The structure and mass spectrum of the 2- $^{[2\text{H}]}$ -methylglycerate-PFB-(TBDMS) $_2$ derivative released from thymidine or thymine glycol by sodium borodeuteride is shown below. The major ions formed correspond to (M-PFB) $^-$ at m/z 348, and is characteristic of PFB esters. The combined PFB-TBDMS derivative exhibits excellent chromatographic and detection properties. The detection limit with signal-to-noise ratio of 3:1 is 41 amol injected on column (equivalent to 5 fg of underivatized 2-methylglycerate). Calibration curves are linear in the range 1 pg - 1 ng of $^{[2\text{H}]}$ thymine glycol standard added per tube.

Thymidine glycol in DNA

Figure 2 demonstrates the linearity of the response when method it is applied to samples with varying (1-20 μg) amounts of DNA. Commercial calf thymus DNA samples were prepared and analyzed in triplicate. Non-zero signal from thymidine glycol can be detected in 4 μg of DNA, a 50-fold improvement relative to the EI assay.

DETECTION OF DNA ADDUCTS BY ELECTRON CAPTURE-MS.

Amir Abushamaa, Yasser Ismail, Daniel Magiera, and Roger Giese. Bouvé College of Pharmacy and Health Sciences, Barnett Institute and Chemistry Department, Northeastern University, 360 Huntington Avenue, Boston, MA 02115.

DNA Adducts

There are two parts to the story of DNA adducts: meaning (interpretation, significance) and measurement. To better understand the meaning of DNA adducts, we need to rely in part on epidemiology, which, in turn, creates a need to measure small samples of DNA (e.g. a fingerprick of blood). The tiny amounts of DNA adducts in DNA in turn leads to a requirement for extraordinary sensitivity. Further, the full meaning of DNA adducts may come clear only after we measure them more comprehensively. Thus great challenges persist in the detection of DNA adducts.

EC-MS

We, like several other groups, have selected electron capture mass spectrometry (EC-MS) for the detection of DNA adducts due to its high sensitivity and specificity. Our attention has been focused on the development of general methods that detect an entire class of DNA adducts, so as to help answer the need for comprehensive detection. We are pursuing three classes at present: diol epoxide PAH, O⁶-guanine alkyl and hydroxyalkyl, and N⁷-guanine alkyl and hydroxyalkyl DNA adducts.

EC-MS vs other MS techniques.

The main weakness of EC-MS is the need to derivatize the DNA adduct, which includes associated sample cleanup steps. Electrospray MS avoids this disadvantage; nevertheless, derivatization in EC-MS helps to achieve sample cleanup and recovery, and makes it possible to take advantage of sample introduction by GC (selectivity and the purity of GC gases). Together these techniques make a good team.

General Literature on DNA Adducts/EC-MS

This general literature is disappointing in two respects. First of all, EC-MS methodology has hardly been applied to small biological samples. Second, the current literature generally fails to report one or more of the following: absolute yield, detection limit, chromatogram for a blank sample, and a complete chromatogram.

Useful Techniques and Tools

In our ongoing development of methods for the detection of DNA adducts by GC-EC-MS, the following techniques and tools have been helpful recently.

1. Pentafluorobenzyl analogs. The challenge of interferences and contamination at the trace level can be significant. One approach to deal with this difficulty is to change the derivatization reagent. For example, 3,5 bis-(trifluoromethyl)benzyl bromide and 4-trifluoromethyltetrafluorobenzyl bromide are available for this purpose.

2. Satellite HPLC. Solid phase extraction can be convenient to minimize contamination for sample cleanup, but its inherent separation power can be limited, and reproducibility can be a problem with different batches of SPE packings. HPLC can provide a reproducible high resolution separation, but the usual system is relatively expensive and typically applied to several projects in a laboratory, which makes it a source of variable interferences for trace cleanup. "Satellite HPLC" is a way to overcome the shortcomings of HPLC. We suggest this terminology for an isocratic, high precision HPLC system that consists of just a solvent reservoir, low-cost pump (e.g. CC-6-S from Eldex), injector, and column. Such a system can be set up for less than \$2500, and one or more such systems can be operated in conjunction with an ordinary parent HPLC to set the conditions for the column. Since it is the injector rather than the column that tends to contaminate in an HPLC system, transferring the column to a satellite HPLC, where the injector is only used for trace samples, keeps the satellite HPLC clean.

3. Evaporative distillation. In an EC-MS method for benzo[a]pyrene diol epoxide DNA adducts, we encountered a contaminant that had the chemical and physical properties of the analyte (Allam, K., Abdel-Baky, S. and Giese, R.W., Anal. Chem. 65 [1993] 1723. This contaminant turned out to be ubiquitous in the method. It could be overcome by exhaustive cleaning of all reagents and components. Recently, such cleaning has been simplified by taking advantage of the convenience of evaporative distillation (Giese, R.W., J. Chem. Educ. 44 [1967] 690). Freshly purifying the solvents in this way, along with solvent rinsing of the glassware, has overcome the contaminant. Thus, we have adopted this technique as a routine method in our laboratory.

Conclusion

Sample preparation, while a potential strength for EC-MS techniques in the detection of DNA adducts in the long-term, continues at present to be a bottleneck. This bottleneck can best be overcome by learning the mechanisms of the losses, interferences, and contamination which complicate sample preparation. In turn, this understanding can lead to techniques which put these problems behind us, and, once combined with emerging GC-EC-FTMS, will help to bring EC-MS to its full potential for the detection of DNA adducts.

Mass spectrometry has proven to be useful for the study of important compounds such as DNA adducts which provide information about how biomolecules are altered by exposure to deleterious agents. The requirements for this research mandate development of instrumental techniques which provide sensitive detection and complete structural characterization of modified nucleic acid constituents such as modified nucleosides, nucleotides, and oligonucleotides. Our approach to the study of DNA adducts has focused on development of Fourier transform ion cyclotron resonance mass spectrometry (FTMS) interfaced with both matrix-assisted laser desorption/ionization (MALDI) and more recently electrospray (ES). The capabilities of FTMS for accurate mass measurements and structural interrogation with collisional dissociation and ion-molecule reactions make this technique well-suited for characterizing these important biomolecules at the isomeric level.

The FTMS used for these studies is a Finnigan FTMS-2000 mass spectrometer equipped with both laser desorption (Nd:YAG pulsed laser, 355 nm) and a home-built electrospray source. Because this FTMS instrument has a dual ion cell, both ionization techniques can be interfaced to a single FTMS system. Samples of modified nucleic acid constituents were obtained through collaborations with Dr. Shantu Amin (American Health Foundation), Dr. Mahesh Lakshman (ChemSyn Science Laboratories), Dr. Donald Jerina (National Institutes of Health), and Drs. Thomas and Connie Harris (Vanderbilt University).

To ascertain the mass range of our 3-Tesla FTMS instrument, MALDI conditions were developed for the examination of proteins and peptides with molecular masses in excess of 5000 u. Molecular ions for bovine heart cytochrome C (MW = 12,327 u) were obtained with 355 nm radiation and a 2,5-dihydroxybenzoic acid (DHB) matrix. Although the mass resolution was poor, this result verified that the useable mass range of our instrument is in excess of m/z 12,000. We have been able to generate molecular (M-H)⁻ ions for modified oligonucleotide 11-mers with 355 nm radiation and 3-hydroxypicolinic acid (HPA), as shown in Figure 1.

Structural information for the modified oligomers can be obtained by at least three different methods. First, the choice of the matrix compound can be used to selectively control the amount of fragmentation. For example, whereas the use of HPA as the matrix compound yields primarily molecular ions with little fragmentation, the use of DHB as the matrix compound generates mostly fragment ions, which can then be accurately measured or further interrogated. Secondly, by controlling the time delay between laser desorption and ion detection, the amount of fragmentation can also be controlled. For example, a short delay (~3 ms) gives primarily molecular ions, whereas the use of a longer delay (~100 ms) produces extensive fragmentation for small oligonucleotides such as hexamers (both acquired with HPA as the matrix compound). Thirdly, the use of collisional dissociation, in particular the new technique of sustained off-resonance irradiation (SORI), was found to be very useful for examining the detailed fragmentation of ions. For example, SORI of the characteristic "w-type" ions from the oligonucleotides generated fragment ions corresponding to both simple bond cleavages as well as more complicated rearrangements such as migration of a phosphate moiety. Accurate mass measurements were necessary to differentiate between a reduced ribose and a phosphate (~60 mmu).

Electrospray FTMS of modified nucleotides (fmol) was observed to produce abundant molecular ions, as shown in Figure 2a. SORI was used to examine the fragmentation of a series of BPDE-adducts of deoxyadenosine monophosphate, and generated characteristic fragment ions corresponding to cleavages between

the nucleic base and ribose (to give (B-H)⁻) as well as dehydration of the PAH moiety, shown in Figure 2b.

We have begun comparison of the MALDI- and ES-mass spectra of oligonucleotide tetramers. For example, by using DHB as the matrix compound, both molecular and fragment ions were observed for d(AGCT). The most abundant fragment ions correspond to the "w" and "a-B" type ions. In contrast, the singly-charged fragment ions observed in the ES-FT mass spectra (generated by increased nozzle-skimmer voltages) of this compound appear to consist primarily of "y" type ions, which are generated by dephosphorylation of "w" type ions. This preliminary data indicates that MALDI and ES may provide complementary data which can be used to interrogate the structures of oligonucleotides and modified oligonucleotides.

Automated recording of MALDI high energy CID MS/MS spectra on a tandem magnetic sector-TOF.

R H Bateman, T Davis, M R Green and R Kingston
Micromass Ltd, Floats Road, Wythenshawe, Manchester, M23 9LZ, UK.

The AutoSpec-TOF incorporates the AutoSpec EBE geometry double focussing magnetic sector mass spectrometer, a gas collision cell and a linear orthogonal acceleration time of flight (oa-TOF) mass spectrometer. The MALDI source uses a 337 nm Nitrogen UV laser operating at 10 Hz repetition rate, and a sample stage at 8 kV. The laser beam position on the target may be automatically scanned vertically along the central axis of the mass spectrometer under computer control. The sample stage includes 12 sample targets in a line, and this may be moved horizontally under computer control such that each target in turn may be scanned across the central axis of the mass spectrometer.

The gas collision cell is normally held at 7.2 kV so that the collision energy is 800 eV. Two gas inlet lines allow switching between helium and xenon collision gases for low and high energy CID respectively. The linear orthogonal acceleration time of flight mass spectrometer, which has an effective path length of 45 cm, re-accelerates the ions back to ground potential. Ions are detected with a two stage microchannel plate and recorded using a time to digital convertor with a sampling rate of 1 GHz. The 150 mm long detector records the full product ion spectrum irrespective of the precursor ion mass.

Figure 1 shows the high energy CID MS/MS spectrum from an estimated 200–400 fmol of a neuropeptide from a single brain cell of the freshwater snail *Lymnaea stagnalis*. A single brain cell was placed on the target, lacerated, and dissolved in dihydroxy benzoic acid with 0.1% TFA. The neuropeptides have a tendency to preferentially crystallise around the perimeter of the cell. Mass spectra from the centre of the cell show a continuum of masses, but acquiring data from around the perimeter allows the discrete mass spectra of neuropeptides to be observed. This, and a precursor ion selection resolution of ~ 1500 (10% valley) allows recording of a CID MS/MS spectrum with good single to noise; virtually free of interferences.

Figure 2 shows the high energy CID MS/MS spectrum of the synthetic peptide for comparison.

Magnetic sector/time-of-flight combination for tandem analysis of MALDI ions using high energy CID.

Raptakis, Emmanuel N.; Makarov, Alexander A.; Colburn, Alex. W.; Derrick, Peter J.

Department of Chemistry & Institute of Mass Spectrometry, University of Warwick, Coventry, CV4 7AL, UK

This work presents the proof of the concept of a novel tandem magnetic sector/time-of-flight mass spectrometer for high-resolution, high-energy CID of MALDI-produced ions. In order to take advantage of the simplicity and superior sensitivity of TOF, a number of interfacial incompatibilities must be overcome, in particular the high energy-spread of fragments must be accounted for.

A parallel linear time-of-flight analyzer and the post-accelerating detector of MS1 are used for optimization of transmission of the chosen parent ions through the sectors. The duration of the precursor ion pack at the exit of MS1 is of the order of 100 ns. As energy spread is the most important contributor, there is a well defined one-to-one relationship between the position of the ions in the ion pack and their individual initial energy. Time-compression of the ion beam can be accomplished by applying a high-voltage pulse on the rear electrode of the ion buncher.

The parent ion pack is focused into the grounded collision cell where it undergoes collision-induced dissociation. A wide choice of collision energies is available, depending on accelerating potential and collision gas. The resulting ion beam consists of parent and fragment molecules all travelling at approximately the same velocity but with a wide range of energies proportional to the range of masses. Therefore a quadratic field ion reflector¹ is utilized in order to time-focus successfully all ions of the beam.

The key characteristic of this type of field is that the time-of-flight of ions within the field is completely independent on the initial energy of the ions. For this prototype instrument a planar symmetry quadratic field was employed; the ions travel in a field-free z direction (upwards), while they are reflected in the x direction. The quadratic field is sustained by voltages on appropriately shaped electrodes etched on the surface of printed circuit boards². A hyperbolic shaped electrode in the end of the mirror allows for better approximation of the theoretical field in the high-voltage area. The front boundary of the mirror consists of a flat plate, housing the entrance slit and the multi-channel-plate detector. The distribution is sustained by resistive voltage dividers.

Figure 1. The magnetic sector/time-of-flight mass spectrometer (Mag-TOF).

Figure 2. Cs_4I_3 tandem mass spectrum. Laboratory frame collision energy 10 keV. Collision gas He.

Figure 3. Unprocessed renin substrate ($\text{M}+\text{H}^+$ 1759) tandem mass spectrum. Collision gas Ar. Laboratory frame collision energy 10 keV.

The field is defocusing in the z-direction; therefore a 60 by 90 mm MCP detector is used. A theoretical model of the processes that may degrade resolution in the quadratic mirror has been developed³. The theoretically predicted resolution was matched by experimental results using CsI clusters (figure 2) as well as various peptides with mass from 1000 to 3000 Da. A tandem mass spectrum for renin substrate (figure 3) demonstrates the complete sequence. The low signal-to-noise ratio in this spectrum is thought to arise from metastable-ion noise, contaminating the baseline of the spectrum. Efforts are being made to suppress the noise by clearing the ion beam from scattered and unbunched residual ions.

A Transmission Geometry Probe for MALDI

John D. Lennon, III, and Gary L. Glish

Department of Chemistry, CB# 3290, University of North Carolina
at Chapel Hill, Chapel Hill, North Carolina 27599-3290

Introduction:

Matrix-assisted laser desorption/ionization (MALDI) has become a powerful technique for the analysis of a wide variety of compounds. MALDI has been coupled to almost all types of mass spectrometers. The goal of this work was to find an easy way to implement MALDI onto a quadrupole ion trap with a remote Nd:YAG laser via a fiber optic. The result was a universal probe that can be used with any mass spectrometer with only minor modifications. In contrast to the majority of MALDI experiments, this probe takes advantage of transmission geometry¹, where the laser irradiates the analyte/matrix mixture from behind. The transmission probe is introduced through a vacuum interlock system, as typical solids probes, and can easily be moved between different instruments in the lab. Spectra will show the effectiveness of the probe as it is coupled to both a quadrupole ion trap and a forward geometry double focusing sector instrument. Sensitivity will be used to compare this new transmission probe to conventional MALDI.

