduction in 1988⁽¹⁾ MALDI has been successful in detecting molecules weighing up to 1000000 u. One of the main criterion for the success of this method is the choice of the matrix. Despite the constant search for suitable matrices and the successful discovery of a few, analysis of real biological samples has been difficult, due to the significant presence of impurities. The presence of such contaminants interferes largely with the quality of the mass spectra depending on the analyte under study. Sodium and potassium have been shown to affect the resolution of mass spectra due to adduct formation. The presence of glycerol, a part of most biological sample preparation protocols, tends to disturb the crystallization process during sample/matrix film formation.

Many purification methods have been introduced such as addition of ammonium salts to reduce adduct formation⁽²⁾, and immobilizing the sample on to membranes⁽³⁾. In this work we demonstrate the use of Immobilon, Nafion and Nitrocellulose films as active substrates for MALDI MS analysis of proteins and DNA. Nafion and Immobilon are thin and homogeneous films that can be easily prepared for MALDI analysis. Nitrocellulose has been used in plasma desorption experiments for selective adsorption and purification of proteins⁽⁴⁾. The presence of nitrocellulose films for DNA screening studies excellently demonstrates the application of on-probe purification methods.

Experimental: The line time of flight mass spectrometer used in this study has been described elsewhere⁽⁵⁾. Efficient detection is achieved by a dual microchannel plate (MCP) in combination with a Cu-Be conversion dynode designed for post acceleration up to ± 15 kV. 3-hydroxypicolinic acid/picolinic acid (3-HPA/PA) and caffeic acid were used as matrices. Near saturated solutions were prepared using 1:1 v/v acetonitrile and water. Nitrocellulose and Immobilon-N were obtained from Millipore while Nafion was obtained from Aldrich Chemicals.

The buccal cell DNA samples were obtained from different individuals in the lab⁽⁶⁾ and subjected to PCR amplification followed by restriction enzymatic digestion. The details of the enzymatic digestion are given in Table 1.

Gene or Exon	PCR Product	Restriction Enzyme	Fragments
Tay Sachs exon 11	199 ^(mut) , 195 ^(norm)	Hae III	84, 56, 43, 12 ^(norm) , 84, 56, 47, 12 ^(mut)
Tay Sachs intron 12	120	Dde I	100, 20 ^(norm) , 64, 36, 20 ^(mut)

Table 1: List of genes and their PCR and restriction enzyme digests studied using MALDI TOFMS

Results: Use of Immobilon substrate. Figure 1 is a comparison of MALDI mass spectra of CNBr digest of cytochrome c (a) without Immobilon-N and (b) with Immobilon-N membrane. Caffeic acid was used as the matrix and 500 fmol of the analyte was loaded for each experiment. Comparison of the two mass spectra in the initial (matrix) ion region (Figure 2a and b) shows the complete absence of Na⁺ and K⁺ ions for the Immobilon-N substrate. This is a very important result demonstrating the on-probe purification capabilities of such active membranes.

Detection of DNA polymorphisms using on-probe purification methods: Figure 3 is a time of flight mass spectrum of PCR products obtained from Tay Sachs exon 11 of a mutant and a normal human gene using a nitrocellulose substrate. This represents ongoing work to determine the mutation that causes Tay Sachs disease in humans. The signal to noise ratios and sensitivity of the mass spectrometer depend on the presence of the nitrocellulose films for these experiments. MALDI mass spectra of the restriction enzyme digested PCR fragments (120 bp) from the intron 12 of the Tay Sachs gene shows both the normal and mutant fragments as expected in Table 1.

Discussion: The results reported here show the effective use of membranes and coated membranes in the successful analysis of large biomolecules in the gas phase using MALDI TOFMS. The mechanisms involved in the use of these membranes as substrates are mainly attributed to the substrate's ion exchange capacity. This has been well-demonstrated by the use of Immobilon-N for the cytochrome c studies in Figure 3. These films are also capable of altering the crystallization process of the matrix/analyte films. Nitrocellulose can effectively bind to inorganic cation contaminants to its 'negative sites' thus limiting their interference during MALDI analysis of DNA digest samples. It was noted that the presence of the Nitrocellulose membrane was required in order to obtain the mass spectral results for DNA screening.

Elemental Sulfur as a Matrix for MALDI-TOF Mass Spectrometry

Daniel C. Brune

Department of Chemistry and Biochemistry,
Arizona State University, Tempe, AZ 85287-1604

In matrix assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry, analyte molecules are incorporated in a dried matrix of small light absorbing molecules, and laser pulses provide energy to desorb and ionize both the matrix and embedded analyte molecules. Typical matrix molecules are sinapinic acid and α -cyano-4-hydroxycinnamic acid (α -CN), which are thought to generate analyte cations by proton transfer (Ehring *et al.*, 1992). Although those matrices work well with biological molecules such as proteins, their acidic nature makes them unsuitable for use with others. For example, chlorophylls are pheophytinized by exposure to these acidic matrices. While these photosynthetic pigments can be desorbed and ionized to some extent in the absence of a matrix, the process is inefficient and fragmentation occurs. These problems can be avoided or ameliorated by using elemental sulfur as a matrix.

Elemental sulfur was dissolved in carbon disulfide at a concentration of 0.6 M (about 0.16 mg/ml) and could be stored indefinitely at room temperature in a closed vial without deterioration. Bacteriochlorophyll *c* was also dissolved in CS_2 at a concentration of about 1 mM and mixed either with an equal volume of the sulfur solution or with a ten fold excess. Analyte concentration was not very critical, and in some experiments solid analytes were simply dissolved in a small amount of CS_2 or dissolved in chloroform and mixed with the sulfur solution. Mass spectra were obtained using a Vestec Lasertec Research instrument incorporating a nitrogen laser providing 3 ns pulses of 337nm light.

Mass spectra of sulfur taken in the positive and negative ion modes are shown in Fig. 1. The major cationic and anionic species are S_5^+ and S_3^- , respectively, suggesting that light absorption causes photodissociation of sulfur, which consists mostly of S_8 rings, with S_5^+ and S_3^- being the primary products. The relatively high stability of S_5^+ was noted previously by Fales *et al.* (1991). Shoulders on the high mass sides of the sulfur ion peaks are due to ions containing ^{34}S , which occurs with a natural abundance of 4.2%.

Fig. 1 Mass Spectra of Elemental Sulfur

Fig. 2 shows mass spectra of bacteriochlorophyll (BChl) *c*, phytyl ester, isolated from *Chloroflexus aurantiacus* and purified by reversed phase HPLC (Brune *et al.*, 1987).

In the absence of a matrix (top trace), BChl *c* fragments by losing the phytyl group to form bacteriochlorophyllide *c* (mass = 588 Da). With α -cyano-4-hydroxycinnamic acid (dissolved in acetone and mixed with BChl *c* in the same solvent - middle trace), the central Mg atom in BChl *c* is replaced by two protons to form bacteriopheophytin (BPheo) *c* (mass = 844 Da). In the mass spectrum with sulfur as the matrix (lower trace), fragmentation of BChl *c* (mass = 866 Da) is inhibited but not entirely prevented. Although α -CN appears to inhibit fragmentation more effectively than sulfur, in fact BPheo *c* is much less susceptible to fragmentation than BChl *c* even in the absence of a matrix (data not shown).

Fig. 2 Mass Spectra of BChl *c*, Phytyl Ester

Sulfur is an interesting matrix because it lacks protons and therefore must promote ionization by electron, rather than proton transfer. Red selenium, which also exists as 8-membered rings, fragments similarly to yield Se_5^+ and Se_3^- , but is considerably less soluble in CS_2 and has not been tested as a matrix. A variety of compounds form positive ions when irradiated in a sulfur matrix, including carotenoids, iron porphyrins, and cyclopropyl adducts of fullerenes. As found with chlorophylls, fragmentation of fullerene adducts (to yield the unsubstituted fullerene, C_{60}) occurs in the absence of sulfur. Sulfur can be used as a matrix for qualitative analysis pigment extracts from photosynthetic bacteria and probably from plants as well. Because sulfur is somewhat volatile and reacts with many metal surfaces, it is probably wise not to leave samples embedded in a sulfur matrix in the mass spectrometer for extended periods. Whether or not sulfur eventually has any deleterious effects on the electron multiplier detectors used in mass spectrometers has not been determined.

Surface-Assisted Laser Desorption Ionization (SALDI) from Frozen Water and Organic Solutions

Sergey Alimpiev, Laser Diagnostic Lab., General Physics Inst., Moscow, Russia
Yu-Chie Chen, Edward Dratz, Paul Kraft, and Jan Sunner
Department of Chemistry and Biochemistry, Montana State University, Bozeman, MT

Surface-Assisted Laser Desorption Ionization (SALDI) was originally developed with room temperature suspensions of carbon powder in liquids such as glycerol (1). Here, we present results for the use of SALDI with rapidly frozen analyte solutions in water. In contrast to liquid SALDI, these laser desorption spectra are obtained from solid/solid interfaces. However, the function of one of the surfaces (carbon) is still to absorb the laser light. Either UV or IR laser can be used for this purpose though in these experiments an IR laser was used. The experiments were performed on a Vestec 2000 linear time-of-flight mass spectrometer. In addition to the standard nitrogen UV laser, the system also included a 7 ns Big Sky Lasers YAG-OPO IR laser at 3.28 μm that has a 3 mJ pulse energy at 10 Hz. The laser beam was focussed onto the probe tip with a 180 mm focal distance lens to an estimated energy density of up to 0.5 J/cm². The electrode in the ion source that makes contact with an insertion probe was cooled to below -150°C by means of a cold-finger arrangement by liquid nitrogen.

It is much easier to obtain mass spectra from analytes in frozen aqueous solutions, or frozen organic solvent solutions, when adding graphite or activated carbon powders, i.e. by the surface-assisted laser desorption ionization (SALDI) process. Spectra are obtained on peptides as well as on proteins. Figure 1 shows a SALDI mass spectrum of bradykinin. The figure shows that the peptide is detected both in the protonated form and as metal ion adducts as is often the case in SALDI. In contrast to IR/MALDI from frozen water solutions, it is relatively easy to obtain spectra also of (small) proteins from these samples by SALDI. The significance of this is that such spectra are obtained directly from a (frozen) aqueous solution. It is noteworthy that extensive multiple charging is observed for proteins.

The reliable detection of non-covalent complexes by mass spectrometry is an extremely important goal. For example, it could make possible fast ligand binding assays. A large number of complexes have indeed been detected by electrospray. Though a few complexes have been detected also by MALDI, this technique has proven more difficult. Presumably, a reason is that most proteins denature in the solid matrices used in MALDI. In aqueous SALDI, frozen water solutions are used instead. The potential of this technique to detect non-covalent complexes is therefore of great interest. Figure 2 shows a water-ice SALDI mass spectrum of myoglobin. Intact myoglobin and apo-myoglobin are present in about equal amounts. This would seem a very promising result; the detection of intact myoglobin in aqueous electrospray was a key event for that technique.

Applications of Activated-Carbon, Surface-Assisted Laser Desorption Ionization

Yu-Chie Chen, Jentaie Shiea, and Jan Sunner
Department of Chemistry and Biochemistry
Montana State University, Bozeman, MT

Activated carbon has been successfully used as the UV-absorbing solid in surface-assisted laser desorption ionization, SALDI, mass spectrometry (1). Mass spectra of smaller proteins are regularly obtained with this material. In addition, the ability of activated carbon to strongly absorb a wide variety of compounds has extended the applications of SALDI not only in biochemistry, but also in areas such as environmental chemistry and drug analysis. A unique characteristic of the methods presented here is that the analytes absorbed on the activated carbon are desorbed directly from the solid, in the ion source, without prior extraction by organic solvents.

Five different application of activated carbon SALDI are presented in this work: Biochemical analysis, volatile organic compound (VOC) analysis, solid-phase extraction (SPE/SALDI), solid-phase micro-extraction (SPME/SALDI), and thin-layer chromatography. A typical sample preparation in activated carbon-SALDI is to first dissolve the analytes in a volatile solvent like methanol or water. Approximately 25 mg of activated carbon powder (1-2 μm) were mixed with 100 μL of sucrose/glycerol/MeOH (5:28:67 by weight). One μL of the activated carbon suspension was added to the sample plate well, and one μL of the analyte solution was applied on top by a pipet. No additional mixing was done. The sucrose serves as an "adhesive" for the carbon particles and limits the risk that these contaminate the ion source to cause electrical breakdown or turbopump problems. (We advice anyone planning to perform SALDI experiments to consider these issues carefully.)

For biochemical analysis, we have demonstrated the extraction of peptide mixture from dilute solutions using the activated carbon and directly followed by SALDI mass analysis. However, because the sensitivity of SALDI is still significantly lower than that of MALDI, the practical gain is not large. We have also demonstrated SALDI protein spectra with a number of smaller proteins.

In the area of VOC analysis, we have demonstrated activated-carbon analysis of a range of compounds such as pyridine, azulene, and 1,2-benzanthracene. An example of a solid-phase extraction result is shown in Figure 1. The diuretic, hydroflumethiazide, was concentrated from 3 mL of a 10^{-3} mg/mL solution. Micro-extractions give very similar results. The sensitivity, however, is lower.

SALDI spectra from TLC plates have been obtained by scraping off the silica gel, eluting, and absorbing the analyte on the activated carbon. In an alternative approach, the analytes is eluted, in-situ, to the surface of the gel plate and absorbed onto the activated carbon particles applied to the surface. Figure 2 shows a spectrum of hydrochlorothiazide (10 mg/mL; 1 μL applied to TLC plate) obtained in this manner.

Figure 1. Activated carbon/SALDI mass spectrum of hydroflumethiazide. The analyte was extracted from 3 mL of a 10^{-3} mg/mL solution into a bed of activated carbon.

Figure 2. Activated carbon/SALDI mass spectrum of hydrochlorothiazide (10 mg/mL; 1 μL) from a TLC plate.

Surface-Assisted Laser Desorption Ionization (SALDI) Mass Spectrometry from Liquid Solutions

Yu-Chie Chen, Edward Dratz, and Jan Sunner
Department of Chemistry and Biochemistry
Montana State University, Bozeman, MT

Laser desorption, time-of-flight mass spectra of peptides and proteins, as well as of lower-molecular weight analytes, have been obtained by using a pulsed nitrogen UV laser (337 nm) to irradiate suspensions of 2-150 μm graphite particles in solutions of the analytes in glycerol and other low-volatility solvents. In SALDI spectra of neat glycerol, protonated glycerol ($m/z=93$) with its characteristic fragment ions ($m/z=75$, 57, 45, 31, and 29), as well as abundant alkali cation glycerol adducts ($m/z=115$, 131, and 225 for Na^+ , K^+ and Cs^+ , respectively) are observed. Similar types of ions are observed for any analytes present in the glycerol solution. Indeed, SALDI spectra of low-molecular weight analytes dissolved in glycerol are very similar to FAB spectra of the same glycerol solution with added alkali salts. In SALDI, carbon cluster ions, C_n^+ , $n=10-30$, usually have a low abundance but may dominate the mass spectra at elevated laser powers.

Figure 1 shows a SALDI spectrum of a cytochrome c tryptic digest. All but one of the tryptic peptides were easily observed in their sodium-adduct form. Suppression effects are typically small in SALDI. For example, peptide spectra show little degradation at 5% SDS added. In many peptide and protein spectra, glycerol ion abundances are very low, and the alkali-ions dominate the spectra at low mass. An example is shown in Figure 2 for cytochrome C. (This spectrum is not typical; it is quite difficult to obtain. However, we believe that this spectrum shows what could be achieved for proteins in SALDI when conditions are correctly optimized.) Spectra with and without abundant solvent-derived ions may correspond to wet and dry surface desorption conditions, respectively. The best spectra of the larger molecules are usually observed under dry conditions. In these experiments, we have obtained a sensitivity in the pico- to nano-mole range which is significantly lower than that of MALDI. The signal intensity, however, is as good as in conventional MALDI. Under optimal conditions, few background peaks appear even at low mass which is an advantage for the analysis of low-molecular weight compounds. A typical SALDI mass resolution is 300.

Laser Desorption Mass Spectrometry from Frozen Water Solutions Using a 3.28 μm YAG/OPO Laser System

Sergey Alimpiev, General Physics Institute, Moscow, Russia

Edward Dratz, Paul Kraft, and Jan Sunner

Department of Chemistry and Biochemistry, Montana State University, Bozeman, MT

Laser desorption mass spectrometry of analytes directly from an aqueous solution is of great theoretical and practical interest. The main reason is that most biomolecules retain and express their biological activity in aqueous solutions. If mass spectrometry is to yield information related to the natural activity of proteins - for example, on non-covalent interactions - the best choice of matrix would seem to be water. To survive the vacuum in a mass spectrometer, the water solution has to be frozen and the solid ice kept at a low temperature. In the last few years, several investigators have performed desorption experiments on water ice with somewhat promising results. However, the question remains as to how large molecule ions can be obtained directly from water ice. Here, we present our first results of laser desorption of peptides from a rapidly frozen aqueous solution, obtained on a linear time-of-flight mass spectrometer and with a 7 ns pulse, 3.28 μm , YAG/OPO laser. The ion source was cooled to about -150°C by means of a cold-finger to liquid nitrogen. A XrF excimer laser was used to obtain post-ionization mass spectra of compounds desorbed from the water ice matrix.

When water is cooled slowly, water crystals form, and analytes concentrate in the medium between crystals. This results in aggregation and possibly denaturation of proteins and DNA. We therefore strive to achieve the fastest possible cooling. In this work, samples were initially cooled by dipping the sample probe in liquid nitrogen. Much faster cooling was obtained by dipping the sample in liquid propanol at -126°C . This cooling method should produce, if not an amorphous, at least a highly disordered ice phase. In all of these experiments, we used 10-50 vol% glycerol as a cryoprotectant.

The neutral yield from water ice was measured by preparing a frozen ice layer with a known thickness on the copper tip. The number of pulses required to "drill" through the layer onto the copper surface was counted. These experiments showed that the neutral yield increases very nearly with the cube of the energy density of the laser pulse. The neutral yield at a "typical" power density of $0.35 \text{ mJ}/\text{cm}^2$ is $0.1 \mu\text{m}$ of water ice. This corresponds to approximately 300 molecular layers of H_2O . It is noteworthy that the extinction coefficient of about 10^4 cm^{-1} predicts that a much thicker surface layer (about $1 \mu\text{m}$) is heated by the IR laser pulse. In addition, one finds that with a modest surface temperature of about 240°C , the calculated evaporation rate from water is large enough to explain the observed neutral yield assuming a 7 ns evaporation time (=length of IR pulse). Finally, little or no water clustering is observed in these laser desorption spectra. These observations strongly suggest that under the present experimental conditions, the desorption process is best described as one of rapid evaporation. Such a

process is expected to give higher-internal temperature ions and less clustering than the "bulk desorption" process that should become important at a surface temperature of about 300°C .

With our experimental set-up as described, it is relatively easy to obtain stable peptide spectra. Figure 1 shows a spectrum of bradykinin at a 1.0 mM original solution concentration. One μL was applied on the probe tip. The mass resolving power varies from about 250 to better than 500. The spectra may be very "clean" as exemplified by Figure 1 or may contain a number of high-intensity, low-mass ions. Only, occasionally have we observed low-intensity protein ions. However, it is possible that this is due to the SALDI process after carbon contamination of the probe in the vacuum lock.

In line with previous reports (1) we find that intense laser desorption mass spectra can be obtained when the aqueous sample is evaporated to near dryness. It is striking that such spectra contain intense singly and even multiply charged atomic ions. Presumably, a very hot plasma is formed, at least locally, on the irradiated surface. Still, intact peptide ions are also observed under these conditions.

Evaluation of Hydrophobic Interactions of the Matrix and Analyte in MALDI

Karen K. Campo and David H. Russell
Laboratory for Biological Mass Spectrometry
Department of Chemistry, Texas A&M University
College Station, TX 77843

It is known that the structure (second degree, third degree, fourth degree) of a protein is sensitive to environment (solvent). Varying the solvent in sample preparation has shown to influence MALDI ion yields [1]. Can it be the changes in the conformation of a protein be affecting the MALDI ion signal?

In order to study this, we used three different proteins (bradykinin, insulin, and melittin) and placed them (separately) in an aprotic environment (acetone). To the acetone, we added five, ten, fifteen, and twenty percent water (v/v) of the solution.

The abundance of the $[M+H]^+$ ion signal as well as the sodium and potassium adduct peaks of the three analytes with the addition of water were compared. We found that increasing the water added to all three analytes increased the $[M+H]^+$ ion signal. Plus, the abundance of sodium and potassium adduct peaks were reduced for all three analytes as the amount of water that was added to the acetone was increased.

The $[M+H]^+$ ion signal of melittin increases as more water is added. The same is seen with bovine insulin and with bradykinin, with two exceptions. The addition of 10% water to bovine insulin decreases the $[M+H]^+$ ion slightly. The same is seen for bradykinin at 15% water addition.

From these results, apparently, water has a greater affinity for the sites on the protein than does sodium or potassium; thus displacing the cations from the sites on the protein.

We suggest that rather than a continual increase in $[M+H]^+$ ion signal as water is added, a plateau is reached where the addition of water no longer greatly affects the $[M+H]^+$ ion signal. It seems that this "plateau" or limit is reached at 1% bradykinin and 5% for both melittin and insulin. We propose that these limits are due to a change in the conformation of the protein. The reason for the difference between 1% water and 5% water may simply be

that bradykinin is much smaller and has an exposed beta-turn due to the proline residues.

Even a small amount of water may disrupt the interaction of the prolines and thus change the conformation.

Characteristics Of Several New Alpha Substituted Cinnamic Acids As MALDI Matrices

*Robert S. Brown and Jinhua Feng, Department of Chemistry and Biochemistry, Utah State University, Logan, UT 84322-0300

Substituted cinnamic acids are one of the more important classes of matrices currently employed for protein and peptide characterization by MALDI mass spectrometry. Although a variety of substituted cinnamic acids are popular matrices for MALDI, the most widely used cinnamic acid matrix is α -cyano-4-hydroxy cinnamic acid. Two primary advantages of this matrix over other cinnamic acid matrices is its low level of matrix adducting to peptide/protein analytes and the extent to which it promotes the formation of higher order charge states in larger proteins. Earlier studies with a limited number of commercially available α -substituted cinnamic acids suggested that the increased extent of multiple charging correlated well with the expected matrix acidity based upon electron withdrawing power arguments of the α substituent. Given the limited number (5) of commercially available α -substituted cinnamic acids and the difficulty in establishing trends from such a small data set, the present studies to synthesize and characterize the MALDI characteristics of additional α -substituted cinnamic acids was begun. This presentation will describe the MALDI performance of 9 new α -substituted cinnamic acids.

The new matrix candidate compounds that were synthesized are listed in Table I, along with their MALDI performance characteristics. Over half (5 out of 9) of the new compounds

TABLE I. MALDI Performance (337 nm) of Newly Synthesized Substituted Cinnamic Acids

MATRIX	Log E ₃₃₇	SUBLIMES	STABILITY	SIGNALS
α -cyano-4-hydroxy-3,5-dimethoxy cinnamic acid	4.12	Yes	P	S
α -cyano-3,4,5-trimethoxy cinnamic acid	4.26	Yes	P	S
α -phenyl-3,4,5-trimethoxy cinnamic acid	3.87	Yes	P	W
α -methyl-3,4,5-trimethoxy cinnamic acid	2.94	Yes	P	N.L.

synthesized were successful as MALDI matrices at the 337 nm desorption wavelength employed for these studies. The unsuccessful compounds all suffered from low molar absorptivities at 337 nm due to insufficient red shifting of the absorbing chromophore and would probably be more suitable for MALDI at a shorter wavelength (such as 308 nm). Solution molar absorptivities, why not an exact measure of the likely solid state absorptive properties of a matrix compound, are much easier to measure and provide a very accurate method for successfully predicting MALDI behavior with regard to desorption. None of the successful MALDI matrices with solution molar absorptivities (Log E₃₃₇) below 3.5 have been observed for the over 50 potential matrix compounds of various structures that have been screened in this manner. It should be noted that additional factors beyond molar absorptivities also play a role in the success of a compound as a MALDI matrix as is evidenced by the performance of the 4-cyano- α -phenyl cinnamic acid matrix. The poor MALDI characteristics of the α -phenyl-3,4,5-trimethoxy cinnamic acid matrix may be due to low level impurities and further and more elaborate purification steps (beyond the sublimation and recrystallization employed in these studies) are underway to better characterize these materials.

We have attempted to correlate the extent of multiple charging observed with each of the synthesized and previously available cinnamic acid MALDI matrices with the solution pK_a's of

each (as determined experimentally by titration and/or spectroscopic methods). The multiple charging observed in the MALDI spectra, using bovine serum albumin as a test probe, correlates well for most matrices with the measured pK_a's. Of the dozen matrices correlated in this manner, only two of the weaker acid matrices were out of order in a ranking of matrices based upon observed multiple charging (+2 to +1 charge state ratio). This may be due to errors in the pK_a measurements or simply reflect the very similar degrees of multiple charging observed for the weaker acids (pK_a's between 3.5 and 4.5) used as MALDI matrices. In this pK_a range, multiple charging was essentially identical within the errors associated with the reproducibility of the multiple charging (typically $\pm 2\%$). This correlation with solution pK_a's (which would not be expected to be the same as gas phase acidities) suggest a memory of the solid state crystallization conditions influence post desorption ionization and may be evidence for the validity of the preformed ion-pair model for MALDI.

Another interesting feature of the new matrices studied, is the extent of early time frame fragmentation that is observed with selected matrices. The α -cyano-3,4,5-trimethoxy cinnamic acid synthesized not only exhibited excellent MALDI characteristics for peptides and proteins (along with a very strongly red shifted UV absorption spectrum) but has exhibited the lowest degree of in-source decay (ISD) of any MALDI matrix studied to date. Indeed, it exhibits significantly lower levels of ISD fragment ions (see figure below) than even the widely employed "super" DHB (a 9/1 co-matrix mixture of 2,5-dihydroxy and 2-hydroxy-5-methoxy benzoic acids) which is known to produce less post-source ion decay (PSD) and also previously exhibit the least amount of ISD fragmentation prior to the current work with α -cyano-3,4,5-trimethoxy cinnamic acid. Further studies into the extent of longer time frame PSD fragmentation with this matrix are planned. It is premature to draw any conclusion as to the reasons why this matrix exhibits so much lower ion activation than other cinnamic acids studied to date, given these limited studies. However, it is tempting to speculate that the lack of an hydroxy group on the phenyl ring in this matrix, usually a prerequisite to red shifting the absorption to an appropriate longer UV wavelength, may be a factor. This could suggest that ISD fragmentation is the result of energetic excited state proton transfers from the hydroxy group to the analyte or that possibly that different photochemically induced reactive species are generated in MALDI of this matrix which leads to the lower extent of ISD.

Fragmentation of Sulfated Dyes, Drugs and Sugars Desorbed as Noncovalent complexes upon MALDI

Andrew Rhomberg and Klaus Biemann

Department of Chemistry, MIT, Cambridge, MA 02139-4307

Highly acidic analytes are difficult to desorb (by FAB, MALDI) or they form extensive cation adducts (ESI), which hinder their mass spectrometric analysis. Complexation with very basic compounds provides a way for ionizing and studying these compounds by MALDI-TOF [1]. The analyte is mixed with small arginine-rich peptides to form noncovalent complexes. The protonated complex ions can be detected in the positive-ion mode and accurate molecular weight information is obtained.

We have investigated the usefulness of the technique for obtaining structural information by prompt or metastable fragmentation. Well-known synthetic compounds such as azo dyes and suramin analogues were used to determine the conditions for such analysis and to study their fragmentation. The compounds selected are of significant industrial, biological and pharmaceutical importance.

An investigation of more than 10 azo dyes showed that these fragment by photoactivated cleavage of the N=N bond adjacent to naphthyl groups and not by C-N cleavage as in EI [2]. This process results in extensive prompt as well as metastable fragmentation. Fragments that retain two or more sulfates are observed as the complexes with the basic peptide. Complexes of fragments with one or no sulfate group remaining dissociate and are not observed in the positive-ion mode.

Post source decay (PSD) analysis of suramin derivatives indicated extensive metastable fragmentation of the amide bonds in the analyte backbone, if complexes were selected that had an excess of sulfonate residues over arginine residues. For complexes where the number of arginine residues was equal or in excess to the sulfonate groups, no fragmentation of the analyte, but fragmentation of portions of the complexing peptide was observed. In all cases, the fragments retained more than one of the complexing peptides.

For both azo dyes, as well as suramin derivatives, selective loss of SO₃ from the para or ortho position to a π electron donating aromatic substituent was observed while sulfonate residues in the meta position did not fragment. The mechanism can be rationalized based on the resonance structures for the protonated transition state.

Complexes with heparin oligosaccharides did not exhibit glycosidic cleavage, which would be useful for mass spectrometric sequencing of glycosaminoglycans. Extensive loss of SO₃ from N- and O- sulfates dominates the PSD spectrum. The failure to obtain useful fragmentation may be linked to the peptides used in this study [mostly (RG)_n; n=2-15]. Medium to large peptides do not permit the fragmentation of the complex after bond cleavage, due to multiple interactions with all the fragments. Furthermore, they often provide a large excess of arginine residues that appears to prevent analyte fragmentation. Small peptides (containing 2-4 Arg) complexed only poorly. This may be related to the wider distance of sulfate groups in heparin.

The study proved that fragmentation of covalent bonds is possible without dissociating the noncovalent complex. The method has already been used to characterize novel medical imaging reagents for Alzheimer's Disease and to identify unexpected synthetic reaction products of high anticancer potency. Further experiments are underway to develop peptides, that form complexes that could be used for the sequencing of sulfated glycosamino-glycans (GAGs).

Abstract: The study of three structurally related compounds, namely, 4-hydroxy-3-methoxyphenylpyruvic acid (HMPPA), indole-3-pyruvic acid (IPA), and indole-3-glyoxylic acid (IGA), for their possible role as matrix in the matrix assisted laser desorption/ionization (MALDI) studies of biomolecules is reported. It was found that HMPPA and IPA were quite effective in protein and peptide analysis while IGA failed to perform as a good matrix. High sensitivity and tolerance towards impurities was demonstrated by HMPPA for the analysis of peptides from biological samples.

Introduction: The discovery of matrix assisted laser desorption/ionization (MALDI) in 1988⁽¹⁾ of proteins from a nicotinic acid matrix has provided a rapid and cost-effective detection technique for the analysis of labile biomolecules in the gas phase. This technique has undergone continuous development in order to accommodate bioanalytical detection requirements. A crucial component of the experiment is the matrix. Some of the successful matrices introduced, include 2, 5-dihydroxy benzoic acid, caffeic acid, sinapinic acid etc. Matrices specific to the analyte molecule are 3-Hydroxycyclopicolic acid (3-HPA)⁽²⁾, a DNA specific matrix, 2, 5-DHB⁽³⁾, widely used for protein and peptide analyses.

This work focuses on characterizing three structurally related compounds (4-hydroxy-3-methoxyphenylpyruvic acid (HMPPA), indole-3-pyruvic acid (IPA), and indole glyoxylic acid (IGA)) in order to evaluate them as MALDI matrices. The structures of the three compounds is shown in Figure 1. HMPPA and IPA were found to be effective for analysis of proteins and peptides. HMPPA demonstrated high sensitivity and tolerance toward impurities while IPA was ineffective for detection of low concentrations of high mass samples.

Experimental: The time of flight mass spectrometer used in this study is described elsewhere⁽⁴⁾. The 355 nm laser pulse for the experiments was obtained from a Spectra Physics DCR 11 Nd:YAG laser. Matrix solutions were prepared at 10-20 mg/ml concentration in either 1:1 acetonitrile/water or 1:1 ethanol/water. The analyte was premixed with the matrix in a 1:1 ratio by volume and air dried before analysis.

Results: Figure 2a is the MALDI time of flight mass spectrum of 0.7 pmol of lysozyme obtained with IPA matrix. The sensitivity and ion signal patterns for this spectrum were comparable with the performance of 2, 5-DHB matrix. The ability of IPA to act as a matrix for the analysis of larger proteins, such as bovine albumin (3 pmol) decreased, particularly for low concentrations (Figure 2b). The performance of HMPPA in the analysis of bovine albumin was better than that observed for IPA. Figure 3 is a MALDI mass spectrum of bovine albumin using HMPPA matrix. It appeared that multiply charged protein ions were generated most efficiently as 2, 5-DHB<HMPPA< α -CHCA. Figure 4 is a demonstration of the role of HMPPA as a matrix in the analysis of commercial milk. The three major proteins, lactoalbumin, lactoglobulin and casein were identified. The results show the tolerance of HMPPA towards the presence of impurities.

Discussion: This work demonstrates that the similarity in the chemical structure of compounds is not the criterion for their behavior as good matrices in matrix assisted laser desorption/ionization studies. Also, the similarities in their UV absorption properties in solution is not directly related to their performance as

MALDI matrices in the solid phase. The properties that differentiate an effective matrix from an ineffective matrix appear to be dependent on the fate of the molecule upon absorption of light. IPA was found to be effective for small proteins and peptides. For detection of high mass proteins, higher laser intensity was required thus rendering the matrix ineffective. The tolerance of a matrix towards impurities is an important criterion for MALDI analysis. Such matrices can be used for analysis of crude samples such as milk and cell lysates.

Photothermal decomposition under experimental conditions has been shown to be important for the effectiveness of a matrix. Since many effective matrices decompose at their melting points (220 °C or ~500 K); it is possible that the desorption temperature does not exceed (<500 K) the melting point of the matrix in a typical experiment. The compounds, IPA and IGA probably decompose under these experimental conditions which might explain their ineffectiveness at high laser intensities (required for protein analysis).

Studies on the Selection of New Matrices for UV Matrix-Assisted Laser Desorption/Ionization MS

Jocrn L. Krauss and Urs P. Schlunegger

Institute of Organic Chemistry, University of Berne, Freiestr. 3, CH-3012 Berne / Switzerland

Introduction:

A large number of very different compounds have been tested with success as matrices for Matrix-Assisted Laser Desorption/Ionization (MALDI) MS since the introduction of this new technique into the MS field in 1988.

The UV-absorption is of special importance for the selection of new potential matrices. Compounds like salicylic acid, which contain a phenolic hydroxy group in ortho position to a carbonyl function often show a special behaviour under UV-irradiation [1,2]. UV-irradiation induces an intramolecular proton shift along the H-bond in these molecules, yielding a metastable excited state [3]. The excitation wavelength of those transitions is in general located in the ultraviolet region. With respect to this it is sensible to test compounds showing the described transition as new potential matrices

Methods:

All presented MALDI-MS measurements have been carried out on a home built linear Time-of-Flight instrument. A pulsed nitrogen laser was used for desorption/ionization of the samples

For the determination of the UV-absorption, UV-Vis spectra of all tested compounds have been measured in ethanolic solution (1 E-4 mole/l) on a Perkin-Elmer UV-Vis spectrophotometer)

Conclusions:

Our results show that compounds which perform a proton transfer under UV-irradiation are actually usable as matrices for UV-MALDI MS.

This was found as well for the tested hydroxy-acetophenone derivatives (figure) as for the tested hydroxy-benzoic acid derivatives (figure). The meta- and para-compounds show a significant lower matrix activity in our experiments.

2,5-Dihydroxy-acetophenone is a very powerful matrix for the analysis of peptides, proteins and oligonucleotides (especially for the analysis of oligonucleotides containing many adenine residues. Another very useful matrix in the positive ion mode is salicylamide (compound 12, figure). Salicylamide also shows the described proton transfer under UV irradiation. Its absorbance is comparably weak, but the performance as a MALDI matrix is nevertheless very good. The low intensity of matrix (fragment) ions allows measurements with this matrix in a mass range from only about 150 Da up to 40 kDa.

Similar results as with the hydroxy-acetophenones were obtained for hydroxy-benzoic acid derivatives. Again the ortho hydroxy-benzoic acid derivatives show high matrix activity (compounds 15, 18, 19, 22) whereas the meta- and para-isomers show no matrix activity. The same result was found for the dihydroxy-benzoic acids. The isomers containing a ortho-hydroxy-group (compounds 24, 25) are powerful matrices for the analysis of peptides and proteins in the positive ion mode.

The results show that new matrices can be selected by choosing compounds which perform an intramolecular proton transfer under UV-irradiation.

Whether the described proton transfer and the resulting metastable excited state is involved in the ionization process or if it just offers an absorption band in the used wavelength area is still not clear so far. Further work is going on.

Results:

The following table presents the results of our measurements with bovine insulin (positive ion mode) and the oligonucleotide d(pA)₄ (negative ion mode) as an analyte, using different potential matrices. The structure of each matrix is given and the resulting ion intensities, resolutions and UV-absorption coefficients are listed.

Matrix-assisted laser desorption/ionization of synthetic polymers with azo compound matrices

H.M. Donny Liu and Urs P. Schlunegger

Institute of Organic Chemistry, University of Bern, Freiestrasse 3, CH-3012 Bern, Switzerland

Azo-compounds have been found to be very good cationization matrix materials for synthetic polymers in matrix-assisted laser desorption/ionization at 337nm laser irradiance. These azo-compounds have been successfully used for the desorption of synthetic polymers such as polyethylene glycol (PEG), polystyrene (PS) and polybutadiene (phenyl terminated). Cationization of the synthetic polymers is more efficient with these matrices than with 2,5-dihydroxybenzoic acid and 3,5-dimethoxy-4-hydroxycinnamic acid. Both the sensitivity and the resolution are improved. Non-polar polymers such as polystyrene and polybutadiene also do not mix very well with the matrices such as DHB and sinapinic acid and failed to produce any signal.

Table 1 and Table 2 listed all the potential matrices for PEG and PS synthetic polymers. It was demonstrated that azo compounds such as 4-hydroxyazobenzene (2), 2,2'-dihydroxyazobenzene (8), 4-(phenylazo)-resorcinol (9) and chromoionophor IV (11) are very efficient matrices for polar polymers in ultraviolet MALDI mass spectrometry with a very wide mass range, including polyethylene glycol samples above 35000 Dalton. Figure 1 shows the MALDI-TOF mass spectrum of PEG 4000 in 4-(4-nitrophenylazo) resorcinol matrix. Several of the azo compound matrices, for example, 4-(phenylazo)-resorcinol (9) and chromoionophor IV (11) have also been successfully used for the desorption of non-polar polymers such as polystyrene up to 100000 Dalton. Figure 2 shows the MALDI-TOF mass spectrum of PS 3700 in chromoionophor IV matrix. For all the positive ion spectra of the PEG and PS samples studied above, cation attached molecular ions are always formed even without addition of alkaline salts.

MALDI-TOF mass spectra of PEG samples obtained with these azo-matrices have an improved sensitivity and resolution compared with other widely used matrices such as 2,5-dihydroxybenzoic acid and sinapinic acids. Multiply charged analyte ions of PEG and PS samples were not often observed for most the azo matrices except in the case of chromoionophor IV which tends to form multiply charged molecular ions in all the MALDI-TOF mass spectrum especially with PEG samples. Further work has been carried out for the analysis of carbohydrate, glycoprotein and glycolipids with these new matrices, which can only be cationated in MALDI. Details related to this work can be obtained in the reference^{3,4}.

Techniques for Automated Molecular Weight Measurements Using Electrospray Ionization Mass Spectrometry

Tom Covey, Matt McLean, Charles Liu, Ron Bonner, Lyle Burton
PE/Sciex Concord, Ontario & Foster City, California

Electrospray ionization is increasingly being used as a tool for automated molecular weight determinations in the synthetic chemistry laboratory. The ease of automating sample introduction and the amenability of the ionization process to a wide variety of compounds have made "on-demand" mass spectral analysis of reaction mixtures a reality. An approach for automation of the data acquisition process (*MS Express*) that retains simplicity and ease of use, but is sufficiently flexible that it can be configured for other techniques is presented.

Automation of the data interpretation process can be difficult in many cases and remains the task of the experienced mass spectroscopists. Problems such as the formation of adduct ions, multiply charged ions, multimers, fragment ions, and charge exchange reactions continue to complicate spectral interpretation such that it is often beyond the capacity of simple software solutions.

This presentation will explore solutions to this problem that have been investigated by automating the generation of additional complimentary spectral information to aid the molecular weight determination process. These include positive/negative ionization, high and low fragmentation voltages in conjunction with Apple scripting as a tool for rapid development of interpretation software. The script "Mole Finder" was developed for this purpose, and applied to the interpretation of 16 different compounds representing 8 different chemical classes. These include weak organic acids, strong organic acids, weak organic bases, strong organic bases, amphoteric, zwitterionic, quaternary amine, and neutral compounds flow injected into 50%CH₃CN/H₂O 10mM NH₄OAc at 50μL/min flow, 30μL injected. Two minutes per acquisition were conveniently achieved under these conditions.

The criteria for identification of the molecular weight were strongly dependent on the characteristics of the chemical class to which a compound belongs. It thus became apparent that any attempt at automated interpretation of spectra must first start with some information input by the chemist regarding the chemical class of the species being analyzed. Eight different classes of small molecules were identified as having distinctive electrospray spectra as predicted from their solution chemistry and thus used different criteria for determination of the molecular weights from the spectra. The importance of the acquisition of both positive and negative spectra is exemplified in the analysis of acids and bases which show a strong preference for one or the other polarity. Easily interpreted molecular ions are obtained in one mode, the other shows adducts from which molecular weights must be back calculated and whose identity must be assumed from solution buffers and contaminants.

Less obvious is the need for simultaneous acquisition of both high and low ion source fragmentation voltages for calculating simple molecular weights. In almost all cases high fragmentation potentials added confirmatory evidence regarding the identity of the molecular ions, especially when the spectra were dominated by multimers as a result of too high a concentration injected. In the case of neutral compounds in solution, high fragmentation voltages were the only means by which a true molecular ion $\{(M+H)^+\}$ could be obtained. See Figure 1 below.

There are some situations where correct interpretation of the molecular weight by a script absolutely requires knowledge of the chemical nature of the compound or a mass error of 1 amu will be assigned. Quaternary amines are the most notable example since they don't produce either $(M+H)^+$ or $(M-H)^-$ but rather produce $(M+)$.

In conclusion we have identified 8 chemical classes, the members of each having sufficient spectral similarities and rules of interpretation to make them amenable to automated data system interpretation from scripts. These 8 classes cover the vast majority of organic chemical species likely to be analyzed by mass spectrometry. For the system to work the chemist must identify the chemical class before (or after) acquisition. The script appropriate for the interpretation of that class would then be automatically evoked. Successful interpretation is enhanced by acquisition modes that provide additional information, in particular positive and negative ionization and high and low source fragmentation voltages.

Neutral Compounds- Characteristic ions in order of priority:

Positive: $(M+H)^+$; $(M+NH_4)^+$; $(2M+NH_4)^+$; $(3M+NH_4)^+$

Negative: $(M+acetate)^-$; $(2M+acetate)^-$

Dehydroepiandrosterone MW=288

Accurate Mass analyses of Combinatorial Chemistry products by Micro Electrospray

R H Bateman, M R Green, N H R Ordsmith, J D Pugh and A R Woolfitt
Micromass Ltd, Floats Rd., Wythenshawe, Manchester, M23 9LZ, UK

A nanoflow electrospray ionisation source that utilises both drawn glass metal coated micropipettes and stainless steel needles has been developed for the AutoSpec-TOF tandem magnetic sector - time of flight mass spectrometer. The electrospray ionisation source operates at 4 kV. The flow rate range is in the region of 3 to 300 nanolitres per minute, depending on the type of sprayer and ID of the needle tip. The signal intensities obtained at these low sample flow rates are comparable with those obtained with conventional electrospray at 100x to 1000x higher flow rates for the same sample concentration. The design incorporates a dual sprayer assembly, enabling a suitable mass reference compound to be introduced independantly of the sample. This enables rapid switching between sample and reference signals which permits accurate mass measurements to be made without any need to contaminate a precious sample solution by the addition of reference material.

Accurate mass measurements by voltage scanning may be made by scanning a mass range covering two reference masses bracketing the mass of interest. The mass measurement of [Glu] Fibrinopeptide B was made from a loading of 12.6 pmol in 1 µl of solvent in a 1 µm ID metal coated borosilicate capillary. The reference masses m/z 745.4198 and m/z 789.4460 from polyethylene glycol (PEG+Na) were chosen. This was introduced via the second of the two nanoflow sprayer assemblies. This uses a nominal 25 µm ID stainless steel needle and the flow rate is 50 ~ 100 nL/min. Figure 1 shows a part of the mass spectrum including the $(M+2H)^{++}$ ion and a PEG+Na reference peak. The sample consumption for each scan is ~ 10 fmol. Mass measurements for the two most intense peaks are:-

Scan	Measured Mass	Error (mDa)	Measured Mass	Error (mDa)
1	785.8438	+ 1.2	786.3452	+ 1.2
2	785.8445	+ 1.9	786.3447	+ 0.7
3	785.8424	- 0.2	786.3473	+ 3.3
4	785.8474	+ 4.8	786.3437	- 0.3
5	785.8394	- 3.2	786.3470	+ 3.2
6	785.8369	- 5.7	786.3480	+ 3.0
7	785.8386	- 4.0	786.3430	- 1.0
8	785.8470	+ 4.4	786.3419	- 2.1
9	785.8366	+ 4.0	786.8378	+ 3.2
10	785.8446	+ 2.0	786.3403	- 3.7
Mean	785.8421	- 0.5 (0.6 ppm)	786.3448	+ 0.8 (1 ppm)

Accurate mass measurement has been investigated with respect to the identification of the products from a combitorial library. A library of 18 tri-peptides of the general composition Ac-Tyr-X-Leu-NH₂ were mass measured by voltage scanning. A resolution of 12,750 (10% valley) was chosen to resolve the Glutamine and Lysine components (see Figure 2).

Ac-Tyr-Gln-Leu-NH₂ Measured mass = 464.2508 Error = - 0.1 mDa (- 0.22 ppm)
Ac-Tyr-Lys-Leu-NH₂ Measured mass = 464.2870 Error = - 0.3 mDa (- 0.65 ppm)

Accurate Mass Determination of Agrochemicals and Their Metabolites Using APCI/MS

Hideji Fujiwara
Analytical Sciences Center, Monsanto Co., 700 Chesterfield Parkway
North, St Louis, Mo 63198

For many years at Monsanto accurate mass mass spectrometry has proven invaluable in the identification of herbicide metabolites since accurate mass measurements can yield elemental composition data on ng - µg quantities of sample. Atmospheric Pressure Chemical Ionization Mass Spectrometry (APCI/MS), a relatively new ionization technique, was recently utilized in my laboratory to obtain accurate mass data for herbicide metabolites as well as endogenous compounds from vegetables. This new technique will be extremely valuable in the identification of xenobiotic and endogenous unknowns.

Endogenous steroidal glycoalkaloids such as solasodine, solasonine from potato and tomatodine and tomatine from tomato were found to be extremely sensitive to positive-ion APCI/MS. The identity and quantity of these steroidal glycoalkaloids in transgenic plants needs to be determined for registration of the plants.

Amino acid and small peptide conjugates of chloroacetanilide herbicides (acetochlor, alachlor, butachlor, metolachlor, propachlor) were also found to be sensitive to both positive- and negative-ion APCI/MS.

The accurate mass determination can be performed using a commercial double-sector mass spectrometer (JEOL SX-102A) with an Analytica APCI source. The success of the determination strongly depends upon the selection of reference standards for both positive- and negative-ion APCI/MS. Ideal reference standards should be very sensitive to APCI and should not interfere with sample signals. Since the flow rate of liquid mobile phases (water or acidic water and organic solvents) should be 2 - 10 times faster than that for Electrospray Ionization Mass Spectrometry (ESI/MS), most residual references are quickly eliminated. Thus accurate mass determination of other samples can be performed immediately if necessary.

Tallowamines (polyethyleneoxide (0- 10)-soy-amines; polyethyleneoxide (0-25)-octynodenolamines; etc...), surfactants are commercially available. They are found to be quite sensitive by positive-ion APCI/MS and are suited as reference standards for that ionization technique.

Perfluorinated acid anhydride/fluorinated alkylalcohol (PF-anh/F-alc) derivatives of glyphosate (N-phosphonomethylglycine) and aminomethyl-phosphonic acid (AMPA), that were previously used for accurate mass determination using negative-ion ESI/MS, were also found to be suited for accurate mass determination by negative-ion APCI/MS.

Positive-Ion APCI Accurate Mass Determination of Protonated Molecular Ions of Steroidal Glycoalkaloids at 5,000 Resolution

Analysis of Polymers using FTMS

Peter B. O'Connor, Ron M. A. Heeren, Marc Duursma,
Gerard Van Rooij, Eric v. d. Hage, Jaap Boon
FOM Institute for Atomic and Molecular Physics
Kruislaan 407, 1098 SJ Amsterdam, The Netherlands

Matrix assisted laser desorption/ionization (MALDI) has been used extensively to generate ions for the analysis of polymers in many mass spectrometers including the Fourier transform mass spectrometer, and a variety of techniques exist for getting these ions into the trapped ion cell. Some systems simply place the MALDI probe millimeters from the cell allowing the magnetic field to focus the ions from the plume into the cell with the disadvantage of higher base pressure at the cell. Others, like ours, ionize outside the field and transfer the ions to the cell using a variety of ion optics techniques with the disadvantage of time of flight broadening of the ion bundle that has been extracted from the plume.

We here demonstrate this distortion, and measure the average median velocity to be ~ 2800 m/s as the ions travel from the source to the cell. Additionally, we show that removal of this distortion by acquiring spectra at a variety of time of flight delays is possible, but that merely summing these spectra, as proposed in

the literature, results in spectral distortions that overestimate the central peaks of a distribution and suppress the wings. Hence, an overlay plot which shows the maximum value for each oligomer generates the best representation of the total oligomer distribution.

Using nitro phenyl octyl ether (NPOE) with AgTFA mixed in a 1:1 mass ratio with poly(styrene), we demonstrate the analysis of the historically difficult to ionize polystyrene compound using MALDI-FTMS demonstrate the advantages of FTMS in accurate determination of the end groups of an amine terminated poly(propylene glycol).

For polymers, the high mass accuracy of FTMS is particularly useful since plotting the masses of the monoisotopic peak of each oligomer versus the polymerization order and extrapolating to zero yields a y-intercept whose mass value is the mass of the endgroups plus the cation. Standard mass accuracy on an FTMS is ~ 0.1 ppm; using such masses for the extrapolation yields a mass error at zero oligomers of approximately 1 ppm for polymers in the 1000 Da range allowing elemental determination of the endgroups.

A COMPARISON OF QUADRUPOLE, SECTORS AND ION-TRAP ANALYSERS TO ASCERTAIN MULTICHARGED IONS ASSIGNMENTS

INTRODUCTION : Initially implanted on quadrupole instruments, ESI sources are currently available on sectors instrumentation (1) and for about one year, have been developed on ITMS (2). In spite of rather different scanning modes, the two latter instrumentations allow high resolution capabilities. In the present paper, a comparative study on the performances of four ESI sources implanted either on quadrupole, sectors or ITMS instruments is presented. Three compounds were studied : two lanthanide complexes and a polysulfated pentasaccharide. The ability of the instrumentations to resolve the multicharged ions isotopic patterns is presented and the place of the new ESI-ITMS technology within the range of more conventional ESI-instrumentation is discussed.

METHODS :

• **Chemicals :** the two lanthanide complexes and the pentasaccharide were prepared as previously described (respectively (3) and (4)).

• **Instrumentation :**

Quadrupole instrumentation : low resolution positive (lanthanide complexes) or negative (pentasaccharide) ESI spectra were obtained respectively either on a VG Platform or a Finnigan TSO 700 instrument.

Sectors instrumentation : an Autospec OATOF instrument (Micromass Ltd, UK) was used.

Ion Trap instrumentation : a LCQ (Finnigan Mat) ESI-ion trap spectrometer was used in different scanning modes : full scan (mass range : 200-1400 amu, 2 sec/scan) and zoom scan (scanning rate reduced by a factor of 10).

DISCUSSION :

For the two *lanthanide complexes*, high resolution data obtained either on a sector or an ITMS instrument on the main multiply charged ions of the ESI spectra reached to a precise determination of the charge state of these ions and allowed a good comparison with their theoretical isotopic pattern (Fig. 1).

These two sets of data showed that no oxydo-reduction phenomena due to the presence of the metal ion occurred during the ESI process. In that context, the same results were obtained with both ESI instrumentation.

ITMS offers the unique opportunity to perform high resolution MS/MS on multicharged parent ions (Fig. 1) thus assisting in the elucidation of fragmentation mechanism. In this paper, this potentiality was applied for the first time to lanthanides complexes.

For the *pentasaccharide* compound, high resolution data were obtained both on sectors and ion trap instrument (Fig. 2). Although of lower quality than those obtained on the sectors instrument, interpretable data were obtained on the ITMS up to the 6⁺ charge state for which the spacing between the isotope peaks was determined.

CONCLUSION :

The present study showed the importance of high resolution ESI data for an unambiguous attribution of the charge state of multiply charged ions.

Despite rather different scanning mode, sectors and ion trap instruments gave similar results for resolving different profiles of multiply charged ions up to the 4 charge state while for upper charge states sectors instrumentation was found more potent.

However, ion trap offers the unique opportunity to perform high resolution MS/MS on multicharged parent ions. Hence, the ESI-ITMS combination with its various capabilities (high resolution MS and MSⁿ, high sensitivity) can be considered as an important analytical tool, both in research and routine analysis.

High resolution accurate mass analysis on a magnetic sector mass spectrometer provides molecular formula information that facilitates the structure elucidation of unknown compounds such as novel natural products, metabolites, and impurities and degradants, as well as the molecular formula confirmation of synthetic products. Traditionally, high resolution accurate mass measurements are done using either electron ionization (EI) or fast atom bombardment ionization (FAB) modes. The polar and thermally labile compound classes encountered in the pharmaceutical industry typically require FAB ionization to determine the accurate mass of the molecular ion species. However, high resolution FAB accurate mass measurements are resource intensive and the ionization of the desired species is often suppressed by reference compounds and other components in the sample. Furthermore, for the compounds that only ionize via electrospray ionization, no molecular formula information is available with high resolution FAB MS. The advent of electrospray ionization on a magnetic sector mass spectrometer³⁻⁵ offers the potential of a nearly universal ionization method for accurate mass analysis with a sample introduction interface that is amenable to automation.

Here we demonstrate a standard automated method for high resolution electrospray ionization (ESI) accurate mass analysis on a magnetic sector mass spectrometer. This method provides unattended instrument set-up, data acquisition, data processing, and result printout for multiple samples with excellent accuracy and reproducibility. Initially, the standard procedures for manual high resolution ESI accurate mass analysis were developed. Once these were optimized, the automated method was developed using as a model our automated ESI method for molecular weight determination that provides MW information on over 95% of submitted compounds.^{1,2} Utilizing a standard mobile phase (CH₃CN/H₂O, 1:1) and universal solvent cocktail (70%CH₃OH, 29% CH₃CN, 1% H₂O), a standard method was developed that is rapid, rugged, maintains the high quality of data and works for greater than 80% of samples. Instrument control procedures and UNIX scripts provide automated instrument setup, data production, data processing and the printing of results. The Finnigan MAT 900S mass spectrometer is operated at 5,000 resolution (10% valley), with a Hewlett-Packard 1050 autosampler and Harvard 22 syringe pump both under data system control. The internal reference compound (PPG) is introduced coaxially in the sheath liquid.

With this automated method, high resolution ESI accurate mass measurements were obtained on a variety of pharmaceutical compounds. The method is rapid (4 minutes/sample) and provides unattended accurate mass analysis with good accuracy ($\Delta < 3$ ppm) and reproducibility ($s = 0.0004$ Da).

Accurate Mass ESI on a Magnetic Sector Mass Spectrometer

Dr. Colin Moore

Uniroyal Chemical Company, Inc., World Headquarters, Middlebury, CT 06749

Accurate mass ESI Mass Spectrometry in conjunction with other spectroscopic techniques was used to Identify an unknown hydrolysis product of the systemic Fungicide Plantvax. The unknown was identified as a Phosphate ester. Accurate mass measurement is a well established Mass Spectrometric technique for ions generated by Electron Impact, Chemical Ionization and Fast Atom Bombardment. Its applicability to the studies of ions generated by Electrospray ionization (ESI) has not been as well documented. From the accurate mass of an ion a list of possible elemental formulae can be generated.

All the data were acquired on a Kratos MS890RFAQ Hybrid double focusing magnetic sector mass spectrometer fitted with an Analytica ESI source and a Kratos DS90 Data System. Peak match data were obtained by continuous infusion of the sample plus compounds to give two reference masses which bracketed the unknown mass. Low chemical background meant that good data were obtained at a mass resolution of 2000 (10% valley definition).

Accurate mass scanning EI data gave m/z 225 as the highest mass ion in the spectrum with the elemental formula $C_{10}H_{11}O_3NS$. The probable structure of this ion is indicated on the structure of Plantvax below (Figure 1). Low resolution ESI spectra confirmed that the molecular weight of the unknown was 323Da since ions were observed at m/z 324 (MH^+) and 346 (MNa^+) in positive ion mode and 322 ($M-H^-$) in negative ion mode.

Negative ion accurate mass data were obtained by using reference ions from alkylated aromatic phenols and are shown in Table 1. The search for the elemental formula of the unknown was limited by using the following information.

- 1) From EI data m/z 225 is $C_{10}H_{11}O_3NS = 225.04597Da$
- 2) From ESI data ($M-1$) is 322.0128Da. Therefore M^+ is 323.0229Da
- 3) Unknown part of Molecule has mass 97.9769Da
- 4) Odd molecular weight, odd number N's.
- 5) Only one S in molecule, from isotope distribution in ESI spectra.

With limits of C 0 to 8, H 0 to 16, N 0 to 2, O 0 to 8, P 0 to 1 and a window of $\pm 15mmu$ the four compositions in Table 2 were obtained. Of these D has the lowest error and also makes the most chemical sense. ^{31}P N.M.R. analysis confirmed that the unknown was a phosphate.

Conclusions

- Unknown identified from;
 - EI spectrum and accurate mass confirmed "Plantvax like" sub-structure.
 - Accurate mass ESI gave elemental formula and hence presence of Phosphorus.
 - Chemical environment of P from ^{31}P N.M.R.

Accurate Mass ESI is a valuable tool in the analysis of unknowns.

ESI/MS of Organometallic Compounds on an LC/MS/MS Ion Trap Mass Spectrometer

Matthew J. Sweeney*, Jonathan L. Josephs, David C. Gale and Mark Sanders

Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Introduction: Organometallic compounds are important as catalysts, therapeutic agents and as naturally occurring biomolecules involved in human metabolism. Electrospray ionization/mass spectrometry provides a "soft" ionization technique facilitating the ionization of organometallics of various sizes and structures. The high resolution "Zoom Scan" mode of the ion trap allows investigation of isotope distributions of multiply charged ions while MSⁿ analysis facilitates structural elucidation. Cisplatin provides an example of a small structurally simple therapeutic agent, ruthenium-tris(2,2'-bipyridyl) dichloride, is a larger organometallic used as a redox catalyst, Vitamin B₁₂ is a large complex naturally occurring organometallic compound which serves as a source of free radicals to catalyze intramolecular migrations involving hydrogen.

Method: *Sample Preparation:* Samples were prepared as 1 µg/µl stock solutions in the appropriate solvents and then serially diluted to the levels used for direct infusion at 5 µl/min into the electrospray source.

Ion Trap Mass Spectrometer Conditions: Mass spectrometry data was recorded with a Finnigan MAT LCQ™ equipped with the Finnigan Electrospray Source. For positive ion, infusion the conditions were: Capillary temp 225°C, needle voltage 4.5 KV, sheath gas 45 psi, auxiliary gas flow 1 unit. For negative ion, infusion the conditions were: Capillary temp 225°C, needle voltage -3.5 KV, sheath gas 45 psi, auxiliary gas flow 1 unit.

Conclusions: Electrospray Ionization Provides a 'soft' ionization technique allowing the generation of intact pseudomolecular ions on a quadrupole ion trap. The high resolution 'Zoom Scan' mode provides sufficient resolution to study the isotope distribution patterns which compare favorably with the theoretical predicted values. The ability to perform MSⁿ on the ion trap facilitates structural elucidation of organometallic species.

Laboratory for Biological Mass Spectrometry*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

Many important biological substances contain coordinate covalently bound metals. Examples include hemoglobin, chlorophyll, vitamin B-12, and enzymes such as CO-dehydrogenase and [NiFe] hydrogenase. The reaction of O_2 with metal thiolates contained within these sulfur rich enzymes is known to inhibit activity and irreversibly deactivate CO-dehydrogenase and [NiFe] hydrogenase. Recently we reported electrospray ionization (ESI) mass spectrometry as a viable technique for investigating the mechanism of dioxygen addition to nickel dithiolate species.¹ Using isotopic labeling with $^{18}O_2$, the mechanism could be elucidated from the isotopic abundances obtained by mass spectrometry. ESI was the preferred technique over fast-atom-bombardment (FAB) and previously reported matrix-assisted laser desorption ionization (MALDI)² since it was more precise in its ability to accurately measure the isotopic abundances. These results motivated us to explore the general utility of ESI to a larger series of synthetic compounds generated to mimic metal active sites in biomolecules.

Positive ion electrospray mass spectrometry was performed on a series of Ni, V, Zn, and Pd metallothiolates. These metals were complexed with several different ligands including 1,5-bis(2-mercaptoethyl)-1,5-diazacyclooctanato (abbreviated as bme-daco), methylated bme-daco, oxygenated and methylated bme-daco, methylated bme-daco iodide salts, and dimetallo- and trimetallo-(bme-daco) complexes. The compounds were analyzed using flow injection analysis in which 1 μ L aliquots of 1 μ g/ μ L analyte solutions were injected into a mobile phase of 100% methanol flowing at 1.6 μ L/minute into a Vestec 201A ESI quadrupole mass spectrometer. Intense molecular ion peaks were observed for the entire series of metallothiolates. The ESI mass spectra were characterized by ion peaks corresponding to a protonated $[M+H]^+$ ion, oxidized radical cation $[M]^{+•}$, and an oxidized proton deficient cation $[M-H]^+$. In addition, sodiated $[M+Na]^+$ and potassiated $[M+K]^+$ ion peaks were observed. Due to the accuracy of the ESI technique in determining isotopic abundances, the percentages of the molecule present as $[M+H]^+$, $[M]^{+•}$, and $[M-H]^+$ could be calculated since each of these species gives rise to a different isotopic pattern. An example of experimental and theoretical isotope distributions for Ni-1* (methylated Ni-bme-daco) is presented in Figure 1. This plot provides the theoretical ion abundance for $[M+H]^+$, the molecular ion traditionally expected in ESI/MS. The predicted theoretical abundance for $[M+H]^+$ is contrasted with experimental values that differ by more than that which can be ascribed to experimental variance. Further calculations show that approximately 40% of the ions originating from the neutral compound Ni-1* are observed as oxidized radical cations, 10% are present as $[M-H]^+$ ions, and only 52% are present as the predicted $[M+H]^+$ ion.

On-line chemical reactions of nickel dithiolates were also performed and monitored by ESI. An example is shown in Figure 2. Under constant infusion of Ni-bme-daco, the mass spectrum obtained is shown in Figure 2a. Upon injection of excess Ni^{2+} , immediate dimerization occurs and is observed (Figure 2b) until the excess nickel has eluted. Finally, the metal thiolates were evaluated for linearity of ESI/MS response and possible quantification. The ESI response was found to be linear over three orders of magnitude, indicating that quantification is possible in the femole-pmole range.

Fourier Transform Ion Cyclotron Resonance Studies of Lanthanide(III) Porphyrin-Phthalocyanine Heteroleptic Sandwich Complexes using Electrospray Ionization

Rebecca L. C. Lau and T. -W. Dominic Chan*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, N. T., Hong Kong.