Experimental:

The transmission MALDI probe design is shown in Figure 1. It consists of a stainless steel rod that allows a fiber optic to be introduced through the center via a SwagelokTM fitting. A LexanTM tip machined in-house comprises the probe end into which a quartz tip (3mm long, 2.5mm dia.) is inserted. The analyte/matrix mixture is then deposited directly onto the end of the quartz tip. The fiber optic approaches the tip from the opposite side. The power density can be controlled roughly by adjusting the distance the fiber is away from the quartz tip.

The transmission probe has been coupled to both a modified Finnigan MAT Ion Trap and a Finnigan MAT 900 EB mass spectrometer. The ring electrode of the quadrupole ion trap has been modified by drilling two small beveled holes radially through the center to allow ions to be generated directly into the volume of the ion trap. The sector instrument was only slightly modified to hold a specially designed MALDI ion volume built in-house, which is open on all six sides allowing the probe to be introduced in line with the ion axis.

The laser used for these experiments was a Continuum Surelite II Nd:YAG frequency tripled to a wavelength of 355nm. The fiber optic was an 8m x 600µm dia. fused silica core fiber purchased from 3M. The matrix used for all experiments was α -hydroxy-4-cyano-cinnamic acid (4-HCCA) used at a concentration of 0.1M in a solution of 7:3 acetonitrile water. The peptides analyzed were substance P, neurotensin and *des*-Arg¹-bradykinin diluted in water to a concentration of 1mM and further diluted as needed for sensitivity measurements.

Results and Discussion:

Finnigan MAT Ion Trap

Most of this work has focused on coupling the transmission MALDI probe to the quadrupole ion trap. An example spectrum, averaging 150 laser shots, is shown in Figure 2 with 1nmol of neurotensin loaded. The total consumption is much less than the total loading, because the signal can last for thousands of laser shots. The best sensitivity that has been obtained is for a loading of 250fmol of *des*-Arg¹-bradykinin, not shown here. It is thought that the sensitivity can be improved by decreasing the diameter of the quartz tip, thereby confining the analyte to a smaller area and more in the center of the higher intensity portion of the irradiating laser. However, the sample lifetime may be reduced.

Finnigan MAT 900

The transmission MALDI probe has also been coupled to our double focusing sector instrument. An example spectrum is shown for 200 pmol *des*-Arg¹-bradykinin in Figure 4. 200pmol is the best sensitivity that has been obtained to date. Obtaining high sensitivity is currently hindered by the difficulty in obtaining a good tuning of the lens, which is mainly due to the low detection efficiency of MALDI generated ions. One of the difficulties with coupling MALDI to sector instruments is that by scanning a narrow mass window over a large mass range most of the generated MALDI ions are not detected. To increase the efficiency of detecting MALDI generated

ions, either an array detector must be used or the mass range scanned must be narrowed. An increase in intensity of almost two orders of magnitude was obtained by reducing the mass range during the detection of substance P (data not shown).

The peak splitting observed in the sector mass spectra are due to the discrete packets of ions arriving at the detector at different times as the magnet is scanning over a given m/z .

Figure 1. Transmission MALDI probe design.

Figure 2. Transmission MALDI spectrum of 1nmol of neurotensin obtained on a quadrupole ion trap

Figure 3. Transmission MALDI spectrum of 200pmol of *des*-Arg¹-bradykinin obtained on a forward geometry double focusing sector.

Conclusions:

A new MALDI probe has been introduced that uses transmission geometry. It is universally adaptable to most mass spectrometers with only a few modifications. The new transmission MALDI probe has been coupled to a quadrupole ion trap as well as to a double focusing EB sector instrument. The best sensitivity obtained using this probe was 250fmol of *des*-Arg¹-bradykinin on the quadrupole ion trap and 200pmol of *des*-Arg¹-bradykinin on the sector instrument. It is thought that the sensitivity can be increased by using a smaller diameter quartz tip, thereby concentrating the analyte in the higher intensity center of the irradiating laser. Also, the sensitivity obtained with the sector mass spectrometer can greatly be improved with a better optimization of the source lens.

Mass Resolution Improvement in MALDI-TOF Mass Spectrometry by Delayed Pulsed Ion Extraction

Wenzhu Zhang; Shufang Niu and Brian T. Chait
The Rockefeller University, 1230 York Avenue, New York, New York 10021

At present, a major deficiency of Matrix-Assisted Laser Desorption/Ionization time-of-flight (MALDI-TOF) mass spectrometry is the low mass resolution and consequently the low mass accuracy. This low mass accuracy limits, in part, the power of mass spectrometry in solving practical biological problem. A higher mass accuracy in MALDI-TOF is especially desirable in analyzing peptide mixtures. This low resolution can be primarily attributed to the initial velocity spread of the ions produced at the sample surface and the delayed pulsed ion extraction has been utilized to improve the mass resolution [1,2,3,4]. However, to the best of our knowledge, no extensive mass accuracy study for delayed extraction has been reported. Our goal is to obtain accurate masses for all peptides in peptide map ($500 < m/z < 3000$).

We have designed a delayed extraction pulsing system as shown in fig. 1. A resolution of 2700 FWHM was obtained for dynorphin 1-13 (average MW 1604.0 Da). Mass accuracy was investigated using internal calibrants. As shown in fig. 2, when the lowest and highest masses were selected as internal calibrants (two peaks marked with the Star), high mass accuracy (as good as 0.01 Da) was observed in the bracketed region and in the vicinity of one of the calibrant peaks. To investigate the mass accuracy over a larger mass range, a peptide ladder (MWs 976-1844 Da) was used (spectrum not shown). Three calibration methods were used as shown in the Table. In calibration methods 1 and 2, the two peptides designated as calibrants are close to each other. High mass accuracy is always observed in the region bracketed by the calibrants. However, lower mass accuracy is observed outside the bracketed region. In calibration method 3, the two calibrant peaks were selected to be far apart and bracket all the other peaks in the ladder. Mass accuracy is high for peaks that are close to one of the calibrants, but decreases for peaks further away from the calibrants.

Our current resolution is limited by the 8ns pulse width of our laser [Nd(YAG)]. A shorter laser pulse of 2-3 ns duration will be implemented and a 2-3 times improvement in resolution is expected. We have observed a mass accuracy trend with internal calibration, and hope to devise a method to easily obtain adequate mass accuracy (better than 0.1 Da) over the full range of interest.

A High Speed, High Voltage Analog Switch with Precise Timing for an IT-TOF MS

Mike Davenport^a, John F. Holland^b, Qinchung Ji^a, Christie Enke^a

^aDept. of Chemistry, University of New Mexico, Albuquerque, NM 87131

^bDept of Biochemistry, Michigan State University, East Lansing, MI 48824

Introduction

Our group has developed a segmented-ring ion storage source (SRS) - TOF instrument that is able to generate quadrupole-like trapping fields for ion storage and a uniform electric field compatible with the ion optics of a pulsed TOF detector. A typical spectrum generation cycle begins in the storage mode with the application of 900 V_{pp} 1.2 MHz RF to the SRS. After ion storage times up to 500 μ s, the RF trapping voltages are removed and HV DC voltages (up to 750 V) are applied, emptying the trap and starting the detection mode. A high speed electronic switch is required to perform the transition from storage mode to extraction mode in < 50 ns. In addition, the switching action must be synchronized with the correct RF for maximum ion signal.

Design

The functionality of the HV analog switch is that of a SPDT switch with a break-before-make action. The design consist of dual optically isolated triggers, dual gate driving circuits and a MOSFET output stage (fig. 1). A TTL pulse is coupled to the floating gate drivers through two high speed opto-couplers. Power for the isolated triggers and associated gate drivers are from separate DC-DC converters. This allows the gate drivers to independently float on the source potentials (-450V to 750V) of the MOSFETs they control. The gate generate a fast break-before-make switching action necessary to protect the RF generator and extraction voltage supplies. The output stage consist of four 900 V_{os} n-channel MOSFETs in an unusual totem pole arrangement (fig.2). Each half of the output stage consist of a pair of common-source, common-gate transistors. This source-to-source configuration has the inherent source-drain diodes of MOSFETs in an anode-to-anode arrangement. The back-to-back diodes provides full wave blocking of the RF when the MOSFETs are off.

The storage/extraction cycle in the SRS-TOF requires variable width pulses to control ionization, ion storage, switching of RF-DC and data collection triggers. The design shown in figure 3 produces all necessary pulses and provides a variable, phase-synchronized extraction trigger. In the RF variable phase trigger, a 1.2 MHz TTL clock supplied by the external RF signal source is divided in two. The 625 kHz clock is sent to a programmable timebase generator and a variable delay circuit. The delay circuit produces the variable phase-shifted clock used to synchronize the RF-DC switching action. The programmable timebase divides the input clock by n and generates 1 to 5 kHz trigger for filament gating, starting the storage/extraction cycle. The trailing edge of the filament gate pulse is routed through a D-latch, clocked with the phase shifted clock previously mentioned. The output of the latch is the phase synched trigger for the extraction pulse generator. This ensures that the extraction

pulse is synched to a constant RF phase. The extraction pulse is also sent through a delay line before triggering a transient averager for data collection. This prevents HV switching noise in the detector from being acquired with the ion signal.

Results

The high speed switch has been able to handle 900 V_{pp} RF voltages and switch DC voltages up to 1000 V. The switching speed is under 50 ns and the variable phase shifted clock allows switching at any phase of the RF with 270° being best for our instrument.

KINETIC ENERGY ANALYSIS OF METASTABLES AND ION ISOLATION USING A TWO-SECTION ELECTROSTATIC PARTICLE GUIDE IN A TIME-OF-FLIGHT MASS SPECTROMETER

Jason S. Page, Curtiss D. Hanson and Nathan Adams

Department of Chemistry, University of Northern Iowa, Cedar Falls, IA 50614-0423

The continued growth in biomolecular analysis has led to a need for efficient instrumentation^(1,2,3). Most biomolecules are difficult to obtain and laborious to isolate resulting in very small available sample sizes. The ability to obtain as much of information from as little of sample is desired. To address this problem, tandem mass spectrometry experiments are performed to obtain structural information from trace samples. Tandem MS is accomplished by first isolating an ion packet, and then analyzing the ion packet to obtain a mass/charge spectrum of the parent ion and its fragments. From these fragments, the overall structure of the sample molecule is achieved. Time-of-flight Mass spectrometry (TOF-MS) has been a preferred choice in analyzing biomolecules because of its high sensitivity^(3,4,5) and, now with advancements in source techniques such as matrix assisted laser desorption ionization (MALDI)⁽⁶⁾, electrospray⁽⁷⁾ and particle desorption ionization, it has almost an unlimited mass range. However, until now tandem time-of-flight instrumentation can only be done with the use of an added second mass spectrometer.

Use of an electrostatic particle guide has been demonstrated in TOF to be an effective method of both ion isolation and reduction of unwanted matrix background⁽⁸⁾. Furthermore, use of a two section electrostatic particle guide (EPG) in a time-of-flight mass spectrometer can be used to perform tandem MS experiments. An EPG consists of an isolated wire electrode that runs down the center of the flight tube, creating a potential field that only effects the ions perpendicular to the flight axis. These field lines can be used in conjunction with a skimmer orifice as a kinetic energy analyzer for daughter ions while still permitting mass analysis along the flight axis.

Mass spectra were obtained on a prototype MALDI-TOF mass spectrometer built at the University of Northern Iowa. A rear entry stainless steel probe with a single extraction was used. The acceleration voltage was maintained at 14kV. The laser optics were mounted in the vacuum chamber at a 45° angle with respect to the probe. Detection of the ions was accomplished using a Comstock CP625/M microchannel plate detector with chevron geometry at the end of a 2 meter flight tube. The detector current was digitized using a LeCroy 9310 digital sampling oscilloscope (100 megasamples per sec.). Background pressure for the system was maintained at 2x10⁻⁸ torr by a Pfeiffer/Balzars TPU 220 turbomolecular pump.

Ions were generated by laser desorption using a Laser Science VSL-337ND-T nitrogen laser producing a 3nsec. Pulse at 337 nm. The selected matrix was 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid) because of its strong absorbance at 337 nm.

The electrostatic particle guides consisted of a 0.25mm diameter stainless steel wire supported by cross-hair wires and insulated from the tube wall. The first EPG began at 25cm from the source and terminated 50cm from the detector. The second EPG began 5cm from the first EPG and was strung down 10cm where it was terminated at skimmer orifice with a radius of 2 cm (figure 2).

Ion extraction can be accomplished by a two-section EPG by use of an attractive negative voltage on the first EPG and applying a calculated pulsing

Figure 1
Ion isolation of Cesium Iodide using a pulsing sequence on the 2nd electrostatic particle guide.

sequence on the second EPG. The first EPG focuses the ions down the center of the flight tube allowing the different compounds to separate out depending on their masses. The second EPG, with a repulsive positive voltage, repels the ions towards the wall of the flight tube as they enter the second EPG region. When the ion of interest enters this region, the EPG is switched to an attractive negative voltage. This potential focuses the ion through the skimmer orifice and to the detector. Once the ion has left the second EPG region, the voltage is switched back to a repulsive positive potential to eliminate the rest of the ions traveling down the instrument. This pulsing sequence can be calculated by using the velocity dependent equation of source acceleration, and is successful in repelling the unwanted ions away from detection and focuses the wanted ion to the detector. This axial flight time isolation allows for the complete ion packet extraction. The various mass fragments, caused by unimolecular decay of the parent ion following acceleration will have the same velocity as the parent ion and are therefore are still contained in the isolated ion packet.

The tandem mass spectrometry experiment can be accomplished by kinetic energy analysis of the daughter ions contained in the parent envelope by a two-section EPG. This is done by the use of an attractive negative voltage on the first EPG and then scanning a repulsive positive voltage on the second EPG. The radius of deflection is calculated by equation (1), where L is equal to the length of the EPG and V is the applied voltage. If this radius is greater than the radius of the skimmer orifice, the ion will be eliminated prior to detection. This permits for the elimination of an ion depending on its kinetic energy. The tandem MS experiment is performed by setting the second EPG at zero volts and allowing the entire ion packet through the skimmer orifice to the detector. The voltage of the second EPG is then increased by a desired increment to a higher repulsive positive voltage. Through consecutive increments, the fragments can be eliminated on the basis of their kinetic energy. The fragment elimination is seen by the decrease of the intensity of the ion peak.

Figure 2
Diagram of 2nd EPG showing ion deflection

The voltage of the second EPG is then increased by a desired increment to a higher repulsive positive voltage. Through consecutive increments, the fragments can be eliminated on the basis of their kinetic energy. The fragment elimination is seen by the decrease of the intensity of the ion peak.

$$r = L \sqrt{\frac{V}{KE_{ion}}} \quad (1)$$

The daughter spectrum is obtained by plotting the intensity of the peak as a function of the voltage applied to the second EPG. A first derivative is then performed on the curve to produce peaks at the corresponding voltages. From the voltage it is possible to calculate the kinetic energy of the fragment, and from this kinetic energy it is possible to calculate the mass. Once the mass of each fragment is known, an overall structure of the sample molecule can be obtained. By the use of this procedure using a two-section EPG, successful tandem MS on a single stage, linear time-of-flight mass spectrometer can be attained.

This improvement, of the addition of a two-section EPG, has led to the ability for successful compound isolation and tandem MS in a single time-of-flight mass spectrometer. This will expand the utility of TOF mass spectrometry for high molecule weight biomolecule analysis.

A Theoretical and Practical Description of an Interleaved-Comb Ion Deflection Gate

Tina A. Erickson, Douglas J. Beussman, and Christie G. Enke

Department of Chemistry, University of New Mexico, Albuquerque, NM, 87131

The interleaved-comb ion deflection gate, also called the Bradbury-Nielson gate, is a device used in time-of-flight (TOF) mass spectrometry to isolate a certain range of m/z packets for either elimination or transmission to the detector. This gate has garnered much interest in recent years, due to an increase in the use of TOF mass spectrometry with matrix assisted laser desorption ionization (MALDI), where it is used to eliminate detection of the MALDI matrix ions¹. Another application is the isolation of one ion packet for dissociation in tandem TOF mass spectrometry². However, as of yet no analytical description of the gate and what performance may be expected from it has appeared in the literature. Therefore, the practical implementation of the gate has required a great deal of trial and error modeling for each specific application. In this work, we have developed a set of equations and graphs which will allow the ready predictability of comb gate performance.

The interleaved-comb ion deflection gate consists of a plane of parallel wire segments in which alternate wires carry equal and opposite potentials with respect to the field-free region when the gate is 'closed' (see Figure 1). In this configuration, incident ions are deflected to the left or right, depending on the polarity of the field through which they pass. To 'open' the gate, the potentials are both pulsed to the field-free potential. During the 'open' portion of the gate sequence, the gate is essentially transparent to the ions, which pass through unhindered.

This study focuses on the use of SIMION modeling as a tool for determining the effect of several parameters on the performance factors of interest. Gate wire spacing, incident ion position, wire voltage, and ion KE are all investigated in terms of their effect on gate 'closed' deflection angle and response time of the ion beam to the transition between gate 'open' and 'closed'. In addition, an analysis of the acceptable tolerances in gate electronics, construction, and placement is included.

Figure 1 Diagram of gate construction

Incident ion position was determined to have a complex relationship to the deflection angle obtained during the gate 'closed' portion of the gating cycle. Spacing between the wires had no effect. The effect of ion acceleration voltage (KE) and wire voltage (V) had a combined effect such that deflection angle depends on V/KE . Including the effect of ion incident position, the range of deflection angles is described by the relation:

$$\begin{aligned}\theta_{\max} &= 10^{1.56}(V/KE)^{1.03} \\ \theta_{\min} &= 10^{1.21}(V/KE)^{0.85} \text{ for } 0.00 < V/KE < 0.67 \\ \theta_{\min} &= 10^{1.16}(V/KE)^{0.39} \text{ for } 0.67 < V/KE < 2.0\end{aligned}$$

The response of the ion beam to the change in gate state from 'closed' to 'open' is affected by several factors, including wire spacing, V/KE , and the requisite deflection angle, or critical angle for a given application. The function of percent transmission with respect to time has the form of a sigmoidal curve whose shape changes with the aforementioned parameters. As wire spacing is decreased, the transition is faster, as it is with decreasing V/KE and with increasing critical angle.

Finally, gate performance is dependent on practical considerations such as electronic risetime and accurate positioning of the gate orthogonal to the ion flight path. These two problems were modeled with surprising results. Counterintuitively, as electronic risetime increases, the time it takes for the ion beam to cross a given critical angle improves. Also interestingly, placement of the gate non-orthogonally to the ion flight path has little or no effect on deflection angle.

CONVERGENCE OF SPATIALLY DISPERSED ION BEAMS FROM REFLECTRONS

Terri L. Constantopoulos, Tina A. Erickson, Qinchung Ji, Christie G. Enke
Department of Chemistry, University of New Mexico
Albuquerque, NM 87131

Spatial broadening of the ion beam from the reflectron due to a wide distribution of ion energy is a common problem in time-of-flight (TOF) mass spectrometry. General broadening of the ion beam increases with both increasing reflection angle and increasing energy range. If the beam becomes broader than the detector, many ions will not reach the detector and therefore peak intensities will be low and detection will be energy- or mass-selective (Figure 1a). Two specific types of problems are illustrated with a tandem time-of-flight (TOF/TOF) mass spectrometer. In the first mass analyzer, which is analogous to a single-stage TOF mass spectrometer, a uniform loss of ions occurs when the kinetic energy of the ions is not a function of mass. Fewer ions reach the interaction region (or the detector in the case of TOF MS) resulting in decreased, energy-selective peak intensities. In the second mass analyzer, where kinetic energy is a function of mass, mass discrimination occurs. Fewer ions reach the detector, resulting in decreased, mass-dependent peak intensities.

Mass discrimination was demonstrated by optimizing the second reflectron in a TOF/TOF mass spectrometer for ions of selected masses. The mass-dependent energies from the second reflectron range from low-energy (low-mass) on the inside of the beam to high-energy (high-mass) on the outside of the beam. Since the ion beam is broader than the detector, only a portion of the beam reached the detector. The reflectron was positioned so that ions of the selected mass reached the detector. Each spectrum obtained in this study showed an increase in the intensity of the peak corresponding to the optimized mass and a decrease in the intensities of the peaks corresponding to the other masses, as predicted.

A simple solution to these problems involves the use of deflection plates which provide an energy-dependent deflection angle to bring about spatial convergence of the ion beam at the detector. SIMION modeling of the use of deflection plates with a simple linear reflectron demonstrates that the deflection plates will converge a broad beam of ions where the position within the beam is a function of kinetic energy. Increasing the voltage applied to the deflection plates decreases the focal length of the ion beam and increases the average deflection angle.

SIMION modeling of beam broadening caused by an actual nonlinear reflectron in a TOF/TOF mass spectrometer revealed that additional broadening and inversion of the ion beam occurs due to lensing effects from the non-linear potential field within the reflection. Deflection plates can correct the broadening due to the energy distribution without losing temporal focusing, however, deflection plates cannot correct the additional broadening due to lensing from the reflectron. A low-distortion reflectron with a more linear potential field is required for effective use of the deflection plates. SIMION was

used to model the use of deflection plates with a low-distortion reflectron (Figure 1b and 1c). The deflection plates solve the problem of beam broadening due to the energy distribution and the low-distortion reflectron solves the problem of beam broadening due to lensing. The SIMION models reveal the optimum detector position to maintain both spatial and temporal focusing as a function of the voltage applied to the deflection plates.

Figure 1. SIMION model of ion beam broadening in a low-distortion reflectron (a). Deflection plates cause convergence of the ion beam (b and c) without losing temporal focusing. Optimum placement of the detector is a function of the voltage applied to the deflection plates.

Time-of-Flight Mass Analysis of Trapped Ions Generated by Electron Impact Ionization

Qinchung Ji¹, John F. Holland², Michael R. Davenport¹ and Christie G. Enke¹

²Department of Biochemistry, Michigan State University, East Lansing, MI 48824

The mass analysis of conventional GC/MS detection suffers from trade-offs among spectral generation rate, ion statistics, mass resolution and mass range. Ion storage in an ion trap is employed to increase sample utilization efficiency. Ions stored in the ion trap are mass analyzed by sequential destabilization or resonance ejection in ITMS instruments. Fast sampling rate is achieved by limiting mass resolution or mass range. Time-of-flight offers an alternative method of mass analysis for ions accumulated in an ion trap[1]. Both TOF/MS and ITMS methods analyze ions in batches. Mass analysis by time-of-flight mass spectrometry is potentially much faster; however, the hyperbolic geometry of the conventional ion trap electrodes are not compatible with the source fields required for time-of-flight mass analysis. A collisional cooling step can minimize the resulting loss in mass resolution but this decreases both the maximum spectrum generation rate and the sample utilization duty cycle.

When a segmented-ring ion trap is used as an ion storage source, TOF/MS, without the collisional cooling step, can provide good mass resolution and fast spectral generation rate for the mass analysis of trapped ions. An segmented-ring ion trap storage source/time-of-flight mass spectrometer (SRS/TOF) has been constructed and used for chromatographic detection with electron impact ionization. The ion build up curve of PFTBA was characterized by increasing the ionization and ion storage time as shown in Figure 1. Although the mechanism of the ion loss during ionization is unclear, most of the ions generated are accumulated linearly for the first 100 microseconds which matches the optimum extraction rate of 10 kHz. Only 2 microseconds of the 100 microseconds analysis period is used for extracting ions into the time-of-flight path. Ions can be accumulated in the ion trap except during the ion extraction period. Thus the duty cycle of ion utilization could be up to 98%. This approach provides more than ample sampling along the chromatographic axis. Ions can be extracted before the ion source is saturated so good sample utilization efficiency at higher sample concentration is maintained.

Because ions are accumulated for only 100 microseconds, there is little or no spectral distortion due to ion molecule reactions. Benzophenone, a compound very prone to self-CI in normal ion trap spectra, was used to evaluate the self-chemical ionization interference in the SRS ion source. Yost et al showed that the peak ratio of the $[M+1]^+/[M]^+$ increased linearly with the amount of benzophenone injected and it reaches a ratio more than 0.6:1 when 50 ng of analyte was injected into a normal ion trap^[2]. Also a significant amount of adduct ions appears in the benzophenone spectrum obtained from the ITMS^[2]. For SRS/TOF mass spectrometric detection, the linear relationship between the peak areas of the m/z 77, 105, 182, 183 at the maximum chromatographic elution concentration position and the amount of sample injected is shown in Figure 2(a). The peak area ratios of $[M+1]^+/M^+$ versus the amount of sample introduced into the mass spectrometer are shown in Figure 2(b). The peak area ratios closely follow the isotopic ratio of 14.5% of the molecular ions of benzophenone up to at least a 100 ng sample introduction. As the sample introduced increases from 5 ng to 100 ng, no adduct ions are observed.

The prototype instrument of the segmented-ring ion trap storage source/time-of-flight mass spectrometer has shown the possible capability of providing simultaneously EI-like spectra, fast spectral generation rate, good mass resolution and good sample utilization efficiency for fast GC/MS detection. This approach significantly relieves the trade-offs inherent in the conventional mass spectrometric detectors for chromatography.

A Proposed Two Dimensional Quadrupole/Electrostatic Ion Trap

Time-of-Flight Mass Spectrometer

C. F. Ijames, National Institute of Mental Health, Bethesda, MD, USA, 20892-1262

Time-of-flight mass spectrometers are well known for their unlimited mass range, high ion transmission, and fast scan rates. More recently, high mass resolution and mass accuracies of sub-5 ppm have been demonstrated for samples of biological interest.⁽¹⁾ Further, this high resolution does not come at the expense of acquisition time, as in Fourier transform mass spectrometry and quadrupole ion traps (QIT). However, TOFMS is a pulsed analysis technique best suited to pulsed ionization sources, and suffers from an extremely poor duty cycle when coupled with continuous ionization sources. One approach to alleviate this is orthogonal extraction, which substantially improves the sensitivity but the short "storage" time requires extremely high repetition rates.⁽²⁾ Another approach is to couple a true ion trap, a QIT, with a TOFMS.⁽³⁾ This allows extended accumulation times but suffers from poor injection efficiency into the trap. Only during short periods of each radio-frequency cycle are the potentials such as to admit ions with kinetic energies suitable for trapping by collision with background gas. During the remainder of each rf cycle ions are either repelled or accelerated into the trap electrodes, so, effectively, there is still a duty cycle limitation.

An ion trap that combines high injection duty cycle, efficient trapping of injected ions, and allows the extraction of trapped ions as a well-localized, short duration ion packet, would substantially improve the sensitivity of ESI/TOFMS. In 1989, Prestage and co-workers described a new ion trap for frequency standard applications.⁽⁴⁾ Their device (Figure 1) uses a conventional two-dimensional rf quadrupole, with pins inserted on axis at each end, with a dc offset applied to these pins, relative to the quadrupole rods, which creates a trapping well along the rod axis. Confinement in the transverse directions is due to the applied rf field. This differs from the three-dimensional QIT where trapping in all three directions is due to the rf, and no dc potential is required. Compared to a QIT, the linear trap provides much greater ion capacity for a given overall size. Later, a second region was added to the linear ion trap by providing a second set of rods co-linear with the first set but with the ability to apply a different dc potential to each end pin and rod set. The gap between the rod sections was sufficiently short that the rf field was not significantly perturbed, and ions could be shuttled back and forth by appropriate biasing of the rods.⁽⁵⁾

The proposed instrument integrates the linear ion trap with a conventional electrospray ionization source (Figure 2). The trap is placed at the end of a conventional rf ion guide, and after accumulation, ions are extracted laterally, between a pair of rods. Extending Prestage's dual-region trap, SIMION modeling has shown that it should be possible to apply dc potentials sufficient for collisional activation between axial rod sections without significant ion loss, and without intervening lenses and rf fringe fields, so long as the gap is much less than the inscribed radius. This should greatly improve transmission. Injection efficiency into the trap should be very high, as again there are no rf fields to penetrate to reach the trap interior. Accumulation efficiency should be much better than the QIT, given the much longer path length for collisional capture. The collisionally cooled ion cloud will be cylindrical, with approximately thermal kinetic energies before extraction.

Introduction

One of the major challenges in modern biochemistry is the unambiguous sequencing of femtomole quantities of peptide mixtures. Electrospray ionisation and CID MS/MS has been applied with considerable success to some major histocompatibility complexes (MHC) (1) and to 2D gel protein separations (2).

Orthogonal acceleration Time of Flight mass spectrometers have been successfully coupled to electrospray ionisation sources to give high sensitivity together with high mass range and good mass resolution (3). They have also been coupled to magnetic sector mass spectrometers to give high sensitivity and high speed MS/MS performance with a wide range of ion sources and collision energy conditions (4).

In this paper we describe a new hybrid Quadrupole - orthogonal acceleration Time of Flight (Q - TOF) mass spectrometer. This instrument has been coupled to a conventional electrospray ionisation (ESI) interface and a nanoflow electrospray (5) interface to produce complete CID MS/MS spectra, with good resolution and mass measurement accuracy, from sub femtomole quantities of peptides.

Description

Ion Source

The ion source is a conventional electrospray source with hexapole ion transport lens. The sampling cone is variable from +/- 250 V and the source accommodates flow rates up to 500 μ l/min with the conventional probe and down to 10 nl/min or less using drawn glass micropipettes.

Quadrupole Mass Filter

The quadrupole mass filter operates as a variable bandpass device, with the bandpass window variable from a single mass to a decade in mass.

Hexapole Gas Cell

The collision gas cell is at ground potential and incorporates a RF hexapole ion transport lens to efficiently transport both precursor and product ions through the collision region. The collision energy may be varied up to +/- 200 V and the gas cell pressure may be raised to give multiple ion molecule collisions for efficient fragmentation. A further RF only hexapole lens follows the collision cell to transport the ions to the orthogonal acceleration chamber of the TOF.

Time of Flight Mass Spectrometer

The time of flight mass spectrometer uses a two stage orthogonal acceleration region and a linear single stage reflectron.