INTRODUCTION Metal porphyrin-phthalocyanine complexes have been served as models in studying the structure and spectroscopic properties of the 'special pair' in the reaction center of photosynthetic bacteria¹. In this report, we were interested in determining the applicability of electrospray ionization mass spectrometry (ESI-MS) to the analysis of a series of neutral heteroleptic lanthanide(III) porphyrin-phthalocyanine complexes represented as $\text{Ln}^{\text{III}}(\text{TPP})(\text{Pc})$, $\text{Ln}^{\text{III}}_2(\text{TPP})(\text{Pc})_2$ and $\text{Ln}^{\text{III}}_2(\text{TPP})_2(\text{Pc})$ where $\text{Ln} = \text{Sm}, \text{Eu}$ or Gd ; TPP = 5, 10, 15, 20-tetraphenylporphyrinate, Pc = phthalocyaninate. In particular, nozzle-skimmer (NS) dissociation and sustained off-resonance irradiation collision induced dissociation (SORI-CID) experiments were performed in an attempt to find out the structural arrangement of the porphyrin and phthalocyanine rings within the triple-decker complexes

EXPERIMENTAL Positive-ion ESI mass spectra were acquired with a Bruker APEX 47e FTMS mass spectrometer (Bruker Instrument, Billerica, MA) equipped with an external ESI source (Analytica, Bradford, CT). Lanthanide samples (~0.1 mg/ml) were sprayed from pure dichloromethane. In all cases NS dissociation experiments were performed by raising ΔNS from normally +100 V to +400 V. For SORI-CID, an excitation pulse with a frequency offset of 1 kHz lower than the corresponding ion cyclotron frequency of the isolated ions were used to activate the molecule-ions to induce dissociation.

RESULTS AND DISCUSSION Figure 1 shows the spectra of the europium series. In all cases, intense signals corresponding to the singly-charged molecular radical cations are observed. Their formation is attributed to electrochemical oxidation at the ES needle². From the fragmentation pattern of the europium complexes under NS dissociation and SORI-CID conditions (Figure 2 and 3), the configuration of the triple-decker complexes are, at the first time, confirmed mass spectrometrically to be $(\text{TPP})\text{Eu}^{\text{III}}(\text{Pc})\text{Eu}^{\text{III}}(\text{Pc})$ and $(\text{TPP})\text{Eu}^{\text{III}}(\text{Pc})\text{Eu}^{\text{III}}(\text{TPP})$.

Analysis of Copper and Ruthenium Complexes by ESI-MS

Brian James, Kirk L. Stevens, D.J. Buzard, John M. Keith,

James G. Pavlovich, Bruce H. Lipshutz

Department of Chemistry, University of California, Santa Barbara. CA 93106

Traditional mass spectrometric methods (EI, CI, FAB) are well established procedures for the accurate determination of molecular weight. However, these methods are often not applicable to many organometallic reagents due to non-volatility or instability. X-ray crystal structures provide structural data for solids. Mass spectrometry and *ab initio* calculations can be applied directly to the gas phase. There remains, however, no direct method for determining solution structures.

The electrospray ionization (ESI-MS) techniques which have been traditionally applied to biopolymers such as DNA and proteins circumvent these inherent problems. The technique relies on the creation of a spray of charged droplets into the source. The sample is desolvated by passing it through an inert blanket gas followed by high vacuum. The ion clusters which were present in solution are then observed in a quadrupole detector. The valence states of the metals present as well as solution composition can be determined from this data. It has been hypothesized that the species observed by ESI-MS are representative of those in solution. Although this does not provide direct structural data, the structural composition of the observed species in solution can be postulated. Since many organometallic compounds are ionic in nature, the solution can be analyzed by ESI with a standard machine without any special apparatus. There has been a long standing debate in the literature as to the solution structure of cuprate reagents, in particular the Higher Order Cyanocuprate. Two camps exist, in which the first postulates that a tricoordinate dianionic copper species is formed. The opposing view is that a dicoordinate, monoanionic (Lower Order)

Cuprate is formed in addition to Lithium Cyanide. Many NMR, IR, *ab initio*, EXAFS and XANES studies have been performed. None of these methods have been conclusive. It was hoped that ESI-MS could shed new light on this ongoing argument.

Both positive and negative ion ESI-MS have been applied to several THF solutions of copper salts, (e.g., $\text{CuCN} \cdot n\text{LiX}$, $\text{CuI} \cdot \text{LiX}$, etc.) as well as the asymmetric hydrogenation catalyst, $\text{BINAP}_2\text{Ru}_2\text{Cl}_5 \cdot \text{NEt}_2\text{H}_2^+$ (**1**) of interest to Merck Research Labs. Some of the clusters observed may represent Higher Order Cuprates. The species determined can often be easily confirmed by comparison with theoretical isotopic fingerprints.

1 as the Et_2NH_2^+ salt

In addition to the interesting results obtained with the halocuprates, the first ever observation of organocuprates by any method of mass spectrometry is presented. Organocuprates derived from CuCN and lithiothiophene or lithioalkynes have been observed in clusters, resembling the data obtained only previously with halides.

Analyses were performed using a Fisons Platform II single quadrupole mass spectrometer with an electrospray interface and direct infusion involving the introduction of liquid samples directly to the instrument source *via* syringe pump. The observed spectra are moderately dependent on the cone voltage applied, and 20 V was found to be optimal in order to avoid unwanted secondary fragmentation.

The use of IonSpray-MS in the Characterization of Metallothioneins

J.C. Yves Le Blanc¹, Jean-Simon Blais²; (1) PE-Sciex, 71 Four Valley Dr., Concord (Ontario) L4K 4V8, Canada; (2) Agriculture Canada, 3600 Blvd Casavant O., St-Hyacinthe (Québec) J5S 8E3, Canada

Metallothioneins (MTs) are small proteins (6-7kDa) which are rich in cysteine residues (20 cysteines) and none of these Cys residues are involved in disulfide bridges [1]. In mammals, MTs are believed to be induced by exposure to metal ions such as Cd^{2+} , Zn^{2+} , Hg^{2+} and Cu^+ . Metallothioneins are also involved in the binding of metal ions that caused their induction through metal-thiolate bonds with the Cys residues and their binding properties have been widely studied, especially for rabbit MTs. Optical studies have shown that different number of metal-thiolate clusters exist in MTs and they form two well defined binding domains [1] where a total of 7 divalent metal atoms are bound; cluster B, which carries 3 metal ions, is found at the amino terminal end of the protein and cluster A is found at the carboxylic end of the protein with 4 metal ions. The binding of metal atoms in both the A and B domain confers to the metallothionein a strong three-dimensional structure. The complexing capabilities of MTs is known to be affected by the acidity of the solution and/or the presence of other chelating agents in solution [1]. Yu et al. [2] have shown that ion spray mass spectrometry (IS-MS) could be used to determine the extent of metal coordination as a function of the solution pH. Metal ions in cluster B are freed in solution at pH 4, whereas cluster A frees its metal ions in solution when the pH is below 3. Agnes et al [3] have shown that a differentially pumped atmospheric pressure ionization (API) interface equipped with an ion spray source could be used for both chemical speciation and for elemental analysis. When the orifice potential (OR) is held at 50 V on an PE-Sciex API 300 (Concord, Ontario) we can observe intact molecular ions of metal species in solution, whereas when OR is >300 V the collision induced dissociation (CID) processes in the interface sampling region of a mass spectrometer are energetic enough to produce bare metal ions.

Based on these observations, we coupled an HPLC system to an API 300 using an IS interface with liquid sheath and the OR potential was controlled with an external power supply (0-400 V). The liquid sheath, used to adjust the solution pH after LC separation, was delivered at 5 $\mu\text{L}/\text{min}$ with a syringe pump. The LC separation was done on a Vydac C4 column (2x100mm) using buffers adjusted at pH 6 with ammonium acetate in order to keep the MTs fully complexed with their metal atoms. Figure 1a shows that when $\text{Cd}_4\text{Zn}_3\text{MT-IIa}$ is injected on column and methanol is used as a liquid sheath, we can separate all of the sub-isoforms of MT-IIa. Peak C gives a molecular weight of 6899 Da which corresponds to (apo-MT-2a+7 Cd^{2+} -14 H^+) and peak I gives a molecular weight of 6570 Da which corresponds to either (apo-MT-2a+4 Cd^{2+} -8 H^+) or (apo-MT-2Ia+7 Zn^{2+} -14 H^+). The observation of $\text{Cd}_4\text{MT-2a}$ and potentially $\text{Zn}_7\text{MT-2a}$ were rather puzzling since a solution of $\text{Cd}_4\text{Zn}_3\text{MT-2a}$ was injected on column. A second injection of the same solution was made under identical chromatographic conditions, except this time, the orifice potential was raised to get elemental composition information (i.e. OR set to 350 V). Figure 2a shows the LC trace obtained when the mass spectrometer was scanned from 60 to 130 m/z with OR=350V. We observed the appearance of an extra peak at 3.02min, in comparison to Figure 1a. Figure 2b shows the mass spectrum corresponding to this new chromatographic peak and we can clearly see the Zn isotope pattern. When the ion chromatogram for the zinc isotopes is extracted from the LC-trace, we obtain a single chromatographic peak that shows-up after void volume (Figure 2c). This latest observation would suggest that a significant amount of free zinc ions were present in excess in the injected solution or that the $\text{Cd}_4\text{Zn}_3\text{MT-2a}$ protein lost its zinc metal during the chromatographic run. When the same LC conditions were used but the liquid sheath was replaced by methanol/formic acid (1% and 10% by vol.) and the instrument operated in the elemental mode (OR=350V), we observed that Cd was the only metal free in solution at the retention time of the protein species. These observations strongly suggest that Cd is exchanged on the column to give $\text{Cd}_4\text{MT-2a}$ and $\text{Cd}_5\text{MT-2a}$ species.

The ability to monitor species and elemental ions from the same instrument provides a new analytical tool for on-line characterization of metal containing proteins. Sample handling and potential contamination are minimized with this approach. Substantial information on protein metal chemistry could be obtained using combined post-column addition of buffer and IS-MS operated in either the speciation or elemental mode.

Figure 1: (A) LC-MS trace for $\text{Cd}_4\text{Zn}_3\text{MT-2a}$ when post-column solvent is methanol and the instrument is operated in the speciation mode. (B) and (C) are the mass spectra for peak C and I, respectively. See text for details

Figure 2: (A) LC-MS trace for $\text{Cd}_4\text{Zn}_3\text{MT-2a}$ when post-column solvent is methanol and the instrument is operated in the elemental mode. (B) Mass spectra for peak C and (C) extracted ion chromatogram for Zn isotopes.

Photolysis of Coordinated Diamine in Bis(2,2'-bipyridine) Complexes of Ruthenium using On-Line ES-MS

Ryuichi Arakawa, Shin-ichi Mimura, Gen-etsu Matsubayashi, and Takekiyo Matsuo^a (Department of Applied Chemistry, Osaka University, 560 Japan; ^aDepartment of Physics, Osaka University, 560 Japan)

Metal ions have been found to catalyze the oxidative dehydrogenation of coordinated amines to imines. Ruthenium diamine complexes have been well studied to undergo four-electron oxidation either chemically or electrochemically to produce α, α' -diimine coordinated in the metal complex. The oxidative dehydrogenation was observed to go in two step processes, giving the final diimine product via the oxidation to a monoiimine intermediate.

Here, we present the application of on-line ES-MS with a flow-through photoreaction cell to identify products or intermediates in the photolysis of diaminebis(2,2'-bipyridine) complexes of ruthenium(II), $\text{Ru}(\text{bpy})_2(\text{en})^{2+}$ and $\text{Ru}(\text{bpy})_2(\text{tn})^{2+}$ (en=ethylenediamine and tn=1,3-propylenediamine) in acetonitrile. A variety of advantages for use of on-line ES-MS [1] is expected to detect readily new products of the aliphatic diamine complexes. Particularly, detection of the monoiimine complex as a primary product was necessary for evidence that the photoinduced oxidation occurs in a stepwise manner. Moreover, some mechanistic details of both oxidation and substitution reactions in photolysis of the diamine complexes will be presented.

Photoirradiation ($\lambda > 420\text{nm}$) was performed using a cylindrical quartz cell (1mm i.d.) which was installed in the middle of a syringe needle. Figure shows positive ES mass spectra of the complex $\text{Ru}(\text{bpy})_2(\text{en})(\text{ClO}_4)_2$: (a) in a dark condition and (b) with photoirradiation. Peaks in the spectra are assigned using nomenclature of $L = \text{bpy}$, $X = \text{ClO}_4^-$ and $\text{AN} = \text{acetonitrile}$. The products $\text{RuL}_2(\text{en-2})^{2+}$ and $\text{RuL}_2(\text{en-2})X^+$ were found near the main peaks (see insets), where (en-2) represents a monoiimine formed by oxidative dehydrogenation.

The complexes with (en+14) ligands were observed together with photosubstitution products. The byproduct of (en+14) complexes has not been reported in oxidative dehydrogenation process. The (en+14) ligand may be an oxygenated imine. Interestingly, the peaks of $\text{RuL}_2(\text{en+14})(\text{AN})^{2+}$ and $\text{RuL}_2(\text{en+14})(\text{AN})X^+$ were related to the photosubstitution intermediate with the monodentate (en+14) ligand. No detection of the complex $\text{RuL}_2(\text{en})(\text{AN})^{2+}$ or $\text{RuL}_2(\text{en})(\text{AN})X^+$ is due to a fast rechelation to get back to a normal state, as compared with the (en+14) complex. Once the oxidized complex

$\text{RuL}_2(\text{en+14})^{2+}$ is first generated, a lifetime of the oxidized intermediate will be longer, and thus, the intermediate with the η^1 bidentate (en+14) was able to be detected. Therefore, the substitution products $\text{RuL}_2(\text{AN})_n^{2+}$ ($n=0-2$) and $\text{RuL}_2(\text{AN})_2X^+$ for the en complex were generated via the oxidized complex, not directly from the photosubstitution of $\text{Ru}(\text{bpy})_2(\text{en})^{2+}$. This route was supported by the spectrum obtained in Ar deaerated solution; no product other than RuL_2^{2+} , $\text{RuL}_2(\text{en})^{2+}$ and $\text{RuL}_2(\text{en})X^+$ was detected. To confirm the photoinduced oxidation of the complex with oxygen, the solution was exposed to air and was irradiated. The same spectrum as Fig. b was obtained.

Electrospray of Borane Salts; Biomedical Applications

Cornelis E.C.A. Hop, Department of Chemistry,
University of Wisconsin-Madison, 1101 University Avenue, Madison, WI 53706.

To date, the primary focus of electrospray ionization (ESI) has been analysis of biopolymers. Much less attention has been paid to inorganic compounds. We will show that ESI is also useful for characterization of borane salts,¹ compounds which cannot be analyzed with EI and liquid SIMS.

A VG AutoSpec magnetic sector (EBE) mass spectrometer was used for all ESI experiments. The following borane salts were examined: $[(\text{Me})_2\text{N}][\text{B}_3\text{H}_8]$, $\text{Cs}_2[\text{B}_{10}\text{H}_{10}]$, $\text{Na}[\text{B}_{10}\text{H}_{13}]$, $\text{Na}[\text{B}_{10}\text{H}_{12}\text{SiH}]$, $[\text{Ph}_3\text{PMe}][\text{B}_{11}\text{H}_{14}]$, $[\text{Ph}_3\text{PMe}][\text{B}_{11}\text{H}_{13}\text{-C}_6\text{H}_{13}]$, $\text{Na}_2[\text{B}_{12}\text{H}_{12}]$, $\text{Na}_2[\text{B}_{12}\text{H}_{11}\text{SH}]$, $[(\text{Et})_4\text{N}][\text{B}_{12}\text{H}_{10}(\text{SCN})_2]$. The samples were dissolved in CH_3CN , $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ or THF (200 ng. μl^{-1}).

All borane salts give mass spectra which characterize the compound. For example, the most prominent signal in the electrospray mass spectrum of $[(\text{Ph})_3\text{PMe}][\text{B}_{11}\text{H}_{13}\text{-C}_6\text{H}_{13}]$ is centered at m/z 217, and it corresponds to the intact $\text{B}_{11}\text{H}_{13}\text{-C}_6\text{H}_{13}^-$ anion. Indeed, the observed isotope pattern of the signal centered at m/z 217 matches the pattern calculated for $\text{B}_{11}\text{H}_{13}\text{-C}_6\text{H}_{13}^-$. All other signals in the mass spectrum correspond to cluster ions having the general formula $\{[(\text{Ph})_3\text{PMe}]_x[\text{B}_{11}\text{H}_{13}\text{-C}_6\text{H}_{13}]_{x+1}\}^-$.

Thus, a wealth of information is available from the ESI mass spectrum:

1. the signal at the lowest m/z value (m/z 217) provides the molecular weight of the anion and the isotope pattern of this signal reveals how many boron atoms are present in the anion
2. the separation between the two signals at the lowest m/z values (m/z 217 and 711) provides the molecular weight of the anion plus cation

ESI works for dianions as well. The signal centered at m/z 197 in the ESI mass spectrum of $\text{Na}_2[\text{B}_{12}\text{H}_{11}\text{SH}]$ is characteristic for the $\{\text{Na}[\text{B}_{12}\text{H}_{11}\text{SH}]\}^-$ ion. Singly as well as multiply charged cluster ions are observed at higher mass. For example, m/z 306 corresponds to $\{\text{Na}_4[\text{B}_{12}\text{H}_{11}\text{SH}]_3\}^{2-}$. Using $\text{Na}_2[^{10}\text{B}_{12}\text{H}_{11}\text{SH}]$ it was determined that the detection limit is substantially less than 2.04 ng. μl^{-1} .¹ Recently, it had been shown that the detection limit by HPLC is about 0.5 ng. μl^{-1} .² Thus, in terms of sensitivity, ESI mass spectrometry can compete with conventional analytical methods and it has the advantage that it provides specific molecular weight information.

Note that $\text{Na}_2[\text{B}_{12}\text{H}_{11}\text{SH}]$ is used in boron neutron capture therapy (BNCT).³ In BNCT a boron compound is admitted to the blood stream and it concentrates selectively in (brain) tumor tissue. Next, the patient is irradiated with neutrons. The ^{10}B atoms capture the neutrons and the (energetic) fission fragments kill the cancer cells. It has been speculated that interaction with plasma

proteins (e.g. BSA) is important for the selective localization of the boron compound.³ In addition, interaction with peptides/ proteins which play a role in rapid cell division (e.g. epidermal growth factor) could be important.^{3a} Therefore, we examined the ESI mass spectra of solutions containing a peptide (20 pmole. μl^{-1}) and $\text{Na}_2[^{10}\text{B}_{12}\text{H}_{11}\text{SH}]$ (60 pmole. μl^{-1}). If a covalent / non-covalent complex between the peptides and $^{10}\text{B}_{12}\text{H}_{11}\text{SH}^{2-}$ is formed, the signals due to the peptide should shift by 164/z. In addition, a dramatic shift in the charge state distribution is anticipated, because of addition of a dianion. The peptides under consideration include glucagon, insulin and epidermal growth factor. It is evident from the electrospray mass spectra that no dramatic shifts in the charge state distribution and the m/z values of the peptide signals occur. Close inspection of the spectra indicates that the mass of the peptides increases by 16 Da. There are two possible explanations: (a) one of the amino acids, possibly methionine, is oxidized or (b) an oxygen atom is replaced by a sulfur atom in one of the amino acids. The exact nature of the modification is the subject of further studies.

Electrospray Ionization Mass Spectrometric Analysis of Oxo-Bridged Manganese Dimers

Susan T. Weintraub

The University of Texas Health Science Center at San Antonio

Yangzhen Ciringh and Colin P. Horwitz
Carnegie Mellon University, Pittsburgh PA

Oxo-bridged manganese coordination compounds serve as useful structural and chemical models for a number of biologically important metalloenzymes. In order to gain insight into the mechanism of action of enzymes in photosystem II, we have been studying the chemistry of Mn(III) and Mn(IV) oxo-bridged dimers which are prepared by the reaction of a Mn(II) monomer with oxygen. Since these compounds are paramagnetic, NMR spectroscopy is not able to provide definitive structural information. ESI/MS, on the other hand, has proven to be a powerful tool for their characterization and has also given us a unique view of gas-phase cation exchange processes which differ from the solution behavior of these compounds.^{1,2}

While the reactions that take place between O₂ and Fe(II) or Co(II) complexes are well understood, in-depth studies of analogous Mn(II) complexes have not been made. For example, there is extensive spectroscopic and chemical evidence to support an O₂ activation pathway for Fe(II) which sequentially involves Fe(III) superoxo and μ -peroxo complexes in addition to an Fe(IV) oxo intermediate, leading to formation of an Fe(III) mono(μ -oxo) dimer. Co(II) also forms a μ -peroxo dimer, but no further oxidation of the cobalt occurs. In contrast, we have shown that a Mn(IV)₂ bis(μ -oxo) dimer is the kinetic oxidation product of Mn(II) monomers. It was, therefore, of interest for us to elucidate the mechanism of oxygenation of the Mn(II) monomer.

In one approach to this problem, we performed the oxidation of the Mn(II) complex with an approximately equimolar mixture of ¹⁶O₂ and ¹⁸O₂. We anticipated that if a Mn(IV)=O intermediate is involved, as has been postulated,³ then three different isotopically labeled Mn(IV)₂ bis(μ -oxo) dimers would be produced: ¹⁶O¹⁶O, ¹⁶O¹⁸O and ¹⁸O¹⁸O. In Figure 1 is the ESI mass spectrum of the Mn(IV)₂ bis(μ -oxo) dimers isolated after reaction with the ¹⁶O₂/¹⁸O₂ mixture and ionized in solution by the addition of sodium triflate (NaSO₃CF₃). The results clearly indicate that no detectable quantities of ¹⁶O¹⁸O

Characterization of Modified Oligonucleotides by Enzymatic Digestion and Ionspray Mass Spectrometry

Huaiqin Wu, Ronald L. Morgan, and Hoda Aboleneen
Abbott Laboratories, Diagnostics Division, 100 Abbott Park Road, Abbott Park, IL 60064

The diverse modifications of oligodeoxynucleotides (ODN) for diagnostic research present unique challenges to the analytical chemist. These modifications often include the incorporation of chemical labels; i.e. phosphate, amine, thiol, biotin or fluoroscein, at the 5' or 3' terminus of a DNA probe (oligonucleotide). Recently, electrospray Mass spectrometry (ES-MS) has been successfully applied in analysis of ODNs containing both normal and modified bases. However, analysis of the above chemical labels and their positions on ODNs has not been reported. In this lab, methods based on ionspray mass spectrometry (IS-MS) and chemical/enzymatic reactions have been developed to identify these labels and their positions.

To determine the position(s) of labels such as biotin and fluoroscein on ODNs, four model ODNs (18mers) containing biotin were synthesized and studied, each with biotin(s) located at different positions: 3'-terminus, 5'-terminus, and in between: 5'- CGT ATG AGT GAT TCC TCC B -3', 5'- CGT ATG AGT B GAT TCC TCC -3', 5'- B CGT ATG AGT GAT TCC TCC -3', 5'- B CGT ATG AGT B GAT TCC TCC -3' (Note that a universal linker HO-CH₂CH₂-OH was attached to 3'-biotin for easy synthesis). Various nucleases, such as nuclease P1, nuclease S1, DNase I, phosphodiesterase I & II, were used to digest these ODNs. For our purpose, nuclease P1 (NP1) digestion was found to give the best results. The final products of NP1 digestion were analyzed by MS. It was found that IS-MS analysis of the digestion products of these compounds gives specific ions in IS-MS, which are indicative of biotin positions along the ODN chain. In this case, 5'-biotin ODN produces an ion corresponding to Biotin-Nucleotide (B-N); 3'-biotin DNA produces an ion of phosphorylated biotin (pB); biotin in between the DNA termini produces pB-N. CID-MS/MS analyses of these ions confirmed that the final digestion products are indeed as proposed above. Utilizing this method, we have successfully analyzed ODNs containing biotin, fluoroscein, carbazole and adamantane. These results indicate that this is a useful method for the determination of positions of labels.

Terminal modifications of ODNs can be determined by enzymatic digestion or by CID-MS/MS of NP1 digestion products. For the terminal phosphate group, bacterial alkaline phosphatase (BAP) can be used. A decrease of 80 Da in molecular weight (MW) after BAP digestion indicates the presence of a phosphate group at one terminus of the ODN. Similarly, a decrease in molecular weight after dithiothreitol (DTT) reduction of the ODN is an indication of S-S bond presence (Thiol group on ODNs is often prepared in the form of disulfide). For the identification of biotin/fluoroscein, CID-MS/MS of the NP1 digestion products (B-N, pB, pB-N) was employed.

Optimization of Enzymatic Sequencing of Oligonucleotides with Ion Spray Mass Spectrometry

Huaqin Wu, Cliff Chan, and Hoda Aboleneen

Abbott Laboratories, Diagnostics Division, 100 Abbott Park Road, Abbott Park, IL 60064

Enzymatic sequencing of oligodeoxynucleotides (ODN) by matrix-assisted laser desorption ionization (MALDI) MS has been well documented in the literature. In contrast, sequencing by electrospray MS (ES-MS) or Ion spray (IS) MS has shown limited success. Limbach et al. [1] reported a method for sequencing a 10-mer using phosphodiesterase (PDE) digestion and ES-MS, while Glover et al. [2] employed an off-line HPLC-ES-MS to sequence a 10-mer with enzymatic digestion (ED). No larger oligonucleotides have been sequenced by either ES-MS or IS-MS. We have investigated the problems associated with the sequencing of larger oligonucleotides using ES/IS-MS, and a practical method has been developed. The critical factors we found include reconstruction of molecular weight (MW) spectrum, selection of digestion solvents, and purification of the ODNs and enzymes.

With enzymatic sequencing, the ODN is digested by exonucleases such as 3'- and 5'-PDEs. The molecular weights of truncated oligonucleotides, generated by the sequential loss of nucleotides from the starting ODN, are determined by IS-MS to provide the sequence ladder. With the present software, noise peaks such as harmonic peaks (Fig 1) cannot be avoided when MW reconstruction is performed over a relatively large range. Since there are only four bases for regular ODNs, logical MW differences between two adjacent ODNs can only be 289 for C, 304 for T, 313 for A and 329 for G. This fact has been used to ignore noise peaks. It has been found that proper selection of MW range, charge range and m/z range for MW reconstruction is critical for noise reduction of the spectra.

Digestion conditions are also critical for sequencing ODNs. For 3'-PDE digestion, an ODN sample of 0.1-0.2 OD (~2µl) is mixed with 8 µl 1/1 CH₃CN/2 mM NH₄HCO₃ (pH 8) and 0.0002 U 3'-PDE. 1 µl of the digestion mixture is analyzed every 5 minutes. 5'-PDE digestion is performed similarly in 10 mM HCOONH₄ (pH 6.6). The buffer pHs are chosen to be close to the optimum pH for the enzymes. The use of acetonitrile increases MS signal and reduces Na⁺ adduction.

Cleanup of DNA samples and enzymes is critical for signal enhancement. Na⁺ adduction of the sample reduces the sensitivity and adds complexity to the reconstructed MW spectra. The original storage solution for PDEs such as ammonium sulfate and glycerol severely inhibits MS signal. For this work, ODNs were purified by HPLC and enzymes were cleaned using Microcon (Amicon Inc., Beverly, MA).

Based on these investigations, a method for sequencing oligonucleotides containing more than 20 bases has been developed for both regular ODNs and terminally blocked ODNs. Complete sequencing of two oligonucleotides, a regular 22-mer ODN (Fig. 2-3) and a 5'-biotin labeled 19-mer (Fig. 4), is demonstrated here. Figure 2 & 3 show some of the reconstructed MW spectra of the time-course digestion products of an ODN 22mer. For 5'-terminally labeled ODN, regular 3'-PDE digestion was performed, and the final product containing the label was analyzed by CID-MS/MS to complete the sequence. We have found that this method is simple, fast, and practical for routine analysis of ODNs.

HPLC and ESI Mass Spectrometric Sequencing of Methyl-oligonucleotides

Robert Glover¹ and Gavain Sweetman²

¹CMHT and ²MRC Toxicology Unit, Hodgkin Building, Leicester University, P.O. Box 138, Lancaster Road, Leicester, LE1 9HN, UK.

Genotoxic carcinogens interact with nucleic acids to form covalently bound products (adducts). In 1982 Grotjahn *et al.* demonstrated that the sequences of small oligonucleotides were obtainable using FAB¹. Since then mass spectrometry has played an increasingly important role in identification of adducts on nucleotides and oligonucleotides². Now ESI-MS is widely used to observe oligonucleotides³⁻⁵, though sequencing oligonucleotides by ESI-MS requires chemical or enzymatic degradation steps prior to mass spectrometry⁶. Coupled HPLC-ESI-MS has been achieved, though large quantities of oligonucleotides are required⁷. An alternative technique is to use an independent HPLC step to fractionate the oligonucleotide digests⁸. This allows the HPLC solvent to be dried off prior to ESI-MS, this requires 100 times less sample than direct HPLC-MS.

Two oligonucleotides containing a modified base were constructed, on an ABI 394 DNA Synthesiser. The sequences incorporated a base-methylated phosphoramidite in an unknown position, however, the basic sequence was maintained. Oligo 1: d(CGTAGCGCTACG) contained one C5-methyl-dC residue. Oligo 2: d(CGTAGCTACG) contained one N⁶-methyl-dA residue.

Sequencing was achieved by a time-dependent enzyme digestion of the oligonucleotides followed by HPLC fractionation and ESI-MS (for full details see ref 8). Two sets of experiments were used to sequence from either end of the oligonucleotides with time points up to 60 min. Calf spleen phosphodiesterase (CSPD) cleaves in the 5' to 3' direction and snake venom phosphodiesterase (SVPD) from 3' to 5'.

HPLC analysis was carried out using a Dynamax 300Å C18 column (4.6 mm x 25 cm Anachem, UK) and monitored at 260 nm. A simple gradient system was used 0 min 0%B, 20 min 22.5%B, 35 min 22.5%B, at 1 ml/min (Solvent A: 50 mM ammonium formate pH 5.4, solvent B: methanol). Fractions were collected and evaporated to dryness (DNA Speedvac, Savant, Farmingdale, NY, USA).

Mass spectra were obtained on a VG Quattro BQ (VG Organic, UK). The mobile phase consisted of acetonitrile/water (1/1 v/v), pumped at a flow rate of 50 ml/min. The samples were redissolved in 14 µl of a solution of acetonitrile/50 mM imidazole (7/3 v/v) and 10 µl injected. The samples were analysed using negative ion ES-MS, with the quadrupole scanned from m/z 300 to 1050 in 2 s. The spectra were combined across the sample bolus, and background subtracted.

Examples of typical HPLC traces from the digestion of Oligo 1 are shown in figure 1. Note that the action of SVPD (and CSPD data not shown) was partially blocked at the modified position. On an unmodified oligonucleotide SVPD digests to the 5mer in 15 min (cf 45 min for Oligo 1). The ESI-MS data confirmed that the modification was at position 6 (counting from the 5' end). Similar results were obtained for Oligo 2, with the modification being found at position 4.

HPLC and ESI-MS have been successfully used to sequence modified oligonucleotides. The ESI analysis was simplified by the prior HPLC fractionation of the enzyme degradation reactions, as the number of components present for identification at any one time was reduced. The positions of the modified bases could be deduced both from the mass differences from ESI analysis and the observed delay in enzyme degradation beyond the site of modification. We are currently applying this technique to the sequencing of modifications induced by known carcinogens *in vitro*.

Mass Spectrometric Methods for Genotyping

Daniel P. Little*, Andreas Braun, G. Scott Higgins, Brigitte Darnhofer, Loretta Leppin, Fiona Craven, David M. Lough, Hubert Koester
SEQUENOM Instruments GmbH, Mendelssohnstr. 15D, 22761 Hamburg, Germany

Developing technologies may enable physicians to shift their focus from current post-symptomatic treatments to a more 'preventive' medicine; characterization of DNA mutant alleles in conjunction with social and environmental factors and subsequent linking of these to clinical effects is a first step in developing treatments based on changes in lifestyle and pharmaceutical or gene therapy. Thus there is an increase for rapid, simple, and conclusive analytical means of detecting such mutations in both research (for linking mutations to clinical effects) and large-scale diagnostic screening for mutations known to have clinical effects.

We present three diagnostic tests amenable to parallel detection using MALDI-TOF. The first depends upon measuring mass differences in digest products resulting from polymorphic sites within the recognition sequence of restriction enzymes. It is demonstrated with the Apolipoprotein E gene, which codes for a 34 kDa protein important in lipid metabolism; its three isoforms (E2, E3, E4) which result from two DNA polymorphisms are related to varying cholesterol levels. Simultaneous digestion of a 253 bp PCR amplified gene fragment with CfoI and RsaI (recognition sequences GCG/C and GT/AC, respectively) yields 14 variant and 12 invariant peaks (indicated with vertical dashed lines in Figure 1) resulting in unambiguous differentiation of the possible genotypes. Diagnostic fragments range in mass from 3 to 18 kDa; the low resolution of TOF makes it difficult to use digestion with CfoI alone for large-scale diagnostics, since the resulting diagnostic fragments from this range from 11 to 28 kDa, and dimer ions from lower mass peaks can overlap with some of these diagnostic peaks depending on crystal characteristics and laser power.

The second test, Competitive Oligonucleotide Single Base Extension (COSBE), uses a pair of primers (N=normal, M=mutant) with the 3'-terminal base complementary to either the normal or mutant allele at a variable (V) position. Upon hybridization and addition of a polymerase and the nucleotide triphosphate one base downstream, only those primers properly annealed (ie no 3'-terminal mismatch) are extended. The $\Delta F508$ mutation of the cystic fibrosis transmembrane receptor gene was used as model system. After PCR amplification of exon 10, biotinylated (-) strand was immobilized to streptavidin coated magnetic beads and denatured to remove non-biotinylated (+) strand. N and M primers were annealed to the immobilized (-) strand and extended by a DNA polymerase in the presence of deoxyGTP. For different genotypes, (N/N, N/M, M/M), a distinctive pattern was observed following MALDI-TOF spectra measured directly from a suspension of the beads in 3HPA matrix. For example, a homozygous normal patient results in extension of the N primer (8509 Da) to an N+1 product (8838 Da), while the M primer (9148 Da) has no associated extension product. Alternatively, a N/M heterozygote has both primers extended (ie 8838 Da and 9477 Da observed). The method has given unambiguous results in all patients analyzed.

Like COSBE, the third method, Primer Oligonucleotide Base Extension (PROBE) is a solid phase extension reaction to detect point mutations and small deletions/insertions in amplified DNA. The method is based on extension of a detection primer which anneals adjacent to a variable region using a DNA polymerase, a mixture of three dNTPs, and one ddNTP (eg dATP, dTTP, dGTP, ddCTP). PROBE requires only one primer per mutation; extension of this yields products differing in length by bases specific for mutant or wild-type alleles. We have successfully designed tests for over a dozen mutations in the CFTR and other genes; characterization of complex samples difficult to analyze with conventional methods (eg heterozygotes and even compound heterozygotes, highly heterogeneous regions like the 506, 507, 508 region of CFTR) are easily and rapidly analyzed by the PROBE method. The three methods described here have been used for screening of over a dozen mutations in systems including CFTR, ApoE, Bglobin, and Ret protooncogene.

Chemical Sequencing of Oligonucleotides with Modified Backbones Using Mass Spectrometry

Lenore M. Polo, Tracy D. McCarley and Patrick A. Limbach
Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803

Antisense oligonucleotides, which generally differ from natural oligonucleotides by backbone modifications, are commonly used to control nucleic acid expression *in vivo*. The viability of the modified oligonucleotides within the cell is increased compared to natural oligonucleotides due to the resistance of the modified backbone to exonuclease digestion. While the backbone modifications of antisense oligonucleotides aid in increasing their lifetime *in vivo*, their resistance to exonucleases presents difficulties for sequence identification. The majority of the mass spectrometric sequencing methods for oligonucleotides currently available rely on at least partial degradation of the oligonucleotide with exonucleases [1,2], and those methods which do not require enzymatic degradation, such as tandem mass spectrometry, have yet to be demonstrated on larger oligonucleotides or oligonucleotides of unknown sequence.

Among the common antisense oligonucleotides are the phosphorothioates which contain a sulfur in place of a phosphate group oxygen. The sequencing approach used here takes advantage of the susceptibility of the phosphorothioate backbone to alkylating agents [3]. Phosphorothioate oligonucleotides are chemically degraded using 2-iodoethanol to yield products similar to those obtained in enzymatic cleavage of phosphodiester oligonucleotides. Analysis of the cleavage products by MALDI-TOF mass spectrometry reveals a "mass ladder" of peaks corresponding to the nucleotide residue lost for that particular cleavage. Peak assignments are easily made by matching the change in mass-to-charge ratio between two neighboring peaks to the mass-to-charge ratio of one of the four nucleotide residues (dA, dC, dG, dT).

Experimental

The mass spectrometer used for analysis was a Perseptive Biosystems Voyager linear MALDI-TOF instrument with a N_2 laser. 2 μ L of the oligonucleotide solution were added to a matrix consisting of 5 μ L of 0.1 M diammonium hydrogen citrate and 10 μ L of 0.5M 2,4,6,-trihydroxyacetophenone. Approximately 0.5 μ L of this mixture was then spotted on the sample plate. Cation exchange resin beads purchased from BioRad were also added to the sample plate to reduce the effects of alkali cations on the spectra. Cleavage reactions were carried out by adding 1 μ L of 12.8 M 2-iodoethanol to the sample in the matrix before spotting and heating the mixture at 95°C for 30-120 seconds.

Results and Discussion

We have used this technique to sequence completely thiolated oligonucleotides (Fig. 1), as well as mixed phosphodiester-phosphorothioate oligonucleotides (Fig. 2). The cleavage is specific for the phosphorothioate linkage, and the phosphodiester linkages remain intact during the reaction in the mixed oligonucleotides. The optimum reaction time for a fully thiolated oligonucleotide is one minute. This reaction time yields a complete "mass ladder" with minimum rearrangement products.

Our approach is a simple and efficient method for the sequence characterization of phosphorothioates. Advantages over previous methods include: sequence information is obtained directly from phosphorothioates; phosphorothioate linkages in mixed phosphodiester/phosphorothioate oligonucleotides are easily identified; cleavage products can be predicted from a simple reaction scheme; and the sample amounts and time of analysis are minimal. This research supported by Louisiana State University and the Louisiana Education Quality Support Fund.

Figure 1. MALDI-MS analysis of the reaction of dC₅(s) for 60 sec with 2-iodoethanol. As can be seen from the spectrum, a full "mass ladder" is generated.

Figure 2. MALDI-MS analysis of the reaction of ACsCGp with 2-iodoethanol for 60 sec. Reaction of this oligonucleotide resulted in one product corresponding to cleavage at the thiolated position along the backbone. This ion also corresponds to cleavage at the phosphorothioate linkage to give 5' sequence products.

Developing a Liquid Chromatography Electrospray Ionization Tandem Mass Spectrometry Assay for 8-oxo-2'-deoxyguanosine

Eileen M. Kowalski,¹ Ajai K. Chaudhary,^{2,3} and Ian A. Blair,^{1,3} Departments of Chemistry,¹ Biochemistry,² and Pharmacology,³ Vanderbilt University, Nashville, TN 37232-6602

Endogenous hydroxyl radicals can attack DNA strands and cause modifications such as 8-oxo-2'-deoxyguanosine (8-oxo-dG; Figure 1). Assays to detect this adduct have been developed using several techniques including high performance liquid chromatography (HPLC) with electrochemical detection, ³²P-postlabeling, and gas chromatography/mass spectrometry (GC/MS). Unfortunately, none of these assays provides both rapid analysis and high specificity. To address this shortcoming, our laboratory is currently developing an LC/MS/MS assay for 8-oxo-dG.

A Finnigan TSQ 7000 mass spectrometer equipped with an electrospray source was used for MS analysis. Tandem mass spectrometry was performed in selected reaction monitoring (SRM) mode to detect the loss of the deoxyribose moiety from the analyte and internal standard. An HP 1090 Series II LC system was employed for solvent delivery. Samples were analyzed using a Zorbax C-8 column (2.1 mm ID x 15 cm) with a two-component gradient. Component A was 5mM ammonium acetate and 0.1% acetic acid in water, and component B was 5mM ammonium acetate and 0.1% acetic acid in methanol. Analyses were performed using the following gradient: 0-5 min, 100% A; 9 min, 30% A; 11 min, 5% A; 25 min, 5% A; 30 min, 100% A. The flow rate was 0.2 ml/min. Under these conditions, 8-oxo-dG eluted at 12.7 minutes.

Initial assay validation was done with commercially available 8-oxo-dG and [¹³C₄,¹⁵N]dG, synthesized in house.^{1,2} The unextracted curves were linear over a range from 0-16 ng for 8-oxo-dG. However, when standards were added to calf thymus DNA and subjected to enzymatic hydrolysis, analysis by LC/MS/MS showed no 8-oxo-dG. This prompted an evaluation of 8-oxo-dG stability during storage and DNA hydrolysis.

To evaluate the effect of temperature on storage, standards were stored for five days at 60°C, 37°C, 25°C, 4°C, and -20°C. The highest and most consistent recovery was obtained from standards kept at 4°C. The optimum hydrolysis procedure was found to be the following: DNA at pH 7 was incubated with 100 units of DNase I for 1 h at 37°C, followed by a second hour of incubation with 15 units nuclease P1 in the presence of 1mM ZnCl₂. Next, the pH of the solution was raised to 7.8 with 0.1 mL of 0.4 M Tris buffer (pH 7.8). After 3 units of alkaline phosphatase were added, the mixture was incubated for 30 min at 37°C.

During the course of these stability studies, concerns regarding differences in the solubility and electrospray characteristics of 8-oxo-dG and dG prompted a change to a stable isotope analogue of 8-oxo-dG as the internal standard. Previously synthesized [¹³C₄,¹⁵N]dG (3.24 ng in 0.090 mL) was mixed with 50 µL of 1.7 M ascorbic acid, 2 µL of 0.2 M CuSO₄, and 50 µL of 30% H₂O₂.³ Immediately after addition of the peroxide, the reaction mixture was injected onto a Zorbax SB-C8 column (4.6 mm i.d. x 15 cm) and eluted with 6% methanol in water. A peak which eluted at 19.6 minutes had a UV spectrum which corresponded to standard 8-oxo-dG; its mass spectrum showed an abundant ion at *m/z* 289, the MH⁺ of [¹³C₄,¹⁵N]8-oxo-dG (Figure 2).

Currently, the assay has a limit of detection of 350 fmol 8-oxo-dG. Preliminary standard curves have indicated that the background level of 8-oxo-dG in calf thymus DNA is 6 8-oxo-dG per 10⁶ DNA bases. Assay validation is in progress; once validation is complete, quantitation of 8-oxo-dG will begin in samples of calf thymus DNA exposed to various *in vitro* oxidative challenges.

Supported by NIH grants ES00267, GM08320-06, and CA65878-01A1, and Department of Education grant P200A500082.

Preparation of [$^{13}\text{C}_5$]adenine and [$^{13}\text{C}_5$]-2'-deoxyadenosine for mass spectrometric studies of DNA-adducts.

Suresh Yeola¹, Sam Saleh¹, Ajai Chaudhary¹, and Ian A. Blair^{1,2,3}

Department of Pharmacology¹ and Chemistry²,
and Center in Molecular Toxicology³,
Vanderbilt University, Nashville, TN 37232.

There is growing interest in the identification and quantitation of DNA-adducts in order to gain further insight into the mechanisms involved in carcinogenesis. Exposure to environmental, nutritional, and endogenous carcinogens leads to the formation of DNA-adducts. Mass spectrometry has become an important tool in the analysis of these adducts because of its ability to detect trace amounts of material that are present in biological samples with high specificity. In order to detect and accurately quantify DNA-adducts by mass spectrometry it is necessary to use stable isotope analog as internal standards. Currently, [$8\text{-}^{13}\text{C}$]guanine and [$8\text{-}^{13}\text{C}$]adenine are the only commercially available precursors for the preparation of appropriate standard compounds. However, for quantitation by mass spectrometry it is necessary to have an internal standard in which at least three of the atoms are labeled. Because of the unique structures of DNA-bases either ^{13}C or ^{15}N have to be used for stable isotope labeling. We report convenient syntheses of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]adenine and [$2,4,5,6,8\text{-}^{13}\text{C}_5$]-2'-deoxyadenosine. We also describe the mass spectral characteristics of the two compounds. The method for preparation of labeled adenine is a simple one step reaction in which commercially available [^{13}C]-labeled formamide was utilized as the starting material. Thus, [$2,4,5,6,8\text{-}^{13}\text{C}_5$]adenine was obtained from [^{13}C]formamide when heated with phosphorus oxychloride in a sealed tube in 48% yield (Scheme 1)

Purification of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]adenine was readily accomplished using silica-gel chromatography. The material was of sufficient purity for further synthetic or mass spectral studies. The ESI mass spectrum of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]adenine showed an intense protonated molecular ion that appeared at m/z 141. There was <0.1% of protium impurity at m/z 136. MS/MS analysis of the parent ion at m/z 141 (collision offset at -15 V and product ion offset at -30 V) gave product ions at m/z 124, 113, 98, 96, 85, 70, 68 and 57 (Figure 1). [$^{13}\text{C}_5$]-2'-deoxyadenosine was prepared in 44% yield from the [$^{13}\text{C}_5$]adenine by enzymatically that utilized thymidine phosphorylase (TPase) and purine nucleoside phosphorylase (PNPase) (Scheme 1). Purification of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]-2'-deoxyadenosine was readily accomplished using silica-gel chromatography. The ESI mass spectrum of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]-2'-deoxyadenosine was

also dominated by an intense protonated molecular ion that appeared at m/z 257. Isotopic purity of the labeled 2'-deoxyadenosine was similar to labeled adenine. MS/MS analysis of the parent ion at m/z 257 (collision offset at -15 V and product ion offset at -25 V) resulted in the formation of product ions at m/z 141, 117, 101, 99 (Figure 2). Source induced dissociation (SD) at high octapole offset voltages (35 V) resulted in the formation of a BH_2^+ ion at m/z 141 so that it became the major ion in the mass spectrum. ESI SD/MS/MS analysis of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]-2'-deoxyadenosine was performed by adjusting the octapole offset to give maximum production of BH_2^+ ions at m/z 141 while minimizing loss of total ion current. CID and MS/MS analysis of m/z 141 was then performed with a collision energy of -60 eV. It was evident from the ESI SD/MS/MS spectrum that significant C-C bond cleavage of the base had occurred. Major ions were observed at m/z 124, 113, 98, 96, 85, 70, 68 and 57 which was very similar to the spectrum obtained from MS/MS analysis of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]adenine.

Figure 1. Product ion mass spectrum of precursor ion m/z 141 (MH^+ of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]adenine)

Figure 2. Product ion mass spectrum of precursor ion m/z 257 (MH^+ of [$2,4,5,6,8\text{-}^{13}\text{C}_5$]-2'-deoxyadenosine)

ELECTROPHORE MASS LABELS FOR TOF-MS DNA SEQUENCING

R. Giese, L. Xu, P. Wang, N. Bian, H. Abushamaa, Z. Wang, S. Pillai, S. Abdel-Baky, D. Magiera, V. Murugaiah, and L. Khundkar, Northeastern University, Boston, MA 02115; G. Church, L. Kutney, and T. O'Keefe, Harvard Medical School; J. Wronka, F. Laukien, and M. Park, Bruker Instruments; D. Smith and S. Carson, Genome Therapeutics.

Introduction

The long-term goal of this project is to establish highly-multiplexed detection technology involving electrophoresis for fast, low-cost DNA sequencing. Electrophoresis are compounds which can be detected with high sensitivity and multiplicity by electron capture mass spectrometry (EC-MS). In the proposed, long-range technology, target DNA is subjected to cycle sequencing, capillary electrophoresis, and EC-MS detection steps, with at least the last two steps 400-multiplexed with electrophoresis. Potentially a single capillary electrophoresis system possessing 60 parallel capillaries could operate in conjunction with a single mass spectrometer to achieve a separation/detection rate which corresponds to a sequencing rate of one human genome in less than one year. Competing technology with four labels would require 100 of such capillary electrophoresis systems, in addition to 100 cycle sequencers, and thereby would tend to be slower and more expensive. High-speed DNA sequencing is important to health because variations in the sequence of human DNA underlie many diseases.

Road Map

We have selected ketone electrophores for our project. Such electrophores can be converted to glycolketo N-hydroxysuccinimide tags (E-NHS) *via* a sequence of Wittig, osmium tetroxide, hydrolysis and carbodiimide reactions. 5'-amino DNA primers or probes are then labeled with E-NHS and used in cycle sequencing reactions to generate a nested set of fragments reflecting the sequence of a target strand. We plan to separate these fragments by capillary electrophoresis, combined with sheath flow of solvent, to deposit the bands as droplets on a membrane such as polyimide. Electrophore tags can then be released as ketones from the DNA fragments by periodate oxidation or thermally. With thermal release, the heat is provided by a pulse of energy from the CO₂ laser, which also volatilizes the ketone electrophores to form a plume for subsequent detection by electron capture TOF-MS. With periodate release, ketones are preformed prior to the pulse from the CO₂ laser.

Roadmap for Electrophore DNA Sequencing

GC/ECNCl/MS/MS Analysis of Electrophore-labeled DNA Adducts

Asoka Ranasinghe¹, Kuen-Yuh Wu¹, Nova Scheller¹, Melva N. Rios-Blanco², James A. Swenberg^{1,2}, Dept. of Envr. Sci. & Eng., Curriculum in Toxicology, University of North Carolina, Chapel Hill, NC 27599

Electrophore-labeling followed by gas chromatography/electron capture negative chemical ionization mass spectrometry (GC/ECNCl/MS) is a powerful tool for the analysis of DNA adducts present in biological samples. The general method for the analysis of hydroxy-alkyl N-7 guanine(G) adducts involves DNA isolation, depurination and several derivatization steps involving pentafluorobenzoylation.¹ The derivatization makes the identification and characterization of structurally similar adducts difficult under ECNCl conditions because mass spectra often lack structurally diagnostic ions. The sensitivity improvement is also often off-set by co-eluting interferences introduced during derivatization procedures. In our previous work, we have demonstrated the potential of high resolution mass spectrometry for the elimination of unwanted mass interferences, resulting in the increase of the S/N ratio.² Tandem mass spectrometry (MS/MS) also allows removal of interferences from the sample because of its ability to mass select the analyte ion and to detect analyte characteristic fragment ion/s generated during the second stage of mass analysis. MS/MS approach, in this work, involves the characterization of fragment ions formed during both high (keV) and low (eV) energy collision activated dissociations (CAD) and the use of multiple reaction monitoring experiments (MRM) to quantitate the adducts in biological samples. Four G adducts, 7-hydroxyethylguanine (HEG), 7-(2-hydroxypropyl)guanine (HPG), 7-(2-hydroxy-1-phenylethyl)guanine (HPEG-I), 7-(2-hydroxy-2-phenylethyl)guanine (HPEG-II), originating from carcinogens, ethylene oxide, propylene oxide and styrene oxide were investigated.

Mass selected fragment ions were allowed to undergo CAD using a hybrid instrument, VG 250-SEQ. The first field free region before the electric sector (E) was used for keV collisions and the first quadrupole (q) after the magnet (B) was used for low energy CAD. The MS/MS product ion spectra (Table 1) revealed characteristic ions due to the analyte itself. For example, the initial PFB loss during ECNCl process occurs from either the N-7 or N-1 position. The fragments undergo additional CAD pathways depending on the initial structure of the M-PFB ion. Structural isomers can also be identified, particularly from high energy collision experiments. For example, HPEG isomers (Fig. 1, Scheme) produce characteristic fragment ions enabling identification and quantitation of one isomer in the presence of the other. Accurate mass, measured at a resolving power of 10,000 using the double focussing front end (EB) of the instrument, confirmed the elemental compositions of the fragments. Preliminary quantitative data obtained using a HPEG-I standard showed detection limits at low fmol levels. Although these detection limits were 5-10 times higher compared to single stage MS studies, quantitative GC/MS/MS approaches can be useful, particularly when structurally similar co-eluting interferences such as isomers are present. A multitude of experimental parameters such as collision gas, Cl reagent gas, collision energy, source temperature, electron energy and emission current are being investigated in order to improve detection limits for MRM experiments.

This publication was made possible by grant numbers 1-P42-ES05948 and 1-R01-CA69463 from the National Institute of Environmental Health Sciences, NIH, and a grant from the Chemical Manufacturers Association.

THE EFFECT OF BACKBONE CHARGE ON THE COLLISION-INDUCED DISSOCIATION OF OLIGONUCLEOTIDES

Michael G. Bartlett and James A. McCloskey
Department of Medicinal Chemistry, University of Utah, Salt Lake City, UT 84112

Sherilynn Manalili and Richard H. Griffey
ISIS Pharmaceuticals, 2292 Faraday Ave., Carlsbad, CA 92008

Results

Analysis of the effect of backbone charge on the collision-induced dissociation of multiply-charged oligonucleotides was conducted by selective replacement of the normal phosphodiester linkage with an uncharged methylphosphonate (MP) linkage. Three different MP-containing oligonucleotides were studied, designed to represent a concentration of charge on the 5'- and 3'-ends of the molecule and with an even distribution of charge along the backbone, compared with a control molecule containing only phosphodiester linkages. The most abundant charge state in all MP-containing oligonucleotides was that corresponding to complete backbone charging, compared with typical charging patterns of about 60% in normal phosphodiester oligonucleotides. This unexpected effect is attributed to charge stabilization by interactions of charged sites with uncharged residues. Analysis of the collision-induced dissociation mass spectra showed that backbone cleavage occurred at every residue (w and a-base ion series) whether or not the linkage was formally charged. It is concluded that under the multiple collision conditions of the quadrupole collision cell that backbone cleavage proceeds through two generic pathways, one involving base loss followed by cleavage of the adjacent C3'-CO bond (McLuckey and Habibi-Goudarzi, JACS **115**, 12085 (1993)) and the other requiring neither base loss nor charged phosphate at the cleavage site. These results suggest that backbone cleavage reactions in conventional phosphodiester oligonucleotides can occur at non-ionized linkage sites, of which there are a high proportion in electrospray-produced molecular ions.

Experimental

Phosphodiester oligonucleotides were synthesized using standard phosphoramidite chemistry and controlled pore glass. All phosphoramidites

were purchased from Glen Research (Sterling, VA). Three different methylphosphonate-containing compounds were prepared using the method of Sinha et al. (Nucleic Acids Research **15**, 3119 (1994)): d(A p A p A p A p A p A p A p A p A) (compound 1), d(ApApApApApApApApApA) (2), and d(ApApApApApApApApApApA) (3), where the p represents a normal phosphodiester linkage and p' represents a methylphosphonate linkage. Oligonucleotide purities were >90% as judged by capillary electrophoresis.

Mass spectra were acquired on a Sciex API-III+ (Thornhill, Ont, CAN) triple quadrupole instrument equipped with an electrospray ion source. The electrospray needle was held at -3100 V and the sampling orifice was held at -50 V. Tuning and calibration was performed using a 10 pmol/uL solution of d(Tp)₁₁T. Oligonucleotides were initially dissolved in water; working solutions were prepared at a concentration of 20 pmol/uL in 1:1 v/v water/isopropanol. Oligonucleotide solutions were infused into the mass spectrometer at 1.5 uL/min.

In CID experiments the third quadrupole was scanned from m/z 50 to 1500 using a dwell time of 5 ms and a pause time of 1 ms. The instrument took about two minutes to complete each scan and ten scans are averaged in each experiment. The collision energy was optimized for each compound within the range 5-15 V (laboratory frame).

Correlation Between ES-MS Charge States for Oligonucleotides and Solution Counterion Condensation

Richard H. Griffey*, Henri Sasmor, and Michael J. Greig
Isis Pharmaceuticals, 2280 Faraday Ave., Carlsbad, CA 92008

The charge state distribution for oligonucleotides using negative ionization electrospray mass spectrometry has been studied as a function of solution counterion concentration. An average charge state (Z) of -7.2 is observed for a 14mer DNA sample (10 μ M solution, neutral pH) in the absence of any added counterions, with $[M-8H]^{8-}$ the most abundant ion. As the solution concentration of ammonium acetate is increased from 0.10 mM (Figure 1a) to 2.0 mM NH_4OAc (Figure 1b), Z decreases to -5.1 and a bimodal distribution is observed. At 100 mM NH_4OAc and above, Z decreases to a minimum value of -3.1 , with $[M-3H]^{3-}$ the most abundant charge state (Figure 1c - 500 mM NH_4OAc). A salt concentration dependent shift in cation condensation around the polyphosphate backbone may occur. Similar studies with 28mer DNA again indicated a plateau for Z at -5.25 . The fraction of neutralized phosphate groups reaches a maximum of 0.79 ± 0.03 independent of length and sequence. Duplex DNA was studied using both mono- and divalent cationic buffers (NH_4OAc and $MgCl_2$) and the observed charge shifts correlated with values predicted by counterion condensation theory. Addition of 1-50 mM glycine to the single strand DNA does not alter Z (Figure 2). This suggests the changes in charge state distribution in salt buffers reflect the solution equilibrium of cations condensed to the DNA, not non-specific gas-phase proton transfers during the electrospray process.

Drug-DNA Interaction Studies Using Electrospray Ionization Mass Spectrometry

Quanyin Gao, Xueheng Cheng and Richard D. Smith

Pacific Northwest National Laboratory, P. O. Box 999, P8-19, Richland, WA 99352

Catherin F. Yang and Irving H. Goldberg

Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, Massachusetts 02115

Electrospray ionization mass spectrometry is a very gentle ionization methods. It has potential applications in bioanalytical chemistry and molecular pharmacology for the characterization of non-covalent interactions.

In this report, ESI-MS technique has been employed to characterize the binding specificity of a bulged 22-mer DNA hairpin with a post-activated neocarzinostatin chromophore (NCS chrom) having two similar forms, where 2a has a -H in a location for which 2b has it replaced by CH₂OH (Fig. 1). Specific binding of 2a to the bulged 22-mer DNA was observed while little binding was detected for 2a to non-bulged 19-mer and 12-mer DNA duplex. The stoichiometry of the 22mer DNA complex with 2a was determined to be predominantly 1:1 (Fig. 2). A substitution of hydrogen in 2a for the hydroxymethylene group, which forms compound 2b, dramatically reduced the binding strength to the 22-mer DNA (Fig. 3). Little complex formation was observed for 2b and 22mer DNA based upon the ESI-MS data, consistent with earlier fluorescent studies [C. F. Yang, A. Stassinopoulos, and I. H. Goldberg, *Biochem.* 34, 2267, 1995].

All experiments were performed on a TSQ 7000 triple-quadrupole mass spectrometer, using a modified microsource for electrospray ionization. This micro-source was operated at a flow rate of 0.3 mL/min using a Harvard syringe pump. For all the complex formation studies, ammonium acetate solutions of ~ 20 mM were used for suppressing sodium adduction. Automatic ESI interface tuning and mass calibration were accomplished in the positive ion mode using a horse muscle apomyoglobin standard solution. SF₆ sheath gas was used for suppressing discharge in the negative ionization mode.

The obtained specific binding results indicate the ESI-MS can be a sensitive technique for probing conformational specificity in the studies of biomolecular binding.

A detailed reference of this work can be found in *J. Mass Spectrum.* 31, 31, 1996.

Detection of Non-Covalent Interactions in Nucleic Acids using MALDI

Paolo Lecchi¹, Carl Garland², Todd H. Miles², Frank B. Howard² and Lewis K. Pannell¹
Laboratory of Analytical Chemistry¹ and Laboratory of Molecular Biology², NIDDK, NIH

Several authors have demonstrated the feasibility of detecting non-covalent interactions between macromolecules by MALDI, including the detection of enzyme-substrate complexes (1), protein polysaccharide interactions (2), peptide-DNA interactions (3), intact quaternary structures of a proteins (4), and interactions between complementary oligodeoxynucleotides (5). In this communication, we report further evidence about the possibility to detect non-covalent interactions between complementary strands of oligonucleotides. One of the key problems in the proof of non-covalent interactions is to distinguish between mass spectrometry created adducts (clusters) and those existing naturally. The method of choice to date has been to compare the spectra of species that do not associate naturally with those that do, e.g. non-complementary and complementary oligonucleotides. Previously we have shown conclusively the spectra of intact ds-DNA by using complementary oligonucleotides of different lengths where no homodimers were observed. For the work below, all samples were acquired according to our previously published conditions (6) on a KRATOS MALDI III mass spectrometer operated in negative ion linear mode at an accelerating voltage of 22 kV. The mass spectrometer was externally calibrated.

There is however another method to conclusively exclude the possibility that the ds-peaks may arise from "instrumental artifacts" (i.e. desorption of mass spectrometry formed adducts). In general, such artifacts occur when there is a large flux of monomer ions. By the examination of individual laser shot spectra, monomer and associated species may be examined individually. The figure below shows a progression of 40 single laser shots individually acquired and plotted on a three dimensional axis. This indicates the distribution on the sample spot of the three species (both monomers and the ds-DNA) which have different MWs. It is apparent that the ds-DNA occurs when little or no single-stranded oligos appear, and vice versa (compare laser pulse 5 with laser pulse 39)

When a 16 mer ds-DNA "stop linker blunt-ended" (Sigma, MO) is analyzed, very little intact ds-DNA is observed. However the addition of calcium ions (or other divalent cations) gives a drastic increase in this signal resulting from its ability to stabilize the hybrid species in solution. While this approach gave intact ds-DNA peaks, these were not good for the determination of molecular mass as the calcium formed multiple adducts and thus moved the mass to higher m/z. The double-stranded species could also be stabilized by the addition of other polyamine cations prior to annealing. Thus when two complementary oligonucleotides of 12 and 16-pb in length were annealed in a buffer containing spermidine tris-HCl (5mM), there was a drastic increase in the peak height of the ds-DNA species compared to that without the spermidine.

We have further examined triple-stranded DNA (ts-DNA) species and the MALDI spectra of these also show the intact hybrids as well as some monomer ions. However when individual laser pulses were studied, again there was no association between a large flux of the monomer and the formation of the ts-DNA. Triple-stranded hybrids of RNA have also been tested and gave formation of the "triplet" in the mass spectra.

Questions remain: (1) is it reasonable to correlate the gas phase condition and that on the sample target to the condition in solution at sample preparation, and (2) after the laser shot, is there a "stabilization" (due to an adiabatic expansion and cooling) or is there a degradation of macromolecular interaction due to the increase of the temperature. Our observations in this work would suggest that the solution condition does reflect what is formed on the sample target and the gas phase, and that there is no significant destabilization in the desorption process. With some more refining (e.g. possibility to detect oligos with higher MW), MALDI will become a powerful tool for study of the structural biology of nucleic acids (e.g. characterization of complicated secondary structure of DNA and/or RNA, such as triple strands and hairpins).

Characterization by MALDI-TOFMS of Side-products in Oligodeoxynucleotide Synthesis

*Bing H. Wang, Alexei Belenky, Eva Budman, Doriana Froim, and Aharon S. Cohen
Hybridon, Inc., One Innovation Drive, Worcester, MA 01605

In recent years, the potential of synthetic oligonucleotides to selectively inhibit the expression of genes has been under intensive investigation. Some modified oligodeoxynucleotides (ODN), e.g. phosphorothioate oligodeoxynucleotides (s-ODN), are used in clinical trials to inhibit the replication of viruses. Although automated synthesis of ODN as well as s-ODN can be achieved with high efficiency, small amounts of side-products are invariably produced during the synthesis. While the majority of these side-products have been recognized to be failure sequences, our recent study of the products from the synthesis of a 25-mer s-ODN by capillary-gel electrophoresis (CGE) revealed the presence of another type of compounds. Because these compounds are present in very low levels, they have not been studied. In this report, the structures of these side-products were characterized by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS).