The detector is a 50 mm diameter dual stage microchannel plate (MCP) assembly. The output of the MCP is sampled using a time to digital convertor (TDC) (Precision Instruments Inc., Knoxville, TN) with a 64K, 16 bit word length histogram memory to store and sum individual ion arrival events. A detector sampling rate of 1 GHz will record ion arrival times up to 65 μ s (approximately m/z 1500) and reducing the sampling rate will extend the mass range to 7 kDa. The ion ejection pulse rate may be varied to give optimum sampling rate for the chosen mass range.

The portion of the beam not sampled by the TOF is detected using a conversion dynode photomultiplier system and may be used for optimising the performance of the system during set - up and data acquisition.

All MS and MS/MS data are acquired on the time of flight mass spectrometer.

Results

In MS mode the mass resolution is shown to be up to 5000 (FWHM).

MS/MS spectra for [Glu¹]Fibrinopeptide B acquired using the nanoflow electrospray probe at about 10 nl/min show good signal to noise. The fragment ion isotope peaks are completely resolved and give RMS mass errors of 0.05 Da for the 11 y⁺ type fragments down to a consumption of only 500 attomoles, using a two point external mass calibration.

Conclusions

Using nanoflow electrospray with the new Q-TOF instrument full MS/MS spectra can be routinely produced with good signal to noise and mass measurement accuracy for the consumption of low femtomole to attomole quantities of material.

The improved resolution (up to 5000 FWHM) of this new hybrid Q - TOF instrument allows ready differentiation of the ionic charge state of ions.

Mass measurements are routinely within 0.1 Da of the expected values using an external two point calibration.

Interpretation of peptide sequences are significantly less prone to ambiguity.

Automatic recording of LC-MS and LC-MS-MS spectra on a magnetic sector - TOF with magnet-bypass.

R H Bateman, T Davis, M R Green, N R R Ordsmith, J D Pugh and A R Woolfitt
Micromass Ltd, Floats Rd., Wythenshawe, Manchester, M23 9LZ, UK.

The combination of a magnetic sector and an orthogonal acceleration time of flight (oa-TOF) mass spectrometer has been shown to give good precursor ion resolution and high sensitivity CID MS/MS product ion spectra with fast acquisition rates. The addition of a "magnet bypass" allows all of the ions from the source to be transported directly to the time of flight mass spectrometer which allows advantage to be taken of its speed and sensitivity in the MS mode of operation.

Figure 1 shows the ion optical arrangement of the AutoSpec-TOF. It incorporates the AutoSpec EBE geometry double focussing magnetic sector mass spectrometer, a gas collision cell and a linear orthogonal acceleration time of flight mass spectrometer. The electrospray ionisation source operates at 4 kV and the gas cell is normally held at 3.8 kV so that the collision energy is 200 eV. The linear orthogonal acceleration time of flight mass spectrometer, which has an effective path length of 45 cm, re-accelerates the ions back to ground potential. Ions are detected with a two stage microchannel plate and recorded using a time to digital converter with a sampling rate of 1 GHz. The AutoSpec is fitted with a "magnet bypass" arrangement whereby all the ions from the source may be transmitted to the oa-TOF mass spectrometer directly without mass analysis. To switch to the MS mode of operation the gas flow to the gas cell is switched off, the magnet is switched off and the electrostatic beam divertors switched on to direct all of the ions from the source through the bypass tube. Switching to the MS/MS mode entails switching the beam divertors off, switching on the magnet to the required mass, and switching the gas flow back into the gas collision cell. All acquisitions are from the oa-TOF 150 mm long detector, which records full mass spectra and full product ion spectra irrespective of the precursor ion mass or charge

To automatically record product ion spectra of eluting peaks during a HPLC run it is necessary to quickly recognise when a peak is eluting, identify the masses of the mass spectral peaks, and decide which to select as precursor ion. Mass spectra acquired on the oa-TOF via the magnet bypass do not exhibit any skew in the data. This eases the task of automatic computer selection of the precursor ion, based on such criteria as most intense peak within a selected mass range, when the signal is changing rapidly as is often the case with eluting HPLC chromatography peaks. It is then necessary to quickly switch the magnet to the required mass and switch gas into the gas cell such that the TOF mass spectrometer is now recording product ion spectra. Figure 2 shows the 1 second acquisition of the electrospray mass spectrum of Angiotensin II. Figure 3 shows the 1 second acquisition of the CID product ion spectrum from the $(M+2H)^+$ ion of Angiotensin II recorded 1.3 seconds after the acquisition of the mass spectrum shown in Figure 2

TIME-OF-FLIGHT MASS SPECTROMETER SYSTEM AS A DETECTOR FOR HIGH SPEED GAS CHROMATOGRAPHY

Viatcheslav Artaev, Nancy Brichford, Joel Mitchell, Ritchard Parry
LECO Corporation, 3000 Lakeview Av., St. Joseph, MI 49085

The ability to reduce analysis times by a factor of 10 or more has resulted in High Speed Gas Chromatography (HSGC) becoming a popular technique in industries with a demand for increased productivity. Typically, HSGC peak widths are very narrow (less than 0.5 s) which places high demands on the GC detector response time and sampling rate. Assuming that 10 data points across a peak are sufficient for accurate quantitative information, a detector sampling rate greater than 20 Hz is required for HSGC. Sampling rate requirements become even greater when, due to retention time reduction, component mixtures can not be completely chromatographically separated. In order to deconvolute those overlapped and coeluted peaks presented in HSGC a chromatogram sampling rate of more than 20 Hz is required for the detector. Moreover, additional information rather than retention time is required to identify and/or quantify compounds correctly.

Analyte confirmation information and low detection limits have made Mass Spectrometry (MS) a well established detection technique for chromatography. However, coupling HSGC with MS does present some difficulties. It has been shown [1] that mass spectrometers based on the time-of-flight principle (TOFMS) are practically ideal for use in HSGC detection. This technology combined with a fast data acquisition system creates a powerful technique for analysis of complex mixtures by means of HSGC [2]. Reduction of analysis time is quite often achieved through an increase of carrier gas flow rate. Therefore, vacuum operational conditions in this case will be different than is customary for TOFMS. It is important to consider the limits of the carrier gas flow rate increase to keep the analytical performances of the system in the proper range and still be able to perform fast analysis. We are presenting here the results of further evaluation of a GC/TOFMS system towards implementing this system as a detector for High Speed Gas Chromatography

The **PEGASUS[®] GC/TOFMS** system (LECO Corp., St. Joseph, MI, [3]) was used to obtain the data presented. This system includes the following components: Time-of-Flight Mass Spectrometer with an electron impact ion source, Reflectron mass analyzer; Data Acquisition System capable of continuous recording data at data acquisition rates up to 500 spectra per second with a 14 bit measurement range per transient (dynamic range); Pentium-based computer system; HP 6890 GC using a DB-5 column (10 m, 0.18 mm i.d.) with Electronic Pressure Control and a heated transfer line.

Under proper GC conditions the reduction of the retention time will cause a GC peak width to decrease and therefore increase the peak height if peak area will remain the same. For this situation sensitivity can be expected to increase but the higher sampling rate required for the narrower peak will limit this positive trend due to the lower number of summed spectra (see figure on this page). Another negative factor is increasing pressure in the mass spectrometer vacuum chamber due to higher carrier gas load. This can result in intensive ion scattering on residual gas molecules and loss of sensitivity. It was shown experimentally that there is no appreciable decrease in peak width with flow rate above 1.5 ml/min. Apparently, under these conditions the main contributing factor to peak width becomes injection bandwidth. Peak intensity will decrease for He flow rate above ~2 ml/min. but still remain higher than for lower flow rates despite pressure increase effects. Library matchable mass spectrum was obtained from injection of a 1 pg HCB (fig 1), high quality spectra and 500 s/s data acquisition rate were demonstrated. Accelerated analysis of component related to EPA Method 525.2 shows short analysis time and excellent linearity across the calibration range.

Fig.1 Signal obtained from the injection 1 pg of Hexachlorobenzene in splitless mode. Sampling rate is 15 spectra/s. Library matchable mass spectrum corresponds to 1 pg of sample is shown on the right (bottom). NIST library spectrum shown on the top of the right part of the figure.

Figure 2. Part of the chromatogram obtained from running a VOC mixture is shown on the left. At isothermal oven conditions and a 2 ml/min carrier gas flow several component peaks are overlapped. It is shown that the coeluted components don't interfere with each other and no skewing has been observed since the ion peak intensity ratios for the individual components remain constant over the whole peak (charts on right side of the figure). Data obtained at **500 summed spectra/s** data acquisition rate. Carbon tetrachloride and 1,1-Dichloroethane are separated only by 0.04s. High data acquisition rate is necessary to be able to deconvolute poorly separated peaks.

Fig.3. Analysis of component related to EPA Method 525.2. Data was obtained at 20 sp/s acquisition rate and a 2 ml/min He flow rate. In order to comply with EPA requirements for base line separation of certain compounds this run was intentionally slowed down but still remains faster than conventional methods. By using the deconvolution technique to quantify overlapped peaks the run time can be reduced dramatically. Calibration curves for several components used in EPA Method 525.2 show excellent linearity across the calibration range required by the method

MALDI-TOF/TOF MASS SPECTROMETRY: APPLICATIONS TO FULLERENES AND METAL-PHTHALOCYANINES

Marcela M. Cordero, Timothy J. Cornish and Robert J. Cotter
The Johns Hopkins University School of Medicine, Baltimore, MD USA

A *tandem reflectron* time-of-flight mass spectrometer developed in our lab¹ provides a unique opportunity to investigate the collision-induced dissociation (CID) of fullerene and phthalocyanine ions formed by MALDI over a range of target gas pressures. The tandem TOF instrument utilizes a non-linear (curved-field) reflectron in the second mass analyzer, that enables recording of high energy CID spectra without scanning or stepping the reflectron voltage.

Calibration. Calibration of precursor ion masses was carried out in the same manner as single TOF instruments using standard peptides and reference matrix ions. On the other hand, product ion calibration is basically an instrument function described by the equation for an ellipse whose constants are programmed into TOFWARE during initial setup of the instrument, by recording the product ion mass spectrum of a compound with known fragment masses.

Fullerenes. Saturated benzene solutions of C₆₀, C₇₀ and α -cyano-4-hydroxycinnamic acid were prepared. 10 μ l of each were mixed and allowed to spread over the probe tip and dry slowly to produce visible crystals.

Phthalocyanines. Saturated solutions of phthalocyanines in formamide (sonicated to improve solubility) were prepared. 1 μ l each 1:1 ethanol:water α -cyano-4-hydroxycinnamic acid and phthalocyanine solutions were applied to the probe tip and allowed to dry. All chemicals used were from Aldrich except the benzene (Baker Laboratories).

Collision-induced dissociation of C₆₀ and C₇₀. CID mass spectra, using helium, argon and xenon as collision gases were obtained separately from C₆₀ and C₇₀ samples (rather than mixtures of the two fullerenes); mass selection (gating) was used to eliminate contributions to the spectrum from prompt fragmentation. As would be expected, the most efficient and informative fragmentation and the best resolved collision-induced dissociation spectra were recorded under conditions that promote fragmentation near the single collision regime. For C₆₀⁺ these correspond to the spectra shown in Figures 1 and 2, in which medium attenuation (approximately 80% attenuation) by helium and argon results in efficient activation of C₆₀⁺ to form high mass C_{2n}⁺ and low mass C_n⁺ ions, respectively. Heavier target gases (argon, xenon and SF₆) were utilized to provide higher collision energies (in the center-of-mass frame). Results were similar to those reported from a wide of mass spectrometric methods^{2a-f}

CID of Phthalocyanines. Metal-Phthalocyanines, commercial dyes of wide application, have been studied by L²TOFMS^{3a} and MALDI^{3b} among others. MALDI of 29H,31H-phthalocyanine produced an abundant molecular ion which was gated and used as precursor ion. Its CID (He) presents some major fragmentation pathways consistent with the symmetry of the phthalocyanine molecule. CID (He) MS of manganese (II) and aluminum chloride showed similar cleavages but this time the fragment ions included the metal. Figures 3 and 4 depict the proposed fragmentation pathways and the CID (He) of manganese. Collision gas effects observed with cobalt (II) phthalocyanine were similar to those from fullerenes.

Conclusions. The MALDI-TOF/TOF presents the unique capability of performing high energy CID on ions arising from a pulsed-ionization technique such as MALDI, rather than the traditional continuous ionization technique. It resembles a multiple sector mass spectrometer, but is much more compact and economic.

Figures 1-4. (1) CID (He) medium attenuation of C₆₀⁺ (2) CID (Ar) medium attenuation of C₆₀⁺ (3) Phthalocyanines and proposed CID fragmentation patterns. (4) CID (He) medium attenuation of manganese (II) phthalocyanine.

Proton Affinities of MALDI Matrices

Richard D. Burton, Clifford H. Watson, John R. Eyler, G. Lisa Lang, Marcella Y. Avery, David H. Powell*
Department of Chemistry, University of Florida, Gainesville, FL 32611

Introduction: Protonated molecular ions of analytes in MALDI are frequently the most intense ions observed especially when the concentration of alkali cations is low. Examination of the laser desorption mass spectra of MALDI matrices usually shows the presence of both molecular radical ions $M^{\bullet}$ and $(M+H)^+$ ions. With some matrices the intensity of the $(M+H)^+$ ion is greater than the molecular radical ion, e.g. 2,5-dihydroxybenzoic acid. A logical source for these protonated analyte ions is proton donation from the $(M+H)^+$ ion of the matrix, but donation could also occur from the radical molecular ions as suggested by Ehring, Karas and Hillenkamp¹. They observed a dramatic change in the $(M+H)^+$ for cytochrome c in indole-2-carboxylic acid when the laser wavelength was shifted from 266 nm to 337. A corresponding increase was also observed for the $(M+H)^+$ ion of the matrix.

Beavis, Chaudhary, and Chait² suggested that the low intensity of matrix ions observed in α -cyano-4-hydroxycinnamic acid (4-HCCA) might involve production of protonated matrix ions followed by exhaustive reaction with analyte or other species. Their supposition is supported by the observation that the protonated peptide signals from 4-HCCA matrices are substantially higher than from other cinnamic acid derivatives used as matrices. Karas and Hillenkamp³ and Spengler *et al.*⁴ proposed that proton transfer occurs from the matrix ions and the analyte. A knowledge of the proton affinities of the common MALDI matrices might be helpful in the understanding why some matrices are "hotter" than others and lead to more post source decay as well as prompt decay. We have determined the proton affinity of eight common MALDI matrices using the bracketing approach with Fourier transform mass spectrometry.

Experimental Method: These studies were conducted using a Bruker 4.7 Tesla FT-ICR mass spectrometer equipped with an external ion source. Separate MALDI matrices were introduced into an external source using a solids probe heated to 150°C. Methane chemical ionization was used to protonate the molecule, and the ions were transferred via electrostatic ion optics to an RF-shimmed analyzer cell. The $(M+H)^+$ matrix ion was selectively isolated in the analyzer cell and allowed to collisionally and radiatively cool for five seconds. A proton transfer reagent of known proton affinity was introduced next via a leak valve to a background pressure of 2×10^{-7} torr in the analyzer cell, and the resulting ions were subsequently detected. The figures to the right illustrate the reaction of $(M+H)^+$ ion of nicotinic acid with morpholine.