A 25-mer s-ODN, 5'-CsTsCsTsCsGsCsCsCsCsCsCsTsCsTsCsTsCsTsCsTsCsTs-3' (the lower case s denotes a phosphorothioate linkage), was synthesized in house. The side-products generated in the process were enriched by preparative anion-exchange liquid chromatography (AE-LC) using a DEAE column. Capillary gel electrophoresis (CGE) was performed in a capillary with an ID of 75 μ m, filled with linear polyacrylamide, urea, formamide, and TBE buffer. Individual components in the mixture were separated by slab-gel electrophoresis (SGE). Separated s-ODN were stained and extracted from the gel by electro-elution. The solution of s-ODN was desalted by drop dialysis on a filter membrane. A mixture of 3-hydroxypicolinic acid and N-(3-indolylacetyl)-l-leucine was used as the matrix. Mass spectra were acquired with a Bruker Reflex MALDI-TOF mass spectrometer. While most of the results were obtained from the instrument equipped with a continuous extraction ion source operating in the linear mode, Figure 2 was obtained from the instrument equipped with a pulsed delayed extraction ion source operating in the reflecting mode. All spectra were the summed results of 10-20 laser shots.

While over 10 components can be found in the electropherogram of a mixture enriched with the side-products (Figure 1), only two peaks are observable in the MALDI-TOF mass spectrum (Figure 2), indicating a suppression effect of the 25-mer on the detection of the side-products. This suppression effect was effectively removed upon separation of the mixture by SGE. All of the components separated by SGE gave strong signals when subjected to MALDI-TOFMS (Figure 3). Besides the fraction (F1) attributed to the 25-mer, the rest of the fractions all have masses higher than that of the 25-mer. Of the first five fractions (F1 - F5) probed by MALDI-TOFMS, the mass difference between two neighboring SGE components have been found to correspond to phosphorothioate dinucleotide residues, although an additional loss of a PO_2S moiety is needed to account for the mass difference between F2 and F1. Thus, F2 - F5 can be accounted for by the addition to F1 of CsTs - PO_2S , CsTs CsTs - PO_2S , CsTs CsTsCsGs - PO_2S , CsTs CsTsCsGsCsCsAs - PO_2S , respectively. Because the sequences of these additional structures are identical to the sequence of the 25-mer on the 5'-end, it seems that branching has occurred. Furthermore, the branching reactions occurred selectively at 2'-deoxycytosine residues. The unusual loss of a PO_2S moiety suggests that during the branching reactions the phosphoramidite group was replaced, instead of the diisopropylamino group. The structures of F1 - F5 can be summarized in Figure 4.

In conclusion, when coupled to SGE and AE-LC, MALDI-TOFMS can be effectively used to characterize the structures of low level side-products generated during the synthesis of a 25-mer s-ODN. Furthermore, by revealing the unusual structures with the phosphorothioate linkage missing at the branching point, MALDI-TOFMS can facilitate the elucidation of the branching reaction mechanism.

The characterization of alkali metal ion interactions ($X^+ = Li^+ - Cs^+$) with nucleic acid components such as nucleosides (M) provides information on intrinsic cation binding tendencies and can be useful when considering more complex real situations. In this work, the interaction of alkali metal ions with guanosine and cytidine, containing two of the common bases in RNA and DNA, are studied by LSIMS in the +ve and -ve ionization modes. In an attempt to characterize the metal ion-containing adducts formed in LSIMS, a substituted nucleoside and nucleobase were studied and solution pH was varied. Typically, the nucleosides are added to DMSO/glycerol saturated by XCl. Basic conditions were achieved with XOH and acidic conditions were obtained using pTSA/glycerol (0.2M) as the solvent.

The metal adduct ions observed in LSIMS for the alkali metal salt (XY)/nucleoside (M) systems are listed in Table 1. First, the cytidine results in will be discussed. The metal ion-containing species, MX^+ and $(M-H+X)^+$, are observed in the molecular ion region. Considering MX^+ , the presence of BHX^+ suggests X^+ attaches to the base portion of cytidine at N3 [1]. Proton substitution by X^+ resulting in $(M-H+X)^+$ formation in LSIMS is believed to occur on the ribose of cytidine. LSIMS of 1-methyl-cytosine confirms this since, with no ribose present, $(M-H+X)^+$ is not formed (Table 1). A potential pathway for $(M-H+X)^+$ formation is the CID of $M(X_2Cl)^+$, a species also formed in LSIMS (Table 1). However, upon changing the alkali metal counter-anion to $Y = CN^-, HCO_3^-$, $(M-H+X)^+$ is still observed in LSIMS but not $M(X_2Y)^+$. Hence, other pathways to $(M-H+X)^+$ formation in LSIMS must be available. The formation of $(M-H+X)^+$ in LSIMS was further investigated by changing the solution pH (Table 1). A LSIMS mass spectrum for cytidine/KCl under basic conditions is shown in Figure 1. It is seen that up to three H^+ on cytidine are substituted by K^+ . The presence of $(B-H+2K)^+$ shows that a H^+ from the amine on the base is substituted by a K^+ with the other substitutions occurring on the ribose. Under acidic conditions, no $(M-nH+nX)^+$ are observed in LSIMS (Table 1). These results demonstrate the importance of condensed phase equilibria on $(M-H+X)^+$ formation in LSIMS.

The -ve LSIMS mass spectrum for cytidine/NaCl in DMSO/Gly is shown in Figure 2. The presence of $(M-nH+nX)Cl^-$, where $n=1, 2$, and $(M-2H-X)^-$ shows that substitution of up to two protons by Na^+ occurs on cytidine. The location of these substitutions can be determined by -ve LSIMS of 1-methyl-cytosine. No metal ion adducts are observed (Table 1) indicating that X^+ substitutions occur on the ribose portion of cytidine. The substitution of two H^+ on cytidine by X^+ in DMSO/Gly in the -ve mode opposed to the substitution of one H^+ in the +ve mode (Tables 1) may reflect the additional stability of $(M-2H+2X)Cl^-$ relative to $(M-2H+2X)^+$ in LSIMS. Substitution of two protons in cytidine yielding $(M-2H+X)^+$ is also observed under basic conditions in -ve LSIMS (Table 1).

The MX^+ and $(M-H+X)^+$ species are also formed in LSIMS for guanosine/alkali metal systems in DMSO/Gly (Table 1). The presence of BHX^+ suggests X^+ attaches to the base of guanosine at O6/N7 [1]. The absence of $(M-H+X)^+$ for 1-methyl-guanosine/XCl suggests H^+ substitution by X^+ takes place at N1 of the base for guanosine (Table 1). Consistent with this, no X^+ substitution occurs in -ve

LSIMS for 1-methyl-guanosine in DMSO/Gly (Table 1). Under basic conditions, substitution of two H^+ is observed in +ve LSIMS for guanosine. The presence of $(B-H+2X)^+$ shows that one substitution occurs on the base at N1, and one on the ribose. The formation of $(M-2H+X)^+$ for 1-methyl-guanosine in -ve LSIMS under basic conditions may illustrate the substitution of two ribose protons by X^+ .

GAS-PHASE CHEMISTRY OF METAL(II) ION COMPLEXES OF TRINUCLEOTIDES

Jill H. Hamilton and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to determine: (1) the gas-phase structures of complexes between metal(II) ions and trinucleotides; (2) whether trinucleotide Me^{2+} complexes, in which $\text{Me}^{2+} = \text{Ca}^{2+}$, Mn^{2+} , Co^{2+} , and Ni^{2+} , reflect solution or gas-phase structures and chemistry. MS^2 and MS^3 experiments were performed using a JEOL JMS-SX102/102A/E five-sector tandem mass spectrometer.

FAB mass spectra of the metal(II) ions complexes of dTTC, ACC, and AAC show formation of 1:1 complexes, or $(\text{M} + \text{Me}^{2+} - \text{H})^+$ ions. Mn^{2+} and Co^{2+} also show formation of 2:1 complexes, or $(\text{M} + 2\text{Me}^{2+} - 3\text{H})^+$ ions.

Metastable ion decompositions reveal various low-energy reaction pathways that differ significantly for the three trinucleotides (Figure 1 $(\text{M} + \text{Ca}^{2+} - \text{H})^+$ and $(\text{M} + \text{Co}^{2+} - \text{H})^+$ complexes of dTTC). The 5' and 3' terminal bases are lost from $(\text{M} + \text{Me}^{2+} - \text{H})^+$ precursors of dTTC. Only the 5' terminal base is lost from $(\text{M} + \text{Me}^{2+} - \text{H})^+$ precursor complexes of ACC. The 3' terminal base is lost from all $(\text{M} + \text{Me}^{2+} - \text{H})^+$ precursor complexes of AAC, and only the 5' base for the Co^{2+} and Ni^{2+} complexes. Low-energy reactions for the 2:1 complexes (Figure 2 $(\text{M} + 2\text{Mn}^{2+} - 3\text{H})^+$ and $(\text{M} + 2\text{Co}^{2+} - 3\text{H})^+$ complexes of dTTC) are more similar than the 1:1 complexes. $(\text{M} + 2\text{Me}^{2+} - 3\text{H})^+$ precursor ions of dTTC lose the furanose ring as $\text{C}_3\text{H}_6\text{O}_2$ and $\text{C}_3\text{H}_6\text{O}_3$ and form c_2 and w_2 ions¹. Both of the ribonucleotides lose the furanose ring as $\text{C}_3\text{H}_6\text{O}_3$ and $\text{C}_3\text{H}_6\text{O}_4$ and form d_2 and w_2 ions.

CID experiments also show different reaction pathways for the trinucleotides. In the spectra of 1:1 metal(II) ion complexes of dTTC, product ions that contain thymine, cytosine, the furanose ring, a portion of a phosphate group, and the metal(II) ion, or $\text{T-Me}^{2+}\text{-C}$ ions, are observed for all of the complexes except Ca^{2+} . There are no $\text{T-Me}^{2+}\text{-T}$ ions, which would contain both thymine bases, the furanose ring, a portion of a phosphate group and the metal(II) ion. In the spectra of ACC complexes, $\text{A-Me}^{2+}\text{-C}$ and $\text{C-Me}^{2+}\text{-C}$ ions are observed. In the spectra of AAC complexes, only $\text{A-Me}^{2+}\text{-C}$ ions are observed. 2:1 metal(II) ion complexes of dTTC decompose to lose thymine, cytosine, and form $\text{T-Me}^{2+}\text{-C}$ ions. 2:1 metal(II) ion complexes of ACC decompose to lose cytosine and adenine for the Mn^{2+} complexes only, formation of neither $\text{A-Me}^{2+}\text{-C}$ nor $\text{C-Me}^{2+}\text{-C}$ ions occurs. 2:1 metal(II) ion complexes of AAC decompose to lose cytosine and adenine for the Co^{2+} complexes only, formation of $\text{A-Me}^{2+}\text{-C}$ ions does not occur.

Binding interaction between oligonucleotides and metal(II) ions in solution depend on which base and metal(II) ion are present. Ca^{2+} interacts only with phosphate groups in poly(A) and poly(C).² Co^{2+} tends to form outer-sphere complexes with oligonucleotides mainly interacting with phosphate groups. Studies with Mn^{2+} and poly(A)³ reveal that every Mn^{2+} is bound directly to two phosphate groups while some of the Mn^{2+} ions are simultaneously bound to adenine bases. Ni^{2+} binds to both the bases and phosphate groups in poly(A); however, Ni^{2+} only binds to phosphate groups in poly(C).⁴ This is consistent with observations that Ni^{2+} does not interact with bases of pyrimidine nucleoside monophosphates. In solution, metal(II) ions bind to trinucleotides and polynucleotides at a ratio of 1:2 for every phosphate group. That is for metal(II) ion complexes with trinucleotides only 1:1 complexes are formed.

Results from this study show that gas-phase structures and the binding chemistry of metal(II) ions and trinucleotides are not reflected in solution. In the gas-phase, metal(II) ions interact with both the bases and phosphate groups of trinucleotides. Evidence for simultaneous coordination to both bases and phosphate groups comes from product ions that contain two bases, the furanose ring, a portion of

the phosphate group, and the metal(II) ion. These $\text{B-Me}^{2+}\text{-B}$ product ions strongly suggest that the metal(II) ion is coordinated to both the bases and phosphate groups in the population of precursor structures. In the gas-phase, several metal(II) ions bind at a ratio of 1:1 with phosphate groups of trinucleotides, thus forming 2:1 metal(II) ion complexes.

METAL(II) ION COMPLEXES OF ACC FORMED BY ELECTROSPRAY IONIZATION

Jill H. Hamilton and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to determine: (1) whether ESI can be used to form complexes between metal(II) ions and oligonucleotides; (2) whether ESI MS/MS can be used to study the binding chemistry and structures of the complexes; (3) if the intrinsic binding chemistry of the ESI-formed complexes is the same as solution chemistry; (4) possible gas-phase structures for the complexes. MS² and MS³ experiments were performed using a JEOL JMS-SX102/102A/E five-sector tandem mass spectrometer.

Present in the ESI mass spectra of Mg²⁺, Ca²⁺, Mn²⁺, Co²⁺, and Ni²⁺ complexes are singly and doubly charged ions representing formation of 1:1 complexes, or (M + Me²⁺ - H)⁺ and (M + Me)²⁺ ions. Present also in the ESI spectra are singly and doubly charged ions representing formation of 2:1 complexes, or (M + 2Me²⁺ - 3H)⁺ and (M + 2Me - 2H)²⁺ ions.

Metastable ion decompositions of doubly charged 1:1 and 2:1 precursor complexes result in several doubly charged product ions. Doubly charged product ions of doubly charged 1:1 precursors result in loss of adenine and cytosine for the Mg²⁺, Ca²⁺, and Mn²⁺ (Figure 1a) complexes, loss of H₂O and the furanose ring as C₅H₈O₄ for all of the complexes. Other product ions are c₂ and d₂ ions¹ for the Ca²⁺ complexes, w₂ ions for the Mn²⁺ complexes, and c₂ ions for the Ni²⁺ complexes. Doubly charged product ions present in the MS-MS spectra of doubly charged 2:1 precursor complexes result in loss of adenine for the Ca²⁺ complexes, loss of H₂O, and the furanose ring as C₅H₈O₃ and C₅H₆O₄ for all of the complexes. Other product ions are y₂ for the Ca²⁺ complexes, d₂ ions for the Mn²⁺ complexes, and c₂ ions for the Mn²⁺ and Co²⁺ complexes.

Metastable decompositions of the doubly charged 1:1 and 2:1 precursor complexes result in several structurally informative singly charged product ions. Metastable ion decompositions of doubly charged 1:1 precursor complexes result in loss of protonated adenine for the Mg²⁺, Ca²⁺, and Mn²⁺ (Figure 1b) complexes and loss of protonated cytosine for all of the complexes. Also present are y₂ ions and c₂ ions for the Mn²⁺ and Co²⁺ complexes. Metastable ion decompositions of doubly charged 2:1 precursor complexes result in loss of protonated adenine for the Mg²⁺ and Ca²⁺ complexes and loss of protonated cytosine for all of the complexes. Other ions present are d₂ ions, c₂ ions for the Mn²⁺ and Co²⁺ complexes, w₂ ions for the Mg²⁺ and Mn²⁺ complexes, ions of -129 for the Mn²⁺ complexes, and ions resulting in loss of the furanose ring as C₅H₆O₃.

There are two major differences in the binding chemistry of ESI-formed metal(II) ion complexes and solution complexes. Firstly, in solution, metal(II) ions bind at a ratio of 2:1 with trinucleotides and polynucleotides; secondly, the metal(II) ion binding sites in polynucleotides differ depending on which metal(II) ion is present. Mg²⁺ and Ca²⁺ interact only with phosphate oxygens in poly(A) and poly(C).² Co²⁺ tends to interact mainly with phosphate groups to form outer-sphere complexes with oligonucleotides. Mn²⁺ interacts with both bases and phosphate groups in poly(A).³ Ni²⁺ interacts with the bases and phosphate groups in poly(A) and only with phosphate groups in poly(C).³ In the gas-phase, metal(II) ions bind not only at a ratio of 2:1 with phosphate groups in trinucleotides, but they also bind 1:1 with phosphate groups. Secondly, there is strong evidence that metal(II) ions interact with both bases and phosphate groups in trinucleotides. Evidence comes from formation of ions in which one of the furanose rings is lost as C₅H₈O₃ or C₅H₆O₄. In order for such ions to be formed, the metal(II) ion must be interacting with both the base and phosphate groups.

Charge-separation reactions can be used to propose possible structures for the doubly charged

precursors. The charge-separation reactions leading to loss of the protonated bases in 1:1 complexes suggests that one charge site is located either on cytosine (Structure 1) or adenine. The charge-separation reactions leading to loss of adenine and cytosine in the 2:1 complexes suggest that the precursor structures must have a proton either on cytosine (Structure 2) or adenine.

Results from this study show that ESI can be used to form complexes between metal(II) ions and oligonucleotides, and that ESI MS-MS can provide a powerful tool for examining the binding chemistry and structures of these complexes.

Analysis of DNA Mixtures by Electrospray Ionization Mass Spectrometry Utilizing Charge-State Reduction

David C. Muddiman¹, James E. Bruce¹, Ljiljana Pasa-Tolic¹, Chris Hopkins²
Raymond Gesteland² and Richard D. Smith¹

¹Macromolecular Structure and Dynamics
Environmental Molecular Sciences Laboratory
Pacific Northwest National Laboratory
Richland, Washington 99352

University of Utah
Salt Lake City, Utah 84112

Cycle sequencing of polymerase chain reaction (PCR) amplified templates by electrospray ionization mass spectrometry can be achieved only if the resulting mass spectrum is interpretable. The complexity of an electrospray mass spectrum of a sequencing reaction mixture results from several issues listed from major to minor: 1) the presence of both the sense and antisense strands produced in the PCR step; 2) the addition of non-templated adenine to the 3' end; 3) the propagation of errors caused by the proof reading ability of the DNA polymerase in the first PCR reaction when conducting tandem PCR to generate sufficient template; 4) the multiple charging phenomena observed in ESI of large biopolymers; 5) cation adduction to the phosphate backbone in DNA; 6) polymorphism's present in the original template DNA to be sequenced (this depends on the position of the base substitution(s)/deletion(s)); 7) single reaction step (*i.e.* all four dideoxy nucleotide triphosphates are present in the reaction) since mass spectrometry has high resolving power.

It is obvious that from a mass spectrometry perspective, several issues need to be addressed and demonstrated: 1) the reduction in spectral complexity by reducing charge states; 2) the suppression or complete elimination of cation adduction; 3) resolution of oligonucleotides at high MW; 4) determining the feasibility of analyzing products produced via Sanger methodology (*e.g.* due to dynamic range issues in a trapped ion cell, etc.). Recently, the means by which the first two goals can be simultaneously accomplished has been investigated (Muddiman, *et al. J. Am. Soc. Mass Spectrom.*, in press). These studies clearly indicated that moderate charge state reduction (*i.e.* shifting to higher m/z values) and "desalting" could be accomplished simultaneously by addition of organic bases to the solution to be infused. This protocol included the addition of piperidine and imidazole to the sample mixture containing 80% organic phase to eliminate Na adduction to the phosphate backbone while maintaining spray stability. These results should facilitate the analysis of Sanger mixtures by electrospray ionization mass spectrometry.

To demonstrate the high mass resolving power of the FTICR technique for the analysis of oligonucleotide mixtures, two 53-mers were analyzed, the difference being a single base substitution representing the worst case scenario (A to T) which is 9 Da mass difference. ESI-FTICR had no difficulty resolving even the 15- charge state (*i.e.* the m/z difference is 0.9). Clearly,

this will be advantageous when analyzing regions of human genomic DNA when a polymorphic site is present.

In this first attempt to use ESI-MS as a method to sequence DNA, the synthetic 53-mer shown below was used with a 20-mer primer shifted 5 bases inward from the 3' end of the template. All four dideoxy analogues were present in the reaction mixture, and thus a single mass spectrum provides all of the necessary information. Details are described elsewhere (Muddiman, *et al.* submitted to: *Anal. Chem.*).

Template (Antisense)/Primer

3'-GGA TGT TGT GGT CCT TCA TGC TCA CGA CTC GGC TCT AGA TGG GCC TGT AGT GG-5'
5'-A ACA CCA GGA AGT ACG AGT G-3'

The figure below shows the ESI-FTICR mass spectrum obtained from the single reaction step mixture (*i.e.* all dideoxy analogs are present in the reaction mixture). The inset shows that isotopic resolution is obtained which allowed assignment of charge states for all peaks. Upon "deconvolution" of the spectrum, all terminates were detected and the entire sequence was read (28 bases of read). Although the entire sequence was read, due to limited cell capacity in the trap, larger read lengths may prove to be more difficult due to product distributions for chain-termination products decreasing with length. Recently, the application of noise filtered quadrupolar excitation over narrow m/z ranges (225) to the same sample clearly indicated that the dynamic range could be enhanced (Muddiman, *et al.*, in preparation for submission to *J. Am. Soc. Mass Spectrom.*), which will increase the dynamic range and allow analysis of a wider range of concentrations in the sample mixture.

Analysis of Oligonucleotides Bound to Positively Charged Surfaces

Bernd A. Bruenner, Kamen Voivodov, Jesus Ching, and T. William Hutchens

Department of Food Science and Technology
University of California, Davis, CA 95616

The presence of buffer salts and sodium or potassium counter ions interferes with the analysis of oligonucleotides by MALDI. The formation of alkali metal adducts along the negatively charged phosphodiester backbone of oligonucleotides results in decreased resolution and detection sensitivity. Common methods used to remove interfering ions include the addition of cation-exchange resin on the MALDI probe surface to bind and remove sodium ions or the addition of ammonium citrate to the matrix solution to displace the counter ions. The opposite approach, selective binding of oligonucleotides directly to a solid support, however, allows more extensive washing and removal of the interfering species.

Our efforts have focused on the use of surface-enhanced affinity capture (SEAC) methods (positively charged/hydrophobic affinity capture probe surfaces) to predetermine the precise location of oligonucleotide presentation, to improve sensitivity, and to increase mass resolution. This approach was used to analyze a 21-mixed based oligonucleotide with a molecular mass of 6,361 Da. Anion-exchange beads and various polymers were used as affinity capture devices to bind oligonucleotides directly to the sample probe. Peak heights and resolution of the desorbed oligonucleotides were evaluated by MALDI.

The SEAC surfaces (polyallylamine and polyallylamine-iminodiacetic acid) were synthesized in our laboratory and 0.5 μ L (solutions in MeOH/water, 1:1) applied to the stainless steel probe surface. In some cases the polymer solutions were applied on top of a hydrophobic polypropylene film, formed by heating polypropylene in decahydronaphthalene and applying 0.5 μ L to the probe surface. The SEAC probes were rinsed by swirling the probe tip in 100 mM ammonium acetate pH 7.0 for 30 s and air dried. Oligonucleotide (0.5 μ L of 20 pmol/ μ L) was applied to the probe surfaces. For samples containing NaCl, 0.5 μ L of a 150 mM NaCl solution was also applied and mixed with the analyte directly on the probe surface prior to drying. The samples were then rinsed three times in deionized water (except the stainless steel control) by swirling the probe in water for 30 s. Finally, 0.5 μ L of matrix (3-hydroxypicolinic acid, saturated solution in 50:50 acetonitrile/150 mM ammonium citrate) was added. The control contained 0.5 μ L of 20 pmol/ μ L oligonucleotide on stainless steel.

Beads (Q-Sepharose, DEAE Sepharose, and Qiagen resin) and poly-N-ethylamine-4-vinylpyridine (synthesized in our laboratory) were rinsed with 100 mM ammonium acetate, pH 7. A 1 μ L aliquot of bead slurry was incubated with 1 μ L 20 pmol/ μ L oligonucleotide solution and 8 μ L water for 1 h at room temperature (final oligonucleotide concentration 2 pmol/ μ L, 10 μ L total volume). Samples containing NaCl were prepared by adding 1 μ L of 150 mM NaCl to the incubation mixture. The beads were then rinsed twice with 100 μ L water. A slurry of beads (0.5 μ L) and matrix (0.5 μ L) were applied to the probe surface. The control sample consisted of 0.5 μ L of a 2 pmol/ μ L solution of oligonucleotide and 0.5 μ L matrix on stainless steel probe.

Samples were analyzed in the negative ion mode using a modified Hewlett-Packard (Palo Alto, CA) 1700XP linear time-of-flight mass spectrometer at an acceleration voltage of 29 kV. A nitrogen laser (337 nm) attenuated to 16 μ J output was used to desorb/ionize the samples. Data was obtained for each sample by summing 20 laser shots per spot from each of four distinct areas per sample. Each sample was prepared and analyzed three separate times to calculate the average peak heights reported.

Initial analysis of the various polymers and beads revealed that poly(allylamine)/polypropylene and Q-Sepharose retained the greatest amount of oligonucleotide after washing. These two surfaces were therefore selected for subsequent evaluation to determine their effectiveness in the removal of physiological concentrations of NaCl. Both poly(allylamine)/polypropylene and Q-Sepharose were effective in retaining the analyte during the removal of NaCl. Peak heights were nearly doubled and resolution was improved over two-fold on these surfaces in comparison to unrinsed stainless steel surfaces (Table 1). The improvement in peak shapes obtained by binding the oligonucleotide to Q-Sepharose is illustrated in Figure 1. These results demonstrate that oligonucleotides can be effectively bound to SEAC probe surfaces through electrostatic/hydrophobic interactions even in the presence of contaminants such as NaCl. The SEAC approach improved mass spectrometric analysis of oligonucleotides by retaining and concentrating these analytes and facilitating subsequent removal of interfering components. Analyses of oligonucleotides by SEAC methods can improve detection sensitivity and mass resolving power. Future efforts will seek to optimize binding and contaminant removal conditions for oligonucleotide analysis on the SEAC polymers and evaluate new SEAC polymers covalently bound to sample probes.

Probe Surface		Peak Height	m/ Δ m
Stainless Steel	(no NaCl, no rinse)	2.8	65
Stainless Steel	(no NaCl, rinsed 3X)	0.1	66
Stainless Steel	+ NaCl (no rinse)	1.0	28
Q-Sepharose	+ NaCl (rinsed 2X)	1.9	69
Poly(allylamine)/Polypropylene	+ NaCl (rinsed 3X)	1.8	61

Table 1. Average peak heights and resolution (m/ Δ m) of oligonucleotides desorbed/ionized from various surfaces, 150 mM NaCl added to samples indicated as described in methods. Values shown were normalized to the value of the MALDI control with NaCl added. Unlike the SEAC samples, the control did not undergo any rinsing procedure.

Figure 1. Negative ion MALDI mass spectra of oligonucleotides ionized from Q-Sepharose (upper trace) and stainless steel probe surface (lower trace). Peak height and resolution were nearly doubled after removal of NaCl from the beads in comparison to the unrinsed stainless steel surface.

Reduced Cation Adduction in Negative Ion ESI Mass Spectra of Oligonucleotides

Robert A. Rieger And Charles R. Iden, Department of Pharmacological Sciences,
State University of New York at Stony Brook, Stony Brook, N. Y. 11794

Introduction

Detection of negative ions in electrospray mass spectrometry of biomolecules is limited to a large extent by the presence of contaminating salts. Cationic species such as sodium and potassium reduce the intensity of the signal output and can also impact mass accuracy by broadening peak widths. A variety of methods have been described which are aimed at reducing the effects of salts in these samples. The most common of these techniques is HPLC which may or may not be coupled directly to the mass spectrometer. Several other methods have been useful and include membrane filtration and precipitation of the analyte. These techniques work well but usually require nanomole quantities of sample, and losses are significant. The addition of various bases such as triethylamine, imidazole, and piperidine, either alone or in combination, has allowed samples to be analyzed directly without any loss of material. However, in some cases salt adducts are still persistent even after the addition of these bases. We have found that the addition of the ammonium form of the cation exchange resin AG-50W to these samples can reduce salt adducts to below limits of detection.

Materials and Methods

The trimer, TTT was synthesized on a Applied Biosystems 394 automated DNA synthesizer using standard phosphoramidite chemistry. The oligonucleotide was HPLC purified on a Hamilton PRP-1 polystyrene column using a Waters HPLC system, dried in vacuo, and stored until used. A 114 mM sodium carbonate stock solution was prepared and diluted for each experiment. Approximately 45mg of AG-50W-8X resin was from Bio-Rad was converted to the ammonium form by the addition of 200 μ L of saturated ammonium acetate. After ten minutes, the ammonium acetate was decanted, and the resin washed several times with water and used in subsequent experiments. A small quantity of resin was transferred to a eppendorf tube and residual water was removed with a syringe. The sample containing 1% triethylamine was added to the resin, and a 10 μ L aliquot was loop injected into the electrospray source

Mass analysis was performed on a Fisons TRIO-2000 quadrupole mass spectrometer system. The source was supplied with a flow of 60% acetonitrile/water at a rate of 12 μ L/min from a Harvard syringe pump. Nitrogen was used as a drying gas (250 L/hr) and also as the nebulization gas (15 L/hr). The instrument was operated in the negative ion spray mode with the high voltage set to -3.3 kV and the source temperature at 70 degrees. The sampling cone was fixed at -68 V and lenses were adjusted to maximize ion transmission of m/z 849.6, the deprotonated molecular ion of TTT. Approximately 8 scans were collected in the multi channel averaging (MCA) mode, baseline adjusted, and digitally filtered to produce each spectrum.

Results

The effect of adding sodium carbonate to the oligomer TTT and its removal by base addition and AG-50W resin is shown in Figures 1 and 2. While the addition of triethylamine reduces adduction, the behavior of the resin in combination with the triethylamine is superior.

ELECTROSPRAY/COLLISION-INDUCED DISSOCIATION OF DERIVATIZED PEPTIDES: STUDIES ON A HYBRID MAGNETIC SECTOR TIME-OF-FLIGHT MASS SPECTROMETER

Ingemar Lindh, William Griffiths, Tomas Bergman and Jan Sjövall,
Department of Medical Biochemistry and Biophysics, Karolinska Institutet,
171 77 Stockholm, Sweden.

Introduction

Previous studies of peptides C-terminally derivatized with 4-aminonaphthalenesulphonic acid have shown that the sulphonate group provides a stable site for a negative charge (Lindh, I. et al., *Rapid Commun. Mass Spectrom.*, **8**, 797 (1994), Griffiths, W. et al., *Rapid Commun. Mass Spectrom.*, **9**, 667 (1995)). When employing fast-atom bombardment or electrospray (ES) ionisation the sensitivity of detection of the derivatized peptides was increased by between one and two orders of magnitude in comparison to the underivatized analogs. Upon high-translational energy collision-induced dissociation (CID) of the pseudomolecular anions, C-terminal fragment ions were formed exclusively.

In the present study we have examined the CID of the peptide derivative $[M-H]^-$ ions in 400 eV collisions with a variety of collision gases.

Mass spectrometry

Negative-ion ES mass spectra were recorded on a hybrid magnetic sector time-of-flight mass spectrometer (VG AutoSpec HF OA-TOF FPD) operated at a source potential of -4 kV. CID spectra were obtained using either helium, argon, xenon or methane as the collision gas in the time-of-flight collision cell. The cell was floated to -3.6 kV thus giving a collision energy of 400 eV in the laboratory frame of reference. Daughter-ion spectra were subsequently recorded on the OA-TOF analyzer.

Results

The fragment ions formed upon CID are highly dependent on the collision gas. The ES/CID/OA-TOF spectra of the $[M-H]^-$ ions of the peptide derivatives generated with helium as collision gas show mainly y and y-80 (-80 due to the loss of SO_3 from the y-fragments) ions. Some N-terminal fragments are also present. By increasing the mass of the collision gas, and thus the center-of-mass collision energy, the appearance of the spectra are radically changed. With xenon, almost a complete set of C-terminal sequence ions and side-chain losses are seen. Shown in Figs. 1 and 2 are the ES/CID/OA-TOF spectra of a derivatized peptide using methane and xenon as the collision gases, respectively. The sensitivity of detection is similar (but fragmentation patterns are different) to those previously achieved by ES ionisation and linked-scan at constant B/E with focal plane array detection.

Does MS/MS always identify the modification sites in peptides?

Viswanatham Katta, Robert S. Rush, Sheila O' Connor and Michael F. Rohde
Amgen Inc., Thousand Oaks, CA 91320-1789

Electrospray and MALDI ionization both provide high sensitivity for analyzing peptides and proteins. Tandem mass spectrometric methods (MS/MS) using electrospray on triple quadrupole instruments or post-source decay (PSD) with MALDI have been used for sequence analysis of peptides. Both these methods have been found to be useful in identifying or verifying the sites of modifications in peptides. The difference in molecular mass from the predicted one is an indicator of the nature of modifications as to glycosylation, phosphorylation or nitration, etc. Generally, the MS/MS techniques provide supportive and complimentary information in pointing the modified residues, and sometimes conclusive evidence about the nature of such modifications. Occasionally, we find information is not sufficient to identify the site of modification and PSD-MALDI and electrospray MS/MS provide contradictory evidences. This discrepancy results from the energetics involved in ion activation and time scales involved in detecting the fragment ions.

Figure 1 shows product ion spectrum of m/z 1394 from a O-linked glycopeptide with four possible sites of glycosylation (*Anal. Chem.* 1995, 34, 1442-52). The spectrum is rich in information about the glycosidic residues (number of sialic acids (SA), hexoses (Hex) and N-acetyl hexosamines (HexNAc)) and some linkage information (one SA is attached to a Hex while the other is attached to a HexNAc), but very little information is available to which Ser/Thr is involved. Glycosidic bonds being the weakest, the fragmentation is essentially directed towards them. Observation of a weak singly charged y_8 ion at m/z 887 (cleavage n-terminal to proline), only precludes either of the threonines from being glycosylated.

Figure 2A shows the product ion spectrum of a tryptic peptide (PVPPGEDSK), that has a modification increasing the peptide mass by 12 Da. The product ion spectrum of doubly protonated peptide shows intense ions at m/z 729, 209 and 181 suggesting that modification is in the first two residues. In contrast the PSD-MALDI spectrum (Figure 2B) shows the y_7 ion at m/z 740.6 as well as peaks at m/z 181, 197 and 209, suggesting that any of the residues could have been modified. Thus, these two spectra are in contradiction as to the location of modification on the peptide.

In the case of phosphorylated peptides, both ESI-MS/MS and PSD-MALDI data are in agreement to the site of phosphorylation. Tyrosine sulfation is a very labile link and by controlling the collision energy, it is possible to get some indication of the linkage site. Overall, it appears that it is difficult to identify the sites in the case of labile modifications, but can be straight forward for non-labile modifying groups.

Acknowledgments: Help of Yue-Rong Hsu for providing the sulfated peptide and Dr. Chao-Yuh Yang for the tyrosine modified peptide is acknowledged.

A NOVEL DERIVATIZATION SCHEME FOR THE COLLISIONAL ACTIVATION OF PEPTIDES

Rich E. Gedamke*, Mark E. Hail, Gerald C. DiDonato, and Mike S. Lee
Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton New Jersey

INTRODUCTION

As an extension of our rapid molecular weight characterization of synthetic organic compounds utilizing ESI, including synthetic peptides, we are developing rapid methods for the sequencing of synthetic peptides using novel N- and C- terminal derivatization schemes. These schemes, which are similar in approach to those recently described by Sherman et al. (1) are driven by the frequent need of medicinal chemists to confirm not only the molecular weight of a synthetic peptide but also the amino acid sequence. The desired derivatization reaction should be simple, quantitative, and provide a driving force to produce easily-interpretable collisional activation spectra.

The derivatization reaction described in this poster is simple, may be performed in a single vial, requires minimal sample clean-up, and offers a high yield of derivatized product. In an effort to mimic the tryptic peptides which often yield informative and easily interpretable product ion spectra by the presence of basic amino acid residues, we have derivatized peptides with arginine methyl ester in the presence of 1,3-dicyclohexylcarbodiimide at pH 9. This results in the addition of an arginine methyl-ester to the C-terminus, resulting in collisional activation spectra containing primarily y-type ions. The methyl ester of arginine was used for derivatization to prevent unwanted polymerization of arginine which reduces the yield of desired product.

EXPERIMENTAL

Derivatization: Place 1-2 μg of peptide into a microconical. Add 3-4 equivalents of dicyclohexylcarbodiimide, (DCC), and 5 equivalents of arginine-methyl ester in 200 μl of deionized water. The pH is adjusted to 9 using NH_4OH . The vial is incubated at 60° C for 2 hours. The vial is cooled to room temperature and loaded into a syringe for infusion. Maintenance of the pH at 9 is crucial to the reaction.

Instrumentation: Experiments were carried out on a Finnigan TSQ700 mass spectrometer equipped with a Finnigan ESI source. Approximately 1-2 μg of derivatized peptides was infused into the mass spectrometer at a flow rate of 5 $\mu\text{L}/\text{min}$.

RESULTS AND DISCUSSION

Based upon previous work, it would appear that placement of a basic amino acid residue at the C-terminus should result in an increase in y type fragmentation. The resultant effect of derivatization with arginine methyl ester can be seen by comparison of the product ion spectrum of underivatized angiotensin II with that of the product ion spectrum of derivatized peptide. The product ion spectrum of the doubly-charged molecular ion yields a weak, uninformative MS/MS spectrum (Figure 1). However, the product ion spectrum of derivatized ACTH shows distinct fragment ions, including the y₁ through y₁₀, and Ser-Tyr fragment. Similarly, derivatization of angiotensin II with arginine methyl ester results in a shift from primarily internal fragment product ions to y ions.

CONCLUSIONS

A simple, rapid, one-step derivatization procedure has been described. C-terminal derivatization of peptides with arginine methyl ester results in the addition of arginine methyl ester to the peptide. Upon collisional activation, the derivatized peptide produces primarily y-type fragmentation. Examples shown in this poster indicate modification of fragmentation from N-terminal or internal fragment ions to C-terminal product ions. This derivatization scheme should prove useful in the sequence determination of small peptides.

CHARACTERIZATION OF A β -ASP33 ISOFORM OF RECOMBINANT HIRUDIN SEQUENCE VARIANT 1 BY LOW ENERGY COLLISION INDUCED DISSOCIATION

P. Schindler¹, D. Müller¹, W. Märk², H. Grossenbacher² and W. J. Richter¹

Central Research Services¹ and Pharmaceutical Division², Ciba-Geigy Ltd., CH-4002 Basel, Switzerland

Recombinant hirudin sequence variant 1 (rHV1), a strong inhibitor of human α -thrombin, is a 65-amino-acid protein expressed in *S. cerevisiae* and purified to homogeneity. A new low-concentration hirudin-related product suspected to be a β -Asp isoform of rHV1 (same molecular mass, but different chromatographic behavior) resulting from hydrolysis of a succinimide-type intermediate (Scheme 1) was isolated and structurally characterized as reported here. Several investigators have shown that, for small enough peptides, the replacement of α - by β -Asp induces specific changes in the high energy collision induced dissociation (CID) behavior of $[M+H]^+$ ions.^{1, 2} Especially, the β -Asp isomers produce one additional highly diagnostic ion which formally corresponds to a $[b_n + H_2O]^+$ adduct comprising the whole sequon *N*-terminal to a β -aspartate residue present in the neighbouring "*n*+1" position. We hypothesized that this $[b_n + H_2O]^+$ ion could be also formed in the low energy regime provided its genesis was not charge-remote.

Determination of the nature and the site of the modification in the hirudin isoform was performed according to the following procedure: (i) reduction of the disulfide linkages with dithiothreitol (DTT) followed by alkylation of the free SH groups with 4-vinylpyridine, (ii) enzymatic digestion of the HPLC-purified pyridylethyl (PE) derivatives with Glu-C, (iii) identification of the modified peptide by ESIMS and rp-HPLC mapping, (iv) subdigestion of the HPLC-isolated peptides [18-35] with trypsin and (v) ESIMS/MS sequencing of the selected "subpeptides" [28-35]. The tandem mass spectrum (Fig. 1b) of the modified peptide [28-35] exhibits, when compared with that of the unmodified peptide [28-35] derived from rHV1 (Fig. 1a), an additional ion at *m/z* 597. This signal corresponds to the expected $[b_5 + H_2O]^+$ ion, which is indicating a β -aspartate in position 6 of peptide [28-35] and, hence, β -Asp33 in the rHV1 isoform.

The formation of $[b_n + H_2O]^+$ requires net OH migration from the side-chain carboxyl group of the β -Asp residue to a neighboring amide carbonyl function. In analogy to an overall mechanistic scheme for its high-energy genesis, we propose the charge-triggered mechanism depicted in scheme 2. In order to probe this as yet unsupported genesis of $[b_n + H_2O]^+$ ions at least with respect to the origin of the "migrating" oxygen atom, the side-chain COOH group of Asp33 as the most likely site of origin was singly ^{18}O -labelled both in rHV1 and β -Asp33rHV1. Both species were obtained by ring-opening of the Asp33-*anhydro*-hirudin under mildly basic conditions in $H_2^{18}O$ solution (cf. Scheme 1 and Ref. 3). When subjected to the above twofold enzymatic degradation scheme, these substrates yielded the required ^{18}O -labelled [28-35]-octapeptides. The MSMS spectrum (Fig. 1d) of the β -Asp isomer provides clear-cut evidence for the suspected transfer of one of the carboxyl oxygens in the Asp side chain to the adjacent serine residue, in that the $[b_5 + H_2O]^+$ is now split in a near 1:1 ratio into the 2 expected components *m/z* 597 and *m/z* 599. In contrast, a mechanistically probably similar process, namely the expulsion of the C-terminal amino-acid with comparable OH-transfer, is preceded by considerable ^{18}O exchange.⁴

The reported findings show that, in analogy to the high energy variety, also low energy CID is suited for distinguishing regular α -Asp from rearranged β -Asp isoforms, by the regiospecific formation of a singular $[b_n + H_2O]^+$ ion. Confirmatory results from ^{18}O -labeling of the suspected migratory oxygen atom (β -Asp33-CO ^{18}OH) together with the low energy genesis suggest a specific charge-triggered rather than charge-remote mechanism for the formation of the ion, in analogy to the well established, stoichiometrically equivalent expulsion of the C-terminal amino acid residue.⁴

A Study of Side-chain Involvement in CAD of tris(trimethoxyphenyl)phosphonium Derivatized Peptides

Kenneth D. W. Roth,[†] Zhi-Heng Huang,[‡] and J. Throck Watson[†]

Departments of Chemistry[†] and Biochemistry,[‡] Michigan State University, E. Lansing MI 48824

Charged derivatives are effective in simplifying the FAB-CAD-MS/MS spectra of peptides. An aliquot of a reaction mixture containing 50-100 pmol of a tris(2,4,6-trimethoxyphenyl)phosphonium-acetyl (TMPP-Ac) derivatized peptide (1) is usually sufficient to obtain a high-quality CAD product ion spectrum. The CAD spectra of 20 TMPP-derivatized peptides were analyzed to determine the effects different residues have on the intensities of N-terminal fragment ions. The CAD spectra of TMPP-Ac derivatized peptides are dominated by a complete series of a-type ions, although a-type ions of glycine are of weaker intensity than those of other residues. The strong a-type ion series makes sequence confirmation of the derivatized peptides much simpler than interpretation of the variety of ions (of often incomplete series) obtained during CAD of underivatized peptides. The d-type ions are typically observed for most non-aromatic residues. The presence or absence of c-type ions is dependent on the residue on the C-terminal side of the site of cleavage with serine and threonine giving the most intense peaks. Ions of the b-type are rarely observed, and C-terminal fragment ions are not observed.

A number of less common fragment ions are also observed in the CAD spectra. Fragments were observed 14, 30, and 46 mass units lower than the masses of strong a-type ions. These fragments are presumed to be the result of a-type fragmentation combined with losses from the TMPP group. Loss of the TMPP head group, yielding C⁺-532 ions, was observed for peptides with basic residues near the N-terminus. Loss of the C-terminal residue was observed for peptides with a basic residue at the C-terminus.

Although most amino acids have only one carboxylic acid group for peptide bond formation, acidic residues (aspartic acid and glutamic acid) can form peptide bonds through the α -carboxylic acid group (like most amino acids) or through the side chain carboxylic acid group. By conventional methodology, side-chain-linked acidic residues (β -aspartic acid and γ -glutamic acid) can be difficult to distinguish from normal α -linked residues. TMPP-Ac derivatization is helpful in identifying peptides containing side-chain-linked acidic residues. Peptides containing a side-chain-linked amino acid were derivatized and analyzed by FAB-CAD-MS/MS. Analogous peptides containing α -linked residues were also analyzed (Figure 1). The peptide pairs can be distinguished by the ratio of the intensities of the b-type ion peak to that of the peak appearing 28 mass units below the b-type ion [$I(b)/I(b-28)$] for the acidic residue in question. For all peptide pairs, the [$I(b)/I(b-28)$] ratio was larger for the side-chain-linked peptide than for the α -linked peptide. For most of the peptides containing α -linked residues, [$I(b)/I(b-28)$] < 1.0, while for most of the side-chain-linked-peptides [$I(b)/I(b-28)$] > 1.0. This method of identifying side-chain-linked peptides was found to be more reliable than a similar method using underivatized peptides (2).

BINDING OF Cu(II) IN DOUBLY CHARGED IONS OF ANGIOTENSIN II FORMED BY ELECTROSPRAY IONIZATION

M. Cameron Sullards and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to elucidate the Cu(II) binding site in the $(M + Cu)^{2+}$ ions of angiotensin II. Effects of modifying amino acid side chains on decompositions of the $(M + Cu)^{2+}$ complexes of angiotensin II were determined. MS² B/E and MIKES experiments, as well as MS³ B/E and MIKES experiments, were performed using electrospray ionization (ESI) and a JEOL JMS-SX102/SX102A/E five-sector, tandem mass spectrometer.

The MS² B/E spectrum of the $(M + Cu)^{2+}$ ions of ang II reveal abundant loss of CO₂ primarily from the C-terminus (Figure 1a). Both loss of C₇H₆O from the tyrosine side chain and $(b_6 + Cu - H)^{2+}$ ions are observed. The $(b_6 + Me - H)^{2+}$ ions are also formed from complexes of Co²⁺, Ni²⁺, and Zn²⁺ and ang II.^{1,2} The MS³ B/E spectrum of the $(M + Cu - CO_2)^{2+}$ ions reveal highly abundant doubly charged product ions (Figure 1b). ¹⁸O labeling of the peptide demonstrates that the additional doubly charged product ions are in fact a-type ions, not $(b_6 + Me + OH)^{2+}$ ions as previously suspected.¹ Additionally, both first- and second-generation doubly charged product ions arise via cleavages in proximity to the His residue.

Modification of amino acid side chains and subsequent MS² and MS³ experiments are used to reveal which sites are involved in metal ion binding. The MS³ B/E spectrum of $(M + Cu - CO_2)^{2+}$ ions of Gly⁷-ang II show no differences in the product ions (Figure 2a). The MS³ B/E spectrum of $(M + Cu - CO_2)^{2+}$ ions of Gly⁶-ang II, however, reveal some significant product ion differences (Figure 2b). Both the $(b_6 + Cu - H)^{2+}$ and the $(a_6 + Cu + H)^{2+}$ ions are no longer observed. The loss of C₇H₆O from the tyrosine side chain remains a major product ion regardless of side chain modification.

Decompositions of tetra- and larger peptide-metal ion complexes reveal the intrinsically favored binding interactions.^{3,4} Metastable ion decompositions show low-energy reacting configurations of the metal ion-peptide complexes.³ In the complexes, cleavages occur in immediate proximity to the metal ion binding site.⁴ The resulting product ions contain the intact metal ion binding site chelate structure.⁴ Furthermore, MS³ experiments can be used to observe dissociation pathways and further elucidate the metal ion binding site.⁵

All complexes formed between ang II and Cu(II) dissociate primarily by CO₂ loss from the C-terminus, not the Asp side chain. Further, all complexes formed between ang II and Cu(II) lose the Tyr side chain. MS² and MS³ experiments reveal that product ions contain Cu(II) remote from the C-terminus. Substitution of the His side chain has the greatest effect on product ions observed. Thus, the His side chain is the most likely site for Cu(II) binding in complexes of ang II.

Interpretation of Peptide Fragment Ion Intensities for a Series of D- and L- Amino Acid Isomers
 David R. Goodlett, David C. Gale, Jonathan B. Crowther, and Tarit Mukherjee
 Goodlett Scientific, Seattle WA 98117
 Finnigan MAT, San Jose CA 95134
 Immunobiology Research Institute, Annandale NJ 08801

Mass spectrometric techniques have been utilized with great success in determining the sequence of small peptides. Prediction of which fragment ions will be observed and the intensity of those ions is not straightforward. Several generalizations about peptide fragmentation can be made. It is generally accepted that in the positive ion mode, the basicity of amino acid side chains can affect the degree to which fragment ions are observed. Peptides containing arginine at or near the amino terminus will exhibit a series of b-type fragment ions. Lack of a basic residue near the carboxyl terminus results in a CID spectrum with few observable y-type ions. In addition to the effects of side chain basicity on fragmentation patterns, the increased basicity of the imide bond of proline over amide bonds produces a facile cleavage site.

For this study, six isomers with the primary sequence, Arg-Lys-Asp-Val-Tyr, were examined by collision induced dissociation (CID). One isomer was the natural peptide with all L-amino acids (TP5). Five of the six peptides had a single substitution of a D- for an L-amino acid. The peptides were: D-Arg-TP5, D-Lys-TP5, D-Asp-TP5, D-Val-TP5 and D-Tyr-TP5. All were introduced into an electrospray ionization source by direct infusion at 3 μ L/min in an acidic solution. Peptide concentrations were 1.5 pmole/mL. Low energy CID spectra were obtained on a Finnigan MAT triple quadrupole (TSQ 7000) and a Finnigan MAT ion trap (LCQ) mass spectrometer. Generally CID spectra were averaged for 1 minute. Collision energies were optimized for each of four sets of experiments: CID of 1+ ion (680.5) on TSQ, CID of 2+ ion (340.8) on TSQ, CID of 1+ ion (680.5) on LCQ and CID of 2+ ion (340.8) on LCQ. The goal of this study was to determine if known structural differences between isomers would produce CID spectra with observable differences in the intensity of common fragment ions such as b_3 (400.3) and b_4 (499.3). Fewer immonium ions were observed in the ion trap CID data compared to the triple quadrupole CID data. In addition, it was generally observed that the ion trap data was less complex in the number and type of fragment ions observed compared the triple quadrupole CID data.

A graphical comparison the ratio of the observed intensity of b_3/b_4 ions in each isomer was calculated and all these values normalized to the same value for the all L-TP5. Shown in Figures 1 and 2 are the CID mass spectra for the 1+ charge state of the peptides acquired by the triple quadrupole mass spectrometer and ion trap mass spectrometer, respectively. The 1+ CID data on both instruments showed differences in the tendency to form b_3 and b_4 when D-amino acids were substituted for certain L-amino acids. The 2+ CID data on both instruments showed little difference between isomers.

Analysis of bacteriorhodopsin cleavage fragments by HPLC-ESI-MS and MS/MS.

M. Busman, J. Wang, L.B. Cowden, J.E. Oatis Jr., N. Chen, R.K. Crouch, D.R. Knapp. Departments of Pharmacology and Ophthalmology, Medical University of South Carolina, Charleston, SC. 29425

Introduction. In the past, structural analysis of membrane proteins by mass spectrometry (MS) has been problematic. (1) One of the sources of difficulty in MS analyses of such proteins, or, more commonly, in the analysis of the products of the cleavages (chemical or enzymatic) of such proteins has been their limited solubility in conditions commonly used for high performance liquid chromatography (HPLC) separations. The goal of this work is to provide a method for analyzing cleavage fragments of membrane proteins by mass spectrometry (MS) and tandem MS to determine sequence, post-translational modifications and experimentally introduced chemical modifications.

Experimental. Sample preparation. Wild type bacteriorhodopsin (BR) was isolated and purified from purple membranes as previously described. (2) Proteins were cleaved with cyanogen bromide (CNBr) in 75% trifluoroacetic acid (TFA). The mutant forms of BR have cysteine replacement for threonine at position 121, in the case of T121-C, or for methionine at position 145, in the case of M145-C. Prior to removal from the membranes, the cysteine residues of the mutant proteins were alkylated with 4-vinylpyridine in the presence of tributylphosphine. **HPLC.** The cleavage fragments were separated by HPLC on butyl columns (Brownlee Aquapore, 30 x 2.1 mm) using a 2% to 98% gradient of 2:1 (v/v) isopropanol/acetonitrile (0.07% TFA) in 0.1% aqueous TFA. Samples (~0.15 mg total peptide) were loaded on to the HPLC column dissolved in 5 mL of the initial condition mobile phase (98/2 aqueous/organic).

MS. FAB. FAB spectra were acquired on a JEOL HX110/HX110 mass spectrometer. Ions were generated with a Xe gun from samples dissolved in a matrix of 3-nitrobenzyl alcohol-glycerol (1/1). **ESI.** A portion (approximately 1:10 split) of the HPLC effluent was directed to the electrospray ionization (ESI) source fitted to the JEOL HX110/HX110 mass spectrometer or to the ESI source of a SCIEX API-III triple quadrupole mass spectrometer.

Results. Preparation. The crude mixture from the CNBr cleavage of wild type BR was analyzed by FAB-MS. The spectra for the peptide mixture are shown in Figure 1. **HPLC.** The HPLC conditions used provide for an effective separation of cleavage mixtures. Figure 2 shows a chromatogram for a separation of wild type BR CNBr products monitored at 214 nm. **LC-MS.** The HPLC of the separation of the wild type BR cleavage peptides was monitored by ESI-MS. Peptides covering the entire protein sequence were detected. Only a fraction of the HPLC flow was used, allowing the remaining flow to be collected for other studies. Figure 3 shows extracted ion chromatograms for the peptides from the full scan data acquired during the chromatographic separation of the cleavage mixture. Chromatograms are shown for all CNBr fragments except #4 (MW 465 Da.) which was below the MS scan range utilized for the LC-MS experiment. **Analysis of mutant forms of BR.** Similar FAB and LC-MS data is obtained allowing identification of sites of mutation. **MS/MS.** Collected fractions were electrosprayed allowing CID-MS/MS experiments to be performed. Results of the MS/MS experiments provided some sequence information for many of the peptides.

Conclusions. The ability to separate and analyze CNBr cleavage fragments of a membrane protein by online HPLC-MS represents an advance in methodology for study of the structures of vision related integral membrane proteins. In particular, the ability to combine HPLC separations with tandem mass spectrometry provides a method for rapidly acquiring structural

information using small quantities of protein. Furthermore, this method provides a convenient technique for evaluating results of covalent crosslinking experiments currently being conducted with the bacteriorhodopsin model.

Stable Isotope Dilution Mass Spectrometry of the Bradykinin Metabolites RPP, PRRG and RPPGF Using ESI-MS

JJ Vrbancac¹ and DJ Staples²

Drug Metabolism Research¹ and Biochemistry²
Pharmacia and Upjohn, Inc., Kalamazoo, MI 49001

Bradykinin (BK) is an extremely potent vasodilator peptide hormone which is a product of the kallikrein-kinin system. BK is cleaved from high molecular weight kininogen by kallikrein or is formed by removal of the N-terminal lysine from lysyl-BK (also a potent vasodilator). This nonapeptide (RPPGFSPFR) has a very short half-life in blood; on the order of 16-20 seconds (1,2). BK is extensively metabolized by the lung and 80-95% of BK is metabolized in one pass through the lungs (1-4). Obviously, direct determination of BK as an indicator of the function(s) of this molecule in mammalian physiology and in disease states is wrought with problems, given the very short half life. In fact, direct determination of this hormone as a measure of some physiological or pathological state has usually proved to be unproductive (5).

Significance. Often a specific metabolic end product(s) of a biologically active endogenous molecule is an indicator of the production/turnover of the molecule. For example, the highly potent locally acting vasoactive eicosanoids PGI₂ and TXB₂ both have very short half-lives in plasma, are generally thought to be locally acting, and are extremely difficult to measure directly. However, metabolic products of each eicosanoid are present in urine and plasma and the concentrations of these compounds is used as an index of the production of these locally acting hormones. The identification of metabolites of BK in urine and/or plasma *in vivo* is a directly analogous situation and the ability to quantitate BK metabolites would be an extremely valuable avenue to gain information as to the role of BK and the kallikrein-kinin system in pathologic states (e.g., septic shock, inflammatory disorders, hypertension, etc.).

Experimental. Synthesis: Internal standards (labeled with ²H₇-proline) were synthesized by standard BOC chemistry; HF cleavage; purified by reverse-phase HPLC; characterized by HPLC-ESI-MS-MS. Sample and Preparation: Urine made 2% with HFBA. ODS adsorption on 3 mL SPE (ODS) cartridges, wash with 1% HFBA, sequential elution with one volume of 10%, 15%, 20% and 50% acetonitrile in water. MS Instrument: Tandem quadrupole mass spectrometer with ESI (TSQ-700, Finnigan MAT, San Jose, CA). Argon collision gas. E_{lab} -20. Chromatography: HP 1050; 2x150 mm Kromacil C-18; 0.3 mL/min, water and TFA with 0.1% TFA; 0.3 mL/min; 98% water for 0.5 min, gradient to 50% at 5 min and 40% at 10 min, return to 98% for 5 min.

Results. Conditions were developed to enable elution of all three analytes within 10 minutes. RPP exhibited tailing and a divided peak under these conditions. Peak heights were used for quantitation. The product ion mass spectra of labeled RPP is displayed below. The B₁ ion dominated the low energy product ion spectrum of RPP and RPPG and was the base peak for RPPGF. This ion also exhibited an ion current that varied only approximately 50% from E_{lab} values of -15 to -25 volts and this ion was monitored as the product ion for all 3 analytes in SRM experiments. The stable labeled internal standards resulted in a linear standard curve over 2 orders of magnitude. However, urinary concentrations of RPP, RPPG and RPPGF were the below the LLOQ (10 ng/mL). SIM did not provide the necessary selectivity to quantitate the analytes. SRM provided selectivity, however, was observed to be far less sensitive. Below are displayed the SRM traces obtained for blank urine and [²H₇]RPPGF (20 mL extracted). The peak area ratio observed was slightly above that observed for [²H₇]RPPGF alone. This contribution represents either an endogenous interference or RPPGF at a concentration of less than 1 ng/mL.

STRUCTURE ELUCIDATION OF OAT PHYTOCHROME A

Xiangyu Jiang, Veniamin N. Lapko, Pill-Soon Song and David L. Smith
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304

Amino acid sequences for many proteins are encoded in multiple genes that differ in only a few places. The extent to which these genes are expressed at various times during development is determined most directly from the levels of each of the protein forms found in the cell. For example, at least four genes have been identified to code for phytochrome A¹, a plant receptor that controls the light dependent development of plants. Phytochrome A is a very large homodimer composed of 1128 residues. The entire amino acid sequences of two phytochrome isoforms (A3 and A4), as well as a partial sequence (residues 1-494) for a third one (A5) are known from cDNA sequencing. The goal of this study has been to develop a method based on peptide mapping and electrospray ionization mass spectrometry for determining the levels of expression of genes encoding for the three phytochrome isoforms. The C-terminal sequence of phytochrome isoform A5 and the sites of post-translational modification were also elucidated.

Phytochrome A, isolated from etiolated oat seedlings², was derivatized with iodoacetamide and digested with trypsin. The peptides were analyzed by electrospray and fast atom bombardment ionization mass spectrometry following fractionation by gel filtration chromatography (Bio-gel P-6) and reversed phase HPLC. Molecular weights corresponding to peptides expected from all parts of the sequences of A3 and A4 were found, thereby confirming the cDNA results. Peptides from the known portion of A5 confirmed that A5 differs from A3 at only 3 residues in the region 1-494. The identities of all of the tryptic peptides were confirmed by determination of the molecular weight of peptides formed by subdigestion with pepsin, Asp-N, Glu-C or chymotrypsin, or by examination of the fragments produced by collision activation (MS/MS) using a Fisons VG Autospec mass spectrometer equipped with an oaTOF analyzer.

The expression levels of the genes for A3, A4 and A5 were determined from the relative abundance of tryptic peptides derived from regions in which the amino acid sequences of the phytochromes differed at only one residue. The amino acid sequence in the 426-444 segment is identical for A3, A4 and A5 except for residue 436 in each isoform. Threonine, alanine and asparagine were found at this position for A3, A4 and A5, respectively. ESI MS of combined fractions containing these peptides showed that the approximate ratio of A5, A3 and A4 is 55:30:15 (Fig. 1). Isoforms A3, A4 and A5 have a tryptic peptide with a molecular weight of 3228 for the region 91-120. Another peptide was found with a molecular weight of 3244 that differed only by substitution of Asp for Val at position 115. The ratio of the UV absorbance of these peaks indicated that the abundance of the peptide with molecular weight 3244 is approximately 12-15% of the total phytochrome A.

Further peptide analysis indicated that the C-terminus of A5 was the same as A3 except in two regions. A substitution of Cys for Tyr at 495 and Ala for Ser at 779 were identified. These studies showed that the two closely related isoforms (A5 and A3) represent approximately 75% of phytochrome A from etiolated oat seedlings.

In addition to acetylation of the N-terminal Ser, a post-translational phosphorylation of oat phytochrome A was found. We showed previously that oat phytochrome A contained approximately 0.4 mole phosphate per mole of protein and that the phosphate could be removed by treatment with alkaline phosphatase. Analysis of tryptic digest of phytochrome A

demonstrated the presence of both the expected N-terminal peptide with M W. 1237 and a peptide with M W. 1317. The 80 u increase is indicative of phosphorylation. Alkaline phosphatase treatment of the phosphorylated peptide produced a peptide with M W. 1237, confirming the phosphorylation. Amino acid analysis indicated a composition of Ser₆Arg₂Ala₁Pro₁ consistent with the N-terminal sequence. The identity was also confirmed by determination of the molecular weights of peptides formed by further digestion with thermolysin.

SELECTIVE SULFUR-BOND CLEAVAGE IN THE LOW-ENERGY CID OF DISULFIDE LINKED PEPTIDES

* Ivan Haller and Brian T. Chait, The Rockefeller University, New York, NY 10021

Mass spectrometric determination of disulfide bridging patterns in multi-cystine proteins remains a significant analytical challenge. In interpreting Collision Induced Decomposition (CID) spectra of disulfide linked peptides in enzymatic digests of proteins, it is desirable to distinguish between fragments arising from peptide and disulfide bond breaks. The ultimate goal is to derive both the amino acid sequence and the disulfide pattern in a single LC/MS/MS run of an enzymatic digest of a native (un-reduced) protein.

In high energy fragmentation mass spectra (FAB, CID in sector instruments) of disulfide linked peptides, complex patterns with simultaneous peptide bond and disulfide bond fragmentations are observed.¹ Triplets marking disulfide bonds sometimes aid interpretation.² In contrast, positive ion electrospray CID spectra in a triple quadrupole instrument show only peptide bond fragmentation.

In the present work we show that in negative ion electrospray CID spectra of disulfide linked peptides in a triple quadrupole instrument, fragmentations of sulfur-sulfur and sulfur-carbon bonds predominate. The complementary pattern of the positive and negative ESI/MS/MS spectra allows easy separation in the interpretation of unknowns as to which masses arise from fragmentations of peptide bonds and which from those involving sulfur. This complementarity is well illustrated in the CID spectra of the oxidized form of glutathione, Fig. 1. In the negative ion spectrum, top frame, the dominant feature is a triplet with the center component corresponding to S-S bond cleavage and the two outer peaks corresponding to cleavage of carbon-sulfur bonds at one the 2 cystine residues. Only the weakest peaks arise from peptide bond fragmentations.

Conversely, the positive ion CID spectrum (bottom) shows series of strong peaks arising from b and y fragmentations, with essentially no peaks observed at masses that would correspond to the sulfur bond fragmentation seen in the negative ion spectrum.

Fig. 1.

In Fig. 2 we compare the negative and positive CID spectra of the disulfide linked peptide obtained in the enzymatic digestion of somatostatin: Again essentially no sulfur bond fragmentation is seen in the positive ion mode, while in the negative spectrum even the weakest components of the disulfide triplets of both the AGCK and the TFTSC fragments have comparable intensity to ions arising from peptide bond fragmentations.

From the higher resolution negative ion CID spectra shown in Fig. 3 we observe that the center component of the triplet is separated by 34 mass units from the lowest mass ion and by 32 mass units from the highest one. This requires that the mechanism involves a heterolytic cleavage accompanied by an inter- or intra-subunit transfer of hydrogen.

Our observations suggest that performing a CID experiment in both the positive and negative ion modes of a digest of a native (oxidized form) of multi-disulfide linked protein may eliminate the necessity of running a separate CID spectra on the enzymatic digest of the reduced form of the protein.

The Observation of d-Type Ions During Low Energy Collisionally Activated Decomposition of Protonated Peptide Ions.

S. G. Summerfield, K. A. Cox and S. J. Gaskell.

Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, UK.

Collisionally activated dissociation (CAD) of multiply protonated peptides is an area of diverse research for both analytical and fundamental applications. In general, the observed decompositions pathways differ significantly between the low and high collision energy regimes. Typically, low energy CAD is performed with laboratory collision energies (E_{lab}) of less than 100 eV. Charge proximal reactions along the backbone are thought to generate the common product ions b_n and y_n [1]. In high energy CAD experiments, E_{lab} is generally in excess of 1,000 eV. In this regime, additional information is observed from higher energy processes, such as side chain cleavages to form d_n and w_n ions. In many studies, the general findings have been that side chain fragmentations have a high energy requirement, thereby excluding these reactions from occurring during low energy CAD. Here we report the formation of highly favored d_n ions under low energy CAD conditions ($E_{lab} < 40$ eV). These results are understood by extending previous observations on acid-base interactions in protonated peptide ions [1].

Figure 1 compares the low energy product ion spectra of $[M+2H]^{2+}$ ions derived from RLAIFFSCFR and the oxidized analogue RLAIFFSC*FR, where C* denotes modification of cysteine to cysteic acid. Both analyses were performed under identical conditions for the target gas and collision energy (E_{lab} 30 eV). Altering the cysteine residue (C) to cysteic acid (C*) results in not only a dramatic enhancement in the fragmentation efficiency of the peptide but also results in the observation of ion at m/z 731.2, having the apparent assignment d_7 . Further mechanistic insights have been gained by studying second generation fragmentation processes, precursor ion scanning and deuterium labelling studies [2]. For these experiments fragmentation was induced in the electrospray interface using a cone potential of 50-60 V. The product ion spectrum of $(b_7-H_2SO_3)^+$, derived from the $[M+2H]^{2+}$ ion, shows a range of second generation product ions of the types a_n , b_n , a_n-NH_3 and b_n-NH_3 . There is no evidence, however, for the formation of d_7 . This is consistent with the notion that the formation of d_n ions requires the presence and interaction of the arginine and cysteic acid groups. The product ion spectrum of the source-formed b_7 ion shows that the d_7 species is the most prominent fragment. These general observations are confirmed further by a scan of the precursors for d_7 [2].

The accumulated evidence suggests that d-type ions may occur *via* further fragmentation of b_n ions (Inset to Figure 1b) or *via* a single stage dissociation of $[M+2H]^{2+}$ or $[M+H]^+$. The interaction between the cysteic acid and arginine residues promotes protonation of the peptide backbone of the peptide backbone. Recent studies by both Hunt [3] and Harrison [4] provide a compelling argument for the formation of b_n ions by nucleophilic attack of an amide carbonyl on the adjacent carbonyl moiety. Both processes ultimately lead an oxazolone structure as the end group of the b_n species. Further fragmentation of b_n to d_n is shown occurring the oxazolone structure (Inset to Figure 1b).

The Charge Remote Loss of 60 Da from Peptides Containing an Arginine Residue at the C-terminus

Michael J. Deery, Scott G. Summerfield, Armelle Buzy and Keith R. Jennings
Department of Chemistry, University of Warwick, Coventry, CV4 7AL.

In previous high and low energy MS/MS experiments of peptides which contain an arginine residue at the C-terminus, it has been shown that peaks corresponding to $(M+n\text{Cat}-60)^+$ are observed in the mass spectra.^{1,2} It is thought that this loss of 60 Da is specific to the C-terminal arginine residue. A mechanism for the formation of this fragment ion has been proposed previously by Tang and co-workers², and it was suggested that the fragment was generated by means of a charge site induced, eight step mechanism when the attached cation was an alkali metal. Losses of 42 Da and 18 were also observed and were attributed to $\text{NH}=\text{C}=\text{NH}$ from the C-terminal arginine and H_2O from the carboxylate group respectively.

This study has concentrated on the fragmentation patterns of protonated peptides (as opposed to metal cationated peptides) by means of low energy tandem mass spectrometry. All experiments were carried out in a VG Quattro II tandem quadrupole instrument, fitted with an electrospray source.

It has been found that there are several differences between the low energy MS/MS spectra obtained in this study and the spectra obtained in the experiments performed by Tang et al.

This can largely be attributed to differences in the charge species. Figure 1 shows the ESI MS/MS spectrum of singly charged lys-[ala³]-bradykinin. It can be seen that losses of 60, 42 and 17 are the main high mass fragment ions ($(M+H-18)^+$ is also observed although it is less intense and partially obscured by the larger $(M+H-17)^+$ fragment). However, no such fragment ions are observed in the MS/MS mass spectrum of the $(M+2H)^{2+}$ precursor ion, suggesting that the mechanism of formation of the fragment ions are specific to singly protonated peptides. In order to gain a greater understanding of the mechanism, a precursor in scan of the $(M+H-60)^+$ ion was acquired. The resulting spectrum (Figure 2) shows three clear peaks corresponding to $(M+H)^+$, $(M+H-18)^+$ and $(M+H-42)^+$ which indicate the parent ions of the $(M+H-60)^+$ ion. It is therefore likely that the mechanism involves the initial loss of water followed by the loss of the neutral species of mass 42, or *vice versa*. The charge site induced mechanism previously proposed suggested that there is an initial interaction between the cation, the carboxylate carbonyl oxygen and a nitrogen attached to the arginine side chain. There then follows a rearrangement resulting in the expulsion of water and the formation of a stable six membered ring. Finally, $\text{NH}=\text{C}=\text{NH}$ is expelled from the arginine side chain to give an overall loss of 60 Da. There is no reason to doubt that the loss of 42 originates from the arginine side chain, although it may actually precede the loss of water. A charge remote mechanism is therefore proposed (Scheme 1) which is consistent with the spectra obtained in Figures 1 and 2. For singly protonated peptides, it is thought that the proton is bound to a site remote from the C-terminus. In the case of lys-[ala³]-bradykinin this site is probably the arginine or lysine residues situated towards the N-terminus. When a second proton is attached to the peptide, the most likely site of attachment is the arginine residue at the C-terminus. Hence, instead of the doubly protonated precursor ion undergoing the loss of 60 Da, NH_3 is lost from the arginine side chain. This is a reasonable explanation for the fact that loss of 60 is observed only from the singly protonated precursor ion and not the doubly protonated species.

**Novel Peptide Dissociation: Gas Phase Intramolecular
Rearrangement of Internal Amino Acid Residues**

Richard W. Vachet, Barney M. Bishop, Bruce W. Erickson, and Gary L. Glush
Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290

Introduction: Due to the longer experimental time frames available, dissociations that are not seen in other instruments can be observed in the quadrupole ion trap. Of particular interest are dissociation reactions, such as rearrangements, that benefit from longer reaction times. Rearrangement reactions can often make interpretation of MS/MS spectra difficult by providing confusing or contradictory information about the structure of the ion of interest.

In the course of examining the dissociation pathways of peptide ions in the quadrupole ion trap, unusual dissociation product ions were observed in a number of peptides. The MSⁿ capability of the ion trap has facilitated the elucidation of these unique rearrangement processes.

Experimental: Experiments were performed on a modified Finnigan MAT ITMSTM fitted for electrospray. Peptides were dissolved in a mixture of 20:75:5 water:methanol:acetic acid to a concentration of 250 μ M. The peptides YGGFL, YGGFLR, VGVAPG, and RPPGFSPF were purchased from Sigma Chemical Company. All other peptides were synthesized in house. Sector experiments were performed on a Finnigan MAT 900 double-focussing mass spectrometer using FAB ionization.

Results and Discussion: MS/MS experiments carried out on YGGFL in the presence of a small percentage of xenon revealed a peak at m/z 323 that was not present in the MS/MS spectrum with helium alone. After further experimentation it was found that the ion at m/z 323 was the main product ion in the MS³ spectrum of the a_4 ion of YGGFL under normal conditions. There is no obvious structural feature that would lead to a loss of 74 Da to form m/z 323. One possibility is the loss of 17 Da combined with a loss of a Gly residue (57 Da). This loss, however, seemed unlikely because the Gly residues are internal residues. MS³ on the a_4 ion of peptides where the 3rd residue (Gly) was replaced (YGSFL, YGPFL, YGLFL, YGWFL) also showed a product ion at m/z 323. These results suggested that the formation of the ion at m/z 323 from the a_4 ion occurred by a loss of 17 Da and loss of the 3rd residue. H-D exchange experiments and MS³ on the a_4 ion of FGGFL revealed that the loss of 17 Da was NH₃. The formation of the rearrangement product ion seems to benefit from the extended experimental time frame available for reactions in the quadrupole ion trap. MS/MS on a source generated a_4 ion of YGGFL in a sector instrument does not show the rearranged product ion. The following peptides formed 4 residue immonium ions that subsequently underwent rearrangement to form a product ion in an analogous manner to YGGFL: YGSFL, YGPFL, YGLFL, YGWFL, FGGYL, FGGFL, YGGFL, YGGFLR, VGVAPG, LGGFL, and LGGAL.

Mechanism: MS³ experiments performed at the threshold of dissociation suggest that the loss of NH₃ from the a_4 ion of YGGFL is the lowest energy dissociation pathway. MS⁴ on the a_4 -17 ion results in the rearranged product ion (m/z 323) being the most abundant product ion. These results suggest that the rearrangement reaction occurs with a loss of NH₃ followed subsequently by the loss of the 3rd residue in the 4 residue immonium ion. Figure 1 depicts the proposed mechanism of this rearrangement reaction. To help verify this mechanism the N-terminus of the peptide FGGFL was acetylated. MS³ on the acetylated a_4 ion of FGGFL fails to show the rearrangement ion. Also the 4 residue immonium ion PPGF produced from RPPGFSPF failed to dissociate to the expected rearrangement ion. In both cases (Ac-FGGFL, PPGF) the amine on the N-terminus is no longer a primary amine. The rearrangement reaction in these cases is prevented by steric interferences. MS⁴ on the a_4 -17 ion of YGGFL is consistent with the structure of m/z 380 in figure 1. MS⁴ on m/z 323

and MS⁵ on m/z 295 are also consistent with their proposed structures.

Conclusions: Due to the kinetics of CID in the ion trap, it is possible for ions to undergo intramolecular reactions that result in unique dissociation product ions. In the case outlined here, the incipient ion in the rearrangement reaction seems to be a 4 residue immonium ion (a_4 or internal fragment ion). The reaction seems to be driven by the transfer of a proton from the immonium nitrogen to the more basic primary amine on the N-terminus of the peptides. This proton transfer leads to a loss of NH₃ and subsequent cyclization which reopens exposing an internal residue on the terminus of the peptide. This residue is then readily lost, and without previous knowledge of the sequence of this peptide, this ion could be mistaken for an a_3 -17 ion, since a_3 -17 ions are common in ion trap MS/MS spectra. It is clear that a better understanding of the dissociation processes of peptide ions in the quadrupole ion trap is needed to accurately provide structural information for peptides.

HIGH SENSITIVITY MS/MS AND MALDI ON A TANDEM 4-SECTOR INSTRUMENT WITH A SCANNING CCD ARRAY DETECTOR

Jeffrey W. Finch¹, Sato Miki¹, Kumar Koli², Shou M. He², and Ron Orlando²

¹JEOL USA Inc., 11 Dearborn Rd., Peabody, MA 01960, ²CCRC, University of Georgia, 220 Riverbend Rd., Athens, GA 30602

Introduction: Static integrating array detectors used in conjunction with four-sector tandem instruments have proven to be effective in significantly increasing sensitivity for acquiring high-energy CID MS/MS data of biomolecules over standard point detection[1,2]. However, the complex nature of these systems (additional dispersive ion optics, magnet stepping control, etc.) are significant disadvantages to obtaining MS/MS spectra on a routine basis.

More recently, scanning array detectors based on charge-coupled devices (CCDs) have been placed on MS2 of four-sector instruments with the goal of improving MS/MS sensitivity while maintaining the simplicity of operating the magnet of MS2 in a scanning mode [3,4]. A new commercially-available scanning CCD array detector, developed for the JEOL line of sector mass spectrometers, has demonstrated increased sensitivity by a factor of 50 or more over the standard point detector [5]. In the current study presented here, application of the scanning CCD array detector is extended by placing the detector at MS2 of a JEOL SX102/102A four-sector tandem instrument. A direct comparison of sensitivity for point detection versus CCD array detection is made for high energy CID MS/MS data of peptides acquired using a static FAB probe, and data is presented for tryptic peptides of β B1 crystallin protein isolated from a human lens. Furthermore, MALDI MS and MS/MS data is presented to demonstrate the capabilities of combining a MALDI source with the tandem instrument for biomolecule analysis.

Methods: The point detector at MS2 of the SX102/SX102A reverse-geometry (BEBE) tandem instrument was replaced with a CCD array detector (JUS-CCD). As the magnet current is scanned exponentially from high mass to low mass, the ion images are "tracked" across the detector by operating the CCD in *time delayed integration (TDI) mode*, where the speed at which charge is shifted across the array is synchronized with the speed of the ion image as it travels across the focal plane. MS1 and MS2 was calibrated with an alkali salt mix, and data was processed using a JEOL Complement Data System running on a Hewlett Packard 32 bit workstation. Tryptic peptides from β B1 crystallin protein were prepared from the water soluble fraction of a homogenized normal human lens. The β -crystallin fraction was isolated (gel filtration) and then β B1 was separated by reversed-phase chromatography. After digestion with TPCK-treated trypsin, the peptide mixture was analyzed using LC/MS where 90% of the column effluent was split and collected in fractions for MS/MS analysis. 1-2 μ L of sample was mixed on the FAB probe tip with 1-2 μ L of a matrix consisting of 1 part thioglycerol/NBA (1:1) mixed with 1 part glycerol w/ 5% TFA. For MALDI, the FAB gun of either MS1 or MS2 was replaced with the lens stack of a MALDI source (JUS-MALDI) and DHB matrix was used.

Results and Conclusions: Figure 1 shows static FAB high energy CID MS/MS data of renin substrate comparing point detection to CCD array detection for 10 keV collisions with He (collision cell at GND potential). The data clearly illustrates a factor of 50 improvement in sensitivity for CCD array detection over the standard point detector. The static FAB MS/MS spectrum of the tryptic peptide GEMFILEK from human β B1 crystallin is shown in Figure 2. The fragment ion series allows unambiguous confirmation of the sequence of this peptide, which contains -Ile-Leu- in the sequence. Due to the integrating nature of the scanning array detector, MALDI MS and MALDI MS/MS data can be acquired even though the ion beam is intermittent with each laser pulse. Figure 3 shows a MALDI MS spectrum

for renin substrate tetradecapeptide obtained using the MS2 ion source with a single magnet scan. In this case, the MS2 ion source was calibrated in FAB mode four days prior to obtaining the MALDI spectrum, which demonstrates that external calibration is stable and that good mass accuracy can be achieved.

Protein Identification by 2D Gel Electrophoresis Combined with Image Analysis, Capillary LC-MS and Tandem MS: Applications

David Arnott and John T. Stults

Genentech, Inc., 460 Point San Bruno Blvd., South San Francisco, CA 94080

The dramatic expansion of protein and DNA databases as genome sequencing efforts proceed has created a need for techniques which relate genomic sequence with expressed proteins. One powerful tool for mapping proteins is two dimensional gel electrophoresis (2D PAGE). Proteins from cell extracts can be resolved by charge and size to produce a pattern of >1000 spots. The position and abundance of each protein can be catalogued and comparisons made among tissue types, disease states, etc. The identification of individual proteins is accomplished by *in situ* reduction/alkylation/digestion followed by MS analysis of the resulting peptides. Peptide masses and MS/MS data are used to search protein or DNA databases. This approach is being used to study heart disease and signal transduction.

2D PAGE was performed using the Pharmacia Multiphor II system according to the manufacturer's instructions. Proteins in O'Farrell's sample buffer¹ were loaded at the acidic end of immobilized pH gradient gel strips (18 cm, pH 4-7 or 3-10) and focussed to 42000 Volt-hours. The gel strips were then applied to SDS-PAGE gels (245x180x0.5mm, 12-14%T) and run at a constant current of 35 mA. Gels used for image analysis were stained by the method of Heukeshoven and Dernick as modified by Rabillaud². Silver stained gels were digitized, and the images analyzed using BiImage 2D software. Spots were detected, quantitated, and matched across a set of gels. Questions were posed to the computer to find spots which significantly change intensity among gels using statistical methods.

Proteins were digested *in situ* with proteolytic enzymes. Gels to be used for digestion were silver stained according to Blum as described by Rabillaud², but without formaldehyde in the silver deposition step; this protocol was chosen to avoid a glutaraldehyde fixing step, incompatible with subsequent digestion. In-gel digestion was performed as per Schvenko et al³. Spots of interest were excised, reduced with DTT, alkylated with iodoacetic acid, and dehydrated. The gel spots were reswollen with digest buffer and incubated at 37 °C overnight. Peptides were extracted with washes of 50% MeCN/5% formic acid. The extracts were concentrated on a speed-vac, and diluted to 10 µL with 1% HOAc.

Samples were analyzed using a Finnigan LCQ ion trap mass spectrometer with an ESI ion source. Samples were introduced by capillary HPLC. RP microcolumns with 75 µm i.d. were packed with 15 cm of POROS R2 10 µm beads. Samples were loaded hydrostatically and eluted with a 15 min. gradient of 0 - 60% MeCN in 0.1 M HOAc at flow rates of 250 nL/min. Ionization was assisted with a coaxial liquid sheath of 70% MeOH at 1.5 µL/min. The LCQ was operated in three scan modes: full mass range, narrow range with high resolution (zoom scan) and MS-MS. Scans were sometimes linked together under computer control, so that ions in the full range scan were automatically subjected to zoom scan or collision induced dissociation. High quality CAD spectra were obtained from 10 fmol of peptides loaded onto the column. Peptide MW and sequences were generated from the MS data and used to search protein and DNA databases using the FRAGFIT program. When sequence data is included, a unique match is often obtained from a single peptide.

2D PAGE was used to examine protein expression upon drug treatment of rat neonatal cardiac myocytes. The enlargement (hypertrophy) of heart cells in congestive heart disease can be modeled *in vitro* by treating neonatal rat cardiac myocytes with phenylephrine.

Proteins were extracted from cells cultured with and without phenylephrine. 2D gels were run and silver stained. Image analysis revealed a set of spots which changed abundance by at least 50% upon treatment, and were shown to differ quantitatively at the 95% confidence level by a T-test. Identification of these proteins is currently under way. The most prominent change is in expression of the myosin light chain I, atrial isoform. This protein has previously been associated with cardiac hypertrophy by molecular biology techniques⁴.

A second application is the examination of post-translational modifications of proteins in the course of receptor mediated signal transduction. A cell line bearing the human growth hormone receptor was stimulated and the cytosolic proteins extracted. Phosphotyrosine-containing proteins were detected by western blotting following 2D PAGE. Such western blots can reveal proteins that undergo changes in phosphorylation state; groups of spots with the same approximate weight (in the 2nd dimension) but shifted in isoelectric point (in the 1st) likely represent the same protein with different numbers of phosphate groups. The sequence of experiments is illustrated in Fig. 1. Each spot was taken from a replicate silver stained gel, and digested with Lys-C. Ion trap MS revealed six peptides; CAD spectra of all six were obtained in a single LC-MS run under computer control (one is shown in Fig. 2). A database search identified the protein as pyruvate kinase. The same peptides were found in each spot, consistent with a single protein in three phosphorylation states.

High Sensitivity Identification of Proteins from SDS PAGE using In-Gel Digestion and MALDI-PSD

Roland S. Annan, Dean E. McNulty and Steven A. Carr
SmithKline Beecham Pharmaceuticals
King of Prussia PA 19406

MALDI TOF MS is an extremely sensitive technique, which is relatively unaffected by modest concentrations of typical biological buffers. For this reason, it is a very useful tool for protein and peptides analysis, and has become the cornerstone for MS based approaches to identifying proteins from SDS PAGE gels. The ability to analyze unfractionated protein digest mixtures allows rapid identification of gel bands, by searching peptide molecular weights against a protein database. Critical to the success of the method is complete protein digestion with few missed cleavages, and quantitative recovery of peptides. We have developed an in-gel digestion procedure that is generally applicable to the identification of sub microgram quantities of protein. Features of the method include a detergent-free digest buffer to minimize interference during analysis, and reduction and alkylation of cystine residues, prior to digestion, which is shown to improve overall recovery.

Peptide mass maps alone may not provide unambiguous protein identification even when the data quality is very high. This is especially true for small proteins or proteins which are highly post-translationally modified. For this reason we routinely acquire PSD data on as many peptides as is possible. Even short stretches of sequence information, when combined with the sequence tag approach developed by Mann (1), frequently provide unambiguous identification. Figure 1 shows the PSD spectrum of an m/z 1537.4 peptide derived from an *in-situ* tryptic digest of a 2D SDS-PAGE purified 55 kDa E.coli protein. Based on a comparison with standard proteins, we estimate the band contained 200–600 ng of protein (3–10 pmol). A MALDI mass map was recorded on the unfractionated digest. The m/z 1537 peptide was selected using an ion gate, which has a resolution of ca. 100. Peptides for PSD are chosen based on intensity,

(1) M. Mann and M. Wilm (1994) Anal. Chem., 66, 4390–4399.

molecular weight, and proximity to other peptides. The PSD spectrum was recorded in eight segments, which were stitched and calibrated under computer control. Although this spectrum contains a large number of abundant fragment ions, it was not possible to identify an extensive b_n or y_n series. Therefore, we searched the protein database using only FV as a sequence tag. The internal series P(G,D)VIFY implied that FV was a y_n series. Unfortunately, we were not able to unambiguously extend this series, even with the information provided by the internal fragments. Nevertheless, we identified this protein as ATP Synthase alpha chain (P00822). Confidence in the ID was provided by assignment of the remaining PSD fragment ions, and matching of the MALDI mass map peptides with the predicted sequence.

Although MALDI TOF MS is an extremely sensitive technique, which is relatively unaffected by modest concentrations of typical biological buffers, the level of excipients present in samples originating from the in-gel digestion of proteins at the low picomole level can sometimes be problematic. While it is frequently quite easy to record a high quality peptide mass map, a useful PSD spectrum requires a very much more intense signal. The application of additional sample to the target usually does not improve the signal, since the buffers and salts in the sample are being added in proportionally greater amounts. Additionally, for very low level samples we would like to have the entire sample present in a 1–2 μ L volume. Therefore, we have developed a simple, manual, micro-column method for sample cleanup and concentration that is rapid, and uses inexpensive, readily available laboratory supplies. The use of this micro column cleanup has improved by approx. an order of magnitude our ability to get sequence information from peptides following in-gel digestion. A gel loading pipet tip is packed with a 1.5–2.0 μ L bed of chromatographic material (Poros R2). After loading the sample, and washing away the salts, the peptides can be eluted with 1–2 μ L of appropriate solvent directly onto the sample target.

In favorable cases, or when larger amounts of sample are available, it is possible using PSD to determine extensive or complete amino acid sequences. Figure 2 shows the PSD spectrum of a peptide isolated by reverse phase HPLC from an *in situ* digest of a 30 kDa protein fragment. An estimated 2–4 picomoles of peptide was recovered following HPLC, and 1/7 of this was applied to the MALDI target (300–600 fmol). The complete sequence of this peptide was determined from this one spectrum.

SEQUENCING ISOBARIC PEPTIDES BY THE APPLICATION OF MSⁿ ANALYSIS ON AN ION TRAP MASS SPECTROMETER

Simin D. Maleknia

Corixa Corporation, 1124 Columbia Street, Suite 464, Seattle, WA 98104 U.S.A.

Introduction

Peptides of similar (within 1-2 Da) or identical molecular weight are frequently encountered in complex biological mixtures including those assembled in combinatorial libraries. The advent of electrospray ionization (ESI) coupled to a tandem mass spectrometer provides a sensitive approach for sequencing peptide components without the need to pre-purify the mixture. Ion trap instruments capable of multiple stages of ion activation and mass analysis are particularly useful in this regard. This study of isobaric peptides demonstrates the utility of a quadrupole ion trap mass spectrometer with an ESI source to identify mixtures and sequence their components.

Experimental

All experimental data were recorded on a Finnigan LCQ quadrupole ion trap mass spectrometer incorporating an electrospray ion source. All peptides were infused at a concentration of 2 μ M in 50:50 methanol : water containing 5% acetic acid. Standard operating conditions were used under automated control. Ion injection times of 50 and 150-300 msec were employed for MS² and MS³ experiments respectively.

Results & Discussion

The MS² spectrum of the $[M + 2H]^{2+}$ ions of a mixture of isobaric peptides [Glu¹]-Fibrinopeptide B and Dynorphin B is shown in Figure 1. The spectrum is dominated by both b and y-type ions including those associated with NH₃ and H₂O loss. Sufficient ions are present to sequence 65% of the [Glu¹]-Fibrinopeptide (NDNEEGFFS) and it is this peptide that is identified using PEPSEARCH (Finnigan MAT). The PEPSEARCH program, however, fails to identify the fact that Figure 1 represents a peptide mixture and Dynorphin B is not identified.

The MS³ spectrum for the y₁₁ ion (m/z 1286) of [Glu¹]-Fibrinopeptide B (Figure 2) yields a series of y-type fragments also observed in Figure 1 which serves to identify MS² fragments associated with this peptide. The MS³ spectrum for the y₇ ion of Dynorphin (Figure 3) affords fragments which provide additional sequence information for this peptide; a peptide segment with the sequence FKVVT can be deduced. This peptide is *not* present in the partial sequence obtained for [Glu¹]-Fibrinopeptide B (NDNEEGFFS). Furthermore, the sum of the residues for this sequence and that for the partial sequence obtained for [Glu¹]-Fibrinopeptide B (1611 u) exceeds that possible for a single peptide with a $[M + 2H]^{2+}$ ion at 785.8 u (monoisotopic). This suggests that the MS² spectrum of Figure 1 represents a peptide mixture, a fact not easily recognized from the MS² data alone. A data base search of the partial sequence (FVKKT) for the remaining peptide using PEPSEARCH identifies several Dynorphin precursor proteins. Similar data was presented for another mixture comprising isobaric peptides derived from the sequence of Influenza A virus nucleoprotein. A noteworthy observation (made from both sets of data) is that y-type ions of the MS² spectrum, which contain aspartic or glutamic acid residues, dissociate further (in an MS³ experiment) to yield dominant second generation y ions to the C-terminal side of these residues. This is apparent from Figure 2.

Figure 1 MS² spectrum of the $[M + 2H]^{2+}$ ions of a mixture of [Glu¹]-Fibrinopeptide B and Dynorphin B

Figure 2 MS³ spectrum for the y₁₁ ion (m/z 1286) of [Glu¹]-Fibrinopeptide B

Figure 3 MS³ spectrum for the y₇ ion of Dynorphin

Conclusions

The additional ion-activation and mass analysis capabilities of an ion trap mass spectrometer are useful for identifying the presence of peptide mixtures and the sequences of each component. It has been found that the further dissociation of y-type ions of a MS² spectrum with large m/z ratios (which represent the C-terminal portion of the intact peptide) affords the most interpretable MS³ spectra. These MS³ spectra may yield some fragments which can be correlated directly with those present in the MS² spectrum in order to associate ions derived from one component. Improvements in programs designed to interpret tandem mass spectra so that MS³ data can be accommodated, should assist mixture analysis by mass spectrometry.

An unusual fragmentation pattern in the determination of the sequence of a cyclic peptide

Pedro Domingues and A. J. Ferrer Correia

Mass Spectrometry Laboratory, Chemistry Department, Aveiro University, Portugal

INTRODUCTION

Mass spectra of most cyclic peptides suggest that protonation occurs in one of the nitrogen atom of the amide bond in a competitive way, and subsequently there is a cleavage between the protonated N and the adjacent carbonyl group. Most of the times, the linear acylium ion is fragmented by successive and competitive loss of the aminoacid residues from the C-terminal¹. However, it is possible that ring opening occurs with formation of a N-formil-immonium ions². When sequencing a cyclic peptide, it is necessary to distinguish between the sequence and the retrosequence of the peptide. The major difficulty of this task results of the possibility of fragmentation of the peptide via the C-terminus or N-terminus. However, this determination should be unequivocal if one determinates the fragmentation of the immonium ion^{2,3}. In fact, Eckart *et al.* have suggested that an ion suitable for this determination is produced by the CO loss of an acylium ion fragment or its isomeric N-formyl immonium ion, resulting in a immonium ion fragment. This ion provides a C-terminal label by the decarbonylation of the C-terminal aminoacid residue

EXPERIMENTAL

FAB mass spectra were acquired with a VG AutoSpecQ (VG Analytical Manchester, UK), used as an EBE geometry instrument. A cesium ion gun was used and the cesium beam intensity was 3 μ A at 15 kV. The applied accelerating voltage was 8 kV. The matrix used was Tioglycerol-DTT (2:1). The cyclic peptide cyclo(Trp-Asp-Pro-Val-Leu) was purchased at Bachem Feinchemikalien AG and used without any additional purification. CID and linked scan at constant B²/E were acquired using Argon as collision gas at a cell pressure that corresponded to an attenuation of the main beam to 50%.

RESULTS AND DISCUSSION

The observed fragments in the CID spectrum of the peptide cyclo(Trp-Asp-Pro-Val-Leu) were sufficient to permit the sequencing of the peptide. To distinguish the sequence from the retrosequence of the peptide we selected the ion of m/z 169.1, that results from the loss of 28 Da of the ion of m/z 197.1 (Pro-Val)⁺, and performed a CID experiment (figure 1) of this ion. In the CID experiment of the immonium ion of structure (Pro-Val - CO)⁺ we would expect to see:

- the ion that corresponds to the loss of (Pro+CO) (m/z=72 Da, structure a, scheme 1) or,
- the loss of Val (m/z=98 Da, structure b, scheme 1). The observation of one of this ions would lead to the correct assignment of the sequence.

However, the most abundant ion observed in the CID spectrum of the immonium ion is the ion m/z 70.1 which corresponds to the neutral loss of (Val+CO). The interpretation of this result (observation of structure c, scheme 2) would lead to the sequencing of this cycle peptide as cyclo(Leu-Val-Pro-Asp-Trp) and not as cyclo(Trp-Asp-Pro-Val-Leu) which is the correct sequence. Linked scan at constant B²/E of the fragment ion m/z 70.1 shows that its principal precursor ion is the ion m/z 169, with a strong contribution of the ion m/z 98.

In face of this results we suggest that ion m/z 70.1 is the result of major CO loss by the Pro ion (m/z 98), corresponding to pathway III' in scheme 2

CONCLUSIONS

This results show that, when sequencing a cyclic peptide, one should not choose an immonium ion containing an Proline residue in the N-terminal portion of the peptide, as this might suffer a major loss of CO, giving erroneous information about the sequence of the peptide.

Figure 1- CID of the ion of m/z 169.1 (Pro-Val - CO)⁺.

Surface-induced Dissociation and FTMS SORI CID Study of Disulfide Containing Peptides

Wenqing Zhong,^{a,c} Vicki H. Wysocki,^b Jean H. Futrell^c

Department of Chemistry, ^a Virginia Commonwealth University, Richmond, VA 23284-2006;

^bUniversity of Arizona, Tucson, AZ 85721; ^cUniversity of Delaware, Newark, DE 19716.

Disulfide bonds are commonly observed in native proteins. They play a very important role in the protein folding process. Determining the position of disulfide bonds is essential for understanding the secondary/tertiary structure and biological functions of proteins. The usual procedures for determination of disulfide bridges are very tedious, and involve enzymatic or chemical cleavage, followed by separation and identification of the cleaved products. Mass spectrometry has recently been used to confirm and/or locate disulfide bridges.^{1,2} Disulfide containing peptides are difficult to fragment by conventional collision-induced dissociation (CID), especially peptides containing intramolecular disulfide bonds. In this investigation, surface-induced dissociation (SID) and FTMS SORI-CID experiments were utilized to study peptides containing intra and intermolecular disulfide bonds.

SID was performed by using an Extrel 4000u tandem quadrupole mass spectrometer.³ SORI-CID experiments were performed on a Bruker 7 tesla BioAPEXTM FTMS equipped with an Analytica (Branford ST) electrospray source. Peptides investigated include oxytocin, [Thr⁴, Gly⁷]-oxytocin, isotocin, [Ala-Gly, Arg⁸]-vasopressin, [D-Pen^{2,5}]-enkephalin, [D-Pen^{2,5}, p-CI-Phe⁶]-enkephalin, Glutathione (oxidized form), CG and VTGG (sulfur bind homo dimer).

Scheme 1 is the suggested nomenclature for describing fragmentation of disulfide containing peptides. b_n -S and b_n +S represent fragment ions obtained by the cleavage of carbon-sulfur bond (A). $y_{m,n}$ and $b_{m,n}$ type ions are typical to peptides containing intermolecular disulfide bonds (B) (m is the cleavage site on one peptide chain and n is the cleavage site on the other chain and containing the intact disulfide bond).

Scheme 1 Nomenclature of intra and intermolecular disulfide containing peptide

In the oxytocin SID spectrum (Figure 1) at 50 eV, dominant y_3 and b_6 ions represent cleavage of the amide bond between the cysteine and proline residues. It is also observed that conventional fragment ions are dominant at the low collision energies (<40 eV). Ions related to the cleavage of the disulfide bond (S-S and C-S bonds) appear at the higher SID collision energy. The SID spectrum of [Thr⁴, Gly⁷]-oxytocin (Figure 2) gives a more extensive

fragmentation pattern than that of SORI-CID spectrum (not shown). On the other hand, SORI CID spectra reflect high sensitivity and high resolution.

Surface-induced dissociation and SORI-CID show promise as ion-activation techniques which could be utilized to sequence disulfide containing peptides and locate the disulfide bonds. Ions obtained by the unsymmetric cleavages of C-S bonds are characteristically observed. Triplets of b_n , b_n +S, and b_n -S type ions are a good indication of the presence and location of disulfide bonds in peptides.¹

USING HIGH- AND LOW-ENERGY CID MS/MS DATA TO IDENTIFY AND CHARACTERIZE AN UNNATURAL AMINO ACID

Ioannis A. Papayannopoulos, Biogen Inc., 14 Cambridge Center, Cambridge, MA 02142

The semisynthetic eicosapeptide FPRPGGGGNGDFEIEPEEYL (Hirulog™) was made by production of the octadecapeptide RPPGGGGNGDFEIEPEEYL in *E. coli* and concatenation at the N-terminus with the synthetically made dipeptide FP. During HPLC analysis of the product, in addition to the main peak with a retention time corresponding to that of the target eicosapeptide, two minor components, each about 1% of the major product, were also detected, and these two peaks were collected and sequenced. Each peak contained a peptide with the correct amino acid sequence except for position 15, where in the first peptide impurity the expected Ile residue had been replaced by Val, while in the second the same Ile residue had been replaced by another amino acid that did not correspond to any of the standard amino acids with which the sequencer had been calibrated. FAB-MS analysis of the two peptide impurities revealed that the first had MW 2165.1 (all mass values given herein are monoisotopic), in good agreement with the calculated MW of 2165.0 for the eicosapeptide FPRPGGGGNGDFEIEVPEEYL, identified by N-terminal sequencing. The MW of the peptide constituting the second impurity was 2193.1, 14 u higher than the MW calculated for the expected eicosapeptide. Taken together the molecular weight and N-terminal sequence data for the second peptide impurity suggest that the amino acid at position 15 has a residue mass of 127 (14 u higher than Ile), which does not correspond to any natural amino acid (6).

To confirm the presence of Val-15 in the first peptide impurity and to characterize the amino acid present at the same position in the sequence of the second impurity, collision-induced dissociation (CID) product ion tandem mass spectrometry (MS/MS) was employed (1,4). The first minor peptide impurity, as was clear from its low-energy [VG Quattro II triple quadrupole instrument] MS/MS spectrum (Figure 1B), contained an amino acid at position 15 which was 14 u lower in mass than Ile-15, present in the main product (Figure 1A); this amino acid is Val, as determined by N-terminal sequencing. The second minor impurity (Figure 1C) contained at position 15 an amino acid 14 u higher in mass than Ile, as had been surmised from the molecular weight sequence data. The peptide fragmentation data from the high-energy [JEOL HX110/ HX110 four-sector mass spectrometer] MS/MS spectrum (Figure 2) for the second impurity with the unusual amino acid at position 15, indicated that this amino acid had an asymmetrically branched side chain that, most likely, contained one methyl group more than Ile (5). Methylation of the α -amino group nitrogen atom of Ile-15, which would also add 14 u to the mass of the peptide, could be dismissed because the C_{14} fragment ion, the structure of which includes the α -amino group of the amino acid at position 15, was present at the same m/z in all three spectra, as shown in Figure 1.

The use of product ion tandem mass spectrometry in the identification of amino acid post-translational and other modifications in naturally-occurring and synthetic peptides and proteins has been demonstrated repeatedly (1-3). Here it has been shown that low-energy CID MS/MS data are sufficient to establish convincingly that an unusual amino acid was incorporated in the sequence of a peptide during biosynthesis, whilst amino acid side chain fragmentation data, obtained from the high-energy CID MS/MS spectrum, are very useful in providing additional structural information necessary to distinguish between possible isomeric structures.

Figure 1. Low-energy CID MS/MS spectrum of the major peptide product (A) and the spectra of the two peptide impurities, one 14 u lower (B) and the other 14 u higher (C) in mass than the major product. All three spectra exhibit essentially the same fragment ions up to m/z 1434 (C_{14} fragment ion). Beyond this ion the m/z values of the fragment ions in the spectra of the two impurities are consistently 14 u lower for the first and 14 u higher for the second, compared with the major component. The C_{14} fragment ion in the spectrum of the second impurity (C), at m/z 1434.8, indicates that the first fourteen amino acids are as expected and the fifteenth amino acid (which is 14 u higher in mass than the expected Ile-15, present in the major product), is not modified at the nitrogen of the α -amino group.

Figure 2. Partial high-energy CID MS/MS spectrum of the second minor peptide impurity (14 u higher in mass than the major product). The fragment ions d_{15} and the less abundant d_{15} are consistent with the amino acid at position 15 having an asymmetrically branched side chain, this amino acid being one of two isomers of 2-aminoheptanoic acid (2-amino, 3-methylhexanoic acid or 2-amino,3,4-dimethyl pentanoic acid). See references 5 and 6 for discussion of amino acid side-chain fragmentation.

Characteristics of CID Spectra of Peptaibols

Michiko Kanai¹⁾ and Tetsuro Fujita²⁾

1) ThermoQuest K.K., 2-5-8 Hatsudai, Shibuya, Tokyo 151, Japan

2) Setsunan University, Nagaotoge, Hirakata, Osaka 573-01, Japan

Introduction Peptaibols are antibiotic peptides, which are characterized by an acylated N-terminus, the presence of an amino alcohol at the C-terminus and a high content of α -aminoisobutyric acids (Aib). Since the N-terminus is blocked, mass spectrometry has principally been used for the determination of the primary structure of peptaibols. Two major fragment ions in the full MS spectra are formed from the predominant cleavage at the Aib-Pro bond. Subsequent CID analysis of these fragment ions is the most common approach to deduce sequence information. In this study, we investigated CID fragmentation characteristics from the various precursor ions using the different CID methods.

Experimental **Mass spectrometers:** A TSQ 7000 triple quadrupole mass spectrometer equipped with an ESI source, a LCQ ion trap mass spectrometer equipped with an ESI source (Finnigan, San Jose, CA) and a HX110/110 double focusing four sector mass spectrometer equipped with a FAB source and an array detector (JEOL, Tokyo, Japan) were used.

Materials: Matsuura et. al. previously isolated a crude hypelcin B (HP-B) mixture from *Hypocrea peltata*, and determined primary structures of HP-B-I, II, III, IV and V.⁽¹⁾ In this study, we used the same crude mixture of HP-B. It was subjected to the HPLC separation, and fractions were collected. The fractions were lyophilized, and were prepared at a concentration of approximately 10 ng/ μ l in both (water / MeOH containing 1 % acetic acid) and (2.5 mM-NaCl / MeOH) prior to the CID experiments. HP-B-I was used as a model peptaibol for the investigation of fragmentation characteristics. Two fractions containing unknown analogs were analyzed to deduce primary structures.

Precursor ions and methods: $(M + 2H)^{2+}$, $(M + 2Na)^{2+}$ and two major fragments (b_{13} and y_7) were selected as precursor ions on the TSQ 7000 and the LCQ. The samples were infused to the ESI sources at a flow rate of 2 μ l/min in most CID experiments. On-line HPLC-MS/MS was also performed on the TSQ 7000. $(M + Na)^+$ and two major fragments (b_{13} and y_7) were selected as precursor ions on the HX110/110. A mixture of glycerol and nitorobenzylalcohol was used as a FAB matrix.

Results and discussion The CID of $(M + 2H)^{2+}$ on the TSQ 7000 and the LCQ provided limited sequence information, especially on the LCQ, because of the predominant cleavage at ¹³Aib-¹⁴Pro bond. The Pro-internal fragments were observed on the TSQ 7000, but were not observed on the LCQ. The MSⁿ (n=2 to 5) were performed on the LCQ to deduce additional information. The CID of two major fragments (b_{13} and y_7) on the TSQ 7000 provided sufficient sequence information. Those on the LCQ provided similar information, but MSⁿ was required, since the product ions in the lower mass range were not detected. The CID spectra of protonated species on the TSQ 7000 and the LCQ consisted mainly of

b-type ions.

The CID of $(M + 2Na)^{2+}$ on the TSQ 7000 and the LCQ provided more information than those of $(M + 2H)^{2+}$. The CID of $(M + 2Na)^{2+}$ on the LCQ (Fig. 1) was easier and more efficient compare to that on the TSQ 7000. Those spectra from both instruments consisted mainly of $(a_n + Na - H)$ and $(y_n + Na - H)$. They provided almost complete information except for the distinction of Leu/Ile.

The CID of $(M + Na)^+$ on the HX110/110 provided complete sequence information. It consisted mainly $(a_n + Na - H)$ and $(d_n + Na - H)$, which allowed to distinguish Leu and Ile.

The primary structures of two unknown analogs of HP-B were determined (Table 1).

Fig. 1. The CID of $(M + 2Na)^{2+}$ at m/z 988 from HP-B-I on The LCQ

The primary sequence of HP-B-I is shown in Table 1.

a_n^* , b_n^* and y_n^* indicate $(a_n + Na - H)$, $(b_n + Na - H)$ and $(y_n + Na - H)$. a_n^{**} , b_n^{**} and y_n^{**} indicate $(a_n + 2Na - H)^{2+}$, $(b_n + 2Na - H)^{2+}$ and $(y_n + 2Na - H)^{2+}$, respectively.

Structural Characterization of the Mannose Specific Lectin from *Dioclea grandiflora* Using MALDI-MS, LC-ESI-MS and MS-MS

Xue-jun Tang^{1*}, Bale M. Swamy² and C. Fred Brewer²
Department of Biochemistry¹ and Molecular Pharmacology², Albert Einstein College of Medicine
1300 Morris Park Ave. Bronx, New York 10461, USA

Dioclea grandiflora seed lectin (DGL) is a Man/Glc specific lectin from Northern Brazil. DGL was shown to be similar to Concanavalin A in many aspects[1]. Amino acid sequence analysis revealed a strikingly common homology, 184 out of 237 amino acids [2]. However, apart from the ambiguity of the assignments of 6 amino acids in the reported sequence [2], DGL was also reported to have three polypeptides with approximate masses of 25-26 000 Da, 13-14 000 Da, and 8-9 000 Da [1,2]. These three polypeptides were considered as separate subunits, and two of each were required to form a complex at neutral pH [1]. Attempts to understand the structural basis of the binding specificity of Con A toward N-linked oligosaccharides has been hampered due to lack of x-ray data on such complexes. However, crystals have been obtained for DGL. In order to solve the crystal structure of DGL complexes with trimannoside, further characterization of the primary sequence and quaternary structure of the lectin was required. In this investigation, the primary sequence of DGL was examined using MALDI-TOF-MS, LC-ESI-MS and ESI-MS-MS in combination with trypsin digestion.

Profiling of DGL Using MALDI-TOF-MS and LC-ESI-MS. The MALDI mass spectrum of DGL indicated that it has multiple components that were not well resolved. LC-ESI-MS analysis of DGL was therefore performed to determine the accurate masses of all its components. Figure 1 shows ESI mass spectra of the major components of DGL found in the LC-ESI-MS experiment. The mass of the major intact subunit, containing 237 amino acids, was found to be 25 551 Da, about 100 Da lower than that calculated from the reported sequence [2]. The mass of the minor intact subunit (relative intensity ~30% of the major subunit) was determined as 25 609 Da, 58 Da higher than that of the major subunit. The inconsistency between the measured molecular masses and the masses calculated from the reported sequences indicates that there are errors in the reported DGL sequence [2]. Approximately 54% of the monomer is present as two cleaved polypeptide fragments. LC-ESI-MS analysis indicates that cleavage occurs between Asn118 and Ser119, and that the N- and C-terminal fragment have molecular masses of 12 874 Da and 12 694 Da (12 752 Da for minor subunit), respectively. These results suggested also that sequencing errors and sequence heterogeneity are on the C-terminal side of the cleavage.

Locations of Sequencing Errors and Heterogeneity Using MALDI-MS and LC-ESI-MS Peptide Mapping and MS-MS. Figure 2 shows the MALDI spectrum of the tryptic digests. Many tryptic peptides have been detected in this spectrum. However, the masses of several tryptic peptides (labeled with the sequence numbers and asterisks) including the most abundant peak do not match masses of the tryptic peptides calculated from the sequence [2]. LC-ESI-MS analysis of the tryptic digests was also performed to provide masses of the tryptic peptides that not detected or not well resolved in the MALDI spectrum. The molecular masses of most tryptic peptides from DGL as determined by MALDI-MS and LC-ESI-MS are in agreement with those calculated from the reported sequence of DGL. To identify the sequencing errors, MS-MS experiments were performed on those tryptic peptides whose masses do not match those calculated from the reported sequence. Amino acids at positions 10, 184, and 196 were determined by Richardson and coworkers [2] as Asn, Ser, and Trp/Ile, respectively. Our results indicate these residues are Asp, Lys and Thr, respectively. Furthermore, the amino acid residues at positions 123, 131, 132, and 204 were indicated as two possible amino acids [2]. Our findings confirm the correct amino acids at these positions. Our results suggest also that the subunit containing Ala-123 is the major form and the Ala/Glu heterogeneity at position 123 is the only major heterogeneity in DGL.

Gel chromatography studies reveal that the two fragmented polypeptide chains along with the intact chain assemble to form a dimer or tetramer depending on the presence of saccharide and the salt concentration.

Figure 1. ESI mass spectra with deconvoluted spectra (inset) of the major components including N-terminal fragment (a), C-terminal fragment (b) and the intact subunits (c) of the DG lectin obtained from LC-ESI-MS analysis.

Figure 2. Positive ion MALDI-TOF mass spectrum of tryptic digests of DG lectin, a-cyano-4-hydroxycinnamic acid was used as the matrix. Peaks labeled with sequence numbers are tryptic peptides predicted from the reported sequence [2]. Peaks labeled with sequence numbers and asterisks are tryptic peptides containing the sequencing errors with the positions and correct residues indicated.

Protein Sequence and Structural Studies Employing MALDI-High Energy Collision-Induced Dissociation.

Medzhiradzky, K.F., Yu, Z., Qiu, Y., Hall, S. C., Chen, Y. D., Maltby, D. A. and Burlingame, A.L. University of California San Francisco, Department of Pharmaceutical Chemistry, San Francisco, CA 94143-0446.

The MALDI technique is one of the most sensitive ionization methods available for studies for a wide array of biological samples. It has been established that high energy collisions impart the greatest amount of internal energy into ions generated by soft ionization techniques, leading to fragmentation that would not be observed under low energy conditions for many structures. In this work we show examples of structure elucidation of covalently modified peptides ionized by MALDI followed by high energy CID analysis, where post source decay (PSD) data were either incomplete or of poor quality, or where LSIMS-CID would not provide data due to insufficient sensitivity or mass range. These examples include the structure elucidation of glycopeptides after endoglycosidase H digestion, structural analysis of conotoxins and a covalent cofactor from bovine lysyl oxidase, and sequencing peptides from a 2-D gel isolated protein and a mutant hemoglobin.

Mass Spectrometry

These experiments were carried out using a Micromass AutoSpec-orthogonal-acceleration-TOF mass spectrometer, equipped with a MALDI source. Scanning the probe surface can be controlled manually or automatically. The N_2 laser (337 nm wavelength) was operated at 10 Hz pulse rate. MS-1 was tuned manually to transmit just the ^{12}C monoisotopic ions of the precursor mass (<2500 Da). The collision gas was Xe, the collision energy was 800 eV, and the gas pressure was adjusted such that there were approximately two ion-molecule collisions for each precursor ion in the gas cell. The MCP detector of the TOF analyzer always automatically records the full product ion spectrum irrespective of the precursor ion mass selected by MS-1. For a source voltage of 8 kV and a collision energy of 800 eV, the mass range accommodated with the present instrument setup is 7200 Da.

The MALDI matrix for these experiments was 2,5 dihydroxy-benzoic acid (DHB). A saturated solution was prepared in acetone containing 2% water, acidified with 5% TFA. Samples were loaded onto the crystallized matrix surface.

This work was supported by grants from the National Institutes of Health National Center for Research Resources, Grant RR01614 and National Science Foundation, Grant 8700766.

Figure 1. MALDI-high energy CID spectrum of a tryptic peptide. Human melanoma (A375) proteins were separated by two dimensional electrophoresis. One of these proteins was in-gel digested with trypsin (single gel-plug), and the unseparated digest was analyzed by MALDI and MALDI-CID. The amino acid sequence of this peptide was determined from the spectrum presented here. (Acrylamide modification of the Cys side chains is a frequently observed side reaction for proteins separated by electrophoresis.) The identity of the protein was established using this sequence for the database search, and it was confirmed by the other molecular ions observed in the digest, as profilin.

Figure 2. MALDI-high energy CID spectrum of a glycopeptide isolated from an endoproteinase Glu-C digest of glucoamylase E4 from *Monascus rubiginosus*, and incubated with endoglycosidase H. The amino acid sequence and the site of glycosylation were confirmed from these data. Only ions with charge retention at the N-terminus are labeled.

Characterization of Proteins Isolated from Cell Nuclei Using MALDI TOF MS and PSD Analysis

Constance M. Murphy, Carol Nilsson*, and Rolf Ekman
Department of Neurochemistry
University of Göteborg
Göteborg, Sweden

The cell nucleus plays an essential role in all aspects of cell function including DNA replication, gene transcription, RNA processing, and cell division. In addition to DNA and RNA the nucleus is known to contain a complex mixture of proteins and peptides. To date, the higher molecular weight protein components (> 30 kD) have been characterized as transcription factors. Little information is available for the lower molecular weight components. Characterization of the lower molecular weight components of the nucleus will lend additional insight into the regulation of genes and their relation to diseases of the central nervous system and the immune system.

In order to identify proteins and peptides contained in the nucleus we have obtained molecular weight information for both intact proteins and their respective tryptic digest fragments utilizing MALDI-TOF MS. Post source decay (PSD) analysis was used to obtain sequence information for selected peptides. The combination of molecular weight information, tryptic digest maps, and sequence information allowed for the identification of known peptides found in the nucleus.

The major component of the low molecular weight acid extract from human lymphocyte nuclei, fraction 3.5 minutes, has been identified as a small "CXC" cytokine (MW= 9,288 Da.). This class of proteins is known to stimulate DNA synthesis, mitosis, and glycolysis. Two minor components, fractions 1.75 min and 5.25 min, were tentatively identified as protein fragments from histones with molecular weights of 9,277 and 13,784 respectively.

MALDI-TOF MS is a fast, efficient technique for molecular weight analysis of proteins and proteolytic digest mixtures. Precursor ion selection, using pulsed deflection, provided sufficient resolution of the precursor ion to allow for PSD analysis of proteolytic digest fragments from simplified mixtures. Database searches utilizing molecular weight, proteolytic digest fragments, and peptide sequence results allowed for confirmation of the identity of known proteins.

Mass Spectrometric Characterization of Protein-Isocyanate Conjugates by Electrospray Ionization

Antti Hesso, Jarkko Tornaesus, Pirkko Pfäffli and Harri Vainio

Finnish Institute of Occupational Health, Dept. of Industrial Hygiene and Toxicology
Topeliuksenkatu 41 a A, FIN-00250 Helsinki, Finland

Isocyanates are highly reactive chemicals, which are in widespread industrial use in the manufacture of polyurethane foams, sprays and paints as well as in production of herbicides and pesticides. They are now the leading cause of occupational asthma in the western world.

Several diisocyanates have been reported to cause allergic reactions in exposed workers. In order to elicit immunological responses, low molecular weight reactive chemicals, such as diisocyanates, need to bind covalently to blood proteins to act as haptens.

Proteins have a number of nucleophilic sites which can react with electrophilic chemicals. It has been suggested that diisocyanates react under physiological conditions with lysine residues of proteins to form stable isocyanate-protein conjugates.

The covalent binding of isocyanate to protein will change the charge state of protein and will increase the molecular weight of the protein depending on the structure of the electrophile and the chemistry of bond formation.

Diisocyanates are bifunctional chemicals and the second isocyanate group might also react with electrophilic groups by forming inter- and/or intramolecular cross-linking reaction products.

In this study ESI-MS has been used to characterise reaction products of myoglobin and hexamethylene diisocyanate (HDI) and toluene-2,4-diisocyanate (TDI) at slightly acidic reaction conditions. Reactions were followed by analysing formed reaction products at two different temperatures.

EXPERIMENTAL

The mass spectra were acquired on a VG AutoSpec mass spectrometer (Fisons Instruments / VG, Manchester, UK), configured EBEQ. An AutoSpec Electrospray with a hexapole focusing device was used in connection with a Merck/Hitachi L-6200A Intelligent LC-pump system (Hitachi Ltd., Tokyo, Japan) fitted with a 20 µl Rheodyne injection loop system (Rheodyne, Cotati, Ca., USA) for introduction of samples into the mass spectrometer. All of the data were acquired on AutoSpec fitted with the standard point detector at 4 kV accelerating voltage.

RESULTS and DISCUSSION

The electrospray mass spectrum of myoglobin exposed to diisocyanates showed multiple peaks on each charge state. This indicates that rather than a single

homogeneous modified protein, a mixture of protein-isocyanate bonded conjugates are formed during incubation.

The reaction was fast at room temperature. The formation of reaction product was also followed at 5 °C by analysing samples taken from reaction mixture.

After 3 min reaction time some unmodified substrate was observed, as well peaks corresponding to the addition of from one to five molecules of HDI per molecule of myoglobin.

In the reaction at room temperature a new series of reaction products was formed. The first component (MW 17120 Da) corresponds the product of addition reaction of isocyanate group with some electrophilic group in myoglobin. The second component (MW 17180 Da) might be the reaction product where the second isocyanate group has reacted by addition mechanism with acetic acid. This secondary reaction product is more stable than the primary product. The reaction products corresponding to addition up to 6 - 7 molecules of HDI per molecule of protein were also observed.

In the reaction of 2,6-TDI with myoglobin at 5 °C the primary reaction product is formed by direct addition mechanism of isocyanate group with some electrophilic group of protein.

Figure 1. shows partial MaxEnt™ computer enhanced ESI mass spectrum of reaction products of myoglobin and TDI after 3 min. reaction time. This group of reaction products contain four components. The component by mass 17474 Da is a reaction product of three molecules of 2,6 TDI with one molecule of myoglobin. The components by masses 17448 Da, 17422 Da and 17396 Da are secondary reaction products, where the free isocyanate group is hydrolyzed to amine.

ESI mass spectrometry is demonstrated to be a powerful technique for analysis of complex protein mixtures of products resulting from reactions of protein with diisocyanates. This method directly measures the number moles of isocyanate per mole of protein and indicates single or multiple reaction during conjugation.

Figure 1. Enlarged MaxEnt™ ESI mass spectrum of components in of reaction products of myoglobin and TDI.

HPLC-ESIMS IN THE QUANTITATION OF ENDOTHELINS IN CELL CULTURE MEDIUM AND ORGAN TISSUE

Klaus Schneider, Stefan van Leeuwen, Carmen Peralta, Daniel Canosa, Joaquín Abián and Emilio Gelpí
Dept. of Medical Bioanalysis, IIBB-CSIC, Jorge Girona 18-26, 08034 Barcelona, Spain

Endothelins (ETs) are the most potent vasoconstricting substances presently known. They also influence such activities as cell proliferation and hormone production and have been implicated in cardiovascular disorders ranging from stroke to ischaemic heart disease (1).

ETs consist of a family of peptides of 21 amino acid residues and are found in various types of tissues. Conventional methods for the determination of endothelins are radioimmunoassay and enzyme-linked immunosorbent assay. Although both methods exhibit high sensitivity, the ability to distinguish between endothelin isoforms ET1, ET2 and ET3 relies on the reproducible production of highly specific antibodies and is not routinely accomplished.

ESIMS has been used for quantitative peptide and protein analysis from biological fluids in only a few cases, e.g. for the determination of a pentapeptide in human plasma (2).

The method developed for the determination of endothelins in supernatants of human umbilical vein endothelial cell cultures employs solid-phase extraction, subsequent HPLC fractionation followed by HPLC-ESIMS for quantitative analysis of endothelins. Relative to our earlier report (3) the method now has been substantially improved by i) the use of two internal standards (endothelin analogs Ala^{3,11}-ET1 and VIC) that allow for compensation of variations in recovery and instrumental performance and that allow the use of an external calibration curve ii) higher ion intensities by lowering the TFA concentration in HPLC-ESIMS from 0.05% to 0.02% TFA without loss of chromatographic resolution iii) specificity increase by simultaneous monitoring of [M+2H]²⁺ and [M+3H]³⁺ ions

Linearity of calibration curves was demonstrated over almost 3 orders of magnitude from 50 fmol to 25 pmol. Limit of detection was set at 10 fmol (S/N= 3.1). First quantitative results for ET1 of 1.78 ± 0.26 pmol/ml obtained by external standard curve are in good agreement with the 1.69 ± 0.22 pmol/ml determined by standard addition. Analysis of a rat liver extract that was spiked with 10 pmol of VIC standard with the HUVEC method failed to yield significant signals of VIC. Clearly, due to masking by matrix effects a much improved purification protocol is needed for analysis of ETs in organ tissues.

Future work suggested by these results, further validation of method, application to studies of endothelin function and the development of improved purification protocol for rat liver extracts.

Regiospecific binding of PAH metabolites to albumin: screening and characterization by LC/MS/MS

Per Brunmark, Paul L. Skipper, Steven R. Tannenbaum, and John S. Wishnok*

Division of Toxicology and Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139

Carcinogen-protein adducts offer a means to monitor internal human exposure to environmental carcinogens and can in some cases serve as indices for DNA damage. Human serum albumin (HSA) is - as the most abundant blood protein - an attractive candidate for this monitoring. While quantitation of adducts of known carcinogens has been used to assess individual human exposure, it remains difficult to detect and identify unknown adducts. Polycyclic aromatic hydrocarbons (PAH) are ubiquitous environmental pollutants that form stable adducts to His(146) in HSA^{1,2}. Screening for these adducts on HSA has previously been performed successfully by high energy CID FAB/MS/MS^{2,3}. Electrospray (ESI) combined with low energy CID MS/MS presents a more-available method that can be easily connected to LC and has been utilized for adduct screening in this study.

Experimental. HSA was reacted with activated PAH metabolites, i.e., cyclopenta[cd]pyrene 3,4-epoxide (CPPE), benzo[a]pyrene 7,8-dihydrodiol 9,10-epoxide (BPDE), benzo[a]pyrene 4,5-epoxide (BPE), and fluoranthene-2,3-dihydrodiol 1,10b-epoxide (FADE). Reaction products were digested with either Pronase, proteinase K or chymotrypsin. Digests were separated on an LC equipped with a Vydac C₄ analytical column and eluted by a gradient system of H₂O/CH₃CN with 0.5 % CH₃CO₂H. The LC system was connected to a Finnigan TSQ 7000 with an electrospray ion source operated at 3.5-4.5 kV. For MS/MS experiments, argon was used as collision gas at a pressure of 1-4 x 10⁻³ Torr and collision energies of 15-25 eV. Digests of the adducted proteins were analyzed by LC/MS/MS using a signal-sensitive automated scan-switching program to generate product ion spectra for peaks detected in precursor ion scan mode.

Results. The analysis of the proteinase K digest of BPDE incubated HSA (Fig 1, upper) shows the product-ion spectrum of the major adduct. Fragmentation of the hydrocarbon moiety of the diolepoxide adducts proceeds via loss of H₂O and CO to form characteristic ions; for BPDE, these are at *m/z* 303, *m/z* 285, and *m/z* 257.³ The remaining strong product ion in the spectra (*m/z* 669) corresponds to the doubly protonated peptide RRHPYFYAPE containing the known adduction site His(146). Comparisons of product-ion spectra from digests of BPDE-, BPE- and FADE-adducted HSA indicate the same peptide and adduction site (Fig 1). No fragmentation of the peptide backbone could be detected in the product-ion spectra of the adducts. To confirm the expected peptide sequence of the adduct, in-source CID was performed to yield ions corresponding to the unadducted peptides, allowing regular sequencing by Q₂-CID. Due to the three basic N-terminal amino acids, the sequencing spectra were dominated by a and b ions (not shown). Pronase digests of the FADE and BPE-adducted HSA yielded the peptide His(146)-Pro(147) revealing His(146) as the only as the only reasonable adduction site.

CPPE-adducted HSA digested with Pronase, proteinase K, and chymotrypsin yielded the adducted peptide chains, Lys, Lys-Tyr, and, Lys-Lys-Tyr, respectively (Fig 2). The sequence Lys-Lys-Tyr occurs only at positions 136-138 in HSA; the binding site for CPPE is therefore Lys(137) which is located in the same subdomain (IB) as His(146). Our results, taken together with previous reports, serve to demonstrate that binding of PAH metabolites to HSA is highly regiospecific.

Fig 1. Product ion spectra of adducted RRHPYFYAPE yielded from proteinase K digests of HSA treated with BPDE, BPE, and FADE, respectively

Fig 2. Product ion spectra of adducted peptides yielded from digests of CPPE treated HSA

We thank NIEHS for support (Grant ES05622, ES02109, and ES04675). The Finnigan TSQ 7000 was purchased with a grant (9402-093) from DOE. A scholarship from the Swedish Work Environmental Fund provided salary for P.B (Grant no 94-0496).