In those cases where proton transfer was observed but had not proceeded to completion, the reaction delay was increased. This was done to insure that the reaction was thermodynamically favorable and not the result of some initial protonation from thermally "hot" $(M+H)^+$ matrix ions.

Results:	Compound	Proton Affinity (kcal/mole)
	nicotinic acid	215 $\pm$ 4.0
	trans-3-indoleacrylic acid	215 $\pm$ 4.0
	1,8,9-anthracenetriol	209 $\pm$ 1.9
	2,5-dihydroxybenzoic acid	204 $\pm$ 3.5
	3,5-dimethoxy-4-hydroxycinnamic acid	204 $\pm$ 3.5
	α -cyano-4-hydroxycinnamic acid	183 $\pm$ 1.8
	ferulic acid	183 $\pm$ 1.8
	2-(4-hydroxyphenylazo)-benzoic acid	183 $\pm$ 1.8

Conclusions: The ground state proton affinities (PA) for eight common MALDI matrices ranged from 183 kcal/mole to 215 kcal/mole. The $(Matrix+H)^+$ was generated by chemical ionization, and the proton affinity was bracketed by reacting the $(Matrix+H)^+$ ion with reference compounds of known proton affinities.

Mechanistic Implications: For proton transfer to occur, the proton affinity of the acceptor must be greater than the proton affinity of the donor. For proteins and peptides, the presence of the amide bond with its high proton affinity suggests a ready route for formation of the protonated peptide by transfer from the ground state $(Matrix+H)^+$ ion, e.g. glycine has a PA = 213 kcal/mole⁵.

These results also suggest that for some matrix/analyte combinations proton transfer does not occur from the ground state, protonated matrix since the matrix proton affinities are too high for this mechanism to be operable, e.g. trans-3-indole acrylic acid and nicotinic acid have PA = 215 kcal/mole. For some synthetic polymers, the dominant form of ionization is through alkali ion attachment. This may reflect the low proton affinity of some of the synthetic polymers, e.g. polyethylene glycols (PA = 193 kcal/mole) which would not enable proton transfer from the ground state $(Matrix+H)^+$ ion of matrices such as dihydroxybenzoic acid.

These results are consistent with suggestions of some authors that proton transfer occurs from excited states of the matrix molecules⁶.

Comparison to Other Results

The results obtained by using this thermodynamic approach agrees for nicotinic acid but differs from that obtained by other authors⁷ using the kinetic approach for several of the matrices tested. The kinetic method these authors employed involved high energy collision induced dissociation of proton bound dimers formed by FAB ionization. The differences in the measured proton affinities may reflect differences in methodology. The kinetic approach can involve internally excited molecules; whereas, the thermodynamic approach used here involved a cooling step prior to the introduction of the reference compound. This cooling step was used to insure that ground state proton affinities were being measured.

Secondary ions and electrons in MALDI: Desorption and Detection

R. Knochenmuss, F. Dubois and R. Zenobi

Dept. of Chemistry, ETH Zürich

Universitätstr. 16, 8092 Zurich, Switzerland

In the MALDI source region we have found that significant numbers of secondary ions are created by impact with the grids used to flatten the accelerating fields. We find that impact on the grids creates as many as 10 secondary charges for each primary ion. The number of secondary charges increases quadratically with increasing accelerating potential, see Fig. 1. At typical MALDI voltages, up to about 100 charges per primary ion are created.

Many workers use conversion dynodes in front of the electron multiplier and ultimately detect secondary rather than heavy primary ions. One such setup simply places a grid before the channelplates. We have found that very fine grids transmit fewer ions than their geometric open area predicts. A 1500 lines/inch copper grid was found to have an effective open area 2-3 times smaller than the nominal geometric open area. This is very likely due to attraction of ions to their image charges in the metal.

We have also investigated the nature and energies of the secondary ions produced on such a grid. By biasing the grid, secondary charges can be collected on the grid, changing the total current detected. We conclude that many negative particles are very low in energy, less than 3.5 eV.

The directly measured current on the pre-MCP grid can be used to approximately correct the channelplate spectrum for mass bias. Since both signals can be recorded simultaneously, there is little extra cost in using the extra data to improve the quantitation capabilities of MALDI.

In addition to secondary charged species, ion impact on a surface results in fast photoemission¹. We have tested a detector based on this effect. We coated the surface of a photomultiplier with a thin layer of scintillator compound (BuPPD), and placed this directly in the ion beam. The resulting mass spectrum in Fig. 2 shows less mass bias than when measured with a channelplate, but the noise level is not yet suitable for routine use.

An Investigation of the Ionization Mechanism in LSIMS for Cis-Stilbene Oxide.

S. Obarewicz¹, G. J. C. Paul² and M. J. Bertrand¹.

(1) Regional Center For Mass Spectrometry, University of Montreal, Montreal, Canada, H3C 3J7. (2) American Cyanamid, Agricultural Research Division, Princeton, New Jersey.

The objective of this work was to get insights into the FAB/LSIMS mechanism leading to anomalous ion formation such as $[M-H]^+$ and M^+ ; $[M+H]^+$ being the most commonly observed ion. Previous works conducted on cyclic acetals, substituted monosaccharides and a triamine (Perhydro-3a,6a,9a-triazaphenylene) indicated that in FAB/LSIMS, $[M-H]^+$ ions were formed through hydride abstraction [1-4]. The site of abstraction was believed to be on a carbon neighbouring a conjugated substituent or a heteroatom with lone pairs of electrons. Such specific structural features allow the resonance stabilization of the positive charge resulting from hydride abstraction. In addition, other previous studies showed that electron removal leading to M^+ formation was possible for aromatic substituted analytes dissolved in matrices such as 3-NBA and 2-HPEA [5].

In our continuing investigation into the FAB/LSIMS ionization mechanism, Cis-Stilbene Oxide (Figure 1-a) has been studied with different matrices such as 3-NBA, 2-HPEA, HEDS, TDE and GLY. The results obtained show that Cis-Stilbene Oxide generates three different types of molecular ions (Table 1) : $[M-H]^+$, M^+ and $[M+H]^+$. These ions are believed to be created by competitive processes related to the structure of the analyte. The formation of $[M-H]^+$ ions is probably brought by hydride abstraction on the centered "C-C" bond. That site is considered to allow for maximum resonance stabilization of the resulting positive charge, through phenyls and lone pairs on the oxygen. The formation of M^+ and $[M+H]^+$ ions is believed to happen by electron loss and protonation on phenyls and lone pairs sites.

Table 1 : Relative intensity (%) of peaks in the molecular ion region in function of time of irradiation in different matrices for a concentration of 1.0 M

Matrix	0 - 30 secs.			~ 1 min.			~ 3 min.		
	$[M-H]^+$	M^+	$[M+H]^+$	$[M-H]^+$	M^+	$[M+H]^+$	$[M-H]^+$	M^+	$[M+H]^+$
NBA	22 ± 2	100	83 ± 1	19 ± 2	83 ± 5	100	11 ± 3	14 ± 8	100
HPEA	23 ± 1	89 ± 2	100	20 ± 1	62 ± 2	100	14 ± 2	26 ± 2	100
GLY	19 ± 2	12 ± 1	100	18 ± 2	18 ± 1	100	14 ± 2	17 ± 3	100
TDG	14 ± 3	15 ± 4	100	10 ± 3	8 ± 1	100	13 ± 2	8 ± 3	100
HEDS	13 ± 2	7 ± 2	100	9 ± 1	5 ± 1	100	7 ± 2	4 ± 2	100

An inversion of the $M^+/[M+H]^+$ relative intensity ratio (Table 1, Figures 1-a,b) is observed in aromatic matrices such as 3-NBA and 2-HPEA. However, that same ratio remains constant in aliphatic matrices such as GLY, TDE and HEDS. At the beginning of bombardment, the electron scavenging properties of 3-NBA and 2-HPEA lead to M^+ ion formation, whereas the aliphatic matrices, owing to their protonating properties, lead to $[M+H]^+$ formation throughout the acquisition. These observations indicate that there is a difference in the beam-induced chemistry between aromatic and aliphatic matrices in the analysis of Cis-Stilbene Oxide by FAB/LSIMS.

2) G.J.C. Paul, R. Th  berge, M.J. Bertrand, R. Feng, M.D. Bailey, *Org. Mass Spectrom.*, **28**, 1329 (1993)

Figure 1 : Spectrum of 1.0 M of Cis-Stilbene Oxide in 3-NBA at (a) beginning of bombardment and (b) after 3 min. of bombardment.

The time-effect observed (Table 1, Figures 1-a,b) in the aromatic matrices can be used to probe the FAB/LSIMS ionization mechanism (Gas-Phase VS Condensed-Phase). The hypothesis of an accumulation of reactive species into the bulk of the sample during irradiation has been reported before [3-4] for $[M-H]^+$ formation and it seems to be a suitable explanation for the time-effect observed here. Such a rationale implies that the beam-induced chemistry at the surface of the sample may be different from that of the bulk. If reactive species were trapped into the bulk, they might have a greater opportunity in time to react with the analyte, as compared to the reactive species subject to desorption at the surface. Also, during erosion of the layers by bombardment, the products created in the collision cascade and trapped into the bulk will eventually reach the surface. Hence, this should contribute to a change in the concentration of ions at the surface of the sample. Thus the relative proportions of ions being desorbed at the surface will change in time because of delayed sampling, as seen in Figures 1-a,b and Table 1. Such phenomena can be reflected as inversions in the ratios of selected peak intensities. Since accumulation of species in the gas-phase is unlikely to happen, the inversions are consistent with condensed-phase ionization.

Figure 2 : ESI spectrum of Cis-Stilbene Oxide, (100 MeOH + 20 H₂O, 1 µl / min.)

To support the hypothesis of a beam-induced condensed-phase ionization mechanism in FAB/LSIMS, the ESI behaviour of Cis-Stilbene Oxide is shown in Figure 2. It is obvious that the peak patterns of LSIMS and ESI are different. The $[M+H]^+$ peak dominates in ESI and there are no $[M-H]^+$ and M^+ peaks observed. Since condensed-phase equilibrium is believed to be the major process for ion formation in ESI, the different peak patterns for ESI and LSIMS can be used to indicate that ions in LSIMS are not created solely through condensed-phase equilibrium prior to bombardment.

Matrix Redox Chemistry and Surface Tension Effects in LSIMS.

R. Th  berge*, G.J.C. Paul and M.J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7.

Matrix selection has long been recognized as a crucial experimental parameter in LSIMS (Liquid Secondary Ion Mass Spectrometry). More specifically, the matrix affects the extent of redox processes as well as the intensity of the analyte signal observed in the LSIMS mass spectrum. The matrix redox chemistry generated under FAB/LSIMS conditions has been the focus of many investigations. However, the majority of studies have been limited to classification of the matrices in terms of their ability to inhibit or effect beam-induced redox processes. Through the study of the mass spectra of the pure matrix compounds as well as the use of radiolytic concepts and data, the extent of beam-induced redox chemistry known to occur in each matrix group can be rationalized. Although the energy regimes of LSIMS and radiolysis are different (keV vs. MeV), a similarity lies in the way an energetic particle generates a 'track' in the medium it penetrates, along which energy is deposited and radicals, ions, excited species and electrons are produced. Generally, the matrices can be separated into three groups in terms of their ability to inhibit beam-induced reduction processes: aromatics, sulfur containing aliphatics, and alcohols [1]. Glycerol is recognised as the matrix with the lowest capacity to inhibit reduction. This can be rationalised by looking at the radiolysis of alcohols.

Most of radicals generated react rapidly with alcohol molecules to generate the $\text{CH}_2\text{OH}^\bullet$ radical (as indicated above) and hence the net reaction of methanol radiolysis is as described in Scheme 2 (vide infra).

The $\text{R}^\bullet\text{-(CH)}_2\text{OH}$ radicals (such as $\text{CH}_2\text{OH}^\bullet$) are α -hydroxyalkyl radicals known to engage in the one-electron reduction of compounds such as dyes, porphyrins, quinones, aromatic ketones as well as some metal ions [2]. The radiolytic radical cascade generated in alcohols is thus reducing. The generation of α -hydroxyalkyl radicals in the FAB/LSIMS of glycerol (Scheme 3) has been repeatedly postulated [3-5] on the basis of the observation of ionic products derived from radical-radical recombinations.

Beam-induced secondary electron production has also been proposed giving the net reaction shown below (Scheme 4). In analogy to the radiolysis of alcohols, the radical cascade induced by keV particles in glycerol is reducing. The fact that keV particle bombardment produces highly reducing transient species in glycerol is compounded by the lack of quenching mechanisms for such species. Hence, the behaviour of alcoholic solvents under radiolytic and FAB/LSIMS conditions is very similar.

For sulfur-containing matrices, the intermediate reduction inhibiting capacity of those compounds can be explained by the beam-induced generation of an oxidizing radical cascade and the capacity of thiols to

scavenge electrons. The oxidizing radical cascade is due to the thiyl radical, $\text{RS}^\bullet$, which is a moderate oxidant ($E_{\text{OX}}=0.8\text{V}$) [6]. The observation of a molecular radical anion in the negative LSIMS spectra of a matrix can be interpreted as a clear indication of its electron-scavenging capacity. The matrix molecular radical anion is clearly observed for hydroxyethyl disulfide (HEDS) and nitrobenzyl alcohol (NBA) in their respective mass spectra shown in Figure 1. This is confirmed by the fact that such matrices are known to strongly inhibit reduction processes [1]. The high reduction inhibiting capacity of aromatic matrices can be explained by their electron scavenging capacity and radiation resistance. Radiation resistance defines the ability of a medium to (a) allow a large fraction of the energy of excited molecules to be channeled to low-energy states that have a low probability of dissociation and (b) have relatively low yields of reactive transients with respect to aliphatic compounds. Benzene is the most common reference point in the radiation chemistry definition of radiation resistance. The importance of matrix surface tension [7] on analyte signal intensity was investigated using 3 matrices of known surface tension. The absolute ion intensity of the M^+ originating from equimolar solutions of the surfactant dodecyl trimethylammonium bromide in each matrix was observed to decrease with decreasing matrix surface tension (Table 1). This result is consistent with the classical physical chemistry of surfactants. This last example illustrates the important effect of matrix physical properties on FAB/LSIMS spectrum quality.

Beam-Induced Redox Processes for the Methylene Blue/Thioglycerol system in LSIMS.

*M. Allard, M.J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, Canada H3C 3J7

Beam-induced reduction is common in liquid secondary ion mass spectrometry (LSIMS). Thioglycerol is often used in routine analysis to mitigate reduction. However, evidence in a kinetic study (1) indicates the occurrence of a spontaneous redox reaction in the thioglycerol/methylene blue system. This undesirable reaction could explain the discrepancies in the published results for this system. A previous study (2) had mentioned bleaching of the solution prior to analysis and recovery of the blue color by the sample after bombardment, but it had not given any explanation for these observations, nor did it mention the variation of the spectral data with time. Thus, this system calls for further investigation.

The progression of the reaction prior to analysis was followed with a 0.1 M solution and the first spectrum of a 2 μ L aliquot was obtained at regular time intervals. A gradual "bleaching" of our solution in the vial was observed, accompanied by an increase in the A+1/A and A+2/A ratios. The sample was then left under continuous bombardment and the obtained spectra showed apparent regeneration of the molecular ion. The remaining sample on the probe tip had recovered its blue color. This visual observation tends to suggest a reversal of the reaction and also that *this beam-induced reaction is a condensed phase process*. The scheme below shows both redox processes taking place in this system.

The beam-induced reaction can be explained by a generation of an oxidizing thyl radical cascade upon bombardment of thioglycerol as suggested by Théberge et al. (3). The true redox extents were evaluated by treating all data using a deconvolution algorithm, SIMBROC, described previously (4). The results for both redox processes are presented in a) and b) where the Red_n and Ox_n variables are presented versus time. As shown in a) the intact molecular ion (Red₀) is

decreasing over time, while both reduction processes are increasing. Leucomethylene blue, the product of the chemical reaction, would be detected at m/z = 286 and therefore correspond to Red₂. In b) the variation in the redox values with bombardment time is rather fast, within 2 minutes of exposure to beam. The raise in Red₀ upon bombardment tends to support the oxidizing thyl radical cascade theory. The two-electron reduction extent (Red₂) is diminishing, while the one-electron reduction extent (Red₁) does not vary significantly with bombardment time, suggesting a different mechanistic pathway in this process. This could also indicate that Red₁ achieves a steady state at the surface of the droplet. Obviously, the underlying mechanistic aspects are complex and details of it cannot be deduce from this study alone. These results serve to prove that *beam-induced formation of radicals or excited species will influence the redox quenching ability or the reductive ability of a matrix in LSIMS analysis*.

Factors Influencing Nucleic Acid Analysis in MALDI: Fragmentation, Positive-Ion Formation and Mixture Analysis

Wei Tang, Lin Zhu, Christine M. Nelson, and Lloyd M. Smith

The development of MALDI mass spectrometry and its demonstrated performance with large proteins, up to 300,000 daltons, has generated substantial interest in utilizing this technique as an alternative to gel electrophoresis for DNA sequence analysis. In this presentation, we studied various factors that impede the analysis of nucleic acids using the MALDI technique.

Studies investigating the formation of positively charged molecular ions of oligonucleotides support a previously published model¹ in which base protonation initiates base loss which leads to subsequent cleavage of the phosphodiester backbone. We explored the formation of positively charged molecular ions in the UV (355 nm) MALDI analysis of oligonucleotides using the matrix 2,5-dihydroxybenzoic acid. Whereas substantial fragmentation is observed in positive-ion mode using the short oligomer d(TAGGT), no fragmentation is evident in negative-ion mode under identical conditions. Several polydeoxythymidilic acids T₄NT₇, where N represents modified cytosine or thymine, were used to investigate positive ion formation. These results support the hypothesis that positive ions are formed by protonation of the nucleobases. Since base protonation initiates base loss, fragmentation is intrinsic to positive-ion formation in the MALDI analysis of oligonucleotides. This result explains the dramatic difference in fragmentation observed in positive-ion compared to negative-ion UV-MALDI mass spectra of oligonucleotides.

Studies in the negative-ion mode compared the propensity of fragmentation for differently modified cytidine in MALDI process. Results using the oligonucleotides d(T₄M₄T₇), where M is either cytosine, or modified cytosine, were also consistent with proposed fragmentation mechanism. It was shown that electron donating group on the modified cytosine increases the stability of N-glycosidic bond and causes less fragmentation, whereas the electron withdrawing group weakens the N-glycosidic bond and leads to more fragmentation. The modifications at the 2' position on the deoxyribose ring demonstrates that a more polar 2' group (especially -F) is more effective at stopping fragmentation.

Mixture analysis has also proven to be a critical parameter in the analysis of Sanger sequencing reactions. Unmodified and modified nucleic acid mixtures were analyzed in various matrices to determine factors influencing the decrease in peak intensities observed with increasing oligomer length.

Quaternary ammonium bromides are molecules comprising a long hydrophobic alkyl chain and a polar hydrophilic head group. Such structures exhibit surface activity and have a propensity to accumulate at the aqueous solution surface and aggregate in solution. The generic structure of the compounds studied is shown in Figure 1. Under LSIMS conditions, quaternary alkyl dimethylammonium bromides are known to form clusters of the type $M_nBr_{n-1}^+$ [1]. The aim of this work was to investigate the effect of the presence of a carboxylic acid group in the quaternary ammonium bromides on cluster formation. In addition, the effect of different matrices on the clustering in LSIMS was studied.

The LSIMS mass spectrum of a quaternary ammonium bromides with $X=COOH$ is shown in Figure 2. This salt reveals a different clustering and a higher number of cluster ions ($[M_n-(y-1)H]^+$ up to $y=4$) relative to the quaternary ammonium bromides with $X=H$, CH_3 and CN for which $M_nBr_{n-1}^+$ is seen up to $x=2$ [1]. This can be rationalized by the formation of zwitterions for quaternary ammonium salts with $X=COOH$ through the loss of a proton from the carboxylic acid. Moreover, charges are believed to be closer within the zwitterionic clusters, which leads to stronger binding and, thus, higher number of clusters.

The quaternary ammonium bromide with a long side chain carboxylic group shows different features when compared to its homologues with smaller chains. As observed in Figure 3, the LSIMS mass spectrum of M10N12COOH shows the M_2Br^+ ion favoured over the $[2M-H]^+$ ion. Consequently, the behavior of M10N12COOH under LSIMS conditions rather mimics that of the quaternary ammonium bromides without a carboxylic acid functional group. Two factors might explain this mass spectral behavior: a decrease of acidity in the long chain ammonium ion or greater steric effects hindering the formation of the $[2M-H]^+$ cluster. In order to determine whether acidity is the limiting factor, a base, such as NH_4OH , was added to the sample solution, favouring deprotonation. Results revealed a much smaller $[2M-H]^+/M^+$ intensity ratio for M10N12COOH compared to M1N12COOH. This suggests that steric effects dictate the type of clusters formed for quaternary ammonium bromides containing a carboxylic group.

Due to the importance of the matrix in FAB/LSIMS, the effect of different matrices on the clustering processes of quaternary ammonium bromides in LSIMS was investigated. Results are presented in Table 1 for M1N14COOH, 0.3 M, a concentration at which the $[2M-H]^+/M^+$ intensity ratio was expected to be a plateau region [1]. It is observed that the $[2M-H]^+/M^+$ intensity ratio varies in the different matrices, following this trend:

DMBA > HEDS > NBA > TDE > GLY > AET > THIO

Thus, oxydizing matrices seem to favour the clustering of this quaternary ammonium bromide as opposed to reducing matrices. From Table 1, it is also observed that the $[2M-H]^+/M^+$ intensity ratio does not follow any trend in the matrix surface tension. The same observation

The rationalization of the variation of the clustering propensity of the quaternary ammonium bromides when changing the matrix in LSIMS is a difficult task. Many factors may affect the results. Firstly, physical properties of the matrix must be taken into account [2]. For example, the dielectric constant reflects on the ion solvation and ion pairing in solution and matrix surface tension is responsible for the migration of surface active analytes to the surface [2]. Unfortunately, not all the matrix properties are available in the literature. The analyte tendency to fragment for a given matrix or to form matrix-analyte adducts may also contribute to lower the abundance of the quaternary ammonium bromide clusters. Furthermore, one must consider that analyte mass transport mechanisms can vary from matrix to matrix, leading to a different surface replenishment which may in turn affect cluster formation. Consequently, there is no simple explanation for the results since many parameters are involved in the LSIMS ionization process. Nevertheless, differences in the matrices dielectric constants seem to be the more logical explanation for the different clustering abilities of the quaternary ammonium bromide when varying the matrix: if the matrix dielectric constant is high, the interaction between ions in solution is small, thus, lower cluster abundance may be expected.

Quaternary ammonium bromides are surface active molecules which accumulate at the surface in aqueous media to form a monolayer, and micelles at higher concentrations. The behavior of these molecules in solution mimics that of structures found in the human body such as cell membrane phospholipids. This work is a comparative study of the clustering behavior of quaternary ammonium bromides under LSIMS conditions in the positive and negative ion modes. These surfactants have the general structure shown in Figure 1. A 9:1 mixture of glycerol and water was employed as the liquid matrix.

Typical positive and negative ion LSIMS mass spectra of the quaternary ammonium bromides studied are shown in Figure 2 and 3 respectively. M^+ dominates the positive LSIMS mass spectrum and the dimer, M_2Br^+ , is the only cluster ion observed. MBr^- dominates the negative LSIMS mass spectrum and a higher number of cluster ions are observed ($[M_xBr_{x+1}]^-$ up to $x=4$) as compared to the positive-ion mode.

Two factors may explain the higher cluster formation in negative ion LSIMS. Firstly, as demonstrated in a previous study, in the positive ion mode, on this series of quaternary ammonium bromides, steric effects due to the side chain length (m) and hydrophobic effects caused by the long alkyl chain (n) destabilize the clusters formed [1]. Since clusters of the type $(MBr)_xBr$ contain a smaller number of quaternary ammonium cations (M) for a given "x" value than the $(MBr)_xM^+$ clusters, steric and hydrophobic effects within the negative LSIMS clusters are lessened. Secondly, cluster ions formed under positive ion LSIMS conditions are self-assembled by the interaction of a lesser number of charges as compared to the clusters in the negative ion mode. This suggests a stronger binding in the negative LSIMS clusters.

The variation of the dimer/monomer intensity ratio with varying analyte concentration for the quaternary ammonium bromides was investigated by LSIMS. In this study, a dimer is defined as a cluster containing two quaternary ammonium cations. Plots which are characteristic of the series of quaternary ammonium bromides in both positive and negative LSIMS are presented in Figure 4 and 5. It can be observed that the $M_2Br_3^+/MBR_2^+$ intensity ratio increases with the analyte concentration until it reaches a plateau where the ratio remains constant. This behavior is consistent with a related positive ion LSIMS study on this series of quaternary ammonium bromides where the M_2Br^+/M^+ intensity ratio was studied [1]. It was shown that the build up of an analyte monolayer occurs at the solution surface until a concentration is attained for which the analyte concentration at the surface remains constant. It is the plateau region where both M_2Br^+/M^+ and $M_2Br_3^+/MBR_2^+$ intensity ratios do not vary. Further analyte addition goes in the bulk of the solution. It is interesting to note that a hump, of about the same magnitude but of different shape, is apparent in the plots before attaining the plateau in both positive and negative LSIMS. The variation of the apparent molar heat capacities with the concentration also shows the same behavior for various surfactants [2]. This hump may be explained by the nonideal behavior of the solution due to the premicellar aggregation, as demonstrated in electrochemical studies

performed on a series of quaternary ammonium bromides [3]. In other words, a nonideal behavior exists in the surfactant solution between the completion of the monolayer and the formation of the micelles.

Also investigated was the glycerol/monomer intensity ratios in LSIMS for the quaternary ammonium bromides. As observed in Figure 4 in positive ion LSIMS, in general, the glycerol oligomer/ M^+ ratio is zero at the onset of the plateau. This is consistent with the complete surface coverage of the sample solution by the surface active analytes. However, Figure 5 shows that glycerol is almost always present in the negative ion LSIMS mass spectra, even at higher concentrations, in the concentration range studied (0-0.22M). $(3Gly-H^-)/MBR_2^-$ is the only ratio that reaches zero. Barber et al. have studied the glycerol trimer/sample ratio with varying cetyltrimethylammonium bromide concentration by FABMS, parallel to surface tension measurements [5]. In negative ion FAB, they have observed that this ratio is zero in the micelle region. Nevertheless, one must consider the drop of intensity of the glycerol oligomer/ MBR_2^- ratios rather than the reach of zero. Every glycerol oligomer/ MBR_2^- ratio reaches a plateau at 0.03M. Thus the presence of glycerol in the negative LSIMS mass spectra of quaternary ammonium bromides does not permit to know the aggregation state of these surfactants.

Laser Stimulated Matrix to Analyte Proton Transfer in Clusters

C. Mark Land and Gary R. Kinsel

The University of Texas at Arlington

Department of Chemistry and Biochemistry, Arlington, TX 76019-0065

The understanding of proton transfer reactions is critical to the elucidation of the mechanism of matrix-assisted-laser-desorption ionization, (MALDI). Although it is generally agreed that a proton transfer occurs in MALDI, the mechanism of the proton transfer reaction remains in question. Laser excitation of clusters of known matrix and analyte compositions may hold clues to the minimum requirements for MALDI to occur. Monitoring of both cationic and anionic products of this reaction should provide support for one or more of the currently postulated MALDI mechanisms[1].

Laser stimulated proton transfer reactions in heterogenous clusters have been monitored using mass spectrometric detection. These studies have revealed information about minimum composition requirements for excited-state proton transfer, (ESPT) from aromatic alcohols to NH_3 . These studies also provided kinetic and conformational data for these reactions[2]. A similar approach can be used to study MALDI matrix to analyte proton transfer if conditions can be identified which allow matrix/analyte cluster formation. These clusters can be used to determine the relative roles of the ESPT and radical-cation proton transfer, (RCPT) mechanisms in MALDI. In addition, the influence of cluster size and composition on proton transfer efficiency and information regarding the kinetics/thermodynamics of the reaction can be investigated. The insight gained from this information will aid in continued development of the MALDI technique.

In order to probe the mechanism of MALDI proton transfer, we have developed a laser desorption jet-entrainment multiphoton ionization time-of-flight mass spectrometer. Initial experiments have focused on the characterization of this instrument and exploration of conditions required for cluster formation. Conditions which lead to maximum laser-desorption/laser-ionization intensity were found by stepwise characterization of each of the timing and positioning parameters. Three events must be correctly timed in order to successfully perform these experiments. These events are the opening of the pulse valve, the firing of the desorbing laser, and the firing of the ionizing laser. Positioning parameters must also be optimized to obtain a maximum signal intensity. This procedure involves alignment of the pulse valve nozzle with the skimmer and movement of the ionizing beam across the source region until the skimmed molecular beam is irradiated with a focused ionizing beam.

Clustering conditions were found by saturating the pulse valve lines with phenol, (Ph), evacuating the lines with a mechanical pump, and adding pure NH_3 until a Ph/NH_3 cluster signal could be seen. The pressure of NH_3 required to see $\text{Ph}(\text{NH}_3)_n$ clustering was surprisingly small; much less than one atmosphere. Figure 1 shows the change in $\text{Ph}(\text{NH}_3)_n$ cluster distribution as a function of increasing NH_3 pressure. As NH_3 is added the $\text{Ph}(\text{NH}_3)_1$ cluster is first detected (Fig. 1, B). A large signal for NH_4^+ is also observed at low pressures of NH_3 . Lack of Ph^+ in the negative ion mass spectrum preliminarily identifies this proton transfer product as being formed by the RCPT mechanism. As the pressure is further increased the $\text{Ph}(\text{NH}_3)_n$ cluster distribution shifts to higher values of n , and the signal intensities decreases (Fig. 2). At even higher pressures the low mass clusters are no longer detectable and the NH_4^+ signal disappears. There are three possible explanations for these results: clusters do not form at high pressures, Ph is not efficiently excited in large clusters, or low signal to noise prevents detection of large clusters. The first explanation is not supported since addition of up to 20 psi of Argon has been shown to have no effect on clustering. This leaves the two remaining possibilities which are currently under investigation.