LC-MS, CZE-MS and LC-MS/MS investigation of protein tyrosine phosphatase inhibition by pervanadate

John Kelly¹, Gregory Huyer^{1,2}, Chidambaram Ramachandram¹, Brian Kennedy¹

¹Merck Frosst Centre for Therapeutic Research, P.O.Box 1005, Pointe Claire-Dorval, Québec H9R4P8, Canada; ²Dept. of Chemistry and Biochemistry, Concordia University, 1455 de Maisonneuve Blvd. W., Montréal, Québec H3G 1M8, Canada

Protein tyrosine phosphorylation plays a pivotal role in the regulation of many cellular processes [1]. The tyrosyl phosphorylation state of a protein is itself controlled by the actions of the protein tyrosine kinases (PTK's) and the opposing protein tyrosine phosphatases (PTP's). Vanadate (VO_4^{3-}), pervanadate and its related peroxovanadate complexes are potent PTP inhibitors [2-4] and are also known to be insulin mimetics [4-5]. However, while kinetic studies have shown that the inhibition due to vanadate is fully reversible upon chelation with EDTA, that due to pervanadate is irreversible. Pervanadate and related complexes are known oxidizing agents and it was speculated that the PTP's were being covalently modified via oxidation. Therefore a study was undertaken to examine the mechanism of inhibition of PTP's by pervanadate and a related peroxovanadate complex (glycylglycine peroxovanadate). Human PTP1B, a cytosolic PTP containing a single catalytic domain, was used as the model protein for this study. Key to this investigation was the use of electrospray ionization mass spectrometry techniques (LC-MS, CZE-MS and MS/MS) to characterize any covalent modifications that may occur.

A POROS® R2 capillary column (250 μm i.d. x 120 mm) proved to be an effective way to desalt the protein prior to electrospray ionization. Useful spectra were obtained for as little as 300 fmol of PTP1B injected (640 nM). Treatment with pervanadate increases the mass of the protein by at least 64 Da. The addition of DTT 10 minutes after the addition of pervanadate gave a molecular weight profile similar to that for the control protein but increased by 50 mass units. Capillary LC-MS of the tryptic digests of the native protein yielded a peak that corresponded in mass to the active site peptide (Fig 1b). This was completely absent from the tryptic digest of the pervanadate-treated protein and a new peptide was observed with a mass 48 Da greater (Fig. 1d). CZE-MS using 0.5M formic acid as the background electrolyte yielded similar results.

LC-MS/MS of the native and modified active site peptides confirmed that the thiol group (-SH) of the cysteine was oxidized to sulfonic acid (-SO₃H). This residue is essential for the functioning of this enzyme and such a modification would likely inhibit its activity permanently. The MS/MS spectrum of the oxidized peptide was dominated by a strong Y ion series (Fig. 2b). A similar phenomenon was observed by Burllett *et al.* in the FAB-MS/MS spectra of peptides containing a cysteic acid close to a C-terminal arginine [6,7]. They attributed this phenomenon to a gas phase interaction between these two residues leading to delocalization of the site of protonation and thus to an increased yield of Y-series ions.

Peroxide Detection in Recombinant Protein Formulations by GC-MS-MS

Edward R. Hoff and Anthony B. Chen, QC Biochemistry
Genentech, Inc., 460 Pt. San Bruno Blvd., So. San Francisco, CA 94080

Introduction

Oxidation of proteins is a common cause of protein degradation. One cause of oxidation is peroxide reactions with methionine residues. Potential sources of peroxides include cleaning agents, catalysts used in polymer manufacture and excipients such as Tween.

The reaction of pharmaceuticals with small reactive molecules has long been an issue. Today, with recombinant proteins, an even greater emphasis must be placed on this issue. In the table below note that a 1 ppm solution of hydrogen peroxide would react with only 0.5% of a 1 mg/mL aspirin solution. However, the 1 ppm hydrogen peroxide solution would be more than a four-fold excess for reaction with a 1 mg/mL recombinant antibody solution.

Percentage Reaction of 1 mg/mL Solutions with 1 ppm H ₂ O ₂		
Molecule	Molecular Weight	Percentage Reaction*
Aspirin	180	0.5%
Recombinant Protein A	22125	65.1%
Recombinant Protein B	59008	173.6%
Recombinant Antibody	150000	441.2%

* assumes a 1:1 reaction with H₂O₂.

Some oxidizing agents are not stable enough for analysis. Other oxidizing agents may not be volatile enough for GC-MS analysis. The data demonstrate that a volatile analog of the methionine side-chain, ethylmethanethiol (EMS), can be used to detect the total oxidizing potential of a solution expressed as hydrogen peroxide. In the presence of peroxides ethylmethanethiol forms ethylmethanethiol sulfide (EMS), which was detected using selected reaction monitoring. The level of peroxide is determined from a standard of hydrogen peroxide.

Sample Preparation

Dilute ethylmethanethiol (Aldrich) 1:250 in isopropanol (Mallinckrodt) with 5 ppm dimethyl

sulfoxide (DMSO, Sigma-Aldrich). To 400 µL of sample in a glass autosampler vial (7 mm x 40 mm) add 100 µL of EMS/DMSO reagent/internal standard. Cap vial, purge with nitrogen and heat at 80°C for 20 minutes in an aluminum heating block.

Instrumental set-up

The chromatographic separation was performed on a Varian 3400 GC with a DB624 column 72.5 m x 0.53 mm (J & W Scientific). The column head pressure was 10 psi helium. The split valve was closed for the first 10 seconds of the run. The injection volume was 1 µL, in triplicate. The injector temperature was set to 230°C. The oven was programmed isothermal at 120°C for 3 minutes and then programmed to 200°C at 11 minutes. The transfer line was set at 200°C.

The Finnigan TSQ7000 mass spectrometer was set up for chemical ionization (CI) with methane gas in the source at approximately 6000 mT pressure. The filament was turned off for the first 7 minutes of the run. The filament current was set at 200 µA and the electron multiplier voltage (emult) was set at 1700 V. A selected reaction monitoring (SRM) experiment was performed. From 7 to 9 minutes Q1 selects for mass 79 (mw DMSO 78+1), Q2 CID argon 1.5 mT, Q3 scans from 63.7 to 64.3 looking for the 64 m/z daughters of DMSO. From 9 to 11 minutes, emult 1900, Q1 selects for mass 93 (mw EMSO 92+1), Q3 scans 64.7 to 65.3 looking for the 65 m/z daughters of EMSO.

Discussion

The assay is linear (correlation coefficient, 0.999; y-intercept 0.324; at 100 ppb y-response is 0.78), however the y-intercept is offset due to the background level of EMSO in the EMS.

The 10 and 100 ppb spikes of hydrogen peroxide gave results of 9.5 and 104 ppb respectively; theoretical recoveries of 95 and 104%. The limit of detection is estimated at 5 ppb based on the standard curve and the typical system noise and the EMSO level in the blank.

CID Spectrum of EMSO

CID Spectrum of DMSO

Sample matrix effects are minimal. Protein and buffer salts are separated in the GC injection port liner where they fail to volatilize. Periodically the injection port liner must be replaced with a clean liner.

Conclusion

The assay is linear over the range from 0 to 100 ppb. The recovery of 95% and 104% at the 10 ppb and 100 ppb spike level is acceptable. GC-MS-MS is a powerful tool for the detection of small reactive molecules.

Further Work

The following areas of further work will be pursued; 1) Reduce the level of EMSO in the blank, 2) Show selectivity for a broad range of other oxidants such as alkyl peroxides, and 3) Investigate other selective reactions that might be predictive of protein reaction potential.

Acknowledgments

The authors wish to acknowledge the contribution of Suresh Kalbag for suggesting the use of EMS as a scavenger for peroxides.

Examination of Metallothionein Isoforms in Drug Resistant Human Tumor Cells.

Tao He¹, John Hilton², Joseph Zaia¹, Daniele Fabris¹, Catherine Fenselau¹.

1) Structural Biochemistry Center, University of Maryland Baltimore County, Baltimore, MD 21228

2) School of Medicine, Johns Hopkins University, Baltimore, MD 21205

Metallothioneins are Cys-rich, low-molecular weight, highly inducible proteins. Previous studies have successfully demonstrated the sequestration of anti-cancer drugs(melphalan, chlorambucil) by metallothionein *in vitro* under near-physiological conditions (1, 2). There are two major isoforms of metallothionein in mammalian cells. The expression of each isoform is tissue and cell type specific. The relationship between the expression of specific isoforms and their possible involvement in drug resistance is still unknown. Techniques with a high degree of resolution will be needed to study the individual metallothionein isoforms(3). Here, we applied reverse-phase HPLC and mass spectrometry to investigate the isoformic expression of metallothioneins from human bladder tumor cells.

Human T24 bladder tumor cell line was used because of its high basal expression of metallothionein. Cell lysate was pretreated by heat and fractionated with a Centricon-30 filter(molecule weight cut-off 30,000). The sample was separated by HPLC using a C-18 reverse-phase column(Vydac, 2.1x250 mm, Separation Groups, Hesperia, CA). MALDI and electrospray mass spectrometry were performed on a Kratos MALDI III mass spectrometer (Shimadzu, Columbia, MD) and the first mass spectrometer of the JEOL (Tokyo, Japan) HX110/HX110 tandem instrument with a thermally assisted electrospray source.

The elution profile of rabbit metallothionein-2a was used to determine the approximate retention time for human isoforms. Since there are no aromatic amino acid residues in metallothionein, protein elution was monitored at 215 and 260 nm by UV detectors. The fractions with high absorbance in 215 nm and low absorbance at 260 nm were collected and concentrated by lyophilization. The MALDI MS determination of the HPLC fractions showed molecular ions with molecular masses about 6 k Da in several fractions(Fig. 1). To obtain more accurate masses, several fractions were pooled and analyzed by ESI MS(Fig. 2). The results from ESI MS data and the comparison with the expected molecular weights of the human metallothionein isoforms were summarized in Table 1. The most abundant peak in ESI MS spectrum corresponds to human metallothionein-2 from Zn ion induced T24 bladder cells, which is consistent with the idea that the MT-II promoter is more responsive than the MT-I promoter to Zn ion induction(4). The characteristic amino acid composition of human metallothionein, i.e., 20 of 61 amino acids are cysteine residues, was used to verify that the protein with the molecular mass of 6081 was indeed metallothionein. Cysteine residues were alkylated by N-ethylmaleimide (NEM) which causes longer retention time in the HPLC and the increased molecular mass in the mass spectrometer. It was found that 15 to 20 NEM moieties bond to metallothionein.

In conclusion, human metallothionein isoforms from T24 human bladder tumor cells were separated by reverse-phase HPLC, analyzed by mass spectrometry and verified by alkylation of the Cys residues. The combination of HPLC and mass spectrometry provides a powerful technique for the characterization of the metallothionein isoforms with highly homologous primary sequences.

ISOTOPIC DIFFERENCES IN HUMAN GROWTH HORMONE PREPARATIONS

Fred P. Abramson, Blaire L. Osborn, and Yohannes Teffera

Department of Pharmacology
George Washington University
School of Medicine and Health Sciences
Washington, DC 20037

In athletic competition there is considerable concern about doping with recombinant human growth hormone (rhGH). Growth hormone is a 191 amino acid protein that exerts many effects in humans. rhGH may be useful in treating a number of diseases beyond GH deficiency, but its action to increase in lean muscle mass makes this compound attractive to athletes. In the US, rhGH is commercially available as bioengineered preparations in the form of Humatrope® from Lilly, Nutropin® from Genentech and a third, Protropin® from Genentech, that has an additional terminal methionine, thus it contains 192 amino acids. Each product is produced by genetically-modified *E. coli*.

One novel idea that has recently been used to distinguish endogenous from exogenous substances is the $^{13}\text{C}/^{12}\text{C}$ isotope ratio. Becchi *et al.* noted that testosterone in some urine samples has an isotope ratio that is significantly lower than others¹. Because synthetic testosterone is derived from chemical, not biological, sources, the isotope ratio of synthetic (i.e., pharmaceutical) testosterone reflects its origin in fossil fuel hydrocarbons where the $^{13}\text{C}/^{12}\text{C}$ ratio is substantially lower. The *E. coli* that are used to produce biosynthetic proteins might be grown in sources of nutrients of various origins. Therefore, it is possible that the isotopic signature of recombinant proteins might differ from endogenously produced molecules as does testosterone. To examine this hypothesis, we obtained the three rhGH samples along with GH derived from human pituitary glands.

As a condensed-phase internal standard, we used horse albumin with an isotope ratio measured as $-21.03 \text{ } \delta^{13}\text{C}\text{‰}$ by off-line combustion and a conventional gas inlet IRMS method. Each injection contained 2 μg of albumin (30 pmol) and 2-3 μg (100-150 pmol) of rhGH. The mobile phases were 0.1% trifluoroacetic acid (TFA) and acetonitrile also containing 0.1% TFA. After a 2 minute hold at 30% acetonitrile, the solvent composition was increased linearly to 70% acetonitrile in 10 minutes with an Isco (Lincoln NE) Model 260 dual syringe pump system. The flow rate was 1 mL/min. The separation was carried out using a PerSeptive Biosystems (Framingham, MA) Poros R2 column (30 mm long, 2.1 mm id).

These experiments were conducted using a newly-developed apparatus² that uses a Universal Interface (UI) to desolvate the particles and the chemical reaction interface (CRI) to convert the analytes into CO_2 . In these experiments, the HPLC/CRI interface was attached to a Finnigan/MAT Delta S IRMS with Isodat software (Sunnyvale, CA) with which isotope ratios on HPLC effluents can be measured with high precision³. Oxygen was the reactant gas for the CRI.

Figure 1 shows a typical chromatogram where the good separation between albumin and rhGH can be seen. Our data set is shown in Figure 2. In $\delta^{13}\text{C}\text{‰}$ terms, the mean $\pm$ SD values for these preparations are: human pituitary, -11.31 ± 0.71 ; Genentech Nutropin®, -12.84 ± 0.90 ; Genentech Protropin®, -10.25 ± 0.56 ; Lilly Humatrope®, -18.47 ± 0.50 ($n = 7-8$). In each case, the observed isotope ratio was different from pituitary GH ($p < 0.05$ by Student-Newman-Keuls multiple comparisons). In practical terms, only the Lilly product has a carbon isotope ratio that is markedly different from pituitary GH. One should also realize that the

carbon isotopic signature we measured on the biosynthetic samples could change considerably between lots if a manufacturer changed sources for the components in the *E. coli* growth media. Other research has indicated that only a small amount of rhGH is excreted in urine, so the idea of using IRMS for rhGH testing has low feasibility.

This work reports only the second attempt to use isotope ratios to differentiate exogenous from endogenous substances to detect doping in athletic competition. We did find differences among the preparations, thus supporting the observation of Becchi *et al.*¹. The use of isotope ratio measurements to detect doping with IRMS could be successful with drugs that have higher urinary concentrations, as would result from a more appropriate combination of higher doses and higher urinary excretion than rhGH.

MALDI AND ESI MS TO STUDY BINDING SITES FOR PHENOTHIAZINE INHIBITORS OF TRYPA NOTHIONE REDUCTASE

Mark S. Bolgar¹, Shinji Itoh¹, Simon J. Gaskell¹, Hong Yin², Cecil Chan², Jacqui Garforth², Kenneth T. Douglas², and Alan H. Fairlamb³.

2) Dept. of Pharmacy, University of Manchester, Manchester, UK

3) Dept. of Medical Parasitology, London School of Hygiene and Tropical Medicine, UK

The parasites causing African sleeping sickness and other tropical diseases contain the enzyme trypanothione reductase (TR) which provides intracellular protection against redox damage by catalyzing the interconversion of reduced and oxidized trypanothione. This protective mechanism is distinct from the equivalent use of glutathione reductase in mammals and therefore provides a potential target for drug design against these diseases. Rational design of TR inhibitors suggested the phenothiazines as leads and their inhibition of TR has been demonstrated [1]. The known propensity of fluphenazine to form radical-ions under the influence of light has been exploited by performing the photolysis of fluphenazine in the presence of TR. The reaction led to irreversible, time-dependent loss of enzyme activity [2]. Both MALDI and electrospray (ESI) MS were used in the characterization of the modified protein product. TR from *Trypanosoma cruzi* was isolated as described [1]. Native TR was reduced with dithiothreitol, alkylated with 4-vinylpyridine, and digested by trypsin or V8 protease. The digests were separated by HPLC.

ESI MS of native TR and derivatized TR: The ESI spectrum of native TR revealed the presence of a single major component with a molecular weight of 53,910 Da (Fig.1). The reported molecular weight of TR is 53,864 Da as calculated from the amino acid sequence inferred from the cDNA sequence [3]. The ESI spectrum of derivatized TR revealed the presence of a single major component with a molecular weight of 54,632 Da. The difference between the mass of native TR and the mass of derivatized TR is 722 Da. This value is approximately 7 times the molecular mass of 4-vinylpyridine, consistent with the presence of 7 cysteine residues in TR from *T. cruzi*.

ESI MS and tandem MS analysis of digest of the derivatized TR: The ESI MS and tandem MS analysis of the two digests of the derivatized TR permitted confirmation of 82 % of the amino acid sequence. The confirmed sequence included the redox-active cysteine residues (C53 and C58).

ESI and MALDI MS of fluphenazine-modified TR: The ESI spectrum of the modified TR revealed the presence of at least 4 components with apparent molecular masses: 54,706; 55,106; 55,501; and 55,894 (Fig.2). The average difference between these masses is 396 ± 3 Da. This value is 41 Da less than the molecular mass of fluphenazine, suggesting more complex chemistry than simple addition is involved in interaction between fluphenazine and TR on irradiation. Based on a mass increase of approximately 396 Da per fluphenazine-derived modification to TR, the components detected correspond to fluphenazine/TR molar ratios of 2-5. The MALDI MS spectrum of the modified TR contained an (M+H)⁺ ion at approximately m/z 55,484. The estimate of average MW derived from MALDI/TOF MS is therefore consistent with the results of ESI MS which achieved resolution of the different substituted forms. The ESI and MALDI MS analysis of the modified TR provided evidence for covalent modification of TR by

fluphenazine following photo-activation. The observation that 2 - 5 molar equivalents of fluphenazine can become covalently attached to TR on photo-activation indicates either that there are multiple sites for these tricyclics to bind and/or that more than one tricyclic nucleus can fit into a single active site.

Characterisation of Ceroid Lipofuscinosis Protein and of its Interactions with F_0 Inhibitors by Electrospray Ionisation Mass Spectrometry and Electrospray Tandem Mass Spectrometry

Armelle Buzy, Edward M. Ryan, David N. Palmer[†] David E. Griffiths & Keith R. Jennings.

Department of Chemistry, University of Warwick, Coventry, CV4 7AL, UK.

[†]Centre for Molecular Biology, Lincoln University, Canterbury, NZ.

Ceroid-lipofuscinosis protein (CLP), the major accumulating protein in several forms of ceroid lipofuscinosis, has an amino acid sequence identical to that of the F_0 -subunit c of normal bovine ATP synthase.^{1,2} Electrospray ionisation mass spectrometry (ESI/MS) showed that ovine CLP and normal bovine F_0 subunit c are identical, including a 42 mass unit post-translational modification (Fig. 1). Collision induced dissociation (CID) of the intact CLP resulted in sequence information for about 80% of the molecule. This partial sequence was consistent with the modification being on amino acids 30-46 with acetylation or trimethylation of Lys-43 being prime candidates for further investigation. Of specific interest was the presence in the CID spectrum of a very prominent series of fragment ions which may be related to the specific protein conformation around Glu-58.

Analysis of mixtures of CLP incubated with several known F_0 inhibitors showed that N, N'-dicyclohexylcarbodiimide (DCCD) and organotin bind covalently to CLP but interactions with oligomycin and venturicidin were not observed. The sulphhydryl inhibitors, 2,3 dimethoxy-5-methyl 1,4, benzoquinone (UQ_0) and N-ethyl maleimide (NEM) were also shown to bind covalently to the protein. The binding stoichiometry and the relative rate of reaction were then determined for each inhibitor. CID experiments performed on the $[M+5H]^{5+}$ ion of the intact CLP and of the complexes UQ_0 -CLP and NEM-CLP allowed the identification of 80 % of the CLP sequence and revealed that UQ_0 and NEM are both bound to Cys-64. A portion of the CID spectrum given by the $[M+5H]^{5+}$ of the complex UQ_0 -CLP is shown in Fig. 2B compared with that of CLP (Fig. 2A).

This work shows the exceptional utility of ESI/MS in studies of the interaction of CLP (subunit c) with a range of inhibitors which are applicable to studies of the F_0 component of ATP synthase.

One crucial role of glutathione (GSH), a tripeptide (Glu-Cys-Gly), is to prevent modifications to DNA by endogenous (*e.g.*, estrogens) and exogenous (*e.g.*, PAHs, steroids, etc.) carcinogens. A family of glutathione transferases (GST) catalyzes the binding of the nucleophilic thiol of GSH with electrophilic groups of carcinogens. Estrogens, once activated to electrophilic quinones, can bind to nucleophilic sites of DNA or GSH. Binding to DNA is not desired whereas binding to GSH results in elimination of the carcinogen. GSH conjugates undergo biochemical degradation to produce *N*-acetylcysteine adducts before they are excreted.

Because tandem mass spectrometric methods are useful for characterizing carcinogen-DNA adducts, one expects a similar benefit for estrogen-GSH conjugates. The level of GSH conjugates present in urine or bile can be used as a marker to determine the level of human exposure to activated estrogens. The low level of conjugates in urine and the instability of the thiols in aqueous solutions necessitate a sensitive and rapid method for detecting and characterizing these materials. This poster describes the applicability of FAB, ESI and NICI mass spectrometry to study estrogen adducts of glutathione and *N*-acetylcysteine. Experimental issues considered are limits of detection and MS/MS capabilities.

All FAB and ES ionization mass spectra were collected by using a prototype VG ZAB-T four-sector mass spectrometer of BEBE configuration. All *n*-propyl-ester pentafluoropropionyl (PFP) derivatized NICI mass spectra were obtained with a Hewlett Packard model 5988 mass spectrometer.

Limits of detection (LOD) were evaluated by using both 3,4-OHE₁-2-*S*-*N*-acetylcysteine (I) and 3,4-OHE₂-2-*S*-*N*-acetylcysteine (II). To assess the amount of impurities, full scan mass spectra were obtained by using FAB, ESI and NICI. In FAB-MS, LODs for adducts I and II are approximately 100 and 130 pmol, respectively. Similar experiments in ESI-MS and GC-NICI-MS required 5 - 8 and 2 - 5 pmol, respectively.

To improve the LOD, a narrower magnet scan over 60 Da was used in ESI, and selected ion monitoring (SIM) was employed in NICI-MS. The signal-to-noise ratios for 5 pmol of I and II consumed are greater than 100-to-1. The ESI LODs for both I and II are 100 fmol, and the calibration curves are linear (correlation coefficient values > 0.995) and establish similar sensitivities for both compounds. Unlike the ESI experiments, sensitivities for PFP-derivatized I and II are different in SIM experiments. The LODs are 500 and 100 fmol for I and II, respectively. The lower sensitivity for I compared to II may be due to poor yield or loss of sample during the derivatization.

Full scan NICI spectra of PFP-derivatized I and II resulted in low abundance of molecular ions at *m/z* 885 and 1033, respectively. Formation of ions at *m/z* 865, 821, 738 and 675 may result from the loss of HF, (CO₂&HF), (CF₃CF₂CO) and (CO₂HF & CF₃CF₂CO) from the molecular ion of I. A similar series of ions was observed with II. A fragment ion that is characteristic of cleavage of the *N*-acetylcysteine moiety at CH₂-S for I and II are observed at *m/z* 609 and 757, respectively. For both I and II, fragment ion due to loss of CF₃CF₂CO from the molecular ion was used for SIM experiments.

A dominant fragment ion due to loss of the estrogen moiety from the molecular ion (*m/z* 162) was observed in FAB tandem mass spectra of CE-1-*N*-acetylcysteine, CE-2-*N*-acetylcysteine, and CE-4-*N*-acetylcysteine. Loss of water from the molecular ion gives rise to fragment ion at *m/z* 430 and 432 for E₁ and E₂ adducts, respectively. As shown in Scheme 1, loss of ketene (COCH₃) from the *N*-acetylcysteine leads to the formation of ions at *m/z* 405/407. The cleavage of the C-S bond results in fragment ions observed at *m/z* 130, 162, 317/319 and 285/287. The fragment ion at *m/z* 317/319 suggests that the estrogen conjugation is achieved by binding to the sulfur atom at the *N*-acetylcysteine moiety.

The tandem mass spectra of glutathione adducts, shown in Figure 1, shows some characteristic fragment ions due to GSH. Fragment ions at *m/z* 463/465 and 517/519 correspond to loss of glycine and glutamic acid constituents of GSH, respectively. The frequent shift of fragment masses by 2 Da is evident that most of its fragments contain the estrogen nucleus. Other fragment ions observed were similar to fragmentation of the *N*-acetylcysteine moiety. Similar to the tandem spectrum of *N*-acetylcysteine conjugate, the observation of fragment ions at *m/z* 317/319 suggests the conjugation of estrogen is at sulfur.

In summary, identification of estrogen adducts of *N*-acetylcysteine is possible by GC-NICI, FAB and ESI mass spectrometry. Quantitation of CE-*N*-acetylcysteine adducts is possible by ESI and NICI mass spectrometry. The discrepancy in LODs of I and II for SIM-NICI-GC/MS may be due to sample loss during derivatization. Quantitation with ESI-MS was reproducible, and similar sensitivities for 3,4-OHE₁-2-*N*-acetylcysteine and 3,4-OHE₂-2-*N*-acetylcysteine were observed. LODs of 100 fmol were achieved for both compounds. Although characteristic fragment ions that are due to estrogen conjugation to *N*-acetylcysteine were present, the application of tandem mass spectrometry to distinguish structural isomers of CE-*N*-acetylcysteine was unsuccessful. Future plans include the application of negative-ion mode FAB to detect structural isomers of CE-*N*-acetylcysteine. We also plan to employ MALDI-PSD to identify and distinguish these type of adducts.

CHARACTERIZATION AND QUANTIFICATION OF OPIOID PEPTIDE ANALOGS IN SHEEP PLASMA BY CAPILLARY LC/MS/MS

By J.L. Tseng, O.O. Grigoriants, L. Yan and D.M. Desiderio

Departments of Neurology and Biochemistry, and the Charles B. Stout Neuroscience Mass Spectrometry Laboratory, University of Tennessee, Memphis, 956 Court Ave., Memphis, TN 38163 USA

Introduction:

Mass Spectrometry and capillary HPLC have been used to study three synthetic peptide analogs (Tyr-D-Ala-Phe-Asp-Val-Val-Gly-NH₂ (Deltorhin-I), Tyr-D-Nva-Phe-Orn-NH₂ (TNPO), and Tyr-Tic^ψ [CH₂NH]Phe-Phe-OH (TIPP[Y])) that were designed to have specific opioid receptor binding properties. The tandem mass spectrometric (MS/MS) behavior of those three peptides was evaluated in preparation for the analysis of those exogenously administered peptides to a pregnant ewe to determine the placental transfer of a peptide analog to the fetus. Quantification of extracted Deltorhin-I from sheep plasma after exogenously administered peptide for different periods of time was also studied by on-line capillary LC/MS in the MRM mode.

Methods:

Sample extraction: 200μl of previously frozen sheep plasma, 1 μg of deuterated Deltorhin-I, and 300 μl of acetonitrile were mixed together, centrifuged for 20 min. at 5,600 x g at room temperature, and evaporated under nitrogen stream. The sample was reconstituted in 1 ml 0.1% TFA and loaded onto a preconditioned Sep-Pak column, and the peptide-rich fraction eluted with 30% acetonitrile. All samples were lyophilized to dryness and reconstituted in 50 μl 0.1% TFA solution for capillary LC/MS analysis.

Mass spectrometry: An AutoSpecQ (E1BE2Q) hybrid mass spectrometer (VG Analytical), fitted with a dynamic LSIMS probe, was used for this study.

HPLC: A varian 9012 HPLC pump and varian 9050 detector (the flow cell was replaced by a UZ capillary flow cell from LC-packing), and a 70:1 splitter (LC-packing) were used in this study. Solvent A was 0.1% TFA with 1% glycerol, and solvent B was 80% acetonitrile, 0.1% TFA, and 1% glycerol. The flow rate was measured at 4.6 μl/min. at 10% B. A Fusica capillary column (300 μm i.d. x 25 cm), packed with C18, 5 μm stationary phase was used for the gradient HPLC separation; the organic modifier gradient was 10 to 60 % B in 30 min. (1.3% per min.).

Results and Discussion:

The product-ion spectra of three peptides are shown in Fig. 1-3. Most of the amino acid sequence-determining ions of Deltorhin-I and TNPO can be readily found from their product-ion spectra. The peptide TIPP[Y] give the very unique peak in its product-ion spectrum due to its particular structure. Chromatograms shown in Fig. 4 indicate this system can be used effectively for the separation of Deltorhin-I from sheep plasma. The mass spectra of Fig. 5 indicate the exogenously administered Deltorhin-I from sheep plasma can be detected and analyzed by mass spectrometry. Calibration curve (Fig. 6) indicates the detection limit is about 3 ng. Table I shows the results of one set of samples, which suggest that more sample was needed for this study.

Conclusions:

This study has demonstrated the application of coupling of capillary LC to a high performance mass spectrometer through the dynamic LSIMS for the qualitative and quantitative analysis, and low energy CID-MS/MS for the determination of amino acid sequence of three opioid peptides that are important peptides for placental transfer studies. Electrospray Ionization Mass Spectrometry in the Discovery of Scorpion Venom Neuropeptide Toxins

A. Daniel Jones¹, Elisabeth Lehmberg¹,
Haim Moskowitz¹, Rafael Herrmann¹, and Bruce D. Hammock²

¹Facility for Advanced Instrumentation

²Departments of Entomology and Environmental Toxicology
University of California-Davis, Davis, CA 95616 USA

Toxins derived from scorpions and other venomous species are promising leads for development of pharmaceutical and agricultural products. Peptide toxins exhibit selective toxicity towards insects and mammals, as well as different modes of action. Baculoviruses have been proposed as insect control agents but are unable to kill insect larvae before they cause extensive crop damage. Recombinant baculoviruses engineered to express scorpion peptide toxins have reduced time to kill insects compared to wild viruses[1].

Scorpion venom consists of complex mixtures of peptide toxins that affect gating mechanisms of ion channels. Smaller peptides (~30-40 amino acids) act on different kinds of K⁺ channels [2,3] and larger peptides (~60-70 amino acids) affect Na⁺ channels [4-6]. Scorpion venom toxins may share little sequence homology but have a common shape conferred by four disulfide bridges.

Much effort in the discovery of insect-selective toxins in scorpion venom has been spent re-discovering toxins that are already known. Mass spectrometry offers the potential to de-replicate such redundant efforts.

EXPERIMENTAL METHODS

Venom from the Israeli yellow scorpion (*Leiurus quinquestratus hebraeus*), Egyptian scorpion (*Leiurus quinquestratus quinquestratus*) and Sahara scorpion (*Androctonus australis hector*) were obtained from Sigma Chemical Co. or from laboratory-raised scorpions

Peptides were purified using three stages of liquid chromatographic fractionation. Fractions were evaluated for contractile and flaccid paralytic activity in larvae of the blow fly *Sarcophaga faciliata*. Mammalian toxicity (LD₅₀) was evaluated in Swiss Webster mice 24 h after subcutaneous injection. Only fractions showing no mammalian toxicity were characterized further.

- Venom was separated on a 10 mL CM-52 cellulose (Whatman) cation exchange column using a gradient of 10-500 mM NH₄OAc, pH 6.4 at a flow rate of 10 mL/h
- Fractions from above were separated on a Vydac C4 column (4.6 mm x 250 mm), solvent A = ACN/H₂O (5/95 v/v) + 0.1% heptafluorobutyric acid, solvent B = ACN/H₂O (95/5 v/v) + 0.1% heptafluorobutyric acid; linear gradient from 0-80% B over 120 min at 0.6 mL/min.
- Fractions from above were separated on a Michrom microbore PLRP-S column solvent A = ACN/H₂O (5/95 v/v) + 0.1% TFA, solvent B = ACN/H₂O (95/5 v/v) + 0.1% TFA; linear gradient from 0-60% B over 60 min at 50 µL/min.

Electrospray ionization mass spectra were acquired in positive ion mode on a VG Quattro-BQ mass spectrometer using loop injections of 10 µL and a cone voltage of +50 V. Molecular masses were determined by transforming the region of m/z 400-1600 to true mass scale spectra using the MaxEnt maximum entropy algorithm. Disulfide bonds were measured by treatment with 20 mM dithiothreitol followed by carboxymethylation with iodoacetic acid. Various proteolytic digestions were also employed for peptide mapping.

RESULTS AND DISCUSSION

Scorpion venom contains a complex mixture of peptides, and useful mass spectra were not obtained after low pressure ion exchange purification. Fractions collected after the C4 HPLC purification usually contained multiple but these were easily recognized from the mass spectra. Toxins recognized as subjects of earlier work based upon their molecular mass were usually not purified further unless new minor constituents were also present.

Fractions collected after the third step of purification were often of high purity and were characterized further via proteolysis, ESI mass spectrometry and Edman sequencing. In some cases the ESI spectra revealed the presence of minor components and guided further chromatographic and electrophoretic separation.

These efforts have led to the discovery of more than 20 new venom peptides. One of these new excitatory toxins, designated LqhIT, differs from a depressant toxin from the same venom (LqhIT₂) by substitutions of only two amino acids in variable loop regions. Another, designated as LqhIV (Figure 1), has 96% homology to LqqIV toxin isolated from *L. quinquestratus quinquestratus* but is at least 10-fold less active in mammals.

Fully Stable-Isotope Labeled Proteins: New Techniques for Production and PK/PD Studies Using CRIMS

Blaire L. Osborn and Fred P. Abramson, Department of Pharmacology, George Washington University Medical Center, Washington D.C. 20037

Highly and uniformly stable-isotope labeled proteins are needed for studies using NMR or CRIMS. A practical method for the production of uniformly stable-isotope labeled proteins from a mammalian cell line is described. Uniformly stable-isotope labeled proteins can be produced using bacterial hosts engineered to overexpress the desired protein. Although stable-isotope labeled medium capable of supporting the growth of bacterial cells has been available for several years, this medium will not support the growth of mammalian cells. The nutritional requirements of mammalian cells are far more complex, and the medium for bacterial growth lacks the required amino acids, vitamins, and cofactors needed to support mammalian cells. In addition, endotoxins and other trace contaminants in medium for growing bacteria inhibit growth and protein production in mammalian cells. This abstract describes a practical method for the production of highly stable-isotope labeled proteins from a mammalian cell line using a commercially prepared stable-isotope labeled medium to make preparation of the labeled protein much less time-consuming. This approach was demonstrated by the preparation of uniformly ^{13}C , ^{15}N -labeled rat growth hormone from the rat pituitary tumor cell line GH₃. These cells synthesize and secrete growth hormone when stimulated by steroids like dexamethasone.

To produce the labeled protein, cells were cultured in Celtone-M, a commercially prepared medium that contains all the necessary ^{13}C , ^{15}N -labeled amino acids as well as a U- ^{13}C -labeled carbohydrate source. Culture with labeled Celtone-M began once the cells had been adapted to growth in an unlabeled version of the Celtone-M medium. Cells were stimulated with 1 μM dexamethasone. Growth hormone was secreted into the culture medium, and this medium was removed from the cells every 3-4 days. The growth hormone was purified from the culture medium using ultrafiltration followed by reversed-phase chromatography. Ten mL aliquots of the medium were ultrafiltered first through a 100 kD molecular weight cut-off filter, and the filtrate was centrifuged through a 10 kD molecular weight cut off filter (both Centrplus, Amicon, Beverly, MA). The retentate (about 2 mL) from the 10 kD molecular weight cut-off filter (the fraction >10 and <100 kD) was further purified using reversed-phase HPLC. A Waters 600E HPLC and 490E UV detector were used for the purification. The mobile phases were HPLC grade water (solvent A) and acetonitrile (solvent B), each containing 0.1% trifluoroacetic acid. One mL aliquots of the concentrated cell culture medium were loaded onto a Waters Delta Pak C18 radial compression cartridge (8 x 100 mm, 300 Å pore size), and eluted with a gradient of 30-70% B over 40 minutes. The growth hormone eluted at 37 minutes (Figure 1). This material was dried in a Speed-Vac and stored at -20°C until used for further studies.

The yield of ^{13}C , ^{15}N -labeled growth hormone was approximately 10 mg/L of culture medium. Several analyses were performed to verify that the isolated material was growth hormone and to determine the extent of label incorporation. Electrospray ionization mass spectrometry (ESI) of the purified material revealed that the molecular weight of the unlabeled material derived from the cell was identical to the molecular weight of a pituitary derived rat growth hormone standard. The ^{13}C , ^{15}N -labeled growth hormone derived from the cells had a molecular weight that was 995 units higher (22804 Da.) than its unlabeled counterpart (21809 Da.). The elemental formula for rat growth hormone is $\text{C}_{975}\text{H}_{1518}\text{O}_{286}\text{N}_{265}\text{S}_{10}$, so there are 975 carbons and 262 nitrogens available for labeling. An increase of 995 units in the molecular weight indicates that 81% of the possible carbon and nitrogen sites in the protein are labeled with a heavy isotope.

An alternative strategy to determine the extent of labeling using HPLC/CRIMS indicated that the protein was 89% ^{13}C -labeled (Figure 2). SDS-PAGE and western blot analyses confirmed that the labeled growth hormone migrated similarly to the unlabeled material, and that both labeled and unlabeled growth hormone were immunoreactive. Analytical HPLC using a Brownlee C4 column and a 15-80% acetonitrile gradient showed that the labeled growth hormone had the same retention time as the pituitary derived growth hormone standard.

There are two possibilities as to why the label incorporation in the protein was not greater. First, it is unlikely that the cells were not in culture long enough to completely deplete the existing ^{12}C precursor molecules, because the cells were in continuous culture in labeled medium for four months. It is also possible that not all of the amino acids in the medium were completely labeled. We identified the HPLC retention times of three selected amino acids, and then used HPLC/CRIMS to evaluate the labeled cell culture medium. The labeling in peaks eluting at the known retention time of the amino acids was calculated, indicating that the amino acids were between 89% and 95% ^{13}C -labeled. It is likely that this is the explanation for the 89% ^{13}C labeling we calculated for the growth hormone. The difference between the 81% for total (^{13}C and ^{15}N) labeling from ESI and the 89% for ^{13}C labeling using CRIMS, may represent a difference in extent of ^{13}C labeling versus ^{15}N labeling of the amino acids in the cell culture medium.

This is the first report of production of highly isotopically enriched proteins in this way. Celtone-M is capable of supporting growth of GH₃ cells. Despite published reports that these cells grow poorly and do not secrete growth hormone in serum-free medium, in Celtone-M the cells were capable of growth and secretion of hormone in quantities that permit isolation of the labeled protein.

These results show that growth of a mammalian cell line in Celtone-M is a practical method for the production of a labeled protein. Once cells have been adapted to growth in Celtone-M, the preparation of highly and uniformly labeled proteins from mammalian cells appears no more difficult than production of their unlabeled counterparts. This will make a much wider range of proteins available for NMR and other applications that employ stable-isotope labeled proteins. This study was supported by USPHS Grant NIH-RO1-GM-36143 and NSF Grant BIR9216935.

Figure 1. Preparative reversed phase HPLC - Reversed phase chromatography of the concentrated cell culture medium using a Waters Delta Pak C18 radial compression cartridge, 30-70% ACN gradient, and absorbance at 280 nm. Growth hormone elutes at 37 minutes, marked by the arrow.

Figure 2. HPLC/CRIMS analysis of labeled growth hormone - The upper trace is of m/z 44 and the lower trace is m/z 45. As can be seen, the majority of the CO_2 formed from the dissociation and oxidation of the protein is $^{13}\text{CO}_2$, rather than $^{12}\text{CO}_2$, indicating a high degree of ^{13}C labeling in the protein. The large peak on the upper trace is an unlabeled carbon contaminant, but not uv absorbing, contaminant.

INTRODUCTION : Peptide hormones are growth factors for human lung cancer cells. Degradation of these growth factors is therefore a potential avenue for therapy. Conversely, inhibition of tumor cell growth using peptidyl negative-growth regulators or antagonists to growth-stimulating receptors could be adversely affected by degradation of the peptide. A number of cell-surface degradative proteases have been identified including Neutral Endopeptidase (NEP, EC 3.4.24.11). NEP is a metallopeptidase located on lung cancer cells which cleaves peptide hormones, including gastrin releasing peptide (GRP). Inhibition of NEP results in increased levels of GRP and increased cell growth in lung cancer cell lines known to produce GRP. These cell lines secrete other peptides such as products of the CALC1 gene, calcitonin (CT) and katecalcin (KAT). In order to design peptides resistant to degradation by NEP, and to ensure that exogenous addition of NEP could catabolize stimulatory peptides to non-active fragments, we carried out this study to determine the NEP cleavage sites for several relevant peptides.

METHODOLOGY : To identify NEP target sites, endoproteolytic digests of CT and KAT were carried out in an 100µL reaction mix containing 20 nmol of peptide, 400 ng NEP, 5 mM HEPES and 0.15 M NaCl, for 30min and 4h. Digests were first analyzed using a C₁₈ HPLC column with a gradient from 0-50% acetonitrile in 0.1 M AmSO₄/0.1%TFA. Several fragments were identified by comparison of UV peak retention to previously identified peptides. Unidentified peaks were collected and freeze-dried for MS. The solid (0.3-1.5 nmol peptide with 0.1-0.4 mmol AmSO₄) was dissolved in 100-200 µL of water/ 0.1% TFA immediately before analysis by LC-MS (Fig. 1).

Figure 1 : LC-MS of peak 5 of NEP digestion of CT purified by AmSO₄/C₁₈ HPLC-UV

50 µL was injected onto a 2.1mm C₁₈ column at 100 µL/min and the effluent diverted from the source for 7 min to allow salt to be eluted. The column was eluted with a linear 1%/min AcCN gradient. The effluent was split 1/20 and 5 µL/min was introduced into the source of a PE-SCIEX API 111-*plus* (the balance was collected and freeze-dried). Q1 scans were carried out from 300-1200 amu at orifice potentials of 60-100V. Resolution was ca. 1000. Polymers (detergent or plasticizers) were present in all samples (Fig. 1). Most peptides were identifiable

by their mass in Q1 scan mode (Fig. 2) All peptides were re-analyzed by LC-MS-MS with Ar/He collision gas (CGT 300-350 mTorr, collision energies 40-120 V) (Fig. 3).

Figure 2 : LC-MS of CT 1016.8 amu

Figure 3 : CAD-MS-MS of CT 1016.8 amu

For direct LC-MS analysis, repeat digestion reactions were frozen and immediately freeze-dried. The samples were dissolved in 110µL H₂O/ 1.0%TFA and 10µL was injected onto a 2.1mm C₁₈ column and eluted at 100µL/min with a linear gradient from H₂O/0.1% HCOOH to AcCN:MeOH: H₂O:HCOOH 40:40:20:0.1% (Fig. 4). Flow splitting and LC-MS conditions were as above.

Figure 4 : LC-ESI-MS analysis of digestion of KAT with NEP

RESULTS : We have identified a number of NEP-generated peptides from CT and KAT using LC-MS and LC-MS-MS. These novel cleavage sites expand previously reported peptidolysis catalyzed by NEP (N-terminal to V, F, I, L, A) to include N-terminal to S, T and H.

Monitoring Enzymatic Reactions by Mass Spectrometry

Rodrigo Chavez, Brian Bothner, Christian Strupp, Donald Hilvert*, and Gary Siuzdak*
Department of Chemistry The Scripps Research Institute La Jolla, CA 92037

The development of efficient and facile methods of assaying molecules for catalytic activity is of considerable importance. The ability to detect product formation of molecules not suitable for spectrophotometric techniques would greatly expand and simplify the monitoring of enzyme reactions.

The most common method of monitoring catalytic activity relies on the release of a chromophore. Alternatives generally require chemical modification of the substrate¹, however, this may alter the reaction kinetics or necessitate time-consuming multi-step synthesis.

Mass spectrometry allows for the direct monitoring of substrate and/or product ions². Sampling over the course of a reaction can then be used for quantitative determination of the reaction kinetics.

METHODS

Lipase-catalyzed ester hydrolysis was used as a model system^{3,4}. The modified triglyceride 1,2-O-dilauryl-rac-glycero-3-glutaric acid resorufin ester (1) was used as substrate at an initial concentration of 120 μM . This allowed the reaction to also be monitored by UV-vis (572 nm) to assess the quality of the mass spec data. Bovine lipoprotein lipase (3.1.1.34) 23 nM, was in 25 mM PBS pH 7.0 containing 20% dioxane/acetonitrile at 25°C. The reaction solution also contained 40 μM 1,2-O-dilauryl-rac-glycero-3-benzyl ether as internal standard.

Electrospray ionization data was generated with a Perkin-Elmer SCIEX API III. Aliquots of the reaction were taken at various time intervals, diluted with methanol/dioxane and analyzed using selected ion monitoring. Samples were infused at 4 $\mu\text{L}/\text{min}$ with a needle potential of 5000V and a declustering potential of 100V. Ion intensity ratios from the sample were then compared to standard curves to determine concentration.

RESULTS

Surprisingly little of the expected mono-alcohol product (2) was observed by ESI. It was found that the resorufin ester rather than the glycerol ester of the substrate (1) was

preferentially hydrolyzed forming the acid ester product (3). As shown in Figure 1, initial formation of the acid ester (33.6 $\mu\text{M}/\text{min}/\text{mg}$) correlates with the release of the resorufin chromophore. The initial rate of formation of the mono-alcohol (2) from the acid ester (3) is 3.19 $\mu\text{M}/\text{min}/\text{mg}$.

Because the resorufin substrate was hydrolyzed in an unexpected manner, we examined the reaction with an unactivated dialkyl ester, 1,2-O-dilauryl-rac-glycero-3-glutaric acid-hexyl ester. This substrate lacks a chromophore making its analysis difficult by other techniques. The formation of both the mono-alcohol (2) and the acid ester (3) were monitored. Cleavage of the glycerol ester was preferred over the terminal alkyl ester by a factor of 6.7:1. The initial rate of hydrolysis 46.1 $\mu\text{M}/\text{min}/\text{mg}$ is slightly greater than that of the resorufin substrate (1), suggesting that the resorufin chromophore greatly perturbs the normal processing of glycerol esters, Figure 2.

FIGURE 1

Kinetic plot for the hydrolysis of modified triglyceride. The expected alcohol was generated much more slowly than the detection of resorufin by UV-vis (592 nm). The rate of formation of the acid ester follows the UV-vis data closely.

CONCLUSIONS

- Contrary to expectations, the large aromatic resorufin leaving group apparently orients the substrate within the active site in such a way as to favor cleavage of the activated ester over the natural glycerol ester.
- ESI-MS can be used as a tool to study enzyme kinetics.
- ESI-MS provides direct molecular information that cannot be obtained by UV-vis or other spectrophotometric techniques.
- This technique can potentially work for any reaction that involves a change in mass from substrate to product.

INTRODUCTION

Hemorphins are endogenous peptides that belong to the family of non-classical opioid peptides generated by hydrolysis of proteins originally derived from non-neural tissue. All hemorphins, regardless of their source, are found in the same beta-chain of hemoglobin. Hemorphins have been isolated from human pituitary, plasma and cerebrospinal fluid (CSF). In addition to their opioid effects, the hemorphins have been shown to have an inhibitory effect on angiotensin converting enzyme activity, suggesting a possible involvement in blood pressure regulation. To exert their biological effects *in vivo*, the hemorphins must be formed from the inactive state inside the hemoglobin structure. It has been suggested that proteolytic enzymes present in the circulatory system, could be involved in a degradation of the hemorphins to smaller fragments.

To further explore the physiological relevance of the hemorphins highly efficient techniques for their detection are of importance. In the present experiments we have studied the *in vivo* metabolism of LVV-hemorphin-7 (LVVYPWTQRF) in rat blood and brain by using microdialysis in combination with micro-electrospray mass spectrometry (micro-ESMS). In addition, we have examined the metabolism of LVV-hemorphin-7 in human plasma and CSF by using microdialysis and micro-ESMS. Experiments were performed with and without different protease inhibitors. Tandem MS (MS/MS) was used in order to further verify the structure of the peptide fragments found.

METHODS

Rats were anesthetized and microdialysis probes were implanted into the jugular vein or the striatum of the brain. LVV-hemorphin-7 was infused alone or together with protease inhibitors through the microdialysis probe and samples were taken every 10 min. The stability and metabolism of LVV-hemorphin-7 in human plasma and CSF were examined by adding the peptide to the fluids. Analysis of the microdialysis samples were performed with a Finnigan TSQ7000 triple quadrupole mass spectrometer equipped with an modified Finnigan ES- or Vestec ES-source. A capillary LC/C18 packed column (50 μ m i.d., 40 nL bed volume) was used for the concentration and desalting of the peptides. The dialysis samples were loaded on to a 10 μ L loop on a 10-port valve and washed onto the capillary C18 column. The mobile phase contained 2% methanol/0.25% acetic acid. After

washing, LVV-hemorphin-7 and its fragments were eluted with 50% methanol/0.25% acetic acid at a flow-rate of 800 nL/min directly into the mass spectrometer.

CONCLUSIONS

1. This study has demonstrated that LVV-hemorphin-7 is metabolized *in vitro* and *in vivo* by proteolytic enzymes in the blood and brain.
2. LVV-hemorphin-7 was metabolized mainly from the N-terminal end of the peptide.
3. The fragments found were C-terminal fragments 2-10, 3-10, 4-10, 5-10, 6-10, 7-10, 8-10 and 9-10.
4. It also evident from this study that LVV-hemorphin-7 exhibits a relatively high stability in human plasma and CSF.
5. It was further indicated in the present study that the major enzyme responsible for the metabolism of LVV-hemorphin-7 in human plasma is an amastatin sensitive exopeptidase.
6. Microdialysis in combination with micro-ESMS is advantageous in studying dynamic chemical processes *in vivo*. This technology is the method of choice because of its unique mass specificity.

LVV-hemorphin-7 is metabolized to N-terminal fragments in human plasma by an amastatin-sensitive enzyme

LC-ESIMS AND MALDI-TOFMS PEPTIDE MAPPING OF THE TETANUS TOXIN C FRAGMENT

Harry B. Hines¹, Ernst E. Brueggemann¹, and Terry Sumpter²

¹Toxinology Division, United States Army Medical Research Institute of Infectious Diseases, Ft. Detrick, Frederick, MD

²Chemical Synthesis and Analysis Laboratory, SAIC-Frederick, NCI-FCRDC, Frederick, MD

INTRODUCTION

Cleaving the heavy chain of tetanus or botulinum toxins with papain produces a polypeptide from the carboxy terminus (C fragment) that has a mass of approximately 50,000 daltons. Neither fragment has any neural effects upon mammals, but both are immunogenic and can be used to protect against the respective parent toxin. As part of an effort to produce more effective treatments for botulism that cover most of the serotypes, producing the botulinum C fragment generally involves using recombinant techniques. Depending upon the microbial system used for production, botulinum polypeptide may be modified, which may affect the efficacy of treatment. In this study, we evaluated mass spectrometric mapping parameters for characterizing recombinant botulinum C fragment. Tetanus toxin C fragment was chosen as the model protein because of its similarity to botulinum C fragment, and its commercial availability. The parameter not evaluated in this study was sensitivity. Early comparisons suggested that sensitivity problems were present even with relatively large amounts of analyte.

EXPERIMENTAL

Recombinant tetanus C fragment was purchased from Boehringer-Mannheim. Lys-C endoprotease was purchased from Sigma Chemical Co. (St. Louis, MO). The polypeptide was reduced and alkylated. The digestion was performed overnight at 37°C. Cleavage was terminated by either injection into the LC or lyophilization.

LC-ESIMS PEPTIDE MAPPING

Peptide mapping was performed on a Finnigan MAT 700 mass spectrometer (San Jose, CA) fitted with a C₄ reversed-phase LC column. The fused silica transfer line passed through an ABI 740 UV detector set at 200 nm into an Analytica of Branford (Branford, CT) electrospray ion source operated in positive ion mode at a voltage of approximately -3400 V. The LC gradient was ramped from 100% A to 100% B in 50 minutes. Solvent A was 0.1% formic acid, and solvent B was 0.1% formic acid in acetonitrile. Column flow rate entering the ion source was approximately 2 µl/min. A sheath flow of 5 µl/min containing 90% methanol in 0.1M acetic acid was also used. The mass range was scanned from m/z 200 to m/z 2000 at 3 secs/scan.

MALDI-TOFMS PEPTIDE MAPPING

Peptide mapping was performed on a Bruker Reflex II MALDI-TOF mass spectrometer using the linear mode. A 1 µl portion of the lyophilized digest mixture was diluted 1:5 with 0.1% aqueous trifluoroacetic acid (TFA) and mixed with alpha-cyano-4-hydroxycinnamic acid (CCA) in a 1:1 ratio. One µl of this mixture was placed on the multiple sample stage and allowed to dry at room temperature. In addition, the following matrix preparations were employed:

- 1) Saturated solution of CCA in 30% acetonitrile/0.1% aqueous TFA (referred to as 30% TA).
- 2) Thin-layer CCA prepared according to method of Vorm and Mann (*JASMS*, 5: 955, 1994). Briefly, a saturated solution of CCA in acetone containing 1-2% of 0.1% aqueous TFA was placed on a sample holder and allowed to rapidly spread and dry. An aliquot of the digestion mixture was placed on the surface of the dried matrix and allowed to dry again. The sample site was then washed twice with 0.1% TFA before analysis.
- 3) Saturated CCA in a 2:3:1 volumetric mixture of 2-propanol:water:formic acid (PF).
- 4) 10 mg/ml of 2,5-dihydroxybenzoic acid (DHB) in 30% TA solution.
- 5) Conventional CCA with 20mM N-octylglucopyranoside (OGP).

Samples were irradiated with a New Wave Nd:YAG laser at 355 nm with a pulse width of ca. 5 ns. The accelerating voltage was 28 kV. A 1 GHz digitizer provided 2 ns resolution. Data acquisition and reduction were controlled by a Sun Sparc 5 computer utilizing Bruker software. Typically, 10-50 laser shots were summed to produce spectra.

RESULTS AND DISCUSSION

Early comparisons indicated that some mass bias existed for MALDI-TOFMS when only CCA was used. Sample matrix, sample solubility, and crystal formation have enormous impacts upon the quality of MALDI spectra. When one or more conditions are not met, peptide ion distribution is severely affected. In this case, either sample solubility or digestion buffer salts seemed to be the principle problem. It was overcome by using different matrix preparations, including some additives such as N-octylglucopyranoside, or by removing digestion buffer salts. Identifying proper analytical conditions lengthens analysis time initially, but, once the proper matrix or condition is identified, analysis time for individual samples shortened for MALDI-TOFMS analysis.

For LC-ESIMS, buffer salts did not interfere with analyses. Chromatographic performance was compromised with formic acid, but trifluoroacetic acid, which produces better peak shapes, severely quenches the electrospray signal. Consistent peptide identifications were obtained, which covered greater than 50% of the expected peptides in the tetanus C fragment. This contrasted with the slightly lower coverage obtained with MALDI-TOFMS, when the best matrix was used to acquire data. Analysis times for LC-ESIMS were relatively constant, although relatively longer. Another attribute for LC-ESIMS was the constancy of analytical conditions, which are applicable to many different protein digests without modification. Buffer salts were easily removed from samples by chromatography in-line. Separate efforts were required for MALDI sample preparation. We also found that map coverage was slightly better for LC-ESIMS, when compared to MALDI-TOFMS. Several notable losses were the larger peptides at m/z 4,018 (L4) and 4,694 (L13). These peptides are hydrophobic. Peptide L4 was found with MALDI. Neither MALDI or ESI identified L13. Based upon these results, LC-ESIMS is the better technique for characterizing recombinant botulinum C fragments, if few samples are analyzed. For many samples, MALDI-TOFMS would be better.

Electrospray Tandem MS for Amino Acid Sequence Determination in Antineoplastic Peptides.

John Roboz, Tsonghui Wang and Long Hua Ma, Div. Neoplastic Diseases, Dept. Medicine, Mount Sinai School of Medicine, One Gustave Levy Place, New York, NY, 10029

OBJECTIVE. Based upon the demonstrated *in vitro* and *in vivo* antineoplastic activity of synthetic tri- and tetrapeptides from which L-m-Sarcosylisin (SL, m[di(2-chloroethyl) amino]-L-phenylalanine) is released,¹⁻³ the objective has been to correlate peaks with substructure in the ESI spectra of the following six sarcosylisin-containing peptide ethyl esters: L-m-SL-L-Arg(NO₂)-L-Norval, L-Ser-L-p-FPhe-L-m-SL, L-p-FPhe-L-m-SL-Asn, L-Pro-L-m-SL-L-p-FPhe, L-p-FPhe-L-m-SL-L-Met and L-p-FPhe-Gly-L-m-SL-L-Norval.

EXPERIMENTAL. Peptides were dissolved in acetonitrile-water (1:1, v/v) to yield 200 ng/μL. NaCl (5 μmole) was added for negative ESI. Five-ten μL aliquots were delivered into the source by a syringe pump (Isco 100D) at 5 μL/min flow rate. After obtaining positive and negative ESI spectra, CID spectra were obtained from MH⁺ and (M+Cl)⁺ precursors at 50-100 V collision energy (Fisons, Model Quattro triple quadrupole mass spectrometer). Sequence and in-chain ions were designated as per Ref. 4, and side chain and other ions were identified.

RESULTS. Fig. 1a and 1b show regular ESI and CID [of the (MH)⁺], respectively, positive ion spectra of L-Pro-L-m-SL-L-p-FPhe (M.W.=594 Da); Fig. 1c shows interpretation using the symbolism of Ref. 4, and Fig. 1d shows the substructures of structurally significant ions. The spectra and interpretation of the other five compounds were similar to the one shown in the figure.

Sequence related ions: (a) A₁ (N terminal) and Y₁⁺ (C terminal) present in all samples, with increased abundance in CID from MH⁺; (b) Important Y₂⁺ ions only appear in CID; (c) B₂ ions appear in all CID spectra (not in all MS spectra), (d) B₃ ions appear in tetra-peptide. In-chain ions: A₂Y₂⁺ and B₂Y₂⁺ (tripeptide) and A₃Y₂⁺, etc (tetra-peptide) ions, when present in CID at high abundance, provided additional sequence confirmation. Most other ions, useful in identifying particular amino acids, came from three kinds of side chains: (a) Loss of Cl-containing moieties from SL subunit; (b) Loss of side chain from Arg subunit; (c) Loss of side chain from Asn subunit;

CONCLUSIONS. *Positive ions:* (a) CID yielded high ion abundances and additional structurally important ions; (b) Abundant peaks characteristic for sarcosylisin were present in all compounds at m/z=259 [NH₂⁺=CH-CH₂-(m)-C₆H₄-N(C₂H₄Cl)₂] and, in CID only, m/z=287 [NH₂-CH(CO)-CH₂-(m)-C₆H₄-N(C₂H₄Cl)₂]; (c) Identity and sequence of amino acids could be defined unambiguously; (d) CID, in the parent mode, of selected ions may be used for the detection and identification of metabolites. *Negative ions:* (a) Little structural information from CID; (b) No (M-H)⁻ ions, but abundant (M+Cl)⁻ ions which may be used for identification of individual peptides in mixtures used in chemotherapy.

Early Time Frame Metastable Ion Decay in MALDI

Robert S. Brown, Duane Reiber and Jinhua Feng, Department of Chemistry and Biochemistry, Utah State University, Logan, UT 84322-0300

Post source decay (PSD) in MALDI has become an important analytical tool for determining peptide sequences. Understanding the underlying processes responsible for generation of these metastable ion decay fragments is also critical in obtaining a complete and accurate model of the actual MALDI mechanism. In addition to these longer time frame metastable ions that are generated during MALDI, much earlier time frame fragmentation is also observed through the use of delayed extraction TOF-MS and is considerably different from PSD in terms of the ion series produced. Obtaining a better understanding of this in-source decay (ISD) fragmentation, along with its relationship, if any, to the longer time frame PSD ion fragmentation will help in developing more accurate general models of the MALDI process.

Early studies of the ISD process had suggested that fragmentation was complete in less than 300 ns after the laser event. By modification of the pulsed extraction triggering circuitry, we have shortened this minimum delay to as little as 170 ns after the laser desorption event and have observed the ISD fragmentation to delay times as long as 2000 ns. Fragmentation remains extremely constant over this time frame range (top figure) when laser fluence is adjusted to produce constant intensities of the molecular ion species and by adjusting the pulsed extraction conditions to properly focus the ISD ions at different delays. No evidence of new PSD type fragment ions can be found in the ISD spectra collected at longer delay times, suggesting these metastable ion decay occur on a time frame longer than 2000 ns.

Several different laser parameters have been examined as to their effect on the ISD fragments formed. Laser pulse width appears to have no effect on the ISD spectra based upon the results from a 700 ps and 5 ns pulse width N_2 laser. The resulting spectra are indistinguishable from each other when the laser fluence employed with each laser is adjusted to produce equal intensities of protonated molecular ion signals. This suggests that photodissociation of initially desorbed ions in the laser beam following the desorption event is not responsible for the observed ISD fragmentation. The laser wavelength employed does effect the extent of ISD fragmentation, although care must be exercised in choosing an appropriately absorbing matrix which has high molar absorptivity at both wavelengths. The intensity of the ISD fragments (scaled to the protonated molecular ion signals) clearly increases significantly when the desorption wavelength is lowered from 337 nm to 266 nm. Additionally, preferentially enhanced cleavage at 266 nm is observed at the two oxidized cysteine amino acid residues in the oxidized B chain of insulin at higher laser fluence and generally is useful as an indicator of the total fluence being employed to generate ISD fragments. Minimizing the differences in intensities of these fragments (y_{11} , c_{18} , y_{23} and c_6) with respect to other ISD fragments insured that excessive laser fluences were not being employed to generate ISD spectra on sample poor matrix surfaces.

The most dramatic changes observed to date in the ISD spectra are due to the use of different MALDI matrices. 2,5-dihydroxy benzoic acid (DHB) is an excellent ISD generating matrix which produces both an intense y and c series of fragments for the B chain of insulin. "Super DHB" (a 9/1 mixture of 2,5-dihydroxy and 2-hydroxy-5-methoxy benzoic acid) has been reported to dramatically reduce the PSD of peptides. In the case of ISD fragmentation, similar decreases are observed in comparison to DHB. The y series ions are almost completely suppressed and the c series are reduced to about a third of their intensities when "super DHB" is utilized instead of DHB (see lower figure). Interestingly, the y series ions are those ISD ions that are similarly observed with PSD. Even more dramatic reductions in the ISD fragmentation is observed with α -cyano-3,4,5-trimethoxy cinnamic acid as a matrix which has recently been synthesized in our laboratory. This significant decrease in ISD fragmentation suggests that the hydroxy substituent common to most MALDI matrices may play a significant role in ISD ion formation. It will be interesting to observe whether similar reductions in the extent of PSD ion formation also occurs with this new matrix or whether the reduced fragmentation is unique to the ISD fragmentation pathways.

Novel Method for the Measurement of the Initial Velocity of Ions Generated by MALDI

Peter Juhasz, Marvin L. Vestal, and Stephen A. Martin
PerSeptive Biosystems, Inc., 500 Old Connecticut Path, Framingham, MA 01701

The initial velocity of ions acquired in the MALDI process is an important variable for the understanding of the underlying desorption mechanism. Several experiments have been reported on this topic [1] and even theoretical calculations have been published, however, there is little consistency among these investigations. Average initial velocities of sample ions were observed between 300 and 1000 m/sec and between 300 and 1700 m/sec for matrix ions. It was found that ejection velocity depends very weakly on the mass of the analyte, but the effects of experimental conditions such as matrix substance, wavelength, and ion polarity, have not been explored. On the other hand, when applying internal calibration to delayed extraction time-of-flight (DE TOF) data, we observed systematic deviation from the linearity of t vs. $(m/z)^{1/2}$ which was attributed to the effects of the initial velocity [2]. Determining the initial velocity by means of delayed extraction experiments offered two goals: a more comprehensive study of the initial velocity than it had previously been possible and use of correct velocity information to improve the calibration procedure and thereby mass accuracy.