Studies of MALDI Matrix Proton Affinities by FT-ICR MS

Nan Li and Gary R. Kinsel

Department of Chemistry, The University of Texas at Arlington, Arlington, TX 76019-0065

Our previous investigations of the proton transfer reactions of a series of para substituted aniline molecules in a 3 R FT-ICR MS (1) have shown that for this series of model MALDI matrices the proton affinities of the neutral molecules are uniformly higher than the proton affinities of their radical cations. Semiempirical calculations of the proton affinities of the neutral molecules suggests that the most acidic of these radical cations are capable of protonating most, if not all, peptides and proteins. This result suggests that the radical cation and radical cation reaction products of MALDI matrices may play an important role in analyte protonation during MALDI.

We have continued our studies of the para substituted anilines by experimentally bracketing the proton affinities of the ionic products resulting from electron impact (EI) ionization of these compounds. In these experiments we chose NOT to isolate a specific intact radical cation or protonated ion since, in a typical MALDI experiment, all of these species and other fragment ions produced via a radical cation precursor pathway may be present. Thus, the proton affinities bracketed in these experiments necessarily represents the species (parent or fragment) having the lowest proton affinity. For these studies the model matrix, introduced via an unheated solids probe, was ionized by 70 eV EI. At variable delay times a reagent gas having a known proton affinity (2) was introduced to the FT-ICR chamber by a opening a series of two pulse valves. Pulse valve opening times were adjusted so the pressure (uncorrected) rose from the baseline of 4.5×10^{-9} torr to ca. 1×10^{-6} torr. After allowing time for the trapped ions and the reagent gas to react, excitation and detection was performed using an in-house constructed data system.

Initial experiments focused on defining the reagent gas pulse profile (see figure 1) as it passed through the FT-ICR cell. These experiments were necessary to define the earliest time that the pulse valve could be opened relative to EI of the model matrix compounds without ionizing the reagent gas. By increasing this delay between EI of the model matrix compound and introduction of the reagent gas, the trapped matrix ions available to undergo reaction with the reagent gas can change. Specifically, matrix radical cations can transfer protons to matrix neutrals to form protonated matrix molecules and / or additional fragment ions can be formed. Thus, these experiments provide a probe of changes in the proton affinity of the trapped species as these chemical transformations occur. Figure 2 shows the result of these experimental sequences applied to aniline with the reagent gases (a) ammonia and (b), (c) methylamine. No proton transfer occurs between the trapped parent and fragment aniline ions indicating that the proton affinities of these species are all greater than ammonia. Proton transfer is observed between the trapped parent and fragment aniline ions and methylamine indicating that the proton affinities of one or more of these species is lower than methylamine. This result is observed regardless of the delay between the aniline ionization and reagent gas introduction suggesting that both the protonated and radical cation forms of aniline have proton affinities lower than methylamine. Table I shows the results of these types of experiments applied to the series of para substituted anilines presently under investigation and the resulting bracketed proton affinities taken from reference 1.

It is of interest to note that the proton affinities of the majority of the model compounds are substantially lower than the proton affinities of the amino acids and the average value generally assigned to peptides and proteins (3). The involvement of these species in MALDI peptide and protein protonation is supported by these results. However, conventional MALDI studies using the model matrices generally give poor ionization of the amino acids. This apparent inconsistency leads us to continue our studies of the proton affinities of these of model MALDI matrices in an effort to further elucidate the mechanism of MALDI ion formation.

Figure 1. The profile of the reagent gas, acetone, admitted through pulsed valves during bracketing experiments.

Figure 2. EI mass spectra of aniline with reagent gases. a) ammonia Proton transfer is not observed b) methylamine using pulse sequence I. Protonated methylamine CH_3NH_3^+ is observed, suggesting that the proton affinities of the radical cations, or protonated form, or the fragments of aniline lie between ammonia and methylamine. c) methylamine using pulse sequence II. Protonated methylamine does not increase, confirming the proton affinity of the radical cation of aniline is higher than aniline

Cluster and Cluster Ion Formation from Organic Molecules Investigated by Multiphoton Ionization

A. Meffert, F. Moritz and J. Grotemeyer, Institut für Physikalische Chemie, Marcusstrasse 9-11, 97074 Würzburg, Germany

The gas phase behavior of some typical MALDI matrices (2,5-dihydroxybenzoic acid, vanillic acid, ferulic acid and sinapic acid) [1] concerning cluster formation has been investigated by means of time-of-flight mass spectrometry. The formation of homogenous clusters and especially of heterogenous dimers between MALDI matrix molecules and amino acids has been studied after IR laser desorption of the neutral molecules into a supersonic beam expansion and following multiphoton ionization (MUI). Multiphoton ionization was performed with ns and fs laser pulses at $\lambda = 260$ nm for comparison.

The aim of this study was to find out whether cluster formation between MALDI matrices and amino acids takes place and if there are hints that such clusters are concerned in the ionization mechanism of UV MALDI.

In first experiments the time-of-flight mass spectra of the pure MALDI matrices were measured after laser desorption and postionization optionally performed with ns or fs laser pulses. Whereas in the case of ns ionization only weak molecular ions but strong fragmentation corresponding to loss of the CO_2 -group are observed there is only little fragmentation with fs multiphoton ionization, the molecular ion always represents the basic peak of the spectrum. Beyond that homogenous clusters of the respective matrix substance are recognized in all fs spectra.

In subsequent experiments the argon jet was already saturated with ammonia before the desorption chamber. The addition of ammonia not only to the molecular ion but also to the homogenous matrix clusters can be noticed but again only in the case of fs-MUI. No free ammonia or NH_4^+ is observed (figure 1).

figure 1: ferulic acid and ammonia, ionization performed with fs laser pulses, $\lambda = 260$ nm

These results led to analogous experiments with amino acids. MALDI matrix and the respective amino acid were mixed in equal molar ratios and co-desorbed out of polyethylene into the supersonic beam. The employed amino acids were glycine, leucine, lysine and glutamic acid.

In all obtained mass spectra the formation of heterogenous dimers between matrix substance and amino acid is observed. More remarkable is the fact that the protonated amino acids are detected. As direct ionization of the amino acids is not possible under the chosen conditions because the molecules do not dispose of an adequate chromophore it seems likely that within the heterogenous dimer formed with the respective matrix substance a proton transfer from matrix to amino acid occurs and that the ionized dimer subsequently dissociates releasing the protonated amino acid. This proposed mechanism is supported by the peak profiles of the protonated amino acids which show a metastable widening.

figure 2: mass spectrum of ferulic acid and leucine obtained with fs-MUI at $\lambda = 260$ nm

The amount of heterogenous dimer as well as of protonated acid detected varies when different amino acids are mixed with the same MALDI matrix. The peak intensities of the protonated amino acids can be correlated to the proton affinities of the amino acids [2] and the heats of reaction ΔH_R for the dissociation of the heterogenous dimer releasing the protonated amino acid calculated with the help of thermochemical data.

CONTRIBUTION OF CHUNK EJECTION TO MOLECULAR ION FORMATION IN PDMS AND SIMS

R.Zubarev, P.Demirev, P.Håkansson, U.Abeywardena and B.U.R.Sundqvist

Division of Ion Physics, Uppsala university, Box 535, S-751 21 Uppsala, Sweden

In particle-induced desorption, the initial parameters of the desorbed species serve as fingerprints of the desorption processes. The time of ion formation and initial kinetic energy distributions are especially important in the time-of-flight (TOF) method of ion separation, where these parameters are directly coupled to the instrumental resolution and mass accuracy. In plasma desorption mass spectrometry (PDMS) involving MeV primary ions, as well as in keV ion bombardment (SIMS), the molecular ions are believed to be formed within 1 ns with an initial kinetic energy of a few eV. This should lead to a resolution of at least 10,000 in TOF mass spectrometry, while in practice it is limited to 4,000-5,000 for biomolecules. This study was undertaken in order to clarify the sources of such a discrepancy.

Initial kinetic energies of secondary ions were measured on a reflector-equipped TOF mass spectrometer using the reflector scanning technique [1]. The method work in the following way. The intensities of ion peaks are measured while the difference between the accelerating voltage U_{acc} and reflecting potential U_{ref} is scanned. The obtained curves are integral distributions which can be converted by differentiating to initial kinetic energy distributions.

The results suggest that, in PDMS, some fraction of molecular, specific fragment (immonium), and low mass ions exhibit energy deficits ranging from few to several tens of eV. The deficit is especially large for non-covalent cluster ions (dimers and trimers), and for large specific fragment ions (such as $[M-COOH]^+$). Such fragment ions as CH_3^+ , NH_4^+ and immonium ions of amino acid residues in peptides show moderate to large deficit.

On the contrary, some low mass ions (H^+ and C^+), directly ionized species (C_6O^+) and preformed molecular ions (complex of valinomycin with Cs^+) show no or very little energy deficit. The percentage of ions possessing the deficit is larger for MH^+ ions than that for MNa^+ . In SIMS, the deficits are similar, except for molecular ions that show only a small deficit. No non-covalently bound clusters have been observed in SIMS.

Unlike MALDI, the ion yields in both PDMS and SIMS are too low for extensive gas-phase ion-molecule reactions. A possible explanation of the observed facts is that the species are desorbed not only as individual ions, but also as charged aggregates ("chunk ejection") dissociating later in the gas-phase. The chunks seem to be larger and cooler in PDMS where they can include non-covalently bound molecular clusters, while in SIMS they are smaller and hotter, and for large biomolecules contain only single species.

In particle desorption techniques, matrices play a crucial role. The best matrix found so far in PDMS is nitrocellulose (NC), combining several important features, like resistance to water, ethanol and weak organic acids, excellent adsorption properties for peptides and proteins, and last but not least - explosive property. Chemical energy released in the interaction of the primary particle with the matrix gives an extra momentum to the sputtered material, allowing more molecules to break the aggregate binding links and escape into the gas phase. The fact that nitrocellulose is also the best matrix in SIMS, where the sputtering mechanism is very different from that in PDMS, demonstrates that the matrix efficiency might be rather independent upon the primary energy-pumping mechanism. The theory of the matrices in particle desorption techniques is not yet developed. It is not known, for example, which of the matrix properties is the most important. This study was undertaken in order to test other conventional explosives, than NC, as potential matrices for PDMS.

Trinitrotoluene (trotyl, TNT), cyclotetramethylenetetranitramine (HMX), hexahydro-1,3,5-trinitro-5-triazine (hexogen, RDX), pentaerythritol tetranitrate (pentrit, PETN) were tested in a comparison with a) the standard nitrocellulose matrix and b) no matrix at all.

Cyclic peptide gramicidin S (MW 1141) was used as a test substance for all matrices. The matrix material was dissolved in acetone and spin-casted on the top of the aluminised mylar backing. The drop of the peptide solution in ethanol was placed on the top of the matrix and let to dry. Commercial plasma desorption time-of-flight mass spectrometer BIOION-20 (BioIon, Uppsala, Sweden) utilising the Cf-252 fission fragments as primary particles, was used in this study. The instrument was equipped with the reflectron in order to increase the mass resolution.

The results suggest that, although all compounds give a pronounced matrix effect (i.e. increase the molecular ion yield compared to the bare sample), none of them can be compared with nitrocellulose in efficiency. At the same time, some of the tested compounds are more powerful explosives than NC. There seems to be no correlation between the rate of detonation of the explosive, and its property as matrix in PDMS. The reason for the diminished matrix effect can be that the other explosives form microcrystals that do not embody the analyte molecules. The micro-detonation wave decays rapidly in such an inhomogeneous media. So, the probability for these materials to sputter bioorganic molecules should be less than that for a rather homogeneous system of polymeric NC with adsorbed biomolecules.

The comparison of two rather similar explosives, RDX and HMX, supports this suggestion. Indeed, the molecule of HMX is just a larger ring than RDX (4 -CH₂-N-NO₂- groups vs. 3). They both have similar physical and chemical properties, and almost the same detonation rate. But as PDMS matrix, larger molecule HMX demonstrates 50% higher yield than RDX. It would be interesting to make such a comparison using even larger molecules of the same type.

The approach of revealing the important matrix parameters for particle desorption mass spectrometry opens the way of creating assisting matrices by using high explosives properly mixed with the analyte molecules and, possibly, with other components assisting the gas phase proton transfer. The custom-made matrix molecule, which is still to be found or synthesised, could be a polymer with mixed nitro- and hydroxyl- groups, soluble in acetone and resistant to water, ethanol and weak organic acids. The matrix will bind the analyte molecules, prevent their aggregation, allow de-contaminating or digesting techniques to be applied *in situ*, supply the chemical energy to the desorption and an access of protons in the gas phase for the molecular ion production. The other possibility is to create water-soluble high explosive that would incorporate the analyte molecules in their crystals, similar to the matrices conventionally used in MALDI. There should also be a way to grow microcrystals of such a matrix (for example, by electrospraying), that would be small enough to be sputtered by a single primary particle. The calculations show that, in PDMS, the lower limit of the sizes for such crystals is ca. 30 nm. The upper limit will be determined by the amount of chemical energy released by the matrix, in other words - by its explosive property.

Primary Ion Dosimetry

One reason for measuring the flux and flux density of a primary beam is for fundamental measurements of sputtering rate, secondary ion yield and other properties related to secondary ion emission. Measurement of primary flux and flux density is a relatively simple matter in cases where the primary beam is comprised of ions, such as Cs^+ . For these types of beams, a simple arrangement of a Faraday cup with a known aperture is sufficient. There are cases, however, where measurement of primary flux and flux density are far more difficult, and the accuracy of the measurement less reliable. A notable example of such a case is the flux and flux density of fast atom beams formed by charge exchange, and widely used in FAB. Another example of interest is for application of multiply charged glycerol clusters to ablate the surface of organic samples. These beams contain glycerol cluster ions with a molecular weight distribution that extends beyond 10^7 , and charge state distribution that includes in excess to +100 electronic charges. By using such a beam, it is possible to obtain secondary ion mass spectra characteristic of the sample, well beyond the dose called the static SIMS limit, at which point, secondary ion emission ceases to be characteristic of the sample.

We have found that the secondary ion spectrum of choline chloride is independent of primary ion dose, and mainly consists of the m/z 104, choline ion. A known amount of choline chloride/methanol solution, typically 1 μL can be deposited onto a surface by using an Eppendorf pipette. The drop will spread rapidly to an area of about 0.75 cm^2 . When the methanol dries, the residual choline chloride spot is readily detected by using a low power microscope. The sample can then be inserted into the mass spectrometer. For our purposes, we measured the intensity of secondary choline ions as a 10 keV Cs^+ primary ion beam of 2 nA was repeatedly rastered over an area of $2.5 \text{ mm} \times 2.5 \text{ mm}$. The intensity of Cs^+ implanted and then re-emitted was also measured.