It was noticed that flight times of ions on a DE TOF instrument increased linearly with increasing extraction delay. This phenomenon could be explained theoretically, and it was shown that the relative change of flight time obeys the relationship: $t^{-1}(dt/d\tau) = \beta v_0$ where t is the flight time, τ is the extraction delay, and v_0 is the average value of the axial component of the initial velocity. Coefficient β is a complicated function of the instrumental geometry, but, importantly, it is independent of voltages, ion mass and charge. It is also required that time measurement is initiated by the extraction pulse. This simple relationship between flight time and extraction delay renders the velocity a readily measurable quantity.

The experiments were carried out on a linear TOF mass spectrometer equipped with a DE ion source as described in Reference 2. After carefully adjusting the electric field zero before ion extraction, changes of flight times were recorded over a

Table 1. Velocity measurements on the ions of bovine insulin desorbed from various matrices.

Matrix	λ (nm)	Polarity	Velocity (m/s)
α CHCA	337	+	311 $\pm$ 22
		-	259 $\pm$ 47
	266	+	339 $\pm$ 47
		-	
Sinapinic acid	337	+	308 $\pm$ 91
		-	264 $\pm$ 54
sDHB	337	+	505 $\pm$ 15
		-	396 $\pm$ 38
HABA	337	+	287 $\pm$ 15
3-HPA	337	+	537 $\pm$ 69
2-thiohydantoin	266	+	376 $\pm$ 56

fixed change of the extraction delay. Many measurements were averaged over different spots on the sample surface. The study was extended to a variety of matrices: α -cyano-4-hydroxycinnamic acid (α CHCA), sinapinic acid, 2,5-dihydroxybenzoic acid mixed with 5-methoxysalicylic acid (sDHB), 2-(4-hydroxyphenylazo)benzoic acid (HABA), 3-hydroxypicolinic acid (3-HPA), and 2-thiohydantoin. Samples included peptides, proteins, and oligonucleotides.

Effect of the matrix. The matrix has the strongest effect on the initial velocity of sample ions. Table 1 summarizes the comparison of various matrices on test sample bovine insulin. A similar order of velocities was observed on the ions of matrices themselves, but the values were 15-40% higher the velocity of insulin ions.

Effect of the molecular weight of the sample. MW dependence was studied on the following samples: bradykinin, synthetic peptide (RG)₁₀, oxidized B-chain of insulin, insulin, ubiquitin, α -lactalbumin, α -chymotrypsinogen-I (in α CHCA, sinapinic acid, sDHB matrices), and DNA 12-mer, 25-mer, 31-mer and 45-mer (3-HPA matrix). Results with different matrices are summarized in Figure 1.

Improvement of calibration by utilizing velocity information. A more complete TOF equation was derived to include the effect of initial velocity. A sample DNA ladder containing failure sequences up to 19-mer was calibrated with and without velocity correction. Using a value of 550 m/sec (which was read out from Figure 1 for 3-HPA matrix) velocity correction decreased mass measurement error on 16 oligonucleotides from 375 ppm to 44 ppm (root-mean-square).

Figure 1 Initial velocity as a function of the molecular weight of the sample.

Measurement of MALDI Initial Ion Velocities

Larry M. Russon, Randy M. Whittal, and Liang Li
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada T6G 2G2

Accurate ion simulations of the time-lag focusing (TLF) concept is dependent on accurate measurements of the initial ion velocities. There have been several groups who have reported measurements of MALDI ion velocities with a variety of results. Beavis and Chait¹ reported a common velocity of 750 m/s for ions in the mass range of 1000-15000 Da. Standing, et al.,² likewise reported a common velocity for all heavy peptides up to 100 kDa, however their value was slightly lower, ~500 m/s. Meanwhile, Pan and Cotter³ reported initial ion energies that correspond to a range of velocities, the lighter ions having higher velocities. It appears that there may be some instrumental factors influencing the results. In an attempt to accurately model the instrument at hand we performed our own set of velocity measurements.

In Beavis and Chait's method the time of arrival of ions desorbed in a constant accelerating field is compared to that of an ion desorbed in a field-free region placed just before the acceleration optics. The difference in flight time is related to the time the ion spend in the field-free region. There is some concern, however, about the effects of the accelerating fields that might penetrate the initial field-free region. Additionally the energy deficit experiments reported by Standing, et al.,⁴ underscores inherent differences in the ionization dynamics in the presence of an electric field.

We have developed a method of measuring the initial ion velocity while maintaining a consistently field-free ionization environment. The source consists of four electrode plates. The first two plates were held at 20 kV, thus establishing an initial field-free region. The third plate was held at 10 kV and the last plate at ground. The distance between the first two plates, and hence the length of the field-free region, was varied. A linear fit to a plot of the peak time of arrival of the ions versus the length of the field-free region yields a function whose slope is the inverse of the ion velocity. Any stray fields that may exist the field-free region will be constant and will affect the intercept of the fitted line, but should not have a significant impact on the slope.

The results of these studies are shown in Figure 1. We find that the initial ion velocities are strongly mass dependent, especially for the lighter ions. As the ion mass increases the velocities level off at around 500-600 m/s. Ions within the mass range of 1000 - 24000 were investigated. The effects of this observation are manifested in the optimization of TLF conditions. Figure 2 shows the optimum pulse voltage for ions of various masses. It is clear that the optimum pulse voltage is dependent on the ion mass in a non-linear fashion. Because the lighter ions have a higher velocity they are farther away from the repeller at the time of the TLF pulse and therefore require a lower pulse voltage for optimum focusing. The same effect is observed when longer delay times are used.

We are also in the process of studying the effect of other experimental parameters on the performance of TLF TOF MS. For example, we found that the observed mass resolution for isotopically resolved peaks is dependent on the vacuum pressure of the system and the pulse width of the desorption laser. When the pressure increases, the resolution is found to decrease. When a short pulse (2 ns) from a Nd:YAG laser at 355 nm is used, the peak width from bradykinin is found to be in the range of 2.50 - 2.95 ns. When the long pulse (5 ns) for the Nd:YAG laser is used, the peak width increases to 4.35 - 4.65 ns.

The Matrix Suppression Effect and Ionization Mechanisms in MALDI

Richard Knochenmuss, Frédéric Dubois, Michael J. Dale and Renato Zenobi*
Laboratorium für Organische Chemie, Universitätsstr. 16, ETH Zürich
CH-8092 Zürich, Switzerland

At appropriate matrix:analyte mixing ratios, small to moderate sized analyte ions (1000-20000 Da) can fully suppress positive matrix ions in MALDI mass spectra [1,2]. This is true for all matrix species, including radical cations and adducts with protons or alkali metal ions, as is shown in Fig. 1. Full matrix suppression is also observed regardless of the preferred analyte ion form, be it protonated or an alkali adduct.

These facts lead us to propose a mechanism where both types of analyte signal, protonated or cationized, are created by chemical ionization pathways involving a common precursor: the electronically excited molecule. Such a mechanism is presented below (mH = matrix, m^*H =electronically excited matrix, A =analyte, X =counterion in sodium salt):

protonation

cationization

There should also be a similar pathway to matrix ions such as mH^+ , when analyte is not in the vicinity:

The first key feature we wish to focus on is the central role of the excited matrix species as a precursor for both protonated and cationized analyte ions. The second key feature is the presence of a second excited matrix molecule in close proximity on both pathways. There are two reasons for including a second excited molecule. First, the 3.7 eV from a single 337 nm nitrogen laser photon is insufficient for efficient charge separation, since the Coulomb energy is 4-6 eV. Second, it is known [3] that desorption begins at laser fluences where matrix fluorescence quenching becomes significant, indicating that the

excitation density is high enough for two excited matrix molecules to meet with substantial frequency. The requirement for (at least) two excited matrix molecules also leads to predictions that are experimentally verifiable.

The model can be tested in numerous ways. It will predict for instance a laser pulse energy dependence rather than a peak power dependence. This can be verified experimentally with a modified MALDI experiment in which the necessary excitation density is created by two temporally separated low-intensity pulses. The two pulses were brought onto the sample with 5.5 ns time difference. The measured pulse width was 3.2 ns, so there was no significant temporal overlap. Clearly both pulses are individually near-threshold, but together yield a good MALDI spectrum (see Fig. 2), as predicted by the model where only the excitation density is important.

Numerous other aspects of the model were found to be consistent with existing and new data.

Fig. 1: Positive ion MALDI mass spectra of substance P in DHB. In the upper spectrum the matrix-to-analyte mole ratio was 1000. In the lower, it was decreased to 100.

Fig. 2: MALDI mass spectra of Valinomycin in the 2-pulse experiment.

²Department of Chemistry, California Institute of Technology, Pasadena, CA 91125.

A critical parameter in the successful application of MALDI, particularly for oligonucleotides, is the selection of a suitable matrix. Matrices are typically low molecular weight compounds (<250 amu) that have low volatility, absorb ultra-violet radiation and can incorporate analyte molecules into their crystal lattices. Matrix is not only important for analyte desorption but also generating a variety of charged species including ionized analyte species. The precise mechanism of ion nascency is yet to be discerned. However, proton transfer reactions are known to be critical for analyte ionization since analyte molecular ions are always detected as either protonated ($M+H$)⁺ or deprotonated species ($M-H$)⁻ depending on the analysis mode (positive-ion or negative-ion).

Proton transfer reactions are also thought to play a central role in oligonucleotides fragmentation during MALDI. Evidence currently indicates that oligonucleotide fragmentation is initiated by protonation of the nucleobase which results in loss of a neutral nucleobase. The positive charge then remains on the ribose ring and cleavage of the sugar phosphate backbone ensues. Previous experiments explain why the four nucleobases display different propensities to fragmentation ($T \ll C < A < G$) but have not explored reasons for the dramatically different amounts of fragmentation observed in different matrices (see Fig. 1). If base protonation initiates fragmentation, then the different amounts of fragmentation observed in different matrices must be related to the various matrices' abilities to protonate the nucleobases. In order to develop a better understanding of the system, accurate thermodynamic data for the species involved is imperative. In this paper, we present the calculated and measured proton affinities for five commonly used MALDI matrices. The calculated deprotonation energies for these same matrices are also presented.

Proton affinities and deprotonation energies were estimated using semi-empirical (AM1) calculations. Proton affinities of the matrices were then measured using bracketing and equilibrium methods in a FT-ICR mass spectrometer. Non-volatile matrix compounds were introduced using a heated probe tip located proximally to the ICR cell. Temperatures of 50-100°C were required to produce sufficient vapor pressures of the matrices.

AM1 calculations predicted PAs within 4.5 kcal/mol. However AM1 calculations did reverse the relative order for 3HPA and THAP.

MATRICES	Proton Affinities ^a		Gas-Phase Acidities ^a	
	AM1 Calculated	Experimental	-OH	-COOH
3HPA	210	214.5	327.6 ^b	338.9
THAP	211	210.8	327.6 ^b	na
SA	207	210±2	326.8 ^c	348.1
25DHBA	202	202.9	331.0 ^b	339.4
4HCCA	202		320.3 ^c	339.9

^aAll values reported in kcal/mol.

^bRefers to -OH ortho to -COOH. In all cases, ortho corresponded to the lowest acidity value.

^cRefers to the hydroxyl group located at 4' position on the benzene ring.

The fragmentation propensity of dT₄GT₁₀ was studied in the five matrices using negative-ion mode conditions on a Vestec VT2000 time-of-flight mass spectrometer. No fragmentation was observed in 3HPA, however varying amounts of fragmentation were apparent in the four other matrices. Fragmentation propensities were quantified by comparing the ratio of ion intensities of the 3'-end fragment (pT_{10}) and the parent ion ($M-H$). A correlation between the fragmentation propensity and the matrix proton affinity was apparent (see Figure 2). This relationship, however rapidly disappears at higher laser powers indicating that matrix PA probably plays a minor role in oligonucleotide fragmentation particularly at higher laser powers.

How matrices influence the amount of oligonucleotide fragmentation during MALDI process is still unclear. Various scenarios have been put forth to explain the observed stability in 3HPA; however, as of yet none have been confirmed. Ongoing research is necessary in order to understand how matrix parameters can be manipulated in order to influence oligonucleotide stability during MALDI. By deepening our understanding of the fundamental chemistry of DNA fragmentation and expanding the data base, we hope to be able to develop MALDI into a powerful robust and versatile methodology for nucleic acid analysis.

This work was supported by Department of Energy Human Genome Program Grant No. DE-FG02-91 ER61130 and NSF Grant No CHE-9007850.

²Molecular Analytical Systems, 2121 Sage Road, Suite 280, Houston, TX 77056

Synthetic polymers with desirable film-forming characteristics have been chemically modified to incorporate, covalently, UV energy-absorbing molecules (EAM) of a type used for matrix-assisted laser desorption/ionization (MALDI) time-of-flight mass spectrometry. The polymer-bound EAM were activated to covalently bind macromolecules *through the carboxylate group of the bound EAM*. The EAM was shown to act as a photolabile macromolecular tether. Biomolecules covalently bound to surface arrays of EAM-polymer were uncoupled and desorbed/ionized with single pulses of laser irradiation.

For a wide variety of surface-based chemical array technologies, it is highly desirable for covalently tethered target molecules to be *simultaneously* uncoupled/desorbed directly by laser irradiation. The optimal biomolecular-surface tether for these purposes should employ a photolytic reaction mechanism that is highly efficient and homogeneous. We chose to investigate chemically modified energy absorbing molecules of the type originally reported to assist laser-induced macromolecular desorption/ionization either in the MALDI mode or bound to the probe surface for operation in the SEND mode. We have synthesized probe surfaces and film-forming polymers with covalently bound energy absorbing molecules using derivatives of -cyano-4-hydroxycinnamic acid, introduced originally used as a "matrix" molecule⁴ for MALDI. We have found the covalently bound EAM to undergo laser-induced photolytic cleavage/release events that are both predictable and reproducible.

The intent was to develop the polymer-bound EAM as a tethering device without loss of the energy absorption/photolytic characteristics necessary to accomplish a subsequent photon-induced uncoupling reaction that would occur simultaneously with desorption/ionization. A separate goal was to use the covalent polymer-EAM-biomolecule assembly to present bound target biopolymers in predetermined arrays on a variety of different probe surfaces (e.g., steel), if necessary, without prior chemical derivatization of the probe platform surface itself.

The polymer-EAM-peptide was next evaluated to determine whether the photolabile nature of the phenoxy ester bond linking the EAM to the polymer on the probe surface was preserved after covalent attachment of the peptide.

One way to exploit the benefits of laser desorption/ionization methods for biological mass spectrometry and to eliminate interference from matrix and other contaminants during interim

analyte modification/recognition events conducted *in situ* is to covalently coupled biopolymer analytes directly to probe surfaces. We have accomplished this by converting bound energy absorbing molecules on a SEND polymer into covalent tethers for biomolecules. We are now exploring the ability of probe surfaces defined by the polymer-EAM-peptide described here to promote laser-induced desorption of the tethered biomolecules without added matrix (in preparation).

These results, involving defined chemistries for presentation of covalently bound analyte can be useful not only to explore ways to eliminate the ambiguities and uncertainties associated with the random process of matrix-dependent distribution of analytes on a probe surface but also to improve our understanding of the chemistry and physics of successful photon-induced desorption/ionization events involving large non-volatile macromolecules.

TX 75235

Peptides presented at the cell surface by Major Histocompatibility (MHC) class I molecules are from degraded cellular proteins as well as viral and tumor antigens. Sequencing MHC class I peptide is a true analytical challenge as bioactive peptides must be isolated and purified from a large pool of similar molecules. At best we are able to isolate 100 femtomoles. The objective of this work is to characterize the diversity and structure of endogenous peptides bound to the major histocompatibility complex (MHC) class Ib molecule (Qa-1^b). Since Qa-1^b proteins display low polymorphism and function as minor transplantation antigens, they may bind a limited spectrum of peptides. We used Qa-1^b specific alloreactive cytotoxic T lymphocytes (CTLs) as well as a Kompact MALDI III and an in house built MALDI/TOF with a curved-field reflectron together with *in situ* enzymatic digests to identify and sequence the Qa-1^b peptide.

Qa-1^b peptide isolation: 1X10⁹ H-2^b lymphoblasts were harvested and acid extracted. The acid extract was size fractionated using Centrprep membrane filters, and the low molecular weight material lyophilized. The lyophilized sample was resuspended in 1 ml of 0.1% TFA/water and fractionated by RP HPLC. CTLs were used to identify the fractions containing the Qa-1^b associated peptide.

Enzymatic Digests: All reactions were carried out on the sample probe. The matrix was a saturated solution of α -cyano-4-hydroxycinnamic acid in 50% ethanol. All buffers used were ammonium buffers. 20% of the bioactive fraction was lyophilized and resuspended in 7 μ l of 0.1% TFA/water/20% acetonitrile. The reaction mixture consisted of 0.3 μ l bioactive fraction + 0.3 μ l buffer + 0.3 μ l enzyme. The mixture was incubated at room temperature and the reaction stopped by adding 0.3 μ l matrix solution.

The bioactive fraction was analyzed by MALDI following digestion with aminopeptidase carboxypeptidase (fig. 1) and chymotrypsin and peptide ladders generated. Post source decay spectra of the bioactive peptide (fig. 2) as well as each of the peptides in the ladders were acquired thus allowing us to deduce the sequence. Combining MALDI-TOF PSD with enzymatic digestion of the bioactive peptide resulted in a powerful tool that allowed us to sequence the Qa-1^b peptide by combining the mass selectivity of PSD with the unambiguous sequence assignment of enzymatic digestions.

Examining the MALDI Ion Formation Process(es)

Ricky D. Edmondson, Damon C. Barbacci, Kent J. Gillig, and David H. Russell
Laboratory for Biological Mass Spectrometry, Department of Chemistry
Texas A&M University, College Station, Texas 77843

We have observed that substantial improvements in mass resolution can be made by optimizing sample preparations. Figures 1 and 2 contain MALDI reflectron TOF mass spectra of melittin. The matrix, amount of analyte, laser fluence, and instrumental parameters are identical for the two spectra, they only differ in how the samples were prepared. The spectra contained in Figure 1 was prepared using the overlayer method, whereas, the spectra contained in Figure 2 was prepared by the dried droplet method. We explain the differences in the observed spectrum in terms of a time component of MALDI ion formation.

The resolution of a MALDI-Linear TOF mass spectrum is certainly limited by the broad kinetic energy distribution of the ions. However, if the only factor limiting the resolution was the kinetic energy spread a reflectron would be able to compensate for this distribution, yielding high resolution mass spectra. When compared to spectra in the linear mode, reflected spectra do show improvements in the resolution of peaks, but the observed increases are not as great as calculations predict. Figure 3 shows the theoretical peak profiles of melittin calculated using a computer program written in-house. The first trace contains the theoretical peak profile for melittin $[M+H]^+$ ions that are formed only during the laser pulse (3ns). The other traces depict the peak profiles of ions with a delayed ion formation (DIF). That is, ions are formed during and up to X ns after the laser pulse. A DIF of 6-8 ns used in the calculation fits the observed spectra from the overlayer prepared sample; whereas, a DIF of 25-30 ns fits the spectra from the dried droplet. Figure 4 contains theoretical peak profiles of bovine insulin b-chain, calculated with several DIF values. Figure 5 contains a MALDI/TOF mass spectrum of bovine insulin b-chain, acquired from a sample spot prepared by the overlayer method. The observed resolution is consistent with a DIF of ~ 6ns. A comparative spectrum prepared by the dried droplet was attempted but ion signal for the $[M+H]^+$ was not observed, presumably due to fragmentation in the drift tube. In addition to increased resolution we also observe an increase in the mass measurement accuracy. MALDI/TOF mass spectra were acquired of a peptide mixture that contained angiotensin II (1045.534), bradykinin (1059.561), angiotensin I (1295.677), α -melanocyte stimulating hormone (1663.793), and melittin (2844.754). Calibration using angiotensin II and melittin yield average mass errors of only 3 ppm for the peptides.

In addition to the energy focusing that occurs using delayed extraction MALDI/TOF we would argue that some of the increased resolution is due to the delay time neglecting the impact of a delayed ion formation.

New Technique for Trapping of MALDI Generated Ions Inside an ICR Cell

M. Knobeler and K.P. Wanczek

Institute of Inorg. and Phys. Chemistry, University of Bremen, D-28334 Bremen, Germany

The coupling of Matrix assisted Laser Desorption/Ionization (MALDI) and the Fourier transform ion cyclotron mass spectrometry (FT ICR MS) becomes difficult by the high initial kinetic energies of MALDI generated ions¹ on the one hand and by the low trapping voltages needed for high mass resolution and mass accuracy at FT ICR MS² on the other hand. Besides other techniques the method of the gated retarding potential³ is very successful for MALDI in front of the ICR cell: a retarding potential U_{ret} is generated inside the ICR cell during the retarding time t_{ret} (0V at the front end electrode and the retarding voltage V_{ret} at the rear end electrode); after it, the potential is switched to the usual trapping potential U_{trap} (trapping voltage V_{trap} at both end electrodes). The method was improved by generating the ions directly at the front end electrode⁴, the ions are produced inside the cell that guarantees no ion loss before the retarding and the action of the retarding potential immediately after the ionization.

Applying a sufficiently high retarding voltage, an ion without a radial velocity component is always trapped and stored if the retarding time t_{ret} coincide with the moment t_{turn} of the turnaroundpoint of the ion motion in the retarding potential ($t_{ret}=t_{turn}$). Unfortunately, t_{turn} depends generally on the axial initial velocity, even for ions of one mass. Due to the distribution of the initial velocity¹ only a portion of the generated ions can be trapped.

For one ion mass, t_{turn} is independent of the initial velocity in the special case of an ideal retarding potential that increases quadratically from the front to the rear end electrode. If $t_{ret}=t_{turn}$ is satisfied, all ions of one mass can be trapped independent of their initial axial velocity (up to a maximum value conditioned by V_{ret}) (fig. 1a). However, the retarding potential inside a cubic cell or inside a cylindrical cell (aspect ratio $L/2R=1$) increases more cubically than quadratically as calculated by SIMION⁵. Simulations with SIMION show that no ion trapping independent of the initial velocity is possible (fig. 1e-h).

Three different solutions are introduced: 1. an almost ideal retarding potential is generated along the z-axis (center line) of the ICR cell by correction electrodes at the side electrodes with 0V, $-V_{ret}$ and V_{ret} ; 2. inside a shortend cell with an aspect ratio of $L/2R=3:4$ the retarding potential is nearly ideal along the z-axis; 3. inside a cubic cell or a cylindrical cell with $L/2R=1$ the retarding potential increases approximately quadratic along the z-axis from the front end electrode to the middle of the cell; by the application of a appropriately raised retarding voltage $V_{ret,real}$ only the first region of the cell is used for retarding. t_{ret} , V_{ret} or $V_{ret,real}$ respectively, can be analytically calculated. The results of simulations with SIMION confirm the ion trapping over a large area of the axial initial velocities (fig. 1b-d).

The ion motion of a radial component of the initial velocity is forced into radial motion by the magnetic field. The radial component of the retarding potential increases the radius of the radial ion motion. However, this negative effect is restricted by the short time of action of the gated retarding potential. The upper mass limit is approximately 1/2 to 3/4 of the upper mass limit that is only limited by the magnetic field and the cell dimension.

The method of the gated ideal retarding potential is suitable for pulsed und simultaneous inlets of ions into the cell with any initial distribution of the axial velocity and limited initial radial velocities, especially for MALDI direct at the ICR cell⁴. Using optimized U_{ret} and t_{ret} , almost all generated ions are trapped. Thereby the sensitivity of MALDI FT ICR MS is essentially increased that allows to minimize the needed amount of sample.

Age-Dating Hydrocarbon Contamination Using High Precision Lead Isotope Analyses
Hurst, Richard W., CHEMPET RESEARCH CORPORATION, Moorpark, CA 93021

Determining the age of a hydrocarbon contaminant, such as gasoline, has been an ongoing problem for environmental professionals, regulators, the petroleum industry, and attorneys. Much of the uncertainty arises from the degradation of hydrocarbons in the environment over time and our inability to quantify the kinetics of these processes under the wide variety of conditions which exist in nature. For example, the figure below summarizes the chronology of gasoline additives and known characteristics of gasolines since 1960 (from the National Institute of Hydrocarbon Fingerprinting, compiled by R.W. Hurst). Although it is possible, in the best situations, to constrain the timing of gasoline releases to 5-10 year intervals using this approach, degradation of hydrocarbons can severely compromise age results based solely on the presence/absence of an additive or gas chromatographic characteristics of a gasoline.

Chronology of Gasoline Additives and Fingerprinting Characteristics

Source: Nat. Inst. Hydrocarbon Fingerprinting
Albuquerque, NM, 1996

Figure Legend

C10+: Hydrocarbons with > 10 carbon atoms
NPBZ: Normal Propyl Benzene
Tol/Benz: Toluene/Benzene Ratio
MTBE: Methyl Tert-Butyl Ether
Mn (MMT): 2-Methyl Cyclopentadienyl
Manganese Tricarbonyl
TEL: Tetraethyllead
EDB: Ethylene Dibromide
EDC: Ethylene Dichloride
Pb: Lead (in grams/gallon)

By comparison, lead derived from the degradation of alkyllead additives in gasoline is retained in soils for decades following gasoline spills, providing a record of the event. But can the lead retained in the environment be used as a chronologic marker of a specific gasoline contamination event?

Research focusing on global lead pollution (e.g. Patterson and colleagues, early 1980's) identified temporal, systematic variations in lead isotope ratios ($^{206}\text{Pb}/^{207}\text{Pb}$, $^{206}\text{Pb}/^{204}\text{Pb}$) of gasoline-derived lead which were attributed to changes in the sources of lead ores used in gasoline additives. Work at CHEMPET, with my partner T.E. Davis and research geochemist B.D. Chinn, indicated lead isotope analyses of kerogens, crude oils, and gasolines had potential as chronologic and fingerprinting tools for both the environmental and petroleum

industries. In 1993, I began to evaluate the possibility that high precision (errors < 0.1%) lead isotope ratios of organically-bound gasoline lead and/or its residue in soils could improve age resolution of gasoline contamination events.

Obtaining well-dated samples of soils impacted by gasoline spills, free products, and archived leaded gasolines, the systematic variations observed by Patterson and others were substantiated, and calibration curves relating lead isotopic variations of gasolines to age were developed (ALAS Model; Anthropogenic Lead ArchaeoStratigraphy). In contrast to Patterson's work, however, ALAS focused on gasoline lead rather than all industrial sources of lead. The ALAS Model has now been used to estimate the timing of gasoline contamination events from 1955 through the present. An example of an ALAS calibration curve and current correlations between the ALAS Model Age and Documented Age of a gasoline contamination event are shown below. The "delta" notation is the difference between the measured lead isotope ratio of a sample and that of an internal standard multiplied by a constant.

ALAS lead isotope ratios (e.g. $^{206}\text{Pb}/^{207}\text{Pb}$) are low in the 1960's (~ 1.15), followed by a rapid increase through the 1970's to values of 1.2, and moderate increases through the 1980's to values of 1.22 (note that these variations are significantly different from analytical errors, typically <0.0005). Since 1988, unleaded gasoline (actually low-lead) lead isotope ratios reflect those of their crude oil source or blends and can be used to help discriminate among different manufacturers' products.

The ALAS Model has been applied successfully in a number of court cases and continues to be refined. Resolution of multiple gasoline contamination events at individual sites over time are also possible and will be addressed in the presentation.

Thermal Desorption - Photoionization Mass Spectrometry of Coals and Soils

Craig W. Bookwalter and Murray V. Johnston
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716

Thermal desorption and degradation products of coal and soil samples are directly characterized by photoionization mass spectrometry. Photoionization (PI) is performed with coherent vacuum ultraviolet radiation from a laser system that generates 1.6 μJ pulses (10^{12} photons/pulse) at a repetition rate up to 100 Hz. A complete mass spectrum is obtained for each laser pulse with a reflectron time-of-flight mass spectrometer (RETOF-MS). When both the photoionization probability and duty factor for ion formation/detection are taken into account, the overall efficiency for PI-RETOF-MS approaches that of electron ionization.

During pyrolysis of coal, complex mixtures of thermal desorption and/or degradation products are released. Mass spectrometric analysis of these products gives information such as rank, maceral content and origin. Figure 1 shows the 10.5 eV photoionization mass spectra of Upper Freeport and Wyodak coal samples. The Upper Freeport sample is classified as a medium volatile bituminous coal and the product distribution is primarily aromatic: alkyl naphthalenes, anthracenes/phenanthrenes and pyrenes/fluoranthrenes dominate the mass spectrum. The Wyodak sample is classified as a subbituminous coal and the product distribution includes small hydroxy aromatic species and large aliphatics: alkyl phenols, dihydroxybenzenes, alkanes, alkenes, and C_{22} to C_{34} fatty acids dominate the mass spectrum. These photoionization spectra are similar to those obtained by field ionization.

Another distinguishing characteristic among coals is the sulfur content. Sulfur exists in both organic and inorganic forms. Organic sulfur species are mainly components of the macromolecular structure of the coal while pyrite is the major inorganic constituent. Organic and pyritic sulfur are indicated by H_2S , CH_3SH , S_2 and H_2S_2 at m/z 34, 48, 64, and 66 respectively. It should be noted that m/z 64 from coal is commonly attributed to sulfur dioxide. However, we can unambiguously assign this ion to S_2 based upon the ionization energies of SO_2 (12.5 eV) and S_2 (9.4 eV), and the photoionization energy (10.5 eV). Upper Freeport contains a relatively large pyritic sulfur content and a relatively small organic sulfur content, while Wyodak contains a relatively large organic content and a small pyritic content. These differences are reflected in the mass spectra: Upper Freeport produces a large S_2 signal at 580°C from pyrite decomposition and a small CH_3SH signal at lower temperatures, while Wyodak produces a larger CH_3SH signal and a smaller S_2 signal. Work is underway to determine whether the signal intensities of these ions can be quantitatively related to the amounts of organic and pyritic sulfur in various coals.

Organic contaminants in soil may become sequestered within the soil matrix over time. Binding of organic molecules to the soil matrix can be assessed by thermal desorption mass spectrometry. Figure 2 shows plots of ion signal intensity vs. temperature for several organic compounds in a sassafras soil matrix. The desorption peaks can be fit to a standard kinetic model to estimate the activation energy for desorption. Changes in the shape or location of the desorption peaks as a function of parameters such as time after the contamination event or organic content of the soil can give information on the sequestration process.

CHARACTERIZATION OF PARAFFIN/NAPHTHENE HYDROCARBONS BY FIELD IONIZATION MASS SPECTROMETRY COUPLED WITH LIQUID CHROMATOGRAPHY

Chang Samuel Hsu, Zhenmin Liang, Saul Blum, Peter Grosshans, and Winston Robbins
Exxon Research and Engineering Company, Annandale, NJ 08801

Saturated hydrocarbons are typically one of the largest molecular types found in petroleum distillate fractions, which consist of several classes of compounds that contribute differently to process performance and product quality. Processes as diverse as lube extraction and catalytic cracking are sensitive to the differences among the straight chain (normal paraffins), branched (isoparaffins), and cyclic (naphthenes) saturates. The measurement of paraffins and naphthene types in saturated hydrocarbons are conventionally characterized by high voltage electron-impact ionization (EI) MS on the basis of intensities of fragment ions. These measurements use established "inverse sensitivity matrices" which are based on two factors: (1) average carbon number estimated from the distribution of low abundance molecular ions of normal paraffins and (2) the normal/isoparaffin ratio estimated from molecular to fragment ion intensities. Ideally, an ionization technique yielding only molecular ions of saturates would allow us to determine not only the distribution of compound types but also the carbon number distribution within each type. Hence, we have investigated field ionization for the on-line LC/MS characterization of heavy saturated hydrocarbon mixtures.

On-line LC/MS for hydrocarbon characterization provides us with many advantages in speed, high chromatographic resolution, repeatability, and accuracy. We have been successful in re-configuring a commercial field ionization source to accommodate a moving belt interface for on-line LC/MS operations. This novel combination generates molecular ions for normal paraffins and naphthenes but significantly fragments isoparaffins. By combining these molecular and fragmentation characteristics we are able to measure levels of naphthenes, normal paraffins, and isoparaffins in a single MS analysis. Hence, the split of normal and isoparaffins can be determined directly for the first time without the need of using GC.

The new technique was validated using a suite of saturated hydrocarbon fractions obtained from a dewaxing process of a lubricant oil extract. The balance of LC/FI/MS results around this separation were in good agreement with the gravimetric measurement of the fractions and normal paraffin measurement by GC. Comparison with results obtained by the conventional ASTM high voltage EI were also favorable.

Total Olefin in Gasoline Determined by Mass Spectrometry and Hydrogenation

Michael Cheng and James Hudson
Chevron Research and Technology Company
Don Drinkwater and Vince Nero
Texaco Research

The Clean Air Act prompted the US EPA to require all gasoline manufacturers to determine total aromatic compounds in gasoline by GCMS. This method is in place and will be a requirement for all gasoline manufacturers starting 1/1/1997. The EPA also expressed interests in the determination of olefin in gasoline. The current method in quantitation of total is ASTM D1319, or the so called fluorescent-indicator-absorption (FIA). This method suffers from lack of precision, because the analyst needs to determine the boundaries of color changes on a silica gel column. There are many proposals to measure total olefin, however, mass spectrometry probably has the greatest potential in not only the quantitation but also the identification of the olefins. We reported earlier a derivatization method to determine the structure of the olefin in gasoline, this report describes an approach in the quantitation of total olefin in gasoline.

There is an ASTM method, D2789 (a modified version is referred to as the 6X6 method), which could be used to measure the concentration, in a gasoline sample, six types of compounds: paraffins, mono-naphthenes, di-naphthenes, alkylbenzenes, benzonaphthenes, and alkyl naphthalenes. The calculation uses the intensity of the characteristic fragment ions from each type of compound. For example, the peaks at m/z 43, 57, 71, 85, and 99 are used to represent the paraffins, the peaks at m/z 41, 55, 69, 83, and 97 are used to represent the mono-naphthenes. This method is only applicable to low olefin gasoline because the olefins will be represented in the mono-naphthene group. To determine total olefin concentration, one can analyze the gasoline sample by the D2789 method, hydrogenate the sample until all of the olefinic double bonds are saturated, then analyze the sample again by D2789. The increase in alkanes and/or the decrease in cycloalkanes will represent the olefin concentration.

We obtained nine gasoline samples, with olefin concentration from 3.8% to 21.4%, by volume, as analyzed by the FIA method. Each sample was analyzed by D2789. Hydrogenation was performed using a Parr shaker over 10% Pd on charcoal at room temperature until hydrogen uptake has halted. The hydrogenated samples were then checked by proton NMR to ensure that olefinic double bonds were saturated. The hydrogenated samples were then analyzed by D2789 again. The decrease in the mono-naphthene group, in volume %, is plotted against olefin in volume % as measured by FIA. The correlation is shown in Figure 1, the decrease in mono-naphthene is labeled as "olefin by 6X6". As shown, if the point were represented by a straight line, they have a R value of 0.948. The slope of the line can be used as a correction factor to determine the concentration of olefins in gasoline samples, if the results are to be comparable to FIA results. The intercept of the line is not zero probably due to the loss of light paraffins in the hydrogenation procedure. Before adding hydrogen, the apparatus was evacuated with a vacuum pump, during that time, small amount of highly volatile compounds were lost. There are probably more volatile paraffins than there are olefins. Another important determination of this procedure is that the sample must be fully hydrogenated. We

originally selected and analyzed twelve gasoline samples, three of them were not included in constructing the correlation plot because NMR showed olefinic protons. If these three were included in the plot, the R value is only 0.845.

The slope of the line in Figure 1 is less than one probably because the naphthenes and the olefins are not additive in a 1:1 ratio. To verify this, we took a standard which contains, by volume, 25% paraffin, 55% naphthene, and 20% aromatic; and added identical known volume of alkenes. Analyzing the products by 6X6, before and after the addition of the alkenes, and the increase of naphthenes are shown in the following table.

COMPOUND	INCREASE IN NAPHTHENE BY 6X6
1-HEXENE	0.9 %
1-OCTENE	0.9 %
1-NONENE	0.4 %
1-DECENE	1.5 %
3-HEXENE	1.5 %
4-OCTENE	3.1 %
4-NONENE	2.8 %
5-DECENE	2.3 %
AVERAGE	1.675 %

As shown, each alkene shows different amount of increase, and there seems to be a difference between the terminal and the internal alkenes. If the alkenes and the naphthenes are 1:1 additive, the increase should be 4.1%, but the average from the table is 1.675%. This factor of 2.44 contributes to the non-unity slope shown in Figure 1. Even though, the alkenes shown in the table are not a good representation of the alkenes in a gasoline sample, this offers an explanation for the lack of 1:1 relationship between the two methods.

THE ANALYSIS OF OLEFINS BY SELECTIVE CHEMICAL IONIZATION MS

S. G. Roussis and J.W. Fedora
Imperial Oil, Sarnia Research Centre, Sarnia, Canada, N7T 7M1

The concentration and nature of the various olefinic structures in complex hydrocarbon mixtures are important in the production of gasolines, lube oils, and chemical plant products (e.g., nonenes, higher olefins, etc.). Conventional mass spectrometric techniques cannot differentiate the olefinic structures from cyclic paraffins because they both have the same molecular weight and empirical formula (isomers) and produce very similar mass spectra. Standard MS tests are only available for the characterization of olefins in samples that do not contain cyclic paraffins (i.e., ASTM D2424-67). The most widely used method for the determination of the concentration of olefins in petroleum products is by Fluorescent Indicator Adsorption (FIA) (ASTM D1319-89). However, this method is long, manually intensive, and provides only the total volume percent of the olefinic content in the sample. Method D1319 does not provide information about the distribution of the olefins in the sample. Most importantly, D1319-89 cannot be used for the analysis of petroleum fractions boiling higher than 315°C.

A successful approach for the characterization of olefins has been the reaction with Fe^+ in the chemical ionization (CI) source of a mass spectrometer. Unfortunately, this technique is not highly suitable for routine analysis of hydrocarbons due to the adverse effects of the metal reagent ion on the ionization source. Previous work in our laboratory (1) has investigated the use of organic reagent compounds for the analysis of olefins. We have found that an acetylating reagent compound has the tendency to react, in the chemical ionization source of a mass spectrometer, with the double bond of an olefin and generate an intense $[\text{M}+43]^+$ adduct ion peak. The reaction of an acetylating reagent gas with a non-olefinic isomeric structure does not produce a similar $[\text{M}+43]^+$ adduct ion. The capabilities of this approach to selectively detect olefins in petrochemical samples has been examined by analyzing model olefin and cycloalkane standard compounds, gasoline samples and their olefin extracts. Acetone- d_6 (Ac- d_6) chemical ionization has been used preferentially to eliminate interferences due to hydrocarbon ion peaks.

The Ac- d_6 chemical ionization mass spectra of 1-heptene and 1-octene are shown in figures 1 and 3. Intense $[\text{M}+46]^+$ peaks are observed in both spectra. Ac- d_6 CI mass spectra of the corresponding cyclic isomeric structures are shown in figures 2 and 4. No $[\text{M}+46]^+$ peaks are observed for the cyclic structures. Similar data have been obtained with several other model compounds. The selectivity of the acetylation reaction for the analysis of mono-olefins in complex hydrocarbon matrices has been examined by analyzing a gasoline sample. Excellent agreement is obtained between the Ac- d_6 results of the whole gasoline and its olefin extract. The gasoline olefin extract was obtained by modifying ASTM D1319-89. Figure 5 shows a partial ion chromatogram for the C_7 mono-olefin. Ac- d_6 chemical ionization allows the analysis of samples that cannot be presently analyzed by D1319-89. As an example, the mono-olefin distribution in the saturates fraction of a light gas oil, obtained by Ac- d_6 CI, is shown in figure 6. The saturates fraction was extracted from the gas oil in order to eliminate possible interferences from the acetylation of aromatic compounds. Application of appropriate response factors and external or internal calibration allows the conversion of the measured areas to weight % concentrations.

Paraffin-Isoparaffin-Olefin-Naphthene-Aromatic (PIONA)
Analysis of Cat Cracked Gasolines by Townsend Discharge
Nitric Oxide Chemical Ionization (TDNOCI) GC/MS

Ismet Dzidic and H. A. Petersen
Shell Development Company, Westhollow Technical Center,
P.O. Box 1380, Houston Texas 77251

It is well known that olefins and naphthenes (cycloparaffins) cannot be distinguished from their electron impact mass spectra, consequently, the content of these two hydrocarbon types in cat cracked gasolines cannot be accurately determined by electron impact GC/MS.

A few years ago we developed the method (1) based on the use of TDNOCI GC/MS for hydrocarbon type analysis, excluding olefins. The method has been extensively used for the analysis of kerosines, jet fuels, diesel fuels and heavy cycle oils. The TDNOCI method has recently been modified and expanded to include the determination of olefins in catalytically cracked gasolines. The modified method uses a capillary instead of packed column and a new set of response factors for different hydrocarbon types which were obtained from the analyses of standard blends and the comparison of the olefinic and aromatic carbon with the values obtained by proton NMR.

The expanded method can distinguish naphthenes from olefins and provide quantitative compositional data for naphthenes, linear and branched paraffins, linear, branched and cyclic olefins, as well as, dienes and cyclic dienes.

Table 1 illustrates the compositional data for a cat cracked blend (114-425 F) determined by the extended TDNOCI GC/MS method. This blend has been used as a quality assurance standard. Using this sample the precision of the method was determined to be 2.5% relative.

The accuracy of the method was verified by comparison with NMR determinations. From the olefinic and aromatic content by carbon number it was possible to calculate the total for the olefinic and aromatic carbon. These values were then compared to the olefinic and aromatic carbon obtained by proton NMR. The comparative results listed in Table 1 show very good agreement between the TDNOCI GC/MS and NMR results, which is an indication of the accuracy of the TDNOCI GC/MS method.

Table 2 compares the compositional values obtained by Analytical Controls by GC at two different labs, and the Norwegian Senter for Industriforskning by electron impact GC/MS and our NOCI GC/MS results. Table 2 also includes the comparison of olefinic and aromatic carbon obtained by proton NMR and NOCI GC/MS. The comparative results confirm the accuracy of the NOCI GC/MS method for the comprehensive analysis of cat cracked gasolines.

The Identification of Organo-Metallic Compounds in Lubricating Oils
by Electrospray Ionization Mass Spectrometry

Vincent P. Nero and Donald D. Drinkwater
Texaco Inc., P.O. Box 509, Beacon, NY 12508

Various types of organometallic complexes are occasionally incorporated into commercial motor oils to prevent wear and oxidation, and to enhance the oil's extreme pressure performance. These organometallic additives have been historically difficult to analyze in lubricating oils because they represent many different classes of chemically fragile compounds. The organometallic complex consists of a core of a central metal atom or clusters of atoms which is coordinated to various ligand groups. The metal core is usually zinc, antimony, or the thio-oxide of molybdenum. The ligands are generally trialkylated amines, dialkyl dithiocarbamates, or dialkyl dithiophosphates. The extensive alkylation on the ligand groups help solvate the relatively polar metallic core into the hydrophobic base oil. The alkyl groups will have chain lengths ranging from three to thirteen carbons and will have various isomeric distributions. The petroleum matrix, in which the organometallic is dissolved further will complicate the analysis.

Electrospray Ionization Mass Spectrometry, ESI/MS, is applied in both positive and negative ion modes to characterize the organo - zinc, molybdenum, and antimony additives in finished lubricating oils. The technique is very useful for elucidating the general structure of zinc, antimony, and molybdenum dialkyl dithiophosphates. It is also valuable for establishing the presence and alkyl distributions of both molybdenum dithiocarbamates and molybdenum amine complexes. The molybdenum and antimony ESI techniques represents a further extension of our previously reported work involving the characterization of zinc dialkyl dithiophosphates.¹

Sample Preparation: All samples were either commercial additive package concentrates consisting of the additive in base oils or completely formulated commercial lubrication oils. Typically, the additive is at 50% in the concentrate and will vary between 1% and 4% in a formulated product. 100 ppm solutions of the additive package or 1000 ppm of the lubrication oil were prepared in various mixtures of methylene chloride, methanol, and hexane. (The solubility of the additive in the methylene chloride/methanol mixture is important. Additives with shorter alkyl chains dissolve well into methylene chloride and methanol solutions alone and produce good ESI results. Additives with longer alkyl chains require higher portions of hexane to enhance their solubility.) All solutions were infused directly into the MS interface at 30 μ L/min.

Instrument Parameters: ESI experiments were performed on a Finnigan MAT TSQ 7000 MS. ESI parameters were 80 psi sheath gas, 10 ml/min. auxiliary gas, 250°C capillary and -3 V octapole. Generally in the positive ion mode, 4-5 kV needle voltage was applied to produce an adequate spray current. In the negative ion mode, about 3 kV needle voltage was used. Scan times were 4 sec. in the profile mode.

Figures I, II, and III illustrate the power and the versatility of the method.

Analysis of Hydrocarbon Polymers by MALDI-FTMS

Salvador J. Pastor and Charles L. Wilkins

Department of Chemistry, University of California, Riverside, California 92521

Introduction

Polyisoprene, polystyrene, and polybutadiene polymers were investigated using a MALDI preparation with 2,5-dihydroxybenzoic acid and silver nitrate. The silver cationized oligomers produce useful spectra that can be signal averaged to characterize polymer distributions up to 6000 Da in mass using a 3 T Fourier transform mass spectrometer. Because an electrostatic ion deceleration protocol was used to extend the mass range, discrimination is shown to exist for wide molecular weight distributions extending beyond about a 2500 Da range from the start oligomer to end oligomer of the distribution. An integral procedure, introduced by Dey and co-workers,¹ is shown to reconstruct the true polymer profile through co-addition of signal transients of varied gated deceleration times. For polymers with narrower mass distributions, silver cationization along with signal averaging provides rapid and accurate polymer characterization for difficult polymer systems using standard MALDI-FTMS instrumentation.

The determination of a polymer's molecular weight distribution is vital to correlating and understanding properties of a particular polymer system and, hence, its applicability for industrial applications. Mass spectrometry provides absolute molecular masses as opposed to relative values that depend on a property of the polymer. In addition, data can be gathered on the repeat unit(s), endgroups, additives, impurities, and side-products. MALDI has been instrumental in providing a soft ionization process to produce intact molecular ions, which has extended the mass range of most mass spectrometers. Results presented here show how spectra of nonpolar polymers can be obtained using standard MALDI-FTMS. This has been difficult in the past for two reasons. First, nonpolar polymers represent a class of polymers that are extremely difficult to analyze mostly because of their chemical inertness. This situation has been greatly improved through the use of chemical ionization agents such as silver, which can readily attach to the polymer. The second difficulty arises from trapping efficiencies for entire distributions. Here gated trapping, having a grounded source trapping plate and high rear trapping plate potential, is used to slow highly energetic species, thus removing excess energy and allowing for more efficient trapping within the analysis cell.

Method

All polymer experiments were carried out using a 3 T dual cell Fourier transform mass spectrometer. A nitrogen laser operating at 337.1 nm was used for MALDI analyses and produced spot sizes on the order of 125 μm by 250 μm . Samples were placed on removable stainless steel probe tips situated approximately 1.0 cm outside of the source trap plate. Chamber pressure was 2×10^{-8} torr. All experiments were done in the source region of the 2-inch cubic dual cell to prevent possible mass discrimination to the polymer distribution. Experimental control and data analysis were done using a Sun data station running Odyssey program software version 3.1. For the narrow MWD polymers, a peak (height) search was done following Hamming apodization, and the molecular weight distributions were calculated using Visual Data Analysis software (Finnigan FT/MS) and were mass corrected for the silver attachment. Samples were prepared by dissolving 10 mg of polymer and a 1:600 to 1:1000 molar ratio (analyte/matrix) of DHB in 10 ml of tetrahydrofuran. From this stock solution, smaller aliquots of 1 ml could be taken for analysis at least up to one week following preparation. Prior to analysis, 50 mg of silver nitrate was added to the sample vial to form a saturated solution with the THF to promote silver cationization. The sample was then applied to the probe tip using a homebuilt spray apparatus as described previously.² The aerospray produces highly homogeneous sample surfaces and uniform crystals. Approximately 200 μl was sprayed onto the probe tip. Because ionization efficiency of nonpolar polymers is low, signal averaging was implemented to improve signal levels and also to average out any anomalies from shot-to-shot irreproducibility imparted by the MALDI process. Although results can be obtained from a single laser shot, results were typically signal averaged up to 81 scans to achieve a theoretical 9-fold improvement in S/N.

Discussion

Although a gated trapping protocol is instrumental in its ability to extend the upper mass limit of a trapped ion cell at any magnetic field by slowing highly energetic ions as they are approaching the rear trapping plate, it is conceivable that not all ions of interest will be trapped properly before the experimental sequence proceeds. By far the major contributing factor for polymer mass discrimination is the trapping protocol. A hydroxyl terminated polybutadiene 1350 polymer was measured at gated trapping increments of 5 μsec following the laser pulse and stepped through sequentially until there was no longer any observable signal. Figure 1 is the summary showing co-added spectra taken 30 μsec apart. Twenty-seven spectra were collected and then combined at different increment values to see their combined effect on the polymer distribution. The overall change appears to be subtle and lies at the extreme ends of the distribution where low intensity oligomers are not given equal weighting and/or sufficient overlap of the other mini-distributions produced by single timed events. Hence, the overall polymer will not appear to be as wide in mass range. Cases show that polymers of wide mass distribution covering a range larger than 2500 Da and collected under a single trapped timing are suspect for discrimination on the extreme ends. It may be possible to reduce this discriminatory effect through use of a lowered gated trap potential at the sacrifice of extended mass range in this 3 Tesla MALDI-FTMS system. Also, the effect of higher magnetic fields may allow for much better ion retention during the ionization/trapping process.

A set of narrow nonpolar polymer standards were chosen to characterize. Figure 2 is the spectrum for polybutadiene 2800 showing a number average molecular weight of 2926.7 and a weight average molecular weight of 2964.0. This characterization was done using the spectral peak height of the oligomers only and not the more favorable peak areas because of current data analysis limitations with the Odyssey software. Several narrow distribution nonpolar polymers in the range between 1000 and 6000 Da were obtained. Because there is no discrimination for narrow distributions less than 2500 Da in range, all spectra could be obtained using a single optimized gated trapping time. Ionization/trapping times were varied until an optimum signal intensity was produced. Spectra could then be signal averaged to improve S/N levels as desired. Polymer distribution values are mass corrected for silver attachment.

Predicting Optimum Resolving Powers for Homolog Type Analysis of Fossil-Fuel Distillates Stuart E. Scheppele, Research Resources Center, University of Illinois at Chicago, Chicago, IL. 60612

Resolution (R) and resolving power (RP) are important considerations for performing mass spectrometric analyses of fossil-fuel distillates in terms of homologs of compound types. Considering only singly-charged ions for the sake of brevity, the resolving power for ions of mass m is conventionally defined as

$$RP = m/\Delta m \quad (1)$$

For double focusing mass spectrometers (DFMS), Δm is usually defined as the peak separation $m_2 - m_1$ corresponding to a 10% valley between two equal magnitude peaks. For Fourier transform ion cyclotron resonance mass spectrometers, Δm is usually defined as the full magnitude-mode peak width at half-maximum peak height for an isolated peak. Unfortunately, such definitions are of limited value in predicting optimum resolving powers to be used in performing molecular ion (homolog) type analyses given the complex nature of fossil-fuel mass spectra and the fact that the resolution of successive ion beams depends upon peak shape, peak width and separation and data acquisition conditions in addition to relative peak heights. For example, the observation of successive peaks having equal signal magnitudes is clearly the exception rather than the rule.¹

Consider an ion beam containing singly-charged ions having masses m_1 and m_2 where

$$m_2 = m_1(1 + 1/R) \quad (2)$$

and R is the mass resolution. As shown in Figure 1, DFMS analysis employing time-based exponential variation of the magnetic field results in peaks having arrival times and maximum signal magnitudes t_1, SM_1 and t_2, SM_2 . The relative abundance r is either SM_1/SM_2 or SM_2/SM_1 such that $r \geq 1$. Assuming that Gaussian functions adequately describe DF mass spectral peak shapes, the time dependence of the acquired ion signal is given by

$$SM(t) = (SM_1) \exp\left\{-\frac{1}{2}\left[\frac{(t - t_1)}{\sigma}\right]^2\right\} + (SM_2) \exp\left\{-\frac{1}{2}\left[\frac{(t - t_2)}{\sigma}\right]^2\right\} \quad (3)$$

From Figure 1, we have that

$$t_2 - t_1 = (t_2 - t_1) + (t_2 - t_1) \quad (4)$$

For exponential scanning, the difference in ion arrival times at the limit of mass resolution is from eq 2

$$\Delta T = t_2 - t_1 = (1/k) \ln(1 + 1/R) \quad (5)$$

where k is the magnetic field decay constant. If RP is defined in

terms of ΔT_{pw} at 5% of the lower magnitude peak if $r > 1$ or by either peak if $r = 1$, then with respect to Figure 1 and eq 3

$$t_2 - t_1 = \Delta T_{pw} / 2 = (1/2k) \ln(1 + 1/RP) = \sigma \sqrt{2 \ln 20} \quad (6)$$

For the higher magnitude peak, we have

$$t_2 - t_1 = (1/2k) \left(\sqrt{\ln 20 r / \ln 20} \right) \ln(1 + 1/RP) \quad (7)$$

Combining eqs 4 through 7 it can be shown that

$$RP = (R/2) \left[1 + \sqrt{\ln 20 r / \ln 20} \right] = \left[m_2 / 2(m_2 - m_1) \right] \left[1 + \sqrt{\ln 20 r / \ln 20} \right] \quad (8)$$

Equation 8 reveals that if $r = 1$ then $RP = R$, but that if $r > 1$ then $RP > R$.

Equation 3 and the terms on the RHS of eq 3 were solved to obtain the peak profiles in Figures 1 and 2 assuming a relative abundance of 4 and a scan rate of 1 mass decade in 1000 sec. Figure 1 shows that a $RP = R = 100\,000$ results in a valley height ($SM(t_3) = 25$) equal to 25% of the lower magnitude peak. For $r = 4$, eq 3 predicts that resolution of the two ion beams requires a RP of 110 872. Figure 2 shows that this value of the resolving power results in a valley height ($SM(t_3) = 10$) equal to 10% of the signal magnitude of the lower magnitude peak. Thus, the peaks in Figure 2 are by definition resolved.

Figure 1: Valley height is 25 for $RP = R = 100\,000$.

Figure 2: Valley height is 10 at $RP = 110\,473$

LOW EV-HR/MS ANALYSIS OF A PORPHYRIN FRACTION SEPARATED FROM CERRO NEGRO PETROLEUM BY LC METHODS

Ronald D. Grigsby

BDM-Oklahoma, Inc.
National Institute for Petroleum and Energy Research
P.O. Box 2565, Bartlesville, OK 74005

Vanadium and nickel complexes in petroleum are significant, not only as biomarkers, but because they poison catalysts used in refining processes. For these reasons, characterization of these types of compounds is receiving much attention from geochemists and others involved with petroleum exploration and refining.

Methods for separating V and Ni complexes from crude petroleum include distillation followed by fractionation of the distillates into concentrates using liquid chromatography (LC). Analysis of the concentrates is performed by UV-visible spectrophotometry, by mass spectrometry, and by other means. Metalloporphyrins, such as deoxophylloerythroetioporphyrin (DPEP) and etioporphyrin (Eto), as the VO and Ni complexes, are detected by their intense absorption in the visible region. Other V and Ni complexes are classified simply as nonporphyrinic types.

In a prior investigation, a >700 °C resid from the Cerro Negro (Venezuelan, Orinoco belt) heavy petroleum was separated by LC methods into concentrates containing V and Ni [1]. Two concentrates highly enriched in vanadium were isolated. One contained 19,500 ppm V and 206 ppm Ni and the other 13,500 ppm V and 148 ppm Ni. The resid, itself, contained 1040 ppm V and 226 ppm Ni. For both concentrates a ratio of about 1:1 porphyrinic:nonporphyrinic V complexes was found based on visible spectrophotometry using vanadyl etioporphyrin as a standard. However, similar chromatographic behavior of the two complexes, as well as other evidence, suggested that the nonporphyrinic forms of V in the neutrals may, in fact, be porphyrinic whose structures are altered in such a way as to modify their molar absorptivities and/or visible absorption maxima. Analysis of the neutrals fractions by high resolution mass spectrometry was suggested as a method that could help identify the nature of the nonporphyrinic vanadium complexes [1].

In the present investigation, the fraction containing the higher concentrations of V and Ni was analyzed by high resolution mass spectrometry using a Kratos MS-50 mass spectrometer operated at 10 K resolving power. Ions were generated by low energy (10 eV) electron ionization. The fraction was introduced into the mass spectrometer from a cooled/heated quartz probe with linear temperature programming at 10 °C/min over a temperature range from ambient to +455 °C. A detailed description of the method (probe microdistillation) is provided in the literature [2].

Figure 1 shows the low eV mass spectrum of the vanadium-enriched neutrals fraction recorded at a probe temperature of 337 °C. Molecular ions in the spectra are assigned formulas of $C_nH_{2n+2}N_4VO$. As seen in Figure 2, etioporphyrins (-28 Z) comprise the bulk of the fraction. However, significant abundances of cycloalkyl and aromatic forms, including DPEP (-30 Z) and benzo-DPEP (-36 Z) strongly suggest that at least a part of the "nonporphyrinic" V is really porphyrinic V that is present in structures having altered visible absorption characteristics compared with those of vanadyl etioporphyrins.

IDENTIFICATION OF LEAD COMPOUNDS FROM COMBINATORIAL MIXTURES: AFFINITY SELECTION-MASS SPECTROMETRY

Y. Huebner, S. Kaur, L. McGuire, D. Tang, G. Dollinger

Chiron Corporation, 4560 Horton Street, Emeryville, CA, 94608

The creation of mixtures or libraries of small molecules by combinatorial synthetic methods in conjunction with high throughput screening is a recent development in drug discovery which has the potential to greatly accelerate the identification of lead compounds (1-3). The libraries can be designed to be structurally diverse for initial lead discovery or more focused to optimize the binding properties of a particular compound (4). One method for the identification of active compounds from libraries involves an iterative process of assay and resynthesis of the library as sets of smaller subpools until the active component or components are identified as single compounds. This approach is both time and labor intensive, especially when there are several pools in a library that demonstrate the desired activity. We have developed a direct and rapid alternative to this process (affinity selection-mass spectrometry), whereby the receptor or target molecule is used to physically isolate the active components from the mixture followed by further identification of the bound compounds by mass spectrometry (5). Our procedure involves incubation of the receptor in solution with the compound library, under receptor-limiting conditions, allowing only those compounds with the highest affinities for the receptor to bind. The receptor/ligand complex is separated from the excess free ligands by rapid size exclusion chromatography. The sample is then concentrated and desalted on-line using a reversed phase peptide trap prior to electrospray mass spectrometry (ESMS). The acidic conditions used for elution of the receptor/ligand complex from the cartridge onto the mass spectrometer are sufficient to dissociate the bound compounds from the receptor. The identities of the bound compounds are then determined by comparison with the expected masses from the compound library. The structures are confirmed by MS/MS and by synthesis of the individual compounds.

Figure 1 shows an example of an affinity selection experiment where our goal was to identify compounds which disrupt an interaction between proteins "A" and "B". Fig. 1a shows the ESMS spectrum of a mixture of 400 components which was shown to be active in inhibiting this protein/protein interaction in initial activity screens. Affinity selection experiments were carried out with each of the individual proteins separately, as well as with both proteins together. The ESMS spectra of compounds which bound to protein "A" alone, protein "B" alone, and those which bound to the protein/protein complex are shown in Fig. 1b-d, respectively. It is apparent that the compounds of m/z 594, 608, 612, 626, and 642 binding to protein "A" (Fig 1b) are competed off in the presence of the second protein (Fig 1d), and are therefore likely to be the compounds in the mixture which inhibit the interaction between proteins "A" and "B". Conversely, the compounds of m/z 391 and 400 (Fig. 1c) are not competed off protein "B" by the presence of protein "A", demonstrating that they bind at a site distinct from the protein/protein interface.

Using this approach, we have been able to rapidly identify lead compounds from a variety of chemical libraries using a variety of protein targets. Additionally, we have been able to rapidly optimize compounds for receptor affinity by carrying out a selection on a library of analog compounds. In cases where more than one compound is selected, analysis of the structural properties of the bound compounds has offered insight into the structure activity relationship for that family of compounds. In many instances, qualitative information regarding relative affinities of selected compounds can also be obtained from the data. In essence, the technique is a competitive binding assay, in which all of the bound compounds can be identified simultaneously. This allows the structural information inherent in the combinatorial library design to be fully utilized in identifying the characteristics of the optimal compound or compounds selected from the library. Affinity selection-mass spectrometry has proved to be a powerful and robust method for the rapid identification and characterization of active ligands from compound mixtures and, as such, has the potential to greatly expedite the process of drug discovery by combinatorial chemistry.

Fig. 1. Electrospray mass spectra, showing a.) Combinatorial mixture of 400 compounds, b.) Compounds selected with protein "A" alone, c.) Compounds selected with protein "B" alone, d.) Compounds selected in the presence of both proteins "A" and "B"

PULSED ULTRAFILTRATION/ELECTROSPRAY MS: A NEW METHOD FOR SCREENING COMBINATORIAL LIBRARIES

Richard B. van Breemen, Chao-Ran Huang, Dejan Nikolic,
Charles Woodbury, Yong-Zhong Zhao and Duane Venton

A promising new approach to drug discovery concerns the screening of combinatorial libraries in order to identify compounds express high affinity for a pharmacologically important biomolecular target. We have developed a flow-through binding system called, "pulsed ultrafiltration (PUF)," interfaced it to an electrospray mass spectrometer, and then used this apparatus both to identify ligands within combinatorial libraries with high affinity for a specific macromolecular receptor, and to measure the classical binding constants that quantitatively describe the interaction of these ligands with their receptor.

Screening of combinatorial libraries in order to identify compounds that express high affinity for a specific receptor has become a fundamental step during drug discovery. Advances in molecular biology and automated chemical synthesis have facilitated the formulation of vast libraries of structurally related molecules. Most approaches have used libraries tethered to solid supports to relate a particular structure in the library to a target biomolecule. Other approaches have used affinity purification of ligands by immobilizing the receptor on a solid support. Although partly successful, a significant limitation of these approaches is that the ligand or receptor is not evaluated free in solution. As a result, false positive and false negative results may be obtained. Alternatively, evaluating libraries free in solution poses its own set of problems, most notably those of sensitivity and structure identification.

We have overcome these obstacles using a combination of pulsed ultrafiltration (PUF) and electrospray mass spectrometry. PUF/mass spectrometry is a new technique under development in our laboratory for the measurement of macromolecular/ligand interactions. During PUF, a macromolecular target is trapped in a flow-through cell by a low molecular weight cut-off ultrafiltration membrane, then an aliquot of ligand or chemical library is pumped through the PUF chamber. How the elution curve of the ligand(s) is altered by the presence of the receptor defines the binding characteristics of the interaction (see Figure 1). We have developed and solved two differential equations that describe the elution curve for a ligand eluting from the PUF chamber containing receptor. The simultaneous solution to these equations contains all the information necessary to calculate the binding constants for the ligand-receptor interaction. Using this simple apparatus, the classical binding parameters including K_d , K_a , K_i , K_m , number of binding sites (n), ΔS and ΔH of binding, etc., may be measured with just a few experiments. Typically, a complete Scatchard plot may be obtained using data from one experimental and one control injection of a ligand.

In addition to being useful for measuring binding constants, we have applied PUF/MS to the screening of combinatorial libraries. When a mixture of ligands is pulsed through the PUF chamber, those ligands with the highest affinity are retained the longest while the non-binding compounds elute immediately (See extraction of pentachlorophenol by serum albumin during PUF/MS in Figure 1). The high affinity ligands that have been retained and concentrated on the receptor in the PUF chamber may be eluted as a bolus by sudden disruption of the ligand-receptor complex using organic solvent, pH change, temperature change, etc. Finally, the eluted ligands may be identified using electrospray mass spectrometry and tandem mass spectrometry, which adds the necessary dimensions of sensitivity and specificity for ligand identification. Our scheme for screening combinatorial libraries is shown in Figure 2.

MEASUREMENT OF MACROMOLECULAR BINDING CONSTANTS USING ELECTROSPRAY MASS SPECTROMETRY

Richard H. Griffey, M. Greig, L. Cummins, H. Gaus, H. Sasmor, Isis Pharmaceuticals, Carlsbad, CA

Electrospray mass spectrometry (ES-MS) has demonstrated utility for the detection of non-covalent macromolecular associations. Complexes have been observed among oligonucleotides, proteins, enzyme-substrate and enzyme-product complexes, and competition among ligands for a receptor. Weaker associations among proteins and peptides also have been observed using ES-MS. Though experiments have shown that gas-phase ions retain solution conformations, arguments that these complexes reflect solution structures or equilibrium distributions have been circumstantial.

Levels of individual free and ligated species can be quantitated directly from their relative abundances within the ES-MS ion envelope. For ligands with multiple binding sites having similar affinities, this information can be used to determine directly the dissociation constants (K_D). This situation is common in biological systems where weak electrostatic and Van der Waals contacts govern recognition. We demonstrate that K_D values for an albumin-oligonucleotide complex can be measured using ES-MS, and that the ES-MS K_D values match solution K_D values obtained using capillary electrophoresis (CE). The dependence of the ES-MS K_D on the ionic strength of the buffer suggests that electrostatic forces dominate the albumin:oligonucleotide interaction.

Figure 1a shows the ES mass spectrum of bovine serum albumin (BSA) at pH 7.5 obtained via infusion of BSA (33.5 ng/mL in 30 mM imidazole buffer containing 10 mM NH_4OAc) at 7 $\mu\text{L}/\text{min}$ through the electrospray interface of a Hewlett-Packard 5998A quadrupole mass spectrometer in negative ionization mode. BSA generates an envelope of ions (highlighted with a P) between m/z 1500-2650 corresponding to the $(M - 26\text{H})^{26-}$ through $(M - 41\text{H})^{41-}$ charge states (mass 66,497 Da).

Mixing BSA with increasing concentrations (0.3 to 30 mM) of a 20mer phosphorothioate oligonucleotide (GCCCAAGCTGCATCCGTCA; MW 6367 Da) generates a new series of ions (Figures 1b-c) corresponding to free oligomer (highlighted with an O; $m/z=1590.9$; $(M - 4\text{H})^{4-}$ charge state of oligomer) and the BSA:oligo complex (highlighted with a C). Deconvolution of the new set of signals from the complex yields a mass of 72,870 Da, corresponding to a 1:1 ratio of BSA:oligo. A second complex (MW 79,273 Da, expected MW 79,231 Da) corresponding to a disodium adduct of BSA:oligo² (labeled C2), appears at higher concentrations of oligonucleotide. Integrated ion abundances from the various charge states have been summed for BSA and each complex as a function of the concentration of added oligomer. A plot of measured $([P]+[C]+[C2])/[P]$ versus added $[O]$ has been fit to a second-order polynomial function. Dissociation constants of 3.1 ± 0.3 (K_{D1}) and 11.9 ± 0.6 mM (K_{D2}) have been calculated ($R^2>.998$) at pH 7.5. Independently, the ratio of K_{D1}/K_{D2} was determined to be 0.26 ± 0.01 from direct measurement of $[P][C2]/[C]^2$ for five values of $[O]$.

The value for K_{D1} measured using ES-MS is sensitive to the ionic strength of the solution buffer, varying from 0.7 mM in the absence of added buffer to ≥ 100 mM in the presence of 100 mM ammonium acetate:30 mM imidazole. For an oligo concentration of 10 mM, a plot of $\log(K_{D1})$ versus $\log[\text{NH}_4\text{OAc}]$ yields a straight line with a slope of 1.3 and $R^2=0.975$ (Figure 2). The K_{D1} is sensitive to pH, decreasing to 15 mM at pH 10.0.

The dissociation constants determined for this model system with ES-MS have been corroborated using capillary electrophoresis. Differences in oligonucleotide migration time as a function of oligonucleotide concentration were measured following pressure injection. Analysis of the two linear

sections generated a K_{D2} of 10.0 ± 0.2 mM ($R^2=0.97$) for the BSA:oligonucleotide² complex, while a K_{D1} value of $\leq 2.8 \pm 0.3$ mM could be estimated for the BSA:oligo complex ($R^2=0.95$). The Scatchard analysis of the K_{D1} value is an approximation, but matches the ES-MS K_{D1} . The small differences in K_D values may result from the different buffer required for the CE experiment.

The accuracy of the determination of K_D using ES-MS is governed by several factors. These include proper solution concentrations of the ligand and substrate near the K_D , solution electrostatics, transfer to the gas phase, and gas-phase stability. The most abundant ion shifts from $[M-31\text{H}]^{31-}$ for BSA to $[M-33\text{H}]^{33-}$ for the BSA:oligo complex to $[M-35\text{H}]^{35-}$ for the bis-complex, and in each case roughly 3/4 of the charge envelope has been observed. Hence, the relative ion abundances are not affected by instrumental parameters. Decomposition of complexes during transfer from the initial charged droplet to the gas phase would affect the measurement of K_D . Two-fold variation in the voltages of the ion optics did not alter relative ion intensities for any species, suggesting that little induced dissociation occurs under conditions described above. ES-MS offers a convenient and rapid technique for measuring stoichiometry and dissociation constants for non-covalent macromolecular complexes, where characterization using conventional solution methods proves difficult.

Figure 1. Electrospray mass spectra for (a) 500 nM BSA in 33 mM imidazole-10 mM NH_4OAc buffer, pH 7.5, charge states 26- to 42-. (b) as above with addition of 10 μM oligonucleotide, (c) with addition of 33 μM oligonucleotide. The signal from BSA is indicated with a P, BSA-oligonucleotide complex with a C, and BSA-oligo² complex with a C2.

Figure 2. Plot of $\log(K_D)$ versus $\log[\text{NH}_4\text{OAc}]$ for the BSA-oligonucleotide complex. Data were obtained by increasing the concentration of NH_4OAc in the buffer while holding the oligonucleotide concentration at 10 mM and the imidazole concentration at 33 mM.

Studies of Noncovalent Interactions by Time-of-Flight Mass Spectrometry

I.V. Chernushevich*, A.N. Krutchinsky, W. Ens and K.G. Standing.
Physics Dept., University of Manitoba, Winnipeg, Manitoba R3T 2N2 Canada

Electrospray ionization (ES) is gentle enough to obtain information on the higher-order structure of biomolecules, but the limited m/z range of most quadrupole mass spectrometers is a problem when studies are performed at near physiological conditions. We have interfaced an ES source to a time-of-flight mass spectrometer [1], which has in principle an infinite m/z range. Recent incorporation of nanospray [2] and an RF-quadrupole ion guide [3] into the instrument has improved both sensitivity and resolution and minimized mass discrimination. The ES-TOF spectrometer is thus an excellent instrument for studies of noncovalent complexes. A few examples are given below.

A classical example of noncovalent associations is provided by a complex of streptavidin with biotin, which has been studied by quadrupole, FTICR and magnet sector instruments [4,5]; it thus permits comparison of the performance of different types of mass analyzers. Fig.1 shows three spectra corresponding to different amounts of biotin bound to the core streptavidin (Boehringer Mannheim). These spectra can be also viewed at the www-site of a protein mass spectrum database at Rockefeller University [6].

Both normal ES and nanospray were used to study the quaternary structure of the enzyme 4-oxalocrotonate tautomerase (4OT) and its four analogs, prepared by total chemical synthesis. Wild-type 4OT was found to be a hexamer of 62 amino acid subunits [7], but very subtle differences in the covalent structure of its analogs led to large changes in both higher order structure and biological activity. It turns out that 4OT can be studied in both positive or negative modes from the same solution with comparable results (Fig.2). An advantage of nanospray in this case is in its less destructive nature compared to usual ES (see Fig.2).

ES-TOF has been also used to measure the oligomeric state and the metal ion stoichiometry of a series of non-heme iron-containing proteins: two types of hemerythrin (Pg-Hr and Lr-Hr) and rubrerythrin (Dv-Rr) [8]. Both hemerythrins were observed as octamers with 2 irons per subunit, as expected from other studies; rubrerythrin was observed as a tetramer, in contrast to gel filtration data, which predicted it to be a dimer.

We have continued our studies of catalases HP I and II (with P.C. Loewen) [9]. HP I from mycobacterium tuberculosis was recorded as a dimer with mass $\sim 161,573$ Da from 5 mM ammonium acetate, while HP I from E. coli was a tetramer with mass $\sim 322,265$ Da in these conditions. The tetramer ions were observed at $m/z \sim 9,000$; this high m/z value seems to be typical for ions with mass $\sim 300,000$ Da, as confirmed by studies of catalases HP I and II, citrate synthase (hexamer) and some other complexes.

About 30 noncovalent complexes have been studied in our instrument up to now, and their average m/z ratio was found to increase with mass. A plot of the most abundant charge state Z versus mass m for all proteins and complexes studied at pH from 6 to 7 in our instrument is shown in Fig.3 (open circles). This empirical relation is $Z \sim (m)^K$, where $K=0.55$. A similar relation but with $K=0.52$ was obtained for clusters of complexes of soybean agglutinin and catalase HP II [9] having masses up to 1.37 MDa. Extrapolation of the Z -vs- m plot to larger masses allows an estimate of charge carried by larger entities. We recorded ions from a sample of brome mosaic virus (BMV, ~ 4.65 MDa), but only a wide hump centered around $m/z \sim 27,000$ was observed as shown in Fig.4. However, this value correlates well with the charge predicted for the known mass of virus, as shown in Fig.3.

Noncovalent Protein Interactions and H/D Exchange Reactions on Target Characterized by UV-MALDI-MS

Michael O. Glocker, Martina R. Jetschke, Sebastian H.J. Bauer, Jürgen Volz
and Michael Przybylski*

University of Konstanz, Faculty of Chemistry, P.O. Box 5560M732, D-78434 Konstanz, Germany

The knowledge of higher protein structures is of importance for structure / function relations and additional characterization methods to X-ray and NMR are highly needed.

While electrospray mass spectrometry has begun to demonstrate its potential for the characterization of higher protein structures, matrix-assisted laser-desorption mass spectrometry seemed not to be applicable to these studies because of limitations in matrix chemistry and sample preparation. Hydrogen/deuterium exchange reactions in solution have been used for probing protein structures and dynamics and have been monitored using a broad spectrum of analytical methods including mass spectrometry. We applied *on-target* deuterium exchange reactions in order to study the effects of MALDI-MS preparation techniques on protein structures.

Fig 1 On-target H/D exchange and depth profile of Neurotensin. Deuterium exchange rate is given in %

First, samples were prepared for MALDI-MS by mixing aqueous protein and peptide solutions with matrix (HCCA) solutions. The matrix was dissolved in acidic solvents that contained organic cosolvents (acetonitrile). Deuterium exchange for labile protons of peptides and proteins prepared in this manner was found to be >90%, indicating that proteins were denatured (Fig. 1). The results from *on-target* H/D-exchange reactions were different from those of native proteins in solution which were monitored by ESI-MS. By subsequent irradiation of one single spot on the target, depth-profiles of the deposited matrix / sample mixtures were recorded and revealed that *on-target* reactions cause

exchange only at the crystal surface. In deeper crystal layers molecular ions of proteins and peptides with unexchanged hydrogens were observed. No molecular ions with intermediate hydrogen exchange were detected. These results indicate that proteins and peptides are incorporated in matrix crystals and that "washing procedures" only reach crystal surfaces.

In investigations to achieve matrix preparations that allow the analysis of intact protein structures, we have developed a sample preparation method in which 6-Aza-2-thio-thymine (ATT) was used as

Fig 2. UV-MALDI-MS analysis of intact RNase S complex in the presence of angiotensin

matrix without any addition of organic cosolvents. Proteins and peptides were dissolved in aqueous buffers (e.g. ammonium citrate). Under these conditions the intact noncovalent protein complexes such as RNase S, the noncovalent complex of S-protein and S-peptide (Fig. 2), and specific dimers of coiled-coil leucine zipper polypeptides were detected by UV-MALDI-MS. Specificity of complex association was ascertained by admixture of non-specific peptides which did not yield detectable aggregate ions. In addition, *on-target* tryptic digests of cytochrome c and leucine zipper peptides were carried out after UV-MALDI-TOF-MS molecular weight determination in the presence of the ATT matrix. Reinsertion of the samples into the mass spectrometer yielded spectra that showed complete digestion of the starting material. These studies showed that proteins maintained native tertiary structures that are necessary for the formation of specific non-covalent protein complexes, and trypsin maintained the functional enzymatic structure and possessed full biological activity with the novel sample preparation method.

Interfacing BIA with MALDI Mass Spectrometry

Jennifer R. Krone, Randall W. Nelson, David Dogruel, Peter Williams
Department of Chemistry and Biochemistry
Arizona State University
Tempe AZ 85287-1604

Biomolecular Interaction Analysis (BIA) is a biosensor technology used in monitoring interactions, in real time and without the use of labels, between an analyte in solution and a surface immobilized binding partner. The technique is based on the non-destructive detection principle of surface plasmon resonance (SPR) which is sensitive to refractive index changes on a sensor surface. The sensor surface (chip) used in this method consists of a carboxylated dextran layer covalently coupled to a thin gold surface on a glass substrate. The dextran layer provides a matrix in which the affinant can be immobilized with high activity and helps eliminate direct absorption of ligands on to the gold surface. When a solution containing the ligand is brought into contact with the derivatized chip, changes in the mass loading of the surface resulting from ligand binding are detected as variations in the SPR signal. BIA is used extensively in the investigation of structure-function relationships, and recent applications extend into the study of receptor-ligand interactions, epitope mapping, the characterization of engineered antibodies, protein-DNA binding, DNA hybridization, virus research, and kinetic and concentration studies.

Although the BIA technique can provide pertinent information on ligand binding and kinetics, SPR is a non-specific detector so that the identity of the ligand(s) is dependent on the specificity of the affinant and may not always be certain. This is particularly true in complex systems where there exists the potential to bind multiple or unknown ligands, either non-specifically or in competition for the surface bound affinant. Such non-defined binding is of obvious concern. By mass spectrometrically analyzing retained ligands it should be possible to, at the very least, detect the presence of non-targeted ligands (with high sensitivity), and to correct for them using quantitative techniques similar to those used in MSIA (1). To avoid transfer losses and achieve the best sensitivity, ligands should be sampled directly from the chip surface rather than eluted into a mass spectrometer. Mass spectrometric methods such as on-chip mapping and sequencing could also be used in conjunction with database searches in the identification of unknown ligands captured from complex samples. Therefore, in recognition of the complementary nature of the two techniques — BIA offering fast, label-free, real-time monitoring while MALDI adds to the analysis by providing qualitative and semi-quantitative information — we have investigated the interfacing of BIA with MALDI mass spectrometry.

Preliminary experiments into the interfacing of BIA biosensor technology with MALDI mass spectrometry were performed using the myotoxin *a* MSIA as a model system. First a BIA analysis was performed on a Pharmacia Biosensor BIAcore 2000 by circulating whole venom from the prairie rattlesnake, *Crotalus viridis viridis*, over a CM5 chip derivatized with anti-myotoxin *a* polyclonal IgG. The BIAcore chip was then removed from the Biosensor unit with the ligands still bound to the surface and sent to our lab where MALDI analysis followed by placing the chip directly into an appropriately configured time-of-flight mass spectrometer (refer to Figure captions 1-3 for experimental conditions).

The combined technologies of Biomolecular Interaction Analysis and MALDI mass spectrometry allow for rapid, sensitive and accurate investigations of biomolecular interactions as well as permit new and novel bioanalytical approaches, e.g., ligand fishing/ identification and quantitation, monitoring site-specific kinetics and binding constants, and multiplex diagnostic assays.

Biomolecular Interaction Mass Spectrometry BIA-MS

Figure 1. Biomolecular interaction analysis/mass spectrometry (BIA/MS). Biosensor chips, having four flow cells each consisting of a 100 nm carboxy-methylated dextran layer coupled to 50 nm gold, are derivatized with affinant and used in the BIA analysis of biological fluids (following standard BIA protocols). The chips are then introduced into the MALDI time-of-flight mass spectrometer and retained ligands are analyzed by virtue of molecular weight.

Figure 2. Myotoxin *a* binding curve from an individual flow cell in which 10 μ L (1 mg/mL in Tween binding buffer) of prairie rattlesnake whole venom was circulated across for ~ 8 minutes. An SPR signal of ~ 100 RU corresponds to ~ 40 fmole total protein bound to the surface

Figure 3. BIA/MS of myotoxin *a* isolated from one flow cell of the anti-myotoxin *a* derivatized Biosensor chip. Signals in the mass spectrum due to the singly- and doubly-charged species of the myotoxin *a* are observed along with minor signals due to residual detergent ($m/z \sim 1,000$ Da). The spectrum is the sum of 50 individual laser shots using a 355 nm pulsed laser and a matrix of α -cyano-4-hydroxycinnamic acid.

MS/MS AS A VALUABLE TOOL FOR DETERMINING THE SEQUENCE SPECIFICITY OF DNA-INTERACTIVE AGENTS

Paula Iannitti, Geoff Wickham, Jacqueline Boschenok, Larry A. Hick and Margaret M. Sheil
Department of Chemistry, University of Wollongong, NSW 2522 AUSTRALIA

DNA alkylation is a key cellular event in the mechanism of action of clinical anticancer drugs, chemical mutagens and carcinogens. Determination of the precise nature of the interaction between a ligand and DNA allows identification of the essential elements giving rise to observed DNA binding characteristics which may in turn be correlated with antitumour activity, thus enhancing the process of drug design. Mass spectrometry has the potential to complement existing sequencing and structural methods by enabling both the sequence selectivity of alkylation and some structural detail concerning the adducts to be determined. The majority of early studies concerned with the sequencing of ligand-DNA adducts by mass spectrometry have involved MS/MS following fast atom bombardment (FAB). ESI has been used for the characterisation of modified oligonucleotides (e.g. methylation) or synthetic oligodeoxyribonucleotides which contain an unnatural base in their sequence. Some of these studies have been extended to include the use of MS-MS for location of the modification/unnatural base within the oligonucleotide sequence, however, there have been few reports to date of the use of ESI-MS/MS for the sequencing and/or structural characterisation of synthetic ligand-oligonucleotide adducts.

We have examined the low-energy MS/MS spectra of $[M-2H]^{2-}$ and $[M-3H]^{3-}$ ions derived from adducts formed between a number of alkylating agents (hedamycin and phenanthridinium bromides) and a range of oligonucleotides (i.e. 5'-CACGTG-3', 5'-CGTACG-3', 5'-CGGTACG-3', 5'-TACGTA-3'). Hedamycin is a naturally-occurring antitumour antibiotic that binds to double-stranded DNA by both intercalation and alkylation.¹ Hedamycin binds to guanines in a highly sequence selective manner, with the preference being 5'-CGT and 5'-TGT for binding to isolated guanines. The phenanthridinium bromides² are synthetic compounds with a preference for guanines in 5'-GT and 5'-(G)_n sequences.

An example of the experimental protocol is given in fig. 1 for the phenanthridinium bromides. Fig. 2 shows the ESI-MS-MS spectra of the two adducts formed upon reaction of the C₁₀-phenanthridinium bromide with 5'-CACGTG-3'. These remarkably simple spectra are typical of all the MS-MS spectra of the alkylated adducts examined and contrast with the spectra of free oligonucleotides which show a large number of fragment ions from cleavages across the entire oligonucleotide backbone. Hedamycin and the phenanthridinium bromides each alkylate the N-7 of guanine with a consequent weakening of the glycosidic bond. This is reflected in the MS-MS spectra where the major fragmentation pathway involves cleavage of the glycosidic bond followed by cleavage of the 3'C-O sugar-phosphate bond in the nucleotide residue from which the guanine has been lost. In the case of alkylation at the 3' terminal guanine (adduct 2), only the ion due to loss of the guanine-ligand adduct is observed. That there are no other fragment ions present confirms the location of the ligand at the 3' terminus. Hence, in both examples the site of binding on the oligonucleotide sequence can be clearly identified. In all the examples of ligand-oligonucleotide adducts we have examined to date the MS-MS results are consistent with gel electrophoretic sequencing and NMR spectroscopic data for these compounds.

The spectral simplicity resulting from the combination of high sensitivity ESI and specific fragmentation in MS/MS spectra clearly demonstrates the enormous potential of this method for the structural analysis of ligand-DNA adducts. Further, while these analyses were conducted with "off-line" HPLC purification these experiments could be extended to LC-MS-MS, thus allowing screening of mixtures of alkylated oligonucleotides which differ in the sequence position of base alkylation. This, in turn, will enable some measure of the sequence selectivity of the agent to be determined very rapidly. We are currently extending this work to a wider range of alkylating agents and oligonucleotide sequences.

The iron-sulfur-containing ferredoxins are small, soluble, electron-transfer proteins found in a large variety of organisms. The "plant-type" [2Fe-2S] ferredoxins, such as that from the cyanobacterium *Anabaena*, transfer electrons between the membrane-bound Photosystem I and the soluble ferredoxin NADP⁺ reductase (FNR). The X-ray crystal structure of *Anabaena* 7120 vegetative ferredoxin has been recently determined to 2.5 Å resolution and refined to 1.9 Å to reveal a [2Fe-2S] cluster located near the protein surface and a secondary structure consisting of four major and three minor β -sheet strands and three α -helices.

We first looked for conditions enabling the mass spectrometric characterization of the intact wild-type (WT) with its cluster. Taking advantage of our good expertise in the characterization of such metalloproteins [1,2], we compared the positive ESI mass spectrum in acidic conditions with the negative mass spectrum in a slightly basic solvent. The spectrum recorded in negative mode yielded a molecular mass of 10872 Da, which precisely corresponds to the mass of the intact protein with its cluster. We also characterized the ferredoxin using MALDI-MS in positive mode with sinapinic acid as the matrix. At an acceleration voltage of 15 kV, we have been able to evidence the intact protein, whereas at 20 kV, a major peak corresponds to the ferredoxin having lost its cluster and other peaks correspond to degradation intermediates.

Four classes of mutations were designed to probe the importance of the volume and of the charge of the side chains on protein stability. The first information about the influence of the mutations were obtained in looking at the charge state distribution of the ESI mass spectra in negative mode. We then tried to get more local information about the influence of mutations on the conformational stability, in contrast with the global information obtained with the CSD. For this, we used a method that we had developed recently [3] and which is a modification of an approach proposed by David Smith some years ago. First, the protein is incubated in deuterated water for 12 hours to let the accessible H exchange against D. Then, the exchanges are quenched at low pH (1.9) with hydrochloric acid and digestion occurs with immobilized pepsin, deposited into the filter cup of a centrifugation filter unit. This immobilized pepsin enables to get very high enzyme-to-substrate ratios (up to 50 to 1) without the risk of autolysis. In these conditions, digestion of the ferredoxin occurs in 30 s. After centrifugation, the peptides are injected onto an HPLC column coupled to an ESI mass spectrometer and part of the effluent is collected. The collected fractions are sequenced using either Edman degradation or PSD in MALDI-MS. A fast gradient is applied to the HPLC column resulting in a very fast separation: the peptides are mass analyzed between 8 and 10 min after their injection. In this way, peptides are identified and the number of D that they had exchanged during deuteration of the protein are determined.

The results obtained for the WT and for three of the mutants are summarized in Table 1. For each peptide, the differences between the measured mass using this procedure and the calculated mass of the non-deuterated form are indicated. The underlined values correspond to the regions for each mutant giving a mass increase at least 0.8 higher than the corresponding region of the WT and thus indicate the regions which are mainly perturbed by the mutation.

In the case of the WT, few D were incorporated. This can be explained by the high degree of secondary structure (β -strands and α -helices). The most exchanged region is the N-terminal part with less than 3 exchanges. We also observed no exchange in the 25-29 region corresponding to the α -helix 1, which is in good agreement with the slow exchange rates observed in NMR for these amide protons. In contrast we had measured up to 6 exchanges for peptides from a bacterial cytochrome c_2 WT [3]. We can also notice that digestion almost exclusively occurred in the non-structured parts of the protein with an exception within α -helix 1. Furthermore, the loop to which the cluster is bound is very accessible to

the protease and was cleaved to very small peptides that we have not been able to characterize. This is the reason why we got no information on the 42-49 region.

Mutation of Glu 94 to Lys brought perturbations mainly in three regions. The first one is spatially far from the mutation site. The second one corresponds to a large non-structured region. The third one is spatially close to the mutation site but there is no influence in the C-terminal part of the ferredoxin whereas the mutation was constructed in the C-terminal α -helix.

With mutation of Phe 65 to Ala, a significant increase in mass occurred in the region of the mutation if we compare the 3.4 Da to the 0.8 Da of the corresponding region in the WT. The same distant region as for the mutant E94K is also perturbed.

At last, mutation of Arg 42, which induced the cleavage of H bonds with Asp 28 and Glu 31 also induces a significant increase in the mass of fragment 25-29, which is a portion of α -helix 1, which did not exchange in the case of the WT. It indicates a destabilization of this α -helix carrying the two acidic amino acids.

In conclusion, these results show that the method we have developed can provide local information on the influence of mutations, even for a highly structured protein like this ferredoxin and sometimes in a region distant from the mutation point. The advantages of this approach are those of MS: compared to X-ray crystallography and NMR, it is fast and sensitive: once the conditions are well defined for the WT, it takes only some days and some hundreds of pmol to study a mutant. At last, we are currently applying this approach to a much bigger protein: a 57 kDa enzyme, potential target of herbicides. We are studying the influence of inhibitors which might become new herbicides and which increase considerably the conformational stability of the enzyme when they bind.

**In situ monitoring by ESI-MS of reactions of
drugs with the zinc finger protein from HIV-1.**

The HIV-1 nucleocapsid protein (Ncp7) is a polypeptide of 55 amino acid residues with two zinc finger domains and plays a crucial role in the viral life cycle. This protein has two highly conserved zinc fingers (Cys-X₂-Cys-X₄-His-X₄-Cys), which make it an interesting target for therapy of HIV-1 infection. Indeed disruption of the zinc finger cluster by electrophilic compounds results in a noninfectious virus (1). Several electrophilic compounds have been shown to cause ejection of zinc from the clusters and intramolecular disulfide bond formation (2). This reaction occurs quickly. Since ESI-MS can be used to analyze intact proteins at neutral pH, we extended this capability to follow *in situ* the progress of the reaction of 2,2'-dithiodipyridine (PySSPy) and disulfiram with Ncp7 in 10 mM ammonium bicarbonate solution pH 7.4. The ejection of zinc in the reaction of Ncp7 with PySSPy occurs in two steps. The zinc is ejected faster from one cluster than from the other. The final accumulated reaction product is apo-Ncp7 with three disulfide bonds. Trapping intermediates by alkylating the free cysteine residues with N-ethylmaleimide after a 2 min reaction of PySSPy with Ncp7, reveals that the C-terminal zinc finger is disrupted first. Both Cys-36 and Cys-49 are shown to be target residues for initial electrophilic attack by PySSPy. In the case of the reaction of disulfiram with Ncp7 the same final product is formed (fully oxidized apo-P7). However the abundance of the intermediates is much lower than in the reaction with PySSPy. More than 75% of the starting material has been converted to the oxidized apo-Ncp7 after a 40 min reaction with disulfiram and only 45% of the starting material was converted at 40 min in the PySSPy reaction. In situ monitoring of reactions of electrophiles with native Ncp7 by ESI-MS at physiologic pH may be a straightforward strategy for screening other potential drugs.

Interactions of proteins with nucleotides are crucial to the regulation and control of a host of functions within living organisms. Stoichiometry and selectivity are important characteristics in understanding how these proteins function. Studies have now demonstrated that many complexes observed by ESI-mass spectrometry in properly conducted experiments reflect known solution behavior, and that highly specific associations can be examined in competitive binding experiments.

The regA protein from bacteriophage T4 is a RNA binding protein that recognizes different mRNAs with limited selectivity. Although it has been found to repress the translation of 35 T4 mRNAs, while not effecting 200 other mRNAs, no consensus sequence has been identified. In the crystal structure of the protein, two polypeptide chains form an asymmetric dimer. It has been suggested the protein takes on this form in the complex, but the crystal structure of the complex has not yet been determined.

We have studied the stoichiometry and binding of regA to RNA by using electrospray ionization to produce the intact complex from aqueous solutions. The mass spectrum of the protein without RNA added shows some evidence of dimerization, as is seen in Fig A. When this solution is diluted by a factor of eight, no change in the monomer:dimer ratio is seen, suggesting this dimerization is at least partly due to solution conformation and not entirely non-specific binding.

We have studied regA 1:1 complexes with a variety of RNAs ranging in size from a 10-mer to a 21-mer. An example of regA complexed with a 20-mer RNA is shown in Figure B. In some cases, the bare protein was seen, even though there was an excess of RNA. No complex having other than 1:1 stoichiometry were observed. Competitive binding experiments have been conducted showing some RNA strands have similar binding strengths while others are quite different. Fig C shows a case where one strand of RNA is clearly favored over another. Here the one strand of RNA "C" was in great excess, but the majority of complex is regA plus the RNA "F" which has a higher binding affinity.

This study clearly shows the mass spectra produced by electrospray ionization under proper solution conditions can be informative regarding noncovalent associations. Specifically, this work addresses the question of the stoichiometry, indicating the regA monomer is the form of the protein involved in the regA: RNA complexes.

We thank the U.S. Department of Energy, Office of Health and Environmental Research, and the National Institute of General Medical Sciences (GM53558) for support of this research. Pacific Northwest National Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy through Contract No. DE-AC06-76RLO 1830.

the kinetic energies of the trapped potential well depth is of the order of 10^4 eV, in each collision of such an accelerated ion with helium gas, some 1% of kinetic energy can be transferred to internal (vibrational) energy in the ion. The continuous accumulation of internal energy leads to dissociation. In summary, resonant excitation leads to dissociation whereas ions become vibrationally excited and dissociate, or recombine.

The collisional activation process in the ion trap involves the competing vibrational energy levels of the ion. The ion is excited to a higher vibrational level by the collisional energy transfer from the neutral gas. The ion then undergoes a transition to a higher electronic state, which is the precursor to the dissociation process. The ion is then cooled by the collisional energy transfer from the neutral gas. The ion is then cooled by the collisional energy transfer from the neutral gas. The ion is then cooled by the collisional energy transfer from the neutral gas.

[illegible]

Two alternative approaches to the use of multiple frequencies, say at intervals of 500 Hz, and at wavelengths up to 10 cm, are being investigated. The use of multiple frequencies is being investigated in the form of a series of frequencies, say 100, 200, 300, 400, 500, 600, 700, 800, 900, 1000, 1100, 1200, 1300, 1400, 1500, 1600, 1700, 1800, 1900, 2000, 2100, 2200, 2300, 2400, 2500, 2600, 2700, 2800, 2900, 3000, 3100, 3200, 3300, 3400, 3500, 3600, 3700, 3800, 3900, 4000, 4100, 4200, 4300, 4400, 4500, 4600, 4700, 4800, 4900, 5000, 5100, 5200, 5300, 5400, 5500, 5600, 5700, 5800, 5900, 6000, 6100, 6200, 6300, 6400, 6500, 6600, 6700, 6800, 6900, 7000, 7100, 7200, 7300, 7400, 7500, 7600, 7700, 7800, 7900, 8000, 8100, 8200, 8300, 8400, 8500, 8600, 8700, 8800, 8900, 9000, 9100, 9200, 9300, 9400, 9500, 9600, 9700, 9800, 9900, 10000, 10100, 10200, 10300, 10400, 10500, 10600, 10700, 10800, 10900, 11000, 11100, 11200, 11300, 11400, 11500, 11600, 11700, 11800, 11900, 12000, 12100, 12200, 12300, 12400, 12500, 12600, 12700, 12800, 12900, 13000, 13100, 13200, 13300, 13400, 13500, 13600, 13700, 13800, 13900, 14000, 14100, 14200, 14300, 14400, 14500, 14600, 14700, 14800, 14900, 15000, 15100, 15200, 15300, 15400, 15500, 15600, 15700, 15800, 15900, 16000, 16100, 16200, 16300, 16400, 16500, 16600, 16700, 16800, 16900, 17000, 17100, 17200, 17300, 17400, 17500, 17600, 17700, 17800, 17900, 18000, 18100, 18200, 18300, 18400, 18500, 18600, 18700, 18800, 18900, 19000, 19100, 19200, 19300, 19400, 19500, 19600, 19700, 19800, 19900, 20000, 20100, 20200, 20300, 20400, 20500, 20600, 20700, 20800, 20900, 21000, 21100, 21200, 21300, 21400, 21500, 21600, 21700, 21800, 21900, 22000, 22100, 22200, 22300, 22400, 22500, 22600, 22700, 22800, 22900, 23000, 23100, 23200, 23300, 23400, 23500, 23600, 23700, 23800, 23900, 24000, 24100, 24200, 24300, 24400, 24500, 24600, 24700, 24800, 24900, 25000, 25100, 25200, 25300, 25400, 25500, 25600, 25700, 25800, 25900, 26000, 26100, 26200, 26300, 26400, 26500, 26600, 26700, 26800, 26900, 27000, 27100, 27200, 27300, 27400, 27500, 27600, 27700, 27800, 27900, 28000, 28100, 28200, 28300, 28400, 28500, 28600, 28700, 28800, 28900, 29000, 29100, 29200, 29300, 29400, 29500, 29600, 29700, 29800, 29900, 30000, 30100, 30200, 30300, 30400, 30500, 30600, 30700, 30800, 30900, 31000, 31100, 31200, 31300, 31400, 31500, 31600, 31700, 31800, 31900, 32000, 32100, 32200, 32300, 32400, 32500, 32600, 32700, 32800, 32900, 33000, 33100, 33200, 33300, 33400, 33500, 33600, 33700, 33800, 33900, 34000, 34100, 34200, 34300, 34400, 34500, 34600, 34700, 34800, 34900, 35000, 35100, 35200, 35300, 35400, 35500, 35600, 35700, 35800, 35900, 36000, 36100, 36200, 36300, 36400, 36500, 36600, 36700, 36800, 36900, 37000, 37100, 37200, 37300, 37400, 37500, 37600, 37700, 37800, 37900, 38000, 38100, 38200, 38300, 38400, 38500, 38600, 38700, 38800, 38900, 39000, 39100, 39200, 39300, 39400, 39500, 39600, 39700, 39800, 39900, 40000, 40100, 40200, 40300, 40400, 40500, 40600, 40700, 40800, 40900, 41000, 41100, 41200, 41300, 41400, 41500, 41600, 41700, 41800, 41900, 42000, 42100, 42200, 42300, 42400, 42500, 42600, 42700, 42800, 42900, 43000, 43100, 43200, 43300, 43400, 43500, 43600, 43700, 43800, 43900, 44000, 44100, 44200, 44300, 44400, 44500, 44600, 44700, 44800, 44900, 45000, 45100, 45200, 45300, 45400, 45500, 45600, 45700, 45800, 45900, 46000, 46100, 46200, 46300, 46400, 46500, 46600, 46700, 46800, 46900, 47000, 47100, 47200, 47300, 47400, 47500, 47600, 47700, 47800, 47900, 48000, 48100, 48200, 48300, 48400, 48500, 48600, 48700, 48800, 48900, 49000, 49100, 49200, 49300, 49400, 49500, 49600, 49700, 49800, 49900, 50000, 50100, 50200, 50300, 50400, 50500, 50600, 50700, 50800, 50900, 51000, 51100, 51200, 51300, 51400, 51500, 51600, 51700, 51800, 51900, 52000, 52100, 52200, 52300, 52400, 52500, 52600, 52700, 52800, 52900, 53000, 53100, 53200, 53300, 53400, 53500, 53600, 53700, 53800, 53900, 54000, 54100, 54200, 54300, 54400, 54500, 54600, 54700, 54800, 54900, 55000, 55100, 55200, 55300, 55400, 55500, 55600, 55700, 55800, 55900, 56000, 56100, 56200, 56300, 56400, 56500, 56600, 56700, 56800, 56900, 57000, 57100, 57200, 57300, 57400, 57500, 57600, 57700, 57800, 57900, 58000, 58100, 58200, 58300, 58400, 58500, 58600, 58700, 58800, 58900, 59000, 59100, 59200, 59300

A FIRST-ORDER MODEL FOR COLLISION-INDUCED DISSOCIATION IN THE PAUL ION TRAP

D.E. Goeringer and S.A. McLuckey
Chemical and Analytical Sciences Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

In our earlier work¹, we showed how Dunbar's thermal model² for low-intensity infrared multiphoton dissociation could be adapted to ion trap CID. In our CID model, which used n-butylbenzene as the parent ion, internal energy changes occurred via discrete, stochastic collisional energy transfer events rather than photon absorption/emission processes. Ion internal temperature was estimated via the kinetic theory of ion transport in gases, the power absorption term being determined from a forced, damped harmonic oscillator model for ion trap resonance excitation. A random walk sequence, corresponding to the processes believed to occur during collisional activation and performed at the predicted internal temperature, then allowed ion internal energy changes due to inelastic ion-helium collisions to be simulated as a function of time. The results indicated that under resonance excitation conditions the parent ion population reaches a steady-state Boltzmann internal energy distribution which is dependent upon both the ion characteristics and experimental conditions.

Ion dissociation kinetics were subsequently included in the (zero-order) model³ by assuming that the parent ion dissociated instantaneously (sudden death) upon reaching the critical energy for fragmentation. A first-order macroscopic dissociation rate constant, k_{diss} , for CID was found from the simulated parent ion decay curve. Although comparison of such simulated data with experimental CID phenomenology showed qualitative agreement, the absolute values of k_{diss} obtained from the model were significantly higher. We have now addressed this discrepancy by including quasi-equilibrium theory (QET) in our model, so that unimolecular parent ion fragmentation occurs at a rate that is a function of internal energy, ϵ (Fig. 1). By requiring the unimolecular dissociation rate constant, $k(\epsilon)$, to exceed the ion-helium collision frequency before dissociation can occur in the simulation, the corresponding k_{diss} values are reduced to the same order of magnitude as found experimentally (Fig. 2). It is interesting to note that the internal energy for appearance of m/z 92 product ions ($\epsilon \approx 1.9$ eV) is also predicted to be greater than the corresponding critical energy (0.99 eV), apparently due to a kinetic shift.

Another test for our thermal model of ion trap CID involves prediction of the m/z 91/92 product ion ratio from the n-butylbenzene molecular ion, the value of which is found experimentally to increase with resonance excitation voltage. However, our simulations yielded extremely low (~ 0.0005) m/z 91/92 ratios which were independent of voltage. Inspection of Fig. 1 reveals that $k(\epsilon)$ for the m/z 91 product ion becomes equal to the collision frequency at $\epsilon \approx 2.8$ eV, which is ~ 0.9 eV above the internal energy for appearance of m/z 92. Because changes in internal energy associated with ion-helium collisions are typically tens of meV, the extremely low m/z 91 abundance in the simulation is due to the low probability for the internal energy of a parent ion to increase from below the appearance energy for m/z 92 to above that for m/z 91 following a single collision. However, other workers have noted that there is a channel for conversion of m/z 92 $\rightarrow$ m/z 91; such a process is a possible explanation for the experimentally observed m/z 91/92 ratios if the corresponding $k(\epsilon)$ is greater than the collision frequency.

Reduction of ion transitional and internal energy prior to detection is important for achieving high mass resolving power and sensitivity in both Penning (FT-ICR) and Paul (quadrupole) ion trap mass spectrometry, as well as for bringing ions to the trap center for laser-induced fluorescence of mass-selected molecular ions (Figure 1a). Available methods for cooling trapped ions and/or electrons are: (a) buffer gas cooling [1] (Figure 1b); (b) adiabatic cooling [2]; (c) evaporative cooling [3]; (d) radiative cooling [4]; (e) resistive cooling [4]; (f) laser cooling [5]; and (g) sympathetic cooling [5] (Figure 1c). Although widely known in plasma physics, several of these techniques are only now penetrating "chemical" mass spectrometry. (a) Collisions of ions with a "buffer" gas cool atomic and molecular ions in both Penning and Paul traps. In FT-ICR, buffer gas cooling is essential for axializing ions by azimuthal quadrupolar excitation to convert magnetron motion to cyclotron motion. (b) In FT-ICR, if the trapping potential is much larger than the ion kinetic energy, ions may be cooled by adiabatically lowering the trapping voltage to allow free expansion of the ion cloud. (c) In both Penning and Paul traps, ions may be cooled "evaporatively" by lowering the trapping potential stepwise and allowing the hottest ions to escape. The remaining ions will relax to a new (lower) temperature. In ultrahigh vacuum, evaporative cooling can yield very cold ions. (d) In a strong magnetic field, electrons self-cool very efficiently (~ 1 s damping constant at 3 tesla) by radiative emission. (e) Ions may be cooled by resistive heating of the external circuit connected to the trap electrodes: ions dissipate energy by inducing electric current in the circuit. Resistive cooling is very effective for electrons and low- m/z ions in both Penning and Paul traps. (f) Atomic ions may be cooled by use of opposed laser beams to reduce the ion velocity by repeated (directional) absorption and (non-directional) emission. (g) In "sympathetic" cooling in Penning or Paul traps, cold electrons or atomic ions cool polyatomic ions by mutual Coulomb interactions. In future, ions in Penning trap may be cooled to 4.2 K for FT-ICR by cooling the vacuum chamber to ~ 4.2 K. Ions may be cooled even further (~ 1 K) by sympathetic cooling by laser-cooled atomic ions or self-cooled electrons. In detecting laser-induced fluorescence of the mass-selected ions, we find that off-resonance quadrupolar excitation and buffer gas can also cool and axialize ions. The Effects of Heavy Gases on the Dissociation Patterns of Peptide Ions in a Quadrupole Ion Trap

Richard W Vachet and Gary L Ghish

Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290

Introduction: Collision-induced dissociation (CID) as traditionally performed on the quadrupole ion trap has some limitations. Among these is the fact that the amount of internal energy typically imparted into ions during resonant excitation is small. Another limitation is that the application of a resonant excitation signal at the theoretically predicted frequency for ions of a given m/z rarely results in the dissociation of that ion. The optimum experimental resonant frequency in most cases must be empirically determined and this process can be time consuming. A third drawback to CID in the ion trap is the limited m/z range over which efficient MS/MS can be performed. MS/MS performed at low q_z values allows for a greater m/z range of product ions to be collected and detected, but at these low q_z values MS/MS efficiency is low.

The previously mentioned shortcomings can be overcome by the addition of a percentage of heavy gases (e.g. Xe, Ar) during CID. In particular the pulsed introduction of heavy gases enables CID to be carried out in the presence of a heavy gas and allows data acquisition to occur after the heavy gas has been pumped away. As a result, any deleterious effects of gases other than helium on the performance of the ion trap can be avoided.

Experimental: Experiments were carried out on a modified Finnigan MAT ITMSTM fitted for electrospray. Peptides were dissolved in a mixture of 20:75:5 water:methanol:acetic acid to a concentration of 250 μ M. Argon, krypton, methane, and xenon were introduced either by a variable leak valve or an solenoid valve actuated by a General Valve Corporation IOTA ONE pulse driver which provided a TTL pulse of variable length.

Results and Discussion: MS/MS experiments were carried out on leucine enkephalin (YGGFL) at different static pressures of various gases. It was found that the ratio of the intensities of the a_4 to b_4 ions of leucine enkephalin was a good gauge of the internal energy deposition. Figure 1 shows a plot of the ratio of the a_4 to b_4 ions versus partial pressures of various gases. It is clear from this plot that xenon is the most efficient at depositing internal energy into ions. Static pressures of heavy gases, however, can have deleterious effects on the sensitivity and resolution of spectra. Figures 2 and 3 demonstrate these effects on the mass spectrum of leucine enkephalin in the presence of helium and 5% xenon respectively. The addition of 5% xenon results in a significant decrease in sensitivity and resolution. A mass spectrum obtained after pulsing in xenon and allowing it to pump away before acquisition results in a spectrum identical to figure 2.

While maintaining performance with respect to sensitivity and resolution, pulsed introduction of heavy gases also allows for increased energy deposition. Figures 4 and 5 show the MS/MS spectra of des-Arg²-bradykinin (RPPGFSPF) in the presence of helium alone and while pulsing in krypton. Substantially more structural information is available (figure 5) after pulsing in krypton when compared to helium alone. The extent of dissociation observed in figure 5 can be changed by varying a delay time between the pulsed introduction of the heavy gas and the application of the resonant signal. By varying this delay time, MS/MS spectra can be optimized to provide the most useful amount of structural information.

The pulsed introduction of heavy gases also affords some other benefits. Ions can be efficiently dissociated during the application of the theoretically predicted resonant frequency. Also as figure 6 depicts, MS/MS can be efficiently performed at very low q_z values for RPPGFSPF, thus extending the m/z range over which product ions can be detected.

Conclusions: The addition of a heavy gas during CID allows for more internal energy to be deposited into ions. Some of the limitations of performing CID by single frequency resonant excitation can be overcome with the pulsed introduction of heavy gases. Also by varying the delay time between the pulse of the heavy gas and the application of the resonant excitation signal, MS/MS spectra can be tuned to provide the appropriate amount of structural information.

IMPROVEMENTS IN PERFORMANCE OF MALDI/QUADRUPOLE ION TRAP DESIGNED FOR BIOLOGICAL APPLICATIONS

Vladimir M. Doroshenko and Robert J. Cotter

Middle Atlantic Mass Spectrometry Laboratory
The Johns Hopkins University, Baltimore, MD, 21205

MALDI is one of the major ionization techniques used in biological mass spectrometry, and interfacing it with another leading technology in mass spectrometry - quadrupole ion trap (QIT), has been the goal of our laboratory efforts for years. As a result a new instrument has been designed in the laboratory with new and unique capabilities which have not been available so far in biological mass spectrometers. Among the features of our MALDI/QIT mass spectrometer are (i) effective trapping of the MALDI ions by increasing RF voltage during ion introduction, (ii) monoisotopic isolation of ions in the mass range up to 1600 Da using a broad band excitation technique with "stretched-in-time" waveforms for ion ejection; (iii) increased CID efficiency for biomolecules at low q_z values by pulsed introduction of heavy gases; and (iv) a linear mass calibration of the instrument in the resonance ejection mode using amplitude modulation of the ejection voltage which simplified calibration and improved the accuracy for mass assignment in mass spectra. Here we report the results of an investigation aimed at further improvement of the instrument performance. Two aspects of the QIT MS operation are considered which are related to (a) mass discrimination during ion injection and trapping in the increasing RF field, and (b) application of a frequency and acquisition locking technique for higher mass analysis.

The RF field profile used for trapping ions (Fig 1) at the middle stage of ramping can be represented in the first approximation as a linearly increasing one. If the mass-to-charge ratio of ions injected in this field depends quadratically on

Fig. 1 RF voltage profile used for trapping ions

Fig. 2. PEG1000 MW distribution at different times of laser firing.

the time (as in time-of-flight mass spectrometer) then effective pseudopotential barrier at the entrance will be the same for all injected ions. For ions injected with the same kinetic energy this means essentially the same injection conditions for all ions. The external MALDI ion source has been designed using electrostatic ion optics which for m/z 1000 ions gives about 15 ns flight time at 200 V acceleration voltage. With this ion source we obtained correct molecular weight (MW) distribution for PEG1000 and PEG1500 polymers when the laser was fired at $t=0$ (Fig 1) and other experimental parameters were optimized for maximum ion signal. Ion injection energy $E_0=21$ eV and RF field pseudopotential well depth $D_z=3$ eV. The value of the E_0 and D_z parameters affects mostly the intensity of the spectra but not the MW distribution. The most interesting effect is that the time of laser firing does not affect very much the MW distribution as shown in Fig 2. The most possible explanation is that the stage of ion injection is not a limiting factor in the overall process of ion injection and trapping at $E_0 > D_z$ and the trapping efficiency is constant (possibly close to unity) for broad interval of the kinetic energy of the injected ions.

In the second part of the work we studied the effect of synchronizing the ejection AC and trapping RF voltage and the acquisition process with the aim to extend the technique developed by Londry and March (*Int. J. Mass Spectrom. Ion Processes* 144 (1995) 87) for high mass analysis. In our work we used RF voltage 1.1 MHz frequency source after frequency dividing as a reference frequency for AC voltage generator and A/D and D/A conversion sampling. The dependencies of the apparent mass position m/z and mass resolution R for protonated molecules of α -Casein Fragment 90-96 (m/z 913.4) on line voltage phase ϕ_{line} and RF-AC locking phase ϕ_{RF-AC} (we retained designations of Londry and March) obtained at $\beta_z=0.5$ ($q_z=0.64$) are shown in Fig 3. Note the increase in the mass resolution from $R=1,400$ for the case without any synchronization (shown by horizontal interval line near R axis) up to 4,000 when frequencies are locked. The results are similar to that obtained for lower mass ions at $\beta_z=0.5$. However, for the same ions we observed small or no improvement in QIT performance when the frequencies were locked at $\beta_z=0.25$ ($q_z=0.35$). At the same time the mass resolution observed for m/z 913.4 ions at $\beta_z=0.25$ without any synchronization was about $R=3,000$ which is comparable with that observed in the case of the frequency locking at $\beta_z=0.5$. The higher resolution observed for $\beta_z=0.25$ in the case of no frequency locking can be attributed to the smaller amplitude of the micromotion of ions at the fundamental RF frequency along the ion trajectories at $\beta_z=0.25$ in comparison with that at $\beta_z=0.5$. The synchronizing of this micromotion with the ejection process results in larger effect for the mass resolution at $\beta_z=0.5$. Thus, the application area of the frequency locking technique is limited by high q_z and β_z values.

Fig. 3. Dependence of apparent mass position m/z and mass resolution R on line voltage phase ϕ_{line} (a) and RF-AC locking phase ϕ_{RF-AC} (b) at $\beta_z=0.5$

Technical Aspects of Matrix-assisted Laser Desorption/Ionization Ion Trap Mass Spectrometry

Jun Qin, Brian T. Chait

The Rockefeller University, 1230 York Ave., New York, NY 10021

We have made a number of significant improvements to matrix-assisted laser desorption/ionization ion trap mass spectrometry (MALDI/ITMS) over the past two years [1]. In our laboratory, MALDI/ITMS is proving to be (1) a robust tool for the verification of protein sequence by peptide mapping and mass spectrometric sequencing and (2) a powerful tool for the elucidation of post-translational modifications (e.g. phosphorylation, glycosylation and disulfide formation). We show elsewhere in this conference that MALDI/ITMS is also an extraordinarily useful tool for sensitive, rapid identification of gel-separated proteins.

In the present paper, we give a comprehensive account of the development of our MALDI/ITMS instrument and associated methodology. In particular, we will discuss ion trapping, ion detection, mass isolation, ion fragmentation, mass accuracy and space charge effects on mass accuracy. We offer suggestions as to the underlying principles for the improvements that we have observed.

Particular developments include an improved version of "dynamic trapping", which we have termed "matched dynamic trapping", that yields high trapping efficiencies (~40% as measured directly). We have found that the detection efficiency can be improved by almost an order of magnitude when ions are detected at substantially lower q_z values (0.1) and AC amplitudes ($3 V_{pp}$) than are conventionally used with resonance ejection.

For mass isolation, we found that a better efficiency (close to unity) is obtained when the RF scan functions are tailored to have no sharp discontinuity in the RF amplitudes (i.e., no sharp RF jumps). We designed a new excitation scheme, which we have termed red-shifted off-resonance (5-10% off resonance) large amplitude ($21 V_{pp}$) excitation (RSORLAE), and have found that RSORLAE is effective in fragmenting peptide ions such as Dynorphin 1-13, a peptide that is resistant to fragmentation in MS/MS. The key element in RSORLAE is that the secular frequency of ions shift to the higher frequency (blue-shifted) under the influence of non-linear field when high AC field is applied to the end-caps [2]. When the red-shifted AC excitation frequency is applied, the maximum excursion builds up, but it is soon slowed down when the secular frequency moves further away from the excitation frequency. The slow build-up of the maximum excursion of the ion trajectory enables the ions to undergo multiple energetic collisions and have sufficient time to dissociate. The RSORLAE process can be modeled by a simple forced and damped harmonic oscillator model assuming the damping constant and the frequency shift are functions of time (see Figure 1).

We have also found that under our new detection conditions, the influence of space charge on the mass accuracy is negligible (within the mass accuracy of the instrument — 100-200 ppm) even when the intensity of the trapped ions is changed by a factor of more than 20.

Steady improvements on the factors discussed above account for large sensitivity gains and our extensive utilization of MALDI/ITMS as a major work-horse for solving challenging biological problems involving the analysis of proteins.

1. Qin, J. and Chait, B. T. *Anal. Chem.* **1996** in press.
2. Williams, J. D., Cox, K. A.; Cooks, R. G.; McLuckey, S. A.; Hart, K. J.; Goeringer, D. E. *Anal. Chem.* **1994**, *66*, 725-729.

Figure 1. A simplified model for RESOLAE. The plot shows the maximum excursion of the ion trajectory as normalized to the maximum excursion when excited under the condition of resonant excitation keeping the damping term constant. It can be seen that under the condition RSORLAE, the build-up of the maximum excursion is slowed down considerably as compared with either resonant excitation or blue-shifted off-resonant large-amplitude excitation.

Reactions of Multiply Charged Biological Cations with Singly Charged Anions in the QITMS

Stephenson, Jr., J.L.; McLuckey, S.A. Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365

Several means have recently been developed to form gaseous multiply-charged ions derived from biopolymers and other high mass species. The phenomenon of multiple charging (for which electrospray is particularly noted) can facilitate the mass measurement of a high mass species by reducing the mass-to-charge ratio to a range of values amenable to mass spectrometry. The multiplicity of ion charge states for individual species can complicate mass measurement when mixtures of species give rise to ions and for very high mass species. The ability to resolve adjacent charge states for large biopolymers can be the limiting factor in determining the highest mass for which a measurement can be made.

The most frequently observed ion-ion reaction involving multiply charged cations and singly charged anions is that of proton transfer. We have recently adapted a Paul trap to allow for the study of multiply charged cations with singly charged anions. The present study was undertaken to address the extent to which high mass multiply-protonated species can be deprotonated with singly charged anions, and to determine the rate dependence of these reactions on cation charge. In contrast with ion/neutral reactions, ion/ion reactions are expected to be exoergic for all combinations of charge states. Ion/ion reactions might therefore be exploited for the partial neutralization of multiply-charged ions to arbitrarily low charge states.

In order to gain a qualitative understanding of the dynamics associated with proton transfer reactions, an examination of the energy surface for the reaction is necessary. Figure 1 shows a generic energy diagram for the ion/ion proton transfer reaction:

drawn in analogy with the Brauman diagram frequently used to represent proton transfer reactions.

The entrance channel for the ion/ion reaction is dominated by the long-range attractive $-Z_1 Z_2 e^2/r$ potential whereas the products, once formed, must overcome ion-dipole and ion-induced dipole potentials to proceed over the exit channel. The enthalpy of the reaction is determined by the difference in the proton affinity (PA) of

$[M + (n-1)H]^{(n-1)+}$ and the proton affinity of A. While relatively little is known about proton affinities of cations, deprotonation of even the strongest of gaseous bases by singly charged anions is expected to be exothermic since there is a significant gap in energy between the highest proton affinities of neutral bases and the lowest proton affinities of anions. The effect of multiple protonation is to reduce the stabilization associated with the addition of each successive proton. Therefore, deprotonation is expected to be exothermic for every value of n.

The analytical utility of these deprotonation reactions for mixture analysis is an area of current research in our laboratory. One of the problems inherent to electrospray is the compression of the "mass scale", placing greater demands on the resolving power of the mass analyzer. The multiple charging process can further complicate mass measurement when ions derived from more than one biopolymer are present. Although algorithms have been developed to extract mass information directly from the electrospray mass spectrum derived from mixtures, the quality of the information derived is dependent upon the ability to resolve peaks.

In Figure 2 is shown the ESI mass spectrum of what appears to be a mixture of two components (ubiquitin and bovine albumin). By subjecting the ions in Figure 2 to proton transfer reactions for 295 ms with perfluoro-1,3-dimethylcyclohexane anions, two additional components (the protein transferrin and another component of albumin) were identified in the mixture as shown in Figure 3. This mixture analysis performed via proton transfer reactions, would be analogous to a chromatographic step applied before the ionization of the mixture.

Fundamental Studies of Ion Injection and Trapping of

Electrosprayed Ions on a Quadrupole Ion Trap

*Scott T. Quarmby, Richard A. Yost, Jae C. Schwartz[†], and John E. P. Syka[†]

Department of Chemistry, University of Florida, Gainesville, FL 32611

[†]Finnigan MAT, San Jose, CA 95134

Ions injected into a quadrupole ion trap cannot be trapped indefinitely because of the excess kinetic energy that allowed them to enter the trap in the first place. Collisions with a buffer gas are the most common method of removing kinetic energy¹. In this work, computer simulations were used to study the experimental trends observed for ion injection. All experimental work was performed using a modified Finnigan MAT LCQ LC/MS[®] ion trap mass spectrometer with an electrospray ionization (ESI) source.

One parameter that has a large influence on ion injection efficiency is the q_z at which an ion is injected. Experimentally, the optimum q_z during injection was found to be inversely proportional to m/z and the range of q_z 's for which ions were efficiently injected decreased at higher m/z as shown in **Figure 1**. In order to explore the processes by which injected ions are trapped, simulations using SIMION 3D v6.0² were performed. The simulations included a Monte Carlo hard-sphere collision model to simulate the effect of random collisions with 1.5 mtorr of helium buffer gas. Because the collision model was based on randomly computed distances between collisions, reseeding the random number generator for each of a series of ions produced statistical information on the percentage of ions that were trapped under various conditions. Simulated ions were started at the entrance endcap with an initial kinetic energy (derived from experimental stopping potential measurements) and an injection angle of 5 or 10 degrees from the normal.

The q_z during injection and the initial RF phase angle (where 0° and 180° are the downward and upward zero crossing of the RF amplitude, respectively) were varied. At each q_z /phase combination, ten ions were injected, each with a different random number generator seed. The contour plot in **Figure 2** shows the distribution of q_z /phase combinations that resulted in efficient trapping of ions. Three different injection energies spanning the range of experimental energies found for the nonmonoenergetic ion beam are shown. Since ESI is a continuous ionization source, the number of ions successfully trapped at each q_z can be summed over all phases and divided by the total number of ions injected at that q_z . By doing so, a plot of the percentage of ions trapped versus q_z can be made (**Figure 3**). This simulated profile for m/z 100 is compared to experimental data for m/z 106.2 ([M+H]⁺ of serine) in **Figure 4**. Similar simulations were performed for m/z 1522 ([M+H]⁺ of Ultramark 1621) and the results are shown in **Figures 5 & 6**. In both cases the agreement between the simulation and experimental data is quite good at the lower q_z 's. It should be noted that the experimental data has been smoothed to remove any fine structure.

Experimentally, the ion signal drops off at high q_z during injection primarily because the injected ion fragments. At higher q_z 's, ions have higher kinetic energies ($E_{\text{max}} \propto q_z^2$ at low q_z) and therefore undergo highly energetic collisions (simulations show that m/z 1522 injected at a $q_z=0.3$ undergoes 106 eV lab frame collisions on average during injection). It is therefore not surprising that ions fragment when injected at high q_z 's. Eventually we would like to incorporate energy deposition and fragmentation into our simulations.

To understand why ions are trapped only at specific q_z /phase combinations, we examined the trajectories of these ions. By simulating trajectories without helium, it was found that at certain q_z /phase combinations, ions underwent pseudo-stable trajectories. In other words, ions were naturally stable for microseconds or even milliseconds before being lost to an electrode or endcap hole. This is an extension on an idea by Chun-Sing O and Hans Schuessler³ whose simulations indicated that injected ions could be stable for long enough to perform a spectroscopic experiment. **Figure 6d** shows the simulated distance traveled by ions injected under the condition of no collisions. **Figures 6a-c** show the number of ions that are successfully trapped at various helium pressures. At low pressures, ions are only trapped at those phases for which ions are pseudo-stable for the longest distances. However, as the pressure is increased, shorter distances are necessary to undergo enough collisions to damp the ion's excess kinetic energy.

Characterization of Combinatorial Chemical Libraries by Ion Trap-Tandem Mass Spectrometry

Jack Henion, Michael Nedved, and Sohrab Habibi, Analytical Toxicology, Cornell University, 927 Warren Dr., Ithaca, NY 14850

INTRODUCTION

Combinatorial chemistry has the potential to increase the diversity of compounds based upon an initial lead compound. Thus, combinatorial chemical methods are of great interest to the pharmaceutical industry because their use will increase the number of compounds in the drug "pipeline." With the rapid development of combinatorial chemical methods used to randomize the synthesis of a target compound, the analytical challenge lies in the development of techniques to rapidly screen these diverse chemical mixtures for desirable biological activity and to identify new target drug compounds.

When a combinatorial chemical mixture has been synthesized, it usually must be screened to determine whether biologically interesting compounds are present. We have reported the use of on-line immunoaffinity extraction combined with coupled-column HPLC and tandem mass spectrometry (IAE/LC/LC/MS/MS) as a possible strategy for coordinating on-line molecular recognition, analytical separation, and structural characterization(1). However, we have noted that a single stage of MS/MS is sometimes not sufficient to provide certain structural details about unknown structures of interest. This report describes how multiple stages of MS/MS (MS^n) in an ion trap mass spectrometer can provide additional useful structural information in such instances.

EXPERIMENTAL

MS^n spectra were acquired using an ion-trap mass spectrometer (ITMS) equipped with an atmospheric pressure ionization source and a heated capillary. The API ion source was constructed in this laboratory. The system utilized an electronics interface borrowed from a Finnigan ITMS. The trap was filled with ultra-pure helium to a partial pressure of about 1 mTorr. Typical ion accumulation times of about 0.1 to 0.3 seconds were used at an rf trapping voltage range of 496 to 958 volts (0-p) which corresponded to a m/z cut-off at m/z 43 to 83. Solutions of chlordiazepoxide standard or the unknown benzodiazepine mixture made in 1:1 acetonitrile/water with 5 mM ammonium formate pH 3.5 were infused into the ion-trap mass spectrometer at 4 μ L/min using a 4 kV sprayer voltage. Unknown mixtures of 20 different benzodiazepines were dissolved from microtiter plate wells and these solutions infused directly to the ITMS system under ion spray conditions.

RESULTS AND DISCUSSION

The MS/MS spectra for chlordiazepoxide and an unknown benzodiazepine are shown in Figure 1. Both compounds have a neutral loss of 17 Da from the protonated molecule and produce the same series of product ions at m/z = 255, 241, and 227. Inspection of the structure of chlordiazepoxide shows that it is an N-oxide, and neutral losses of 17 could be

explained by a loss of an OH species from the protonated molecule. An analogous loss of 16 Da (O) is observed for N-oxides in electron ionization mass spectra. The similarities of the MS/MS spectra suggest that the unknown benzodiazepine is also an N-oxide similar to chlordiazepoxide although its molecular mass is 14 Da greater than that of chlordiazepoxide.

To obtain more structural information, solutions of the known standard and the unknown mixture were introduced by infusion to an ion-trap mass spectrometer (ITMS) under ion spray conditions. Multiple degrees of fragmentation obtained in MS^n experiments create a more detailed fingerprint of the fragmentation pattern to confirm or refute structural predictions. The proposed fragmentation sequence shown in Figure 2 depicts the findings obtained from four stages of MS/MS. We suggest these data can be very useful for the characterization of unknown compounds in combinatorial libraries.

Many particle computer simulations of ion motion in Paul and ICR ion traps

Dale W. Mitchell and Richard D. Smith

Environmental Molecular Sciences Laboratory

Pacific Northwest National Laboratory

P.O. Box 999, M.S. P8-19, Richland, WA 99352

Treating Coulombic effects by direct particle-particle interactions is generally impracticable for large numbers of particles due to the N^2 scaling of the Coulomb force calculations where N is the number of particles. The particle-in-cell (PIC) method [1-3] effectively solves the Coulombic many body problem by replacing the direct particle-particle summation with the introduction of a spatial grid to calculate the potential (trap + space charge + image charge) and the introduction of finite-sized particles. PIC has been used extensively in diverse areas such as galactic simulations and plasma simulations.

Initial positions and velocities are assigned to the N interacting particles (each particle carries the total charge and mass of many individual ions with the m/z of a single ion). At each time step in the PIC simulation, charge density is assigned to the grid points on the computational mesh by interpolation from the particle positions, the total potential within the trap is determined by solving the finite difference form of Poisson's equation, the electric field is calculated at each particle position from the potential; the particle positions and velocities are updated at a fixed time step by solving the Lorentz force equation and the Newton equation of motion, and ion-neutral collisions are implemented by the Monte-Carlo method. Both hard sphere and Langevin collisions are included. We employ direct (noniterative) Poisson solvers (based on cyclic reduction and FFT) which rapidly and exactly solve the finite difference Poisson equation on the spatial grid. While the direct Poisson solvers are restricted to the special cases where the trap boundaries coincide with coordinate lines (e.g., a cylindrical trap if a cylindrical Poisson solver is used), the method is generalized to any arrangement of interior electrodes by the capacitance matrix method [3]. CPU times on an IBM RISC workstation to solve Poisson's equation are 0.07 s for a 64×64 Cartesian grid, 0.33 s for a 128×128 Cartesian grid and 0.17 s for a 64×128 cylindrical grid. For $N > 1000$ particles, these times are a relatively small part of the total simulation CPU time.

The most important benefit of PIC is that computational effort scales linearly with N . A comparison between a two dimensional PIC simulation using a 128×128 Cartesian computational mesh with a program which directly sums the N^2 Coulomb forces shows that the CPU time required for the N^2 summation is $\approx (0.1)N$ greater than the full PIC simulation for $N >$ several hundred particles. As an example, a PIC simulation involving 20,000 particles and 50,000 time steps was carried out on an IBM RISC work station, requiring 9 hours of CPU time. On the other hand, a direct particle-particle simulation would require 20 years of CPU time to evaluate the Coulomb forces for the same parameters.

As a vivid demonstration of Coulomb effects in an ICR trap, figure 1 depicts particle positions at nine different times in a two dimensional (xy) PIC simulation of a ring shaped ion cloud (hollow cylinder) whose origin is coincident with the trap z-axis and magnetic field $B = 1$ T (normal outward from the figure). The ring distribution has radius 1 cm, width 0.1 cm, and contains a total charge of 10^6 e. In this simulation the guiding center equation for motion is integrated, allowing for large time steps [4]. The trap is at zero potential. Neglecting Coulomb interactions the hollow distribution remains constant in time. However, the space charge $E \times B$ drift results in a strong instability, called the diocotron or slipping stream instability, which drives the initial configuration to an axisymmetric equilibrium with

density maximum at the origin. The on-set of instability is characterized by the formation of a number of vortices (density clumps) and has been observed in experiments [5]. We anticipate that PIC will be a very useful tool to investigate whole devices in mass spectrometry and ion optics when space charge effects are important.

NON-LINEARITY OF ION OSCILLATIONS IN ION TRAP: THE KEY TO THE MYSTERY OF ULTRA-HIGH MASS RESOLUTION

Alexander A. Makarov, General Physics Institute, 38 Vavilov Str., Moscow 117942 Russia

In response to the growing experimental evidence of importance of non-linear phenomena in ion trap operation, a new theoretical model of ion ejection is developed. The pseudopotential well approximation for forced ion oscillations in an ion trap under the conditions of ion-molecule collisions [1], is modified to include octapole perturbation on the quadrupole field. The resulting dimensionless equation of axial motion is reduced to one-dimensional first-order approximation

$$\frac{d^2x}{d\tau^2} + 2\delta \frac{dx}{d\tau} + x + x^3 = E \cdot \sin(\theta(\tau)) + \xi$$

The terms are $\tau = \omega_0 \cdot t = \frac{q_z \Omega}{2\sqrt{2}} t$, dimensionless time, $x = \frac{2\sqrt{2}f}{r_0} \cdot z$, dimensionless axial coordinate,

$E = \frac{e}{m} \cdot \frac{A_1 V_s}{q_z^2 \Omega^2 r_0^2} \cdot 16\sqrt{2}f$, the amplitude of excitation, $\delta = \frac{1}{2} \cdot \frac{C}{\omega_0}$, the coefficient of viscous damping,

$d\theta/d\tau = \omega(\tau)/\omega_0 \equiv \nu(\tau)$, the dimensionless excitation frequency; C , the rate of non-reactive momentum relaxation at near-thermal energies in neutral bath gas [2], $\omega_0 = q_z \Omega / (2\sqrt{2})$, frequency of oscillations in pseudo-potential well, Ω , fundamental angular frequency, q_z , reduced parameter of ion trap, m/e is ion mass-to-charge ratio; r_0 is radius of the ring electrode, V_s , amplitude (0-peak) of the excitation voltage applied across end-cap gap $2z_0$, $\omega(\tau)$, excitation frequency; $f = A_1/A_2$ and ξ is the residual term. Dimensionless parameters A_2 and A_4 depend on the trap design and could be determined from the graphs in the paper of Wang and Franzen [3]. The factor A_1 compensates for the hyperbolic shape of the end-caps. Though internal resonance is possible between radial and axial oscillations, the non-linear terms shift the frequencies in the opposite directions resulting in the self-destruction of the resonance and stabilization of radial amplitude at a constant level. As a result, coupling of radial and axial motions do not change the physics of vibration and therefore is included in the residual term ξ along with higher multipoles.

The solution of the equation is obtained in the form $x = a \cdot \cos(\theta(\tau) + \psi)$, where a is amplitude and ψ is phase. Using Mitropolsky asymptotic method [4], the dependence of amplitude a on excitation frequency ν (the resonance curve) could be derived (Figure 1). When ν is increased slowly from zero (point M), a is gradually increasing until point B is reached. As the frequency tends to grow, it can not suddenly start to decrease. Therefore, the part of the curve from B to D in Figure 1 can not be followed. Instead, a sudden quenching of the oscillations occurs and the amplitude drops from B down to point C, after which it slowly decreases with ν . If the frequency ν is decreasing from N towards D, then a is gradually increasing until point D is reached. Again, as ν is bound to decrease, curve from D to B can not be followed. Instead, the system jumps to the point A, i.e. the amplitude increases instantaneously, as if there is no friction at all!

When frequency ν is changed with the finite rate $d\nu/d\tau = \beta$, the non-stationary resonance curve may be derived by numerical methods. New features of this curve are the overshoot and small oscillations following the jump (Figure 2). Duration S of the jump and relative change of amplitude λ appear to be independent on scan rate below $\beta = 10^{-6} \cdot 10^{-7}$ (Figure 3), where β is expressed through mass scan rate a_m (in a m.u./s) and ion mass M (in a m.u.) as $\beta = a_m / (\omega_0 M)$.

Analytical estimations of mass peak width ΔM (in a m.u.) and excitation voltage V_s are obtained assuming that the frequency dispersion is comparable with the width of the jump:

$$\Delta M \approx \frac{\lambda^2 (\lambda - 1) \eta \sqrt{2}}{3f} \cdot \frac{a_m}{q_z \Omega} \cdot \left(1 + \frac{q_z}{2}\right)^2 \cdot \left(\frac{r_0}{z_0}\right)^2 \quad V_s \approx \frac{3f}{2A_1} \cdot \frac{m}{e} \cdot \frac{q_z^2 \Omega^2}{\lambda^3} \cdot \left(1 + \frac{q_z}{2}\right)^{-3} \cdot \left(\frac{z_0}{r_0}\right) \cdot z_0^2$$

where η is a constant that has a value on the order of 1. For the Finnigan MAT ion trap, $\Omega/2\pi = 1.1$ MHz, $r_0 = 0.01$ m, $z_0 = 0.00783$ m, $f \approx 0.02$, $A_1 \approx 1.26$. Then for $q_z = 0.86$ and $\eta \approx 1$ minimum mass peak width is expected to be about 0.5 a.m.u. at the standard scan rate 5555 Da/s improving up to $3 \cdot 10^{-5}$ a.m.u. at scan rate 0.1 Da/s, in satisfactory agreement with experimental results [4].

NEGATIVE ION PHOTOELECTRON SPECTROSCOPY OF TRANSITION METAL CLUSTERS

Doreen G. Leopold, Simson Alex, and Susan M. E. Green
Department of Chemistry, University of Minnesota, Minneapolis MN 55455

Laser photoelectron spectroscopy of negative ions provides a powerful method with which to probe the ground and low lying electronic states of neutral and anionic gas phase metal clusters. We report here the photoelectron spectra of the bare transition metal triatomics Cr_3^- , V_3^- and V_2Ni^- , and also present preliminary results for the ligated cluster Nb_4CO^- . The anions were prepared in a flowing afterglow ion-molecule reactor equipped with a metal cathode discharge source, and were photodetached at 488 nm following mass selection.

The spectrum of Cr_3^- (shown below) displays two active vibrational modes with frequencies ($\pm 15 \text{ cm}^{-1}$) of 480 cm^{-1} (ν_1) and 125 cm^{-1} (ν_2) for the lowest observed state of neutral Cr_3 . The former value is even higher than the frequency in Cr_2 (452 cm^{-1}), which has a formal bond order of 6, indicating that at least 2 of the Cr atoms in this state of Cr_3 are highly multiply bonded. Assigning this state as the ground state yields an electron affinity of $1.391 \pm 0.006 \text{ eV}$ for Cr_3 . A transition to a low-lying excited state of Cr_3 is also observed, with a long progression in 165 cm^{-1} intervals (ν_2 in this state).

The spectra of V_3^- and V_2Ni^- also each display two active modes with frequencies of 460 and 200 cm^{-1} for the lowest observed state of V_3 , and 415 and 245 cm^{-1} for that of V_2Ni . In contrast to the V_3^- and Cr_3^- spectra which show only short vibrational progressions in the transitions to the lowest observed neutral molecule states, the V_2Ni^- spectrum (shown below) displays a long ν_2 progression indicative of a larger bond angle change upon photodetachment. Assigning these as the ground states yields electron affinities ($\pm 0.006 \text{ eV}$) of 1.109 eV for V_3 and 1.112 eV for V_2Ni .

We also present vibrationally resolved photoelectron spectra of Nb_4CO^- , prepared by injecting CO into the flow tube downstream of the liquid nitrogen cooled metal cluster source. Interestingly, the spectra reveal the presence of two different isomeric forms of this anion whose relative abundances depend sensitively on the ion source conditions.

PHOTOELECTRON SPECTROSCOPY OF SMALL CLUSTER ANIONS: DIPOLE BOUND, GROUND STATE SYSTEMS; Hendricks, Jay; Lyapustina, Svetlana; de Clercq, Helen; Fancher, Chuck; Lippa, Tim; Collins, John; Thomas, Owen; Witonsky, Scott; *Bowen, Kit; Department of Chemistry, Johns Hopkins University, Baltimore, MD 21218, USA

In the vast majority of atomic and molecular systems, electrons are bound to monopolar charges, i.e., to positively-charged nuclei. One might wonder, however, whether higher terms in the multipole expansion, for example the dipolar term, could also bind electrons. Theory says this can occur, and it provides substantial guidance as to the likely characteristics of dipole bound systems. In particular, an excess electron attached to a neutral dipole is expected to be very weakly bound. The excess electron cloud in such a system should be very diffuse, resembling a Rydberg electron. There is a minimum dipole moment necessary to bind an electron, and it is thought to be around 2.5 D. Furthermore, the structure of a dipole bound anion is expected to be essentially the same as its corresponding neutral.

Using negative ion photoelectron spectroscopy, we have studied a wide variety of ground state anions in which their excess electrons are bound primarily by the dipole moment of the system. In the course of this work, we have come to recognize a distinctive spectroscopic signature for dipole bound anions. The photoelectron spectra of dipole bound anions are dominated by an intense, narrow peak at very low electron binding energy with much weaker molecular vibrational features at higher electron binding energy. This spectral fingerprint is unlike any other seen in negative ion photoelectron spectroscopy.

The main subject of this presentation deals with our work on the anions of nucleic acid bases and some of their cluster anions. The anions of nucleic acid bases play important roles in radiation-induced mutagenesis. When ionizing radiation interacts with living organisms, one of the mechanisms for genetic damage involves the attachment of electrons to DNA and RNA bases. The resultant radical anions then participate in a chain of chemical reactions that can lead to the permanent alteration of the original bases and to genetic damage. Because of these considerations, nucleic acid base anions have been the subject of numerous experimental studies in the condensed phase. Information about isolated (gas-phase) nucleic acid base anions, however, has come primarily from theoretical studies. Interestingly, while nucleic acid base anions are known to exist in the condensed phase as stable conventional (valence) anions, none of the numerous theoretical studies on them has found a stable, conventional isolated nucleic acid base anion. The nucleic acid bases, however, possess large dipole moments (~ 5 D), and recent calculations by Adamowicz found isolated nucleic acid base anions to be dipole bound anions.

In this talk, we present our photoelectron spectra of uracil and of thymine anions. Their spectra clearly indicate, via the above-mentioned spectral fingerprint, that they are indeed dipole bound anions with similar electron binding energies to those predicted by theory. No evidence for conventional (valence) anions was observed in our study of these species.

This left us with a curious situation in which nucleic acid base anions are dipole bound in isolation, but conventionally bound in condensed phases. A transformation due to environmental effects was implied. We then solvated uracil anions with water molecules and recorded their photoelectron spectra (up to 12 waters per uracil). We expected to see a gradual transformation with hydration number from a dipole bound spectral signature to a conventional (non-dipole bound) spectral pattern. We were then quite surprised when the uracil anion with a single water molecule, i.e., (U-W)-, completely lost its distinctive dipole bound signature and instead exhibited a broad, higher electron binding energy spectral pattern that is not unusual for conventional anions. Even one water molecule was able to transform the uracil anion from a dipole bound species to something else, presumably a conventional anion. Solvation by additional numbers of water molecules gave spectra and solvation trends which are typical for the hydration of conventional anions.

After obtaining this surprising result, we solvated uracil anions with weaker solvents, arguing that water is such a powerful solvent, that it obscures the observation of the transformation from dipole bound to conventional anion forms with solvent number. When we solvated uracil anions with argon and with krypton atomic solvents, the dipole bound signature persisted, although the

observed spectral shifts indicated that they had been stabilized by these solvents. When we solvated uracil anions with xenon, however, something dramatic happened. Both a dipole bound and a conventional anion signature appeared side by side in the same spectrum, the latter similar to that of (U-W)-, but at lower electron binding energy. Xenon appears to be just strong enough to make this system teeter between dipole bound and conventional anion forms. When two xenon atoms were solvated onto a uracil anion, the ratio of conventional anion to dipole bound anion intensities increased.

Reaction Energetics: Nucleophilic Displacement and Proton Transfer

Vincent F. DeTuri, Paul A. Hintz, and Kent M. Ervin*
 Department of Chemistry and Chemical Physics Program,
 University of Nevada, Reno, Nevada 89557

Guided ion beam techniques are used to measure the cross sections of proton transfer and nucleophilic displacement (S_N2) reactions of halogen anions as a function of translational energy. The reaction threshold energies provide information about the reaction endoergicity or the translational activation barrier.

Our recently constructed guided ion beam tandem mass spectrometer is shown in Fig. 1. Reactant anions are produced with a microwave discharge source in a flow tube reactor (flowing afterglow) source. The ions are extracted from the flow tube, focused, accelerated, and mass selected by a magnetic sector mass spectrometer. Then the ions are decelerated to the desired kinetic energy and injected into an octopole radio frequency ion beam guide. In the octopole region, the ions are allowed to react with a neutral reagent gas. Ionic products are collected by the octopole and analyzed by a quadrupole mass spectrometer detector. Absolute reaction cross sections are obtained as a function of pressure and extrapolated to the zero-pressure, single-collision limit.

Figure 2 shows the cross section threshold behavior for two endoergic proton transfer reactions, $F^- + CH_3OH \rightarrow HF + CH_3O^-$ and $Cl^- + C_6H_5OH \rightarrow HCl + C_6H_5O^-$. The cross sections may be fit to an empirical threshold function to obtain the reaction threshold energy, which yields the difference between the gas phase acidities of the organic molecule RH and the reference acid HF or HCl. This method provides precise values for the gas phase acidities of RH molecules.

We have also examined the prototypical S_N2 reaction, $Cl^- + CH_3Cl \rightarrow CH_3Cl + Cl^-$. The S_N2 process is monitored via isotope exchange. Fig. 3 shows the quadrupole mass spectra of $^{35}Cl^-$ and $^{37}Cl^-$, obtained using a second Mathieu stability region scan which provides excellent isotopic separation. Fig. 4 shows the cross section. The reaction probability is extremely small at near thermal energies because of the intrinsic activation barrier at the S_N2 transition state and because translational energy is inefficient at promoting reaction. Above an apparent threshold of 0.5-1.1 eV, however, the S_N2 process can be induced via collisional activation.

SIZE AND STRUCTURAL EFFECTS IN THE ENERGETICS OF GAS PHASE ION-MOLECULE ASSOCIATION REACTIONS

Terry McMahon^{*} and Tim Hoffman
Department of Chemistry; University of Waterloo
Waterloo, Ontario; CANADA N2L 3G1

Previous studies of the formation of proton bound dimers of compounds containing simple oxygen based functional groups have shown that there is a remarkable consistency in the enthalpy change, $\Delta H^\circ_{\text{ion}}$, for their production from protonated base plus the associated neutral monomer. For example, water and small alcohols, ethers and ketones all exhibit a value of $\Delta H^\circ_{\text{ion}}$ of 31 ± 1 kcal mol⁻¹. The number of species examined of each functional group type is, however, relatively small and there has been no concerted attempt to examine systematically the effects of chain length and structure on the energetics of these simple association reactions. In particular it was felt to be of interest to examine the entropy changes, ΔS° , for these association reactions since it is possible that as the chain length of a given alkyl substituent on the oxygen functionality increases there should be an increased probability of steric interference of the alkyl groups of the two monomer units. Such a steric interference would then manifest itself as an unusually unfavourable entropy of association.

In order to investigate these phenomena, we have undertaken a study by high pressure mass spectrometry (HPMS) of the formation of proton bound dimers of a series of aliphatic ketones. For the most part, the ketones chosen have been as "symmetric" as possible. That is, for odd numbers of carbons in a straight chain ketone the middle carbon was the site of the ketone function (e.g. 5 nonanone), while for even numbers of carbons in the chain the ketone function was placed such that there was a difference of only one methylene group on the two sides. The exception to this was a series of nonanones, for which several different isomers were examined. In addition cyclic ketones were also examined. The data are summarized in Table 1. As anticipated, the constancy of the value of $\Delta H^\circ_{\text{ion}}$, in this case 30 ± 1 kcal mol⁻¹ was maintained. In addition an increase in the negative entropy of association with increasing chain length was observed, although of a magnitude less than anticipated. Evidently, the alkyl groups are able to orient themselves in such a way that relatively little steric interference and inhibition of internal rotations results.

An additional goal of obtaining this data was to find a series of compounds for which the association energetics were relatively constant as the molecular size increased and to study the ambient infra-red radiation induced unimolecular dissociation of the adducts in a Fourier transform ion cyclotron resonance cell. From a study of the temperature dependence of such unimolecular dissociations, as well as an analogous study of the power dependence of CW CO₂ laser induced dissociation, it was hoped to be able to define ion temperatures associated with given laser powers. An unusual bleaching effect in the laser induced dissociations makes this temperature calibration problematic.

TABLE 1.

THERMOCHEMICAL DATA FOR THE FORMATION OF PROTON BOUND DIMERS OF KETONES

KETONE	$-\Delta H^\circ$ (kcal mol ⁻¹)	$-\Delta S^\circ$ cal mol ⁻¹ K ⁻¹)
acetone	30.6	30.2

ION CHEMISTRY OF PROTONATED LYSINE DERIVATIVES

A.G. Harrison and T. Yalcin, Department of Chemistry, University of Toronto, Toronto, Ontario M5S 3H6, Canada.

In addition to ions arising by the cleavage of the backbone, CID of protonated peptides often produce low mass (<m/z 160) ions characteristic of the amino acids comprising the peptide [1]. Although many of these low mass ions are immonium ions, a particularly intriguing species is the m/z 129 ion frequently observed in the CID mass spectra of peptides containing lysine (see Fig 1). The m/z 129 ion also is observed in the fragmentation of protonated lysine ($[MH^+ - H_2O]^+$) and, in the absence of rearrangement, corresponds to the acylium ion $H_2N(CH_2)_4CH(NH_2)CO^+$. However, it is known [2,3] that such α -amino acylium ions are unstable and spontaneously eliminate CO to form the immonium ion. This strongly suggests that the stable form of the m/z 129 ions must have a different structure.

Table 1 presents the unimolecular (metastable ion) fragmentation reactions occurring in the quadrupole cell of a hybrid BEQ mass spectrometer [4] for a variety of protonated lysine derivatives. The m/z 129 ion is formed not only from H-Lys-X.H⁺ but also from N^α-Ac-Lys-X.H⁺ and H-Gly-Lys-X.H⁺ where X represents a variety of derivatives. Precursor ion scans and energy-resolved CID studies show that, in the latter two cases, m/z 129 is formed by sequential loss of HX followed by loss of ketene for the acetyl derivatives and loss of the glycine residue for the H-Gly-Lys-X.H⁺ species.

Figure 2 compares the CID mass spectrum of protonated α -amino- ϵ -caprolactam with that of the m/z 129 formed by unimolecular fragmentation of protonated N^α-Ac-Lys-OH. In the latter experiment MH⁺ was mass-selected by the magnetic sector and underwent fragmentation in the field-free region between B and E; the m/z 129 ion so-formed was selected by the electric sector and underwent CID in the quadrupole cell. The good agreement of the CID spectra strongly supports the conclusion that the m/z 129 ion from the lysine derivatives has the protonated α -amino- ϵ -caprolactam structure. The first step in the cyclization process is outlined in Scheme 1.

A major fragmentation channel for protonated lysine is loss of NH₃; isotopic labelling shows that the ϵ -amino group is lost exclusively. When the ϵ -amino group is substituted with methyl groups loss of the appropriate methylamine is the dominant fragmentation reaction. Our tandem MS experiments support the conclusion that cyclization also has occurred in this case to form protonated pipecolic acid.

Photodissociation spectroscopy and dynamics of the N_2O_2^- anion

David L. Osborn, David J. Leahy, Douglas R. Cyr, and Daniel M. Neumark

Department of Chemistry, University of California, Berkeley, California, 94720
and Chemical Sciences Division, Lawrence Berkeley Laboratory, Berkeley, California 94720

In recent years, photodissociation experiments have been performed on a considerable number of neutral molecules and positive ions. These experiments have proved invaluable in understanding the electronic spectroscopy and dissociation dynamics of these species. In contrast, there have been relatively few photodissociation studies on negative ions. Anion photodissociation is problematic because, in most negative ions, bond dissociation energies are higher than the threshold for electron detachment, so that the dissociative anion state one might hope to access is generally embedded in the neutral + e^- continuum. Nonetheless, photodissociation studies have been carried out on open shell anions such as Cl_2^- or CO_3^- for which the smallest bond dissociation energy is less than the electron binding energy, and on species such as O_3^- and O_4^- in which photodissociation occurs at energies well above the threshold for electron detachment. In this paper, we use a fast ion beam experiment to investigate the photodissociation spectroscopy and dynamics of the N_2O_2^- anion, an open-shell species with a high electron binding energy.

The work presented here is motivated by recent results on the gas phase spectroscopy and dynamics of the N_2O_2^- anion, especially in relation to the ion molecule reaction

When the reactants are fully isotopically labeled, it is found that the products are completely isotopically scrambled. These studies show that reaction occurs through O⁻ attack at both the terminal and central N atoms on N_2O . In a photoelectron spectroscopy study, Posey and Johnson¹ demonstrated the existence of two distinct isomers of N_2O_2^- which can each be prepared selectively in the gas phase by electron impact on a supersonic expansion of different gases. These stable isomers are identified as a C_{2v} structure formed from O⁻ attack at the central N atom in N_2O , and an ONN O⁻ isomer formed by O⁻ attack at the central N atom in N_2O . Posey and Johnson found that at 532 nm and 355 nm, the only peak in the photoelectron spectrum of the C_{2v} isomer is from the photodetachment of O⁻ atoms. Thus, at these wavelengths, photodissociation to $\text{O}^- + \text{N}_2\text{O}$ occurs rather than photodetachment of the parent N_2O_2^- anion. More recently, Arnold and Neumark² have measured the photoelectron spectrum of this isomer at 266 nm and 213 nm. They found that at these higher photon energies, photodetachment of N_2O_2^- does occur, populating several previously unknown electronic states of neutral N_2O_2 . From this work alone, however, one cannot determine at what energy the observed N_2O_2 states lie relative to the various asymptotic channels ($\text{O} + \text{N}_2\text{O}$, $\text{N} + \text{NO}_2$, $\text{NO} + \text{NO}$, etc.). One of the goals of this study is to answer this question by determining the dissociation energy of the N_2O_2^- anion.

In this abstract, we describe recent work on the excited state spectroscopy and photodissociation dynamics of the C_{2v} isomer, which will henceforth be referred to simply as N_2O_2^- . Using the technique of fast beam translational spectroscopy, we have measured the relative photodissociation cross section of N_2O_2^- as a function of wavelength, and have performed more detailed dynamical measurements at selected wavelengths. We observe fragmentation to

two channels, $\text{O}^- + \text{N}_2\text{O}$ and $\text{NO}^- + \text{NO}$, and have measured kinetic energy and angular distributions for both channels. These measurements yield bond dissociation energies and a wealth of information concerning the detailed photodissociation mechanism. The interpretation of our results is aided by *ab initio* calculations on the ground and excited states of N_2O_2^- .

The wavelength resolved total photodissociation cross section spectrum shows several broad, reproducible features which are presumably due to excitation of multiple vibrational modes in the upper electronic state. The main information we obtain about N_2O_2^- photodissociation is derived from dissociation dynamics data acquired at three wavelengths; 570, 532, and 500 nm. These spectra are shown below for the $\text{O}^- + \text{N}_2\text{O}$ and $\text{NO}^- + \text{NO}$ channels. Along with the experimental data (solid lines) is shown the predicted translational energy release for a prior distribution of product states (dotted lines). The overall shape of the distributions agree with the statistical model for the $\text{O}^- + \text{N}_2\text{O}$ channel, for which we propose a dissociation mechanism of rate limiting internal conversion, followed by statistical decomposition on the ground electronic surface. In contrast, for the $\text{NO}^- + \text{NO}$ channel the experimental distributions depend on photon wavelength, and the agreement with the statistical model is poor. For this reason we attribute the $\text{NO}^- + \text{NO}$ channel as arising from coupling of the initially populated state with an excited state that correlates to these products.

Ab initio calculations have been carried out for the lowest state of each symmetry in this ion. Based on the agreement between experiment and theory, the transition in the total dissociation cross section spectrum is assigned to $B(^2A_2) \leftarrow X(^2B_2)$. From the translational energy distribution for $\text{O}^- + \text{N}_2\text{O}$ at 570 nm, we can determine the following thermodynamic data: $D_0(\text{O}^- - \text{N}_2\text{O}) = 1.40 \pm 0.03 \text{ eV}$, $D_0(\text{N}_2\text{O}_2^- \rightarrow \text{NO}^- + \text{NO}) = 1.25 \pm 0.04 \text{ eV}$, and $\Delta H_{f,0}^0(\text{N}_2\text{O}_2^-) = 0.58 \pm 0.04 \text{ eV}$. This information shows that the covalently bound neutral N_2O_2 species found in Arnold and Neumark's photoelectron spectroscopy study are accessible in the $\text{N} + \text{NO}_2$ reaction.

Conformation of Gas-Phase Lysozyme Ions As Revealed by Surface Impact Defects

P.A. Sullivan, C.T. Reimann, J. Axelsson, A.P. Quist, P. Hakansson, B.U R Sundqvist
Uppsala University, Ion Physics Group Box 535, S-751 21 Uppsala, Sweden

Electrospray ionization (ESI)¹ and matrix-assisted laser desorption (MALDI)² have proven to be powerful techniques for producing gas-phase protein ions. Subsequently, the conformations of these ions have been examined indirectly through the linkage between conformation and characteristics such as collision cross sections^{3,4}, hydrogen-deuterium exchange^{5,6} and charge stripping⁷. Yet the conformations of gas-phase proteins are still not rigorously understood^{8,9,10}. We have probed the overall conformation of electrosprayed myoglobin and lysozyme by accelerating these gas-phase ions to ~45 km/s towards highly-oriented pyrolytic graphite (HOPG) and other target surfaces and measuring with tapping mode scanning force microscopy (TM-SFM) the protein imprint produced by individual impacts¹¹.

As each ion impacts the surface, a large volume density of kinetic energy is deposited in a nanometer-scale near-surface region of the target¹². Before this energy diffuses away from the impact point, it causes significant modification to the local morphology of the surface, due to the thermal response of the material. Figure 1 shows typical 500 by 500 nm TM-SFM images of hillocks generated by 146 keV disulfide-intact lysozyme and disulfide-reduced lysozyme projectiles incident on HOPG. The hillocks are of the order of 1 nm in height and 20 nm in width. The lengths of the hillocks range from 20-60 nm, depending on the charge state and type of incident protein. Myoglobin and disulfide-intact lysozyme generated compact, elliptical hillocks, as did a lower charge state +9 of apomyoglobin¹¹. In contrast, disulfide-reduced lysozyme and the higher charge states of apomyoglobin produced a distribution of hillocks ranging from compact to more oblong, extended hillocks. These distributions were skewed: elongated hillocks were more common than compact hillocks. Also, the extension of the hillocks increased with the charge state of the incident protein projectiles.

Assuming the shape of the hillock reflects the shape of the incident projectile, then apomyoglobin at charge state +9, myoglobin charge state +10 and disulfide-intact lysozyme charge state +9 are all compact in the gas-phase. In contrast, the higher charge states of apomyoglobin and disulfide-reduced lysozyme are more extended or "stick-like", generating a distribution of hillock lengths owing to their random orientations upon impact with the target surface. By use of a simple thermal model describing the response of HOPG to the energy deposited by incident energetic projectiles of different overall lengths¹¹, and considering the tumbling motion of the protein ions as they impinge on the target, the physical extension of disulfide-reduced lysozyme at charge state +14 was determined to be about 36 nm. This length is consistent with this "denatured" gas-phase protein ion having retained considerable secondary structure while being significantly elongated with respect to the native globular physiological conformation. Comparing our results with those from a recent hydrogen-deuterium exchange experiment shows a discrepancy. Gross et al. indicated that charge states +11 to +15 of disulfide-reduced lysozyme gas-phase ions are completely extended structures⁶. The differing results might be due to different ESI source conditions between the respective experiments. However,

the degree of extension deduced by Gross et al. is linked to the value used for the effective shielding of the charges by the protein, and as pointed out by Schnier et al.⁹, a higher shielding value would be consistent with a lower deduced length.

We found that apomyoglobin gas-phase ions, also at charge state +14, displayed a length similar to that of disulfide-reduced lysozyme, even though these two proteins differ significantly in their number of amino acids. A length of 36 nm is consistent with apomyoglobin being substantially elongated relative to the native conformation, but again maintaining significant secondary structure such as alpha helices. An apomyoglobin protein in solution, characterized by a helical content of ~60%¹⁴, and extended as much as possible without destroying the alpha helices, would stretch to a length of around 36 nm, the length we observe for this protein in the gas phase. The width of an α -helix is ~1 nm, so using the value of L we obtained the gas-phase collision cross section is predicted to be 36 nm²; in good agreement with observed gas-phase collision cross sections³.

Microscopic examination of energetic surface-impact defects involving protein ions is a powerful, visually-oriented means of outlining the broad features of the conformations of gas-phase ions^{11,15,16}.

Fig. 1 TM-SFM images (500 nm by 500 nm) of hillocks generated on HOPG by impacts of 146 keV disulfide-intact charge state +9 (right) and disulfide-reduced charge state +14 (left) lysozyme.

QUANTITATION OF CARCINOGEN-DNA ADDUCTS IN HUMANS: THE ROLE OF MASS SPECTROMETRY

Stephen S. Hecht, American Health Foundation, Valhalla, New York 10595

Epidemiologic studies strongly indicate that lifestyle factors such as tobacco and alcohol use or diet are involved in the etiology of a large number of commonly occurring cancers in the U.S. (1,2) Specific chemical carcinogens play a major role in causing these cancers. For example, nitrosamines, polynuclear aromatic hydrocarbons (PAH), and aromatic amines are major causative agents for all cancers associated with tobacco use. Heterocyclic aromatic amines, nitrosamines, and aflatoxins are well established dietary carcinogens. All of these carcinogens require metabolic activation in order to exert their carcinogenic effects. There are competing detoxification pathways. The metabolic activation process is generally initiated by cytochrome P450 enzymes, which oxygenate the compound making it more polar and readily excretable. Some of the intermediates generated in this process are electrophilic and can react with nucleophilic sites in DNA or protein forming covalent binding products referred to as adducts. A large amount of data indicate that DNA adducts are critical in the carcinogenic process. When DNA adducts persist unrepaired, replication leads to miscoding and the introduction of a permanent mutation. When this mutation occurs in a critical gene such as an oncogene or tumor suppressor gene, normal growth controls can be overcome leading to development of cancer (3).

Metabolic activation and detoxification processes will differ among individuals (4). Carcinogen-derived biomarkers can be used to assess these reactions in people. Carcinogen-derived biomarkers are adducts or metabolites that can specifically be related to exposure and uptake of a given carcinogen. These biomarkers include DNA adducts, hemoglobin adducts, and urinary or serum metabolites. DNA adducts are important biomarkers because they are directly involved in the cancer induction process. Monitoring DNA adducts and other carcinogen biomarkers in humans can provide information not only on carcinogen exposure, but also on uptake, metabolic activation and detoxification. The biologically relevant dose that reaches critical cellular targets can potentially be determined, and this information can lead to an assessment of individual risk for cancer. The underlying hypothesis is that individuals who metabolically activate carcinogens extensively will be at higher risk for cancer development than those who are able to detoxify these substances. A number of methods have been developed to quantify DNA adducts in humans. These include immunoassays, ³²P-postlabelling, HPLC-fluorescence, HPLC-electrochemical detection, and GC-MS (5,6). All of these techniques have some limitations. MS methods have the potential to be the most specific and broadly applicable although sensitivity limitations have prevented widespread use to date.

Our research in this area has focused on nitrosamines and PAH involved in lung cancer associated with tobacco use. 4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) is a potent pulmonary carcinogen believed to be involved in the induction of lung cancer in humans (7). NNK undergoes metabolic activation by hydroxylation of the carbons adjacent to the nitroso group leading to intermediates which can methylate or pyridyloxobutylate DNA. Both pathways are mutagenic and are involved in cancer induction by NNK. The pyridyloxobutyl adducts with DNA and hemoglobin can be quantified by GC-MS of 4-hydroxy-1-(3-pyridyl)-1-butanone (HPB) released upon acid or base hydrolysis. Sensitivity in the attomol range can be achieved by NCI-SIM of HPB-pentafluorobenzoate (8). This methodology has proven to be very useful in animal studies of NNK carcinogenicity, particularly when chronic dosing

protocols are used. These protocols would be impractical with radiolabelled NNK. For example, the carcinogenicity of NNK can be partly or completely blocked by phenethyl isothiocyanate (PEITC). Studies of HPB-releasing DNA adduct levels in different cell types of the lung have clearly shown that pyridyloxobutylation of the alveolar type II cells is critical in carcinogenesis by NNK. Moreover, parallel decreases were observed in hemoglobin adduct formation in these studies. Thus, the modulation of DNA and hemoglobin adducts of NNK parallels modulation of its carcinogenicity. HPB-releasing DNA and hemoglobin adducts have been detected in smokers (8,9). The DNA adduct methodology has not yet been widely applied due to limits in sensitivity. Thus, 0.2-1 mg DNA is presently required and this cannot be conveniently obtained from readily available sources such as blood.

PAH are important in lung cancer induction and several methods have been employed for quantitation of their DNA adducts in humans. Most of these lack specificity to individual PAH. This is an important shortcoming because PAHs which have similar structures can differ widely in their carcinogenic activities. MS methods have the potential to overcome this shortcoming. We have developed a method for quantitation of hemoglobin and DNA adducts of benzo[a]pyrene and chrysene (10). Adducts of their ultimate carcinogenic diol epoxide metabolites are hydrolyzed with acid, releasing tetraols which are derivatized to the corresponding tetramethyl ethers. These can be detected with excellent sensitivity by GC-NCI-SIM. Using this methodology, adducts of benzo[a]pyrene and chrysene diol epoxides have been quantified in hemoglobin of smokers and non-smokers. Benzo[a]pyrene adducts have also been detected in DNA samples.

In summary, quantitation of DNA adducts of environmental carcinogens can provide important insights into cancer induction mechanisms in humans. Adducts in human DNA can be quantified by a variety of methods, but few have the specificity and potential general applicability of MS. With the increased sensitivity of developing MS methods, we can anticipate wider application of MS for detection of DNA adducts in humans.

DNA adducts vs protein adducts as carcinogen biomarkers in humans. John S. Wishnok, Division of Toxicology, Massachusetts Institute of Technology, Cambridge, MA 02139

Molecular dosimetry is estimating the bioeffective exposure of individuals to activated forms of genotoxic agents by measuring interactions of these activated forms with biopolymers such as proteins or nucleic acids. This is a powerful technique that - at least in principle - takes into account individual differences in initial exposure as well as individual differences in distribution and metabolism of the compounds being studied. The objective is to develop efficient methods to quantitate markers of exposure or - preferably - risk and to then apply this to large selected populations in order to reveal associations between individual bioeffective exposure and genotoxic (e.g., cancer) risk.

Although molecular dosimetry can be applied to any class of xenobiotics to which people can be exposed, it is generally focused on carcinogens or mutagens, i.e., compounds that alter the expression of affected DNA. Quantitation of carcinogen-protein adducts as a means to measure individual human exposure to carcinogens is a vigorous research area in which mass spectrometry has played a major part. Albumin and hemoglobin, for example, are abundant in the body, are easy to obtain, and are relatively long-lived. Covalent adducts, therefore, often increase to sufficiently high steady-state levels that they can be routinely measured by readily-available commercial techniques, e.g., NCI-GC-MS. This has typically been done by removing the adduct from the protein by hydrolysis and then quantitating a derivative. The prototypical example from our laboratory is the measurement of the hemoglobin adduct of 4-aminobiphenyl as a potential index of bladder cancer risk for smokers. Other laboratories have quantitated a large number of protein adducts, e.g., tobacco-specific carcinogens such as NNK¹, industrial carcinogens such as styrene oxide², or dietary carcinogens such as aflatoxins³.

Carcinogen-DNA adducts, although more directly related than carcinogen-protein adducts to genotoxic risk, are much more difficult to quantitate epidemiologically. This is due to several factors including low absolute amounts of DNA in the body, difficulty of obtaining samples from target organs, repair of adducts, and dilution of adducts by cell-division. Methods such as ³²P post-labeling, while sufficiently sensitive, provide little structural information. Mass spectrometric techniques such as electrospray ionization - especially in combination with tandem MS or FTICR - and improved sample handling, e.g., affinity purification or desalting methods - have resulted in steadily increasing sensitivity and analytical power to the point where the qualitative and quantitative demands of DNA adduct research in humans may be near to an intersection with the capabilities of mass spectrometry. A major factor in molecular dosimetry with carcinogen-DNA adducts is sample size. Adduct levels in human samples - except perhaps in special cases such as cancer chemotherapy - cannot be manipulated by dosing. Actual sample sizes are limited by ethical, physiological, cultural, and emotional factors. Analytical methods must therefore be sufficiently sensitive to detect adducts at their actual levels in whatever samples can be realistically obtained. Carcinogen-protein adducts are typically present on hemoglobin or albumin, for example, at the pg adduct/ g protein level. These adducts can often be quantitated by GC-MS on small samples, e.g., 250 µL of blood. Many people are comfortable with donating even larger samples of blood. Far fewer people, however, would be equally comfortable with donating an equivalent amount of tissue, especially from target sites such as colon, esophagus, liver, breast, bladder, or lung.

In addition to quantitation of known adducts, an important goal for both DNA and protein adduct research is to develop screening methods for unknown adducts. Some developing areas that will

probably become important in DNA dosimetry include accelerator mass spectrometry, nanospray technology, time-of-flight mass spectrometry, CZE/ESI/MS, or FTICR, perhaps in combination with the polymerase chain reaction (PCR). While carcinogen-DNA adduct levels decrease as cells divide, the adducts may lead to fixed mutations in surviving cells. The patterns (hotspots) of these mutations are often characteristic of the causative mutagens. Amplification of these mutations by PCR, and subsequent sequencing, e.g., by FTICR or MALDI/TOF could then potentially identify the original genotoxic agent(s) to which an individual had been exposed.

The figure below - which relates the amounts of tissue required for quantitation of a given level of modification at a given detection limit - illustrates the practical problems associated with analysis of carcinogen-DNA adducts in human samples. GC-MS and LC-MS, with routine detection limits often in the low femtomole range, would require 10 mg - 100 mg of tissue for adduct levels in the range of 100 - 10 adducts per cell. Lower adduct levels would require larger amounts of tissue. Although the willingness to donate tissue will vary from person to person, there is no question that the smallest possible sample-size would be preferred in any case.

Tissue requirements vs detection limit and adduct level

Recent advances in the application of mass spectrometry to the identification and quantitation of DNA and protein adducts clearly demonstrate its utility for biomedical research. We have used GC/ECNI/MS to investigate the formation and persistence of N²,3-ethenoguanine (EG), a highly promutagenic DNA adduct of vinyl chloride and fluoride, and N-7-hydroxyethylguanine (HEG), the major DNA adduct of ethylene oxide. Molecular dosimetry studies have shown that the relationship between EG and hemangiosarcoma induction in livers of rats and mice chronically exposed to vinyl fluoride is linear, whereas it is highly nonlinear for external exposure due to saturation of metabolic activation. Endogenously formed EG was present in rat, mouse and human liver DNA. While the source of the endogenous adducts remains unknown, it is likely that these adducts are important contributors to spontaneous tumor formation in all three species. Rats and mice exposed to low concentrations of ethylene oxide had HEG concentrations that were linearly related to external exposure. Again, endogenous HEG was present in rats, mice and human tissues. Of interest was the fact that human liver had 10-15 times more endogenous HEG than did rodents. This methodology was then applied to determining whether or not ethylene was metabolized to ethylene oxide and what tissues were active. By examining both hemoglobin adducts and HEG, it was clear that ethylene could be metabolized to ethylene oxide in liver and lung, but that metabolism became saturated at ~1000 ppm. Similar studies are being conducted on propylene and propylene oxide. Additional studies are being conducted on the DNA and hemoglobin adducts of butadiene, an important industrial chemical that is highly carcinogenic to mice, but only weakly carcinogenic to rats. A combination of GC/ECNI/MS and LC/ESI/MS-MS techniques are needed to examine the molecular dosimetry of butadiene. GC/ECNI/MS is presently the most sensitive method for the N-7 guanine adducts of butadiene mono- and diepoxide, whereas LC/ESI/MS-MS is the most sensitive for the N-3 adenine adducts. By understanding the amount of each of the adducts in DNA and hemoglobin, it will be possible to determine similarities and differences between mice, rats and humans so that more accurate estimates of carcinogenic risk can be obtained. Endogenous carcinogens, arising from normal metabolism are known to cause modifications to DNA by reacting with bases to form adducts. In our laboratory, we have developed methodology based upon gas chromatography/electron capture negative chemical ionization mass spectrometry (GC/EC NCI MS)^{1,2} and liquid chromatography/electrospray ionization/tandem mass spectrometry (LC/ESI MS/MS)^{3,4} for the analysis of endogenous DNA adducts in biological matrices. Malondialdehyde is a well-characterized endogenous carcinogen that forms an adduct with 2'-deoxyguanosine (M₁G-dR). We have developed a method for quantitation of M₁G-dR based upon GC/EC NCI MS. The limit of sensitivity of the assay is approximately 3 adducts per billion base pairs starting with 1 mg DNA. Using this assay we have been able to show the presence of M₁G-dR in liver DNA of disease free humans (9 adducts per 10 million bases, n=6). We have also developed technology based upon LC/ESI MS/MS for the characterization of endogenous DNA-adducts. Using this method, it was unequivocally established that the malondialdehyde adduct of 2'-deoxyguanosine is a constituent of human liver DNA. Recently, MDA-DNA adducts, presumably arising from the reaction of MDA with 2'-deoxyadenosine, have been detected *in vivo* using ³²P-postlabelling. However, the structures of these adducts were not established. In the present report, we describe the use of electrospray ionization tandem mass spectrometry coupled with HPLC to characterize a malondialdehyde-2'-deoxyadenosine (M₁A-dR) adduct in calf thymus DNA modified with MDA.

LC/ESI MS and MS/MS studies were performed on a Finnigan TSQ-7000 interfaced with an HP 1090 series II liquid chromatograph. Solvent A was 5 mM aqueous ammonium acetate containing 0.04 % acetic acid and solvent B was 5 mM methanolic ammonium acetate containing 0.04 % acetic acid. LC was performed on a narrow bore C8 column (Zorbax, Mac Mod Analytical Inc., Chadds Ford, PA, 100 mm x 2.1 mm i.d.; 5µm) maintained at 40 °C with as flow rate of 200 µL/min. A linear gradient was run as follows: 0 min, 0 % B; 5 min, 0 % B; 10 min, 70 % B; 12 min, 95 % B; 15 min, 95 % B; 20 min, 0 % B; 25 min, 0 % B. Nitrogen gas (Liquid Air, Walnut Creek, CA) was used as sheath (70 psi) and auxiliary (20 psi) gas to assist with nebulization. An ESI spray voltage of 4.5 kV was applied to the spray needle. The capillary was heated to 200 °C in order to provide optimal desolvation. The ESI interface and mass spectrometer parameters were optimized to obtain maximum sensitivity without sacrificing unit resolution. Argon (Liquid Air, Walnut Creek, CA) was used as the collision gas. Constant neutral loss (CNL) scanning was performed by setting a mass offset of 116 daltons (corresponding to the loss of the deoxyribose moiety) between the first and the third quadrupole. The collision cell pressure and skimmer pump pressure were 2.22 x 10⁻³ and 8.47 x 10⁻¹ Torr, respectively. The CID offset of the octapole lens was used to cause "in-source" dissociation of the analyte molecule.

The chromatogram of MDA-modified calf thymus DNA hydrolyzate was analyzed by LC/ESI CNL MS/MS. The reconstructed ion chromatograms for *m/z* 228, 243, 252, 268, and 304 showed the presence of dC, dT, dA, dG and M₁G-dR, respectively. The presence of M₁A-dR was detected by reconstructing ion chromatograms for *m/z* 306 (MH⁺). This showed the presence of a component eluting at 11:54 min. Reconstructed ion chromatograms of *m/z* 252 (dA), 268 (dG), 304 (M₁G-dR), and 306 (M₁A-dR) are

shown in the Figure 1a. For further elucidation of the structure, product ion spectra were obtained for precursor ions of M₁A-dR and M₁G-dR (*m/z* 306 and 304, respectively). The LC MS/MS spectrum of *m/z* 306 at -22 eV collision offset showed a distinct peak for BH₂⁺ ion at *m/z* 190. Another ion was observed at *m/z* 162 representing the loss of 28 Da (loss of C=O). The LC MS/MS spectrum of *m/z* 304 at -22 eV collision offset showed a distinct peak for BH₂⁺ ion at *m/z* 188. LC/ESI source-induced MS/MS analysis of M₁G-dR and M₁A-dR was performed by adjusting the octapole offset to give maximal production of the BH₂⁺ ions at *m/z* 188 and 190 while minimizing the loss in total ion current. CID and MS/MS analysis of *m/z* 188 and 190 was then performed with an octapole offset of -52 eV. It was evident from the ESI SD/MS/MS spectrum that significant C-C cleavages of the base adduct had occurred. Major product ions for *m/z* 190 (M₁A) were observed at *m/z* 162, 135, 119, and 94. The ion at *m/z* 162 results from the loss of C=O and at *m/z* 135 results from the loss of the aliphatic side chain. (Figure 1b) These results support the structure of this adduct to be derived from the reaction of dA with MDA.

In addition, quantitative methodology based upon LC ES/MS/MS has been developed for the analysis of M₁G-dR (as an index of DNA damage arising by lipid peroxidation) and 7,8-dihydro-8-oxo-2'-deoxyguanosine (as an index of oxidative DNA damage). (supported by NIH grants CA 47479, 1RO1-65878-01A1 and ES 00267).

Figure 1. (a) LC/ESI CNL MS/MS analysis of the hydrolyzate from MDA-modified CT DNA. (b) Product ion spectrum of *m/z* 190 obtained by source induced dissociation followed by CID and MS/MS analysis.

HPLC/ESI/MS May Be The Technique of Choice for the Analysis of Certain DNA Adducts

Ten-Yang Yen, Nadia Gueorgieva, Nova Scheller, Sharon Holt, James A. Swenberg and M. Judith Charles, Department of Environmental Sciences and Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-7400.

Introduction. The attomolar sensitivity and selectivity of methodologies employing electrophore labelling in combination with gas chromatography/electron-capture negative chemical ionization (GC/ECNI/MS) make quantification of DNA adducts in human tissues possible. Different reagents however have different derivatizing efficiencies and affinities for different targeted analytes. For DNA adducts that are very polar, the derivatization is often difficult and less successful. Also interferences and artifacts may arise from derivatization than lead to inaccurate identification and quantification of DNA adducts.

Others employ liquid chromatography in combination with electrochemical detection (LC/ECD) to obviate problems associated with GC/MS methods, but the technique is not suitable for DNA adducts that can not be detected amperometrically. LC/electrospray ionization mass spectrometry (LC/ESI/MS) affords the detection of femtomolar quantities of polar molecules and thus is an attractive alternative to GC/MS and HPLC/ECD methods. To investigate the potential of HPLC/ESI/MS to analyze DNA adducts, we explored parameters affecting the electrospray ionization of nucleobases and nucleosides, and we developed and applied a method for the analysis of N²,3-ethenoguanine (εGua), a highly promutagenic adduct generated by exposure to the carcinogen, vinyl chloride. We selected this adduct as a model compound because the protocol for isolating and enriching this adduct was well characterized in our laboratory. Our findings are relevant to the analysis of other DNA adducts and address artefactual formation of oxidized bases during chemical derivatization, a broader issue of concern to scientists investigating the effect of xenobiotics and endogenous processes on the initiation of cancer.

Results. Experiments were performed to ascertain optimum conditions for the analysis of DNA adducts. We investigated the effect of the concentration of the analyte, and the nature of acid employed to modify the solution pH on the intensity of the (M+H)⁺ ion signal for N⁶-methyladenosine (pK_a=4.0) and thymine (pK_a=0.0). The concentrations of acetic and trifluoroacetic acids ranged from 10⁻³ to 1 mole/L and the concentration of the analyte was 5, 50 and 500 μM. The trends in the response was similar among the three concentrations of the analyte. We observed a small (≤ 3x) increase in the ion signal at low concentrations of acid for N⁶-methyladenosine that can be explained as a shift in the solution equilibrium to favor formation of protonated ions. An initial increase in the response of the (M+H)⁺ ion for both compounds (≤ 3x) was observed at low trifluoroacetic acid concentrations followed by a rapid decrease (5-10x) in the response of the (M+H)⁺ ion at acid concentrations exceeding 10⁻³ M. This decrease is likely due to ion pair interactions for N⁶-methyladenosine but not for thymine. For thymine and other compounds with pK_a<3, gas-phase proton transfer reactions are important, and we found that the (M+H)⁺ ion intensity can be enhanced by employing ammonium acetate to promote such reactions.

We chose methanol/water as the mobile phase without any modifiers for the development of the LC/ESI/MS method because the ion signal for εGua in a methanol/water solution acidified with 1% formic acid was 3x weaker than for a similar solution that was not acidified. We evaluated the

precision of the method by analyzing replicate samples of chloroethylene oxide (CEO) treated calf-thymus DNA (n=14), and we determined the accuracy of the method by analyzing matrix spikes (CEO treated calf-thymus DNA enriched with 3 pmol of εGua). A mean and standard deviation of 2.57±0.35 pmol was obtained from the CEO- treated calf-thymus DNA enriched with 3 pmol εGua samples that provided an accuracy of 86±14%. A mean and standard deviation of 55.3±8.3 pmol εGua/mg DNA was obtained for the analysis of 14 CEO-treated calf-thymus DNA that provided a precision of 15% among the samples. We also conducted a more stringent test of the accuracy of the method by analyzing εGua extracted from the livers of unexposed rats of liver spiked with 8 μL of 27-538 fmol/μL εGua standards. The limit of detection for an authentic standard of εGua was 5 fmol with a S:N=2.5:1.

We applied the method to analyze EG in rats treated with CEO via portal vein injection of 70 or 290 nmol CEO/g per body weight of rat. The lowest concentration of εGua, with a mean and standard deviation of 0.15±0.05 pmol εGua/mg DNA, was found in a rat treated with 70 nmol CEO after 6 h exposure. The highest concentration of εGua (1.49±0.19 pmol εGua/mg DNA) was found in a rat treated with 290 nmol CEO after 2 h exposure. The data establish the concentration of εGua in DNA from CEO-treated Sprague-Dawley rat livers increases with the dose of CEO, and decreases with time after exposure. We also applied LC/ESI/MS to measure the endogenous εGua in human liver. The concentration of εGua in one human liver DNA sample was 0.06±0.01 pmol/mg DNA (We employed 7.4 mg DNA and obtained a S:N=5:1 on 70 femtomoles in this measurement). If we extrapolate the data obtained to obtain a S:N=3:1 on all the measurements, we obtain a detection limit of about 50 femtomoles at a S:N=3:1 on the biological samples. This limit of detection is about 50x greater than the detection limit that can be routinely obtained by using derivatization with trifluoromethyl-tetrafluorobenzyl bromide and gas chromatography/electron-capture negative chemical ionization/high-resolution mass spectrometry (HRMS) detection.

We also compared the analysis of chloroethylene oxide treated calf-thymus DNA by using LC/ESI/MS and GC/ECNI/HRMS. The mean ± S.D. for 5 samples obtained by using LC/ESI/MS was 32.3 ± 2.3 pmol/mg DNA and the mean and standard deviation obtained by using the GC/ECNI/MS method was 59.7 ± 10.2 pmol/mg DNA. The 2x fold difference between the methods can be explained either as an underestimation by the LC/ESI/MS method or an overestimation by the GC/ECNI/MS method. A decrease in the response factor of the analyte to the internal standard after silica-gel purification of the derivatized bases prior to GC/HRMS detection, and the accuracy of the LC/ESI/MS method as established by matrix spikes suggests that the GC/ECNI/MS method overestimates the amount of εGua.

Summary. By using εGua as a model compound, we demonstrated that DNA adducts can be accurately and precisely quantified by using LC/ESI/MS. The detection limit for εGua is about 50x less sensitive than for the comparable GC/ECNI/HRMS method. Further work is needed to increase the sensitivity to afford analysis of endogenous levels of DNA adducts. Comparison of the LC/ESI/MS method and the GC/ECNI/MS method for the analysis of chloroethylene oxide treated calf-thymus DNA indicates that the employment of a chemical derivative can cause artefactual formation of εGua, leading to an overestimation of this adduct. Thus, in certain cases, HPLC/ESI/MS can be the method of choice. Whichever method is chosen, measures need to be incorporated into the analytical protocol to ensure the quality of the data (i.e., testing and evaluation of the methods through the analysis of matrix spikes, and confirmation of the identity of the compound by another means when one ion is monitored).

DETECTION OF ENDOGENOUS N²,3-ETHENOGUANINE BY GC/ECNCI/HRMS

Nova Scheller, Asoka Ranasinghe, Nadia Gueorguieva, Ten-Yang Yen, Amy Ham and James Swenberg

Department of Environmental Sciences and Engineering, University of North Carolina, Chapel Hill, N. C. 27599-7400

The ongoing optimization and refinement of the isotope dilution mass spectrometry method used to detect and quantify N²,3-ethenoguanine (εG) has included many changes instrumentally as well as in sample processing. The introduction of high resolution mass spectrometry (HRMS) in combination with gas chromatography-electron capture negative chemical ionization (GC-ECNCI) has increased analyte specificity without sacrificing the limit of detection (LOD)¹. Optimization of instrumental parameters including conversion from cool-on-column injection to high temperature direct injection has demonstrated a dramatic increase in the LOD in real samples.¹ Additionally there have been other changes to the published method² including improved hydrolysis of DNA samples prior to εG enrichment as well as employment of a more efficacious derivatizing reagent, 4-trifluoromethyl-2,3,4,5-tetrafluorobenzyl bromide (TTBBBr).¹ Currently we have investigated the application of the improved method to liver DNA samples of unexposed male and female rodents and humans.

Instrumental parameters have been detailed previously.¹ *In vivo* samples were processed using 500-800 μg DNA each. Unexposed rodents were controls from a vinyl fluoride exposure study (du Pont) and were 12 months old at the time of sacrifice. Human liver tissues were acquired from accident fatalities. During the course of analysis, instrumental performance was monitored by injecting a known calibration mixture of derivatized εG and [¹³C₄]-εG after every fifth sample. A matrix recovery study was accomplished with parallel analyses of εG calibration solutions spiked into unexposed rat liver DNA by electrospray (ES, on underivatized samples)³ and GC-MS. Additional cleanup using an immunoaffinity polyclonal antibody was used on enriched εG samples prior to derivatization and/or ES analysis.

All unexposed samples, both rodent and human derivatized successfully. The range of S/N for human samples (n=10) was 27 to 54: each sample hydrolysate was processed twice with standard deviations ranging from 1-16 %. For mice (n=8) the range included S/N 24 to 102 and for rats (n=8), S/N 27 to 58. See Fig. 1A-1C. The mean value for mice was 0.62 ± 0.24 pmol εG/mg DNA while for rats the mean was 0.25 ± 0.07 pmol εG/mg DNA. The values for humans ranged from 0.26 to 1.04 pmol εG/mg DNA. The results of the matrix recovery experiment revealed a quantitative discrepancy between ES and GC analyses. While both methods gave excellent linearity (R² = 0.97), the slope for the GC-MS method was about two times higher than ES (1.66 vs. 0.846). Among proposed explanations was with guanine present in samples, could it convert to a small amount of artifactual εG during derivatization? 2.5 mg of [¹³C₄]-guanine was derivatized and yielded [¹³C₄]-εG with an efficiency of 1x 10⁻⁶ %. Another possibility presented itself when old (4-6 weeks) ES samples were reinjected: the amount of εG originally measured had doubled. We surmise that the harsher conditions of derivatization and requisite high temperatures used in GC analysis may be driving an alternate compound to form artifactual εG during electrophore labelling. Immunoaffinity cleanup has demonstrated that it can remove all residual guanine present in a sample, which will solve this possible source of artifactual εG. Fig. 2A-2B show how effective cleanup is when used with processed underivatized rat liver DNA samples. Finally, the matrix recovery experiments have helped us

determine that a practical cutoff in our quantitating *in vivo* samples is 100 fmol/sample: below which we enter a realm of uncertainty often present in trace analysis. All data presented herein meet this criteria.

The present status of the εG method demonstrates high specificity and sensitivity. Sensitivity is determined not only by LOD of derivatized authentic standards as well as *in vivo* samples, but also by the quantity of DNA required for sample processing. The high quality of each sample's ion chromatogram as well as the large S/N presents strong evidence for endogenous εG in unexposed rodents and humans. Although guanine has been present in all samples prior to derivatization, immunoaffinity cleanup offers a viable solution for its removal as well as additional sample cleanup.

Assessment of DNA Oxidative Damage by Quantification of 2-Methylglycerate from Thymidine Glycol

Dmitry Naritsin and S.P. Markey
National Institute of Mental Health, Bethesda, MD 20892

Oxidative damage to DNA has been implicated in the etiology of various human diseases. We are developing strategies to test the hypothesis that progressive diseases of aging, such as Alzheimer's and Parkinson's, are the product of accumulated and unrepaired DNA damage to neurons. Toward that goal, we are developing methods for direct measurement of oxidized nucleosides in human brain tissue DNA. One target analyte is thymidine glycol, the product of hydroxyl radical reaction with thymidine. Thymidine glycol, like 8-hydroxy-2-deoxyguanosine, has been well established as an index of DNA oxidation. We have published a modification of a radiochemical procedure employing alkaline hydrolysis of thymidine glycol residues in DNA followed by sodium [^2H]borohydride reduction and methanolic hydrochloric acid solvolysis to release methyl-2-methyl- $^{[2\text{H}]}$ glycerate, measured by EI/GC/MS using isotope dilution (JASMS 1993, 4, 336-42). This EI assay permits a limit of detectability of 100 pg per tube and quantification of background levels of thymidine glycol in 200 μg of undamaged DNA, an amount unavailable in many biological experiments.

We have sought to use the sensitivity of ECNI relative to EI in order to reduce the quantity of DNA required for measurement. A prerequisite for ECNI-MS, however, is efficient derivatization to form compounds with good electron capture as well as gas chromatographic properties. Previously, we failed to attain this objective because efficient esterification of 2-methylglycerate at trace levels failed in repeated trials with a variety of published procedures and reagents. In the present study we report techniques for the facile derivatization of 2-methylglycerate to form a combined pentafluorobenzyl-tertbutyldimethylsilyl derivative for measurement by GC/ECNI-MS. Efficient derivatization of 2-methylglycerate at trace levels is accomplished using tetrabutylammonium sulfate assisted anhydrous esterification.

We set out to determine why esterification of trace levels of 2-methylglycerate failed. Radiolabeled thymidine glycol was prepared, and used first to determine that the recovery of 2-methylglycerate by hydrolysis and sodium borodeuteride reduction of thymidine glycol is quantitative. The same material was then used to confirm that pentafluorobenzyl esterification methods (phase transfer or anhydrous) failed to yield a radiolabeled product. From studies of other polar organic acids, we had observed that esterification could be facilitated by adding a large excess of tetrabutylammonium sulfate (TBAS) to aqueous solutions of the organic acids, evaporating the water, and reaction in acetone with pentafluorobenzyl bromide and diisopropylethylamine. We postulate that the excess matrix of TBAS works by several mechanisms - TBAS prevents losses of trace materials onto active surfaces, prevents insoluble films from irreversibly trapping compounds, and activates carboxyl functions by formation of quaternary ammonium salts. With radiolabeled 2-methylglycerate, esterification yields of 60-80% theoretical were realized, in comparison with no measurable product in the absence of TBAS. Following these observations, GC/MS was used to test the optimum reaction conditions and secondary derivative formation for ECNI and chromatographic properties. TBDMS derivatization (TBDMS-imidazole) was selected on the basis of stability, molar response and relative background.

ECNI Mass Spectra of 2-Methylglycerate Derivatives