Figure 1 is a plot of the results obtained from a sample of 1 μL of 10^{-2} M choline chloride. Up to a dose of approximately $4.5 \times 10^{13} \text{ ions/cm}^2$ primary Cs^+ ions, no effect is observed in the emission, or the recorded mass spectra. From calculations based upon ion implantation studies Cs^+ is implanted to a depth of 316 $\text{\AA}$ in choline, and none are backscattered, consistent with the data. However, beyond this dose, secondary ion emission of the choline gradually diminishes until at a dose of 10^{14} , although there is no evidence of chemical noise in the spectra. Similar results were obtained from solutions of different concentrations, except that the rate of decay of the choline emission varied inversely with sample thickness. Based upon the number of moles choline chloride and the area of the dried spot, it is estimated that the spot thickness of the sample shown in Figure 1 was about 34 molecular layers, approximately 230 $\text{\AA}$, less than the implant depth of 10 keV Cs^+ on choline chloride. Some variation in this thickness is expected, owing to variations in drying, and a Marangoni effect, i.e., surface tension driven migration of choline to the periphery of the droplet.

From these data, it is possible to establish two things. First, we estimate that approximate

10-20 choline molecules are sputtered per incoming primary ion beam. Secondly, by measuring the loss of choline secondary ion emission from a sample of known thickness, it is possible to establish the primary flux and flux density of a high energy primary beam, at least in terms of the sputtering rate of 10 keV Cs^+ .

INTRODUCTION

We are evaluating a new method for mixture analysis using ion induced desorption, Time-of-Flight mass spectrometry and coincidence counting data analysis. Our approach is to identify secondary ions (atomic, molecular, fragment and cluster) detected together from the same primary ion impact and related by their origin from the same molecular compound. This is possible made by monitoring the co-desorption or coincidental emission of secondary ions. By comparison to an internal standard, the relative intensity distribution of ions can be adjusted to produced patterns that correlate secondary ions from the same compound. This provides chemical characterization of heterogeneous samples using only a single linear TOF mass analyzer.

EXPERIMENTAL METHOD

MeV energy primary ions (252-Cf fission fragments) were used for this study, although keV monoatomic and polyatomic ions can also be used. Secondary ion mass analysis is by Time-of-Flight. Because the experiment is performed in the event-by-event mode, coincidence counting methods allow us to collect spectra that are composed of only those primary ion impacts that produce at least a secondary ion of interest. Coincidence mass spectra contain the sum of those desorption events, and provide data on the frequency with which two or more secondary ions are desorbed from the same ion impact. A series of coincidence spectra can be acquired simultaneously with a conventional mass spectrum (all secondary ions from all primary ion impacts) using dedicated software.

RESULTS

The relative intensity of a secondary ion in any particular coincidence spectrum can be adjusted by dividing it by the relative intensity of the same ion in the coincidence with H^+ spectrum. There is an equal probability among all

secondary ions (within 10% variance) for co-desorption with H^+ . Thus the H^+ coincidence spectrum can be used as an internal standard. A plot of the relative intensity ratios calculated using the data from the coincidence with Na^+ , coincidence with K^+ and coincidence with Cs^+ mass spectra acquired from the same equal mole mix sample of NaF, KCl and CsI in shown in figures 1a, b and c respectively. The fingerprint patterns that are produced show that those ions that originate from the same compound have ratio values much greater than unity.

Figure 1

CONCLUSION

Using a careful measure of the co-desorption frequency of secondary ions with each other and with H^+ from mixture samples of simple alkali halides, correlation patterns can be derived that identify those secondary ions that are related by virtue of origin from the same component. This information can be considered analogous to that gained using the MS/MS methods of mass spectrometry. Future work will center on applying this methodology to the analysis of mixtures of unknown composition using statistical models. The advantage to this approach is that the coincidence spectra (up to 10 different spectra) are collected simultaneously with a conventional TOF spectrum in one experiment, without the need for multiple mass analysis stages.

Comparison of FAB and MALDI in the Evaluation of Amino Acid Proton Affinities

Francisco M. L. Amado^{*1}, M. Graça Santana-Marques¹, A. J. Ferrer-Correia¹ and Kenneth B. Tomer²

¹ Department of Chemistry, University of Aveiro, 3830 Aveiro, Portugal

² Laboratory of Molecular Biophysics, PO Box 12233, Research Triangle Park, NC 27709

INTRODUCTION

It has been suggested that ion production in FAB and MALDI is dependent on the hydrophobic properties of the sample and on its basicity (proton affinities), e.g. on its ability to protonate.^{1,2,3} Published models for the ionisation processes for FAB and MALDI describe desorption and ionisation as separate processes. The authors, in general, agree that formation of a dense gas-phase region occurs during the desorption process.^{1,4,5,6} For MALDI the neutral ion ratio is approximately 10^{-3} to 10^{-4} or even 10^{-5} .⁸ For FAB similar values have been proposed.¹

It was demonstrated by Bokelmann *et al.*⁹ that ion formation in MALDI is a gas phase mechanism. It has also been shown that basic peptides present the higher signals and that the peptide amino acid composition has a dominant role in ion production in MALDI.² For FAB discussion about the phase where the ionisation occurs, liquid or gas, still remains an open question. A strong correlation of the ion yield with the hydrophobic properties of the neutral amino acid has been found¹⁰.

In this work we compare the relative abundance values of protonated amino acids, isolated and in binary mixtures, for FAB and MALDI, and also the relative abundances of the proton bound dimers with glycerol, for FAB.

RESULTS and CONCLUSIONS

In FAB, the hydrophobic properties of the amino acids are more important than in MALDI, where the basic amino acids Arg, Lys, Pro and His have the highest relative abundances (data not shown). Both basicity and hydrophobic properties play important roles in these two desorption techniques. Comparing the results obtained with FAB and MALDI we suggest that similar competition processes determine the protonated ion yield.

The order obtained by the variation of the ratio of the relative abundances in binary mixtures agrees with published proton affinities, with no relation with solutions basicities (Table 1). This suggests for both cases a gas phase ionization mechanism. The order of the relative abundances of amino acid-glycerol clusters obtained for FAB (Figure 1) leads to the same conclusion.

The method used in this work may be useful for proton affinities evaluation of similar compounds, e.g. to PA evaluation of peptides or even proteins, if taking in consideration mass and chemical discrimination.

Table 1 - PA values obtained with different methods^{11,12} are compared with the order found for FAB and MALDI experiments. It can be seen that there is a good correlation between our results and the published PA values.

Amino Acid	Increasing order of PA determined by FAB	Increasing order of PA determined by MALDI	PA values by Gorman <i>et al.</i> [11] (kcal/mol.)	PA values by Bojesen <i>et al.</i> [12] (kcal/mol.)	pkb ₁

Conditions in favor of a linear dependence of analyte ion signals on concentration in FAB MS

G. Klesper, Ch. Mertens, S. Pätzold and F.W. Röllgen
Institut für Physikalische Chemie, Universität Bonn, Wegelerstr. 12,
D-53115 Bonn, Germany

The use of FAB MS for quantification of analyte concentrations is difficult for a number of reasons [1]. The analyte ion signal depends on the concentration in the near surface layer of the sample/matrix solution which, prior to the onset of bombardment, reflects the surface activity of the analyte and changes with solvent evaporation. The surface concentration and the ionization conditions also change during bombardment of the layer due to the accumulation of radiation damage and preferential sputtering and evaporation of matrix molecules. To achieve a linear dependence of the analyte ion signal on concentration conditions are required which keep the concentration in the near surface layer proportional to the concentration in the bulk of the solution. In addition the ionization conditions must be independent of concentration.

Experimental conditions which should favor a linear dependence of molecular ion signals on concentration are the following: a) the use of a matrix of low vapor pressure, such as glycerol without cosolvents of high vapor pressure, b) a short residence time of the sample solution in vacuum prior to the onset of bombardment, c) the recording of the molecular ion intensities after removal of the initial surface layer by sputtering, and d) the use of an incident particle beam of high current density which is important for fast removal of the surface layer and for establishing sputtering and ionization conditions determined by the bulk of the solution.

We have measured the dependence of molecular ion signals on concentration by FAB MS for different compounds dissolved in pure glycerol. Results are shown for raffinose and adenine in Fig. 1. While raffinose is well soluble at any concentration in glycerol, adenine is only soluble up to a concentration of about 0.2 mol/dm³ and is surface active. The lowest concentration used was limited by the chemical noise. As shown in Fig. 1a and 1b the concentration dependence of the (M+H)⁺ ions does not reflect surface activity. It is linear up to about 0.01 mol/dm³ and slightly deviates from linearity above, i.e. decreasing for both compounds. This deviation is compensated for, or overcompensated, by the decrease of the glycerol cluster ion signal in this concentration range as shown in Fig. 1c and 1d, where the concentration dependence of the intensity ratio $I(M+H)^+/I(G_n+H)^+$ is shown. The decrease of the molecular ion intensity at higher concentration can be attributed to a change in the ionization conditions as indicated by a slight increase of the fragmentation of raffinose.

[1] E. Junker, K.P. Wirth and F.W. Röllgen, Int. J. Mass Spectrom. Ion Phys. 122 (1992) 3.

Fig. 1: Dependence of the (M+H)⁺ ion intensity and of the $I(M+H)^+/I(G_n+H)^+$ intensity ratio on concentration in FAB MS of raffinose, (a) and (c), and adenine, (b) and (d), with pure glycerol as matrix/solvent.

Ion Yields from Matrix Surface Bombarded with 6 keV Xe, Ar, He, Air, and Isobutane Beams

Mitsuo Takayama

Pharmaceutical Sciences, Toho University, 2-2-1 Miyama, Funabashi, Chiba 274, Japan.

It is of interest in connection with the elastic and inelastic characteristics in two-body collisions to consider dynamic events which are induced by bombarding the surface of a matrix solution with a high-energy (~ keV) atom beam, under fast-atom bombardment (FAB) conditions. The time sequence of the events could be divided into following steps;¹⁾

- i) t_0 : collisions between a molecule in the matrix surface layer, B_{surf} , and a fast-atom, A_{fast} , and a momentum transfer from A_{fast} to B_{surf} , ($t=t_0$, a most early event).
- ii) t_1 : collision cascade with a momentum transfer between matrix molecules, B , and/or analyte molecules, M , in a condensed-phase, ($t_1=t_0 \sim fsec/elementary\ cascade$).
- iii) t_2 : formation of a dense gas-like "cavity" consisting of molecules having a high translational energy, B_{fast} and M_{fast} , ($t_2=t_0 \sim psec$).
- iv) t_3 : gas-phase ion/molecule reactions owing to frequent collisions between ions and/or neutral species in the cavity, the sputtering of ionic and neutral species, and the recovery of a disturbed-surface, ($t_3-t_2 \sim psec$ (frequent collisions), life time of a cavity).

In these FAB processes, the ion formation first occurs by the collision cascade (ii) and the ion formation as a secondary process occurs by ion/molecule reactions in the cavity formed (iv). The former might reflect solvation structures such as "preformed ion" and "hydrogen bonding" states in solution, and the latter reflects gas-phase ion chemistry relating to proton affinity, electron affinity, hydride affinity, and ionization energy of matrix and analyte molecules.

On the other hand, the sputter yield for i -th ionic species per cavity, y_i , under matrix FAB conditions could generally be given by

$$y_i = n \times w_i = n \times (r_i + k_i) \quad (1)$$

where n represents the gas-phase population of ionic and neutral species per cavity and w_i the probability for i -th ion formation. The probability w_i could be divided into a rate $r_i (=n_i/n)$ corresponding to the ions n_i sputtered directly from solvation states and a kinetic term k_i due to gas-phase ion/molecule reactions. The gas-phase population n seems to be a most important quantity for the ion yield. The quantity n , which gives a cavity size and is caused by desolvation and phase-explosion, may increase with increasing the degree of elastic collisions between B_{surf} and A_{fast} . Since the most early event (i) is a two-body collision,

$$E_{max} = E_0 \{m_B / (m_B + m_A)\} \quad (2)$$

we would apply a relation (2) for inelastic collisions to our system. E_{max} means maximum internal energy for a target molecule of mass m_B (matrix molecule), that can be converted from the kinetic energy E_0 of a fast-atom of mass m_A . The E_{max} will be utilized to ionize and degrade the molecules B like a gas-phase FAB process. Here we introduce a relation for elastic collisions, which is modified from (2), as follows;

$$W_{min} = E_0 - E_{max} = E_0 \{1 - m_B / (m_B + m_A)\} \quad (3)$$

W_{min} means the minimum energy or work for the formation of a cavity. From (3), the degree of elastic collisions, X_{min} , can be defined as

$$X_{min} = W_{min} / E_0 \quad (4)$$

Since the X_{min} could be directly correlated with the population n , it seems to be significant to examine a relationship between the ion yield y_i and X_{min} by changing fast-atom species A_{fast} .

Employing *m*-nitrobenzyl alcohol (NBA, m.w.153), 6 keV fast-atoms, and 6×10^6 Torr source

pressure, the ion yields for some different analytes sinapinic acid (m.w.224), Trolox (m.w.250), methyl stearate (m.w.298), α -tocopherol (m.w.430), compound 1 (m.w.472), and esperamicin A₁ (m.w.1,324) are plotted against the X_{min} values for He ($X_{min}=0.025$), Ar ($X_{min}=0.207$), and Xe ($X_{min}=0.461$) (Fig. 1).

Figure 1

Furthermore, the ion yields with 6 keV fast-molecule (air, isobutane) have been compared with those with fast-atom (Fig.2). For all the compounds examined, the order of ion yields was He<Isobutane<Air<Ar<Xe which is not in accord with the order of increasing mass or X_{min} of fast-particles, though the ion yields with fast-atom could be successfully correlated with X_{min} (degree of elastic collision), as shown in Fig.1. This may be due to a limit of the classical collision theory employed here, i.e., the distinction regarding the collisional energy partitions between atom and polyatomic systems. For the ion yield estimation, some effects (polyatomicity, atom number, degree of freedom, and structure) of fast-particles on the two-body processes should be considered in collision theory (2). The result obtained here was not in accord with the ion yield in a SIMS experiment.²⁾

Electrospray - MS/CAD/MS Investigations of Transition Metal Ion Complexation with a New Hexahomotriazacalix[3]arene

Calin G. Znamirovski, Si Wu, Philip D. Hampton, and Christie G. Enke

Department of Chemistry, University of New Mexico, Albuquerque, New Mexico, 87131-1096, USA

Electrospray mass spectrometry (ES-MS) applied to coordination and organometallic systems has recently become a preferred tool for inorganic analytical and synthetic chemists. In the present study we applied ES-MS to the study of hexahomotriazacalix[3]arene, a novel polydentate, macrocyclic ligand (H_3L) (Figure 1), and

Figure 1 - The structure of hexahomotriazacalix[3]arene

that it is a more favorable complexation medium in this particular instance. Also, we noticed the appearance of ligand substructures (L'), either complexed or uncomplexed, which are consistent with the trimeric structure of H_3L , and with the expected losses of N-pendant arms (P).

A comparative study of the complexation of the three transition metals considered was also performed. The ES-MS spectra of methanolic solutions of Sc(III) and Y(III) are shown in Figure 2. The appearance of a 1:2 "sandwich" complex ion in these ES-MS spectra is surprising, the species being apparently a product of an "in-source" process associated with the electrospray ion formation. Collisionally activated dissociation (CAD) in conjunction with tandem mass spectrometry was employed for both structure elucidation and charge state determination for certain ionic species that appeared in the ES-MS spectra. Specific dissociation patterns were noticed in the CAD spectra of the precursor ions at m/z 685 (Figure 2.a) and m/z 707 (Figure 2.b), that conclusively proved the doubly charged state for these structurally analogous species.

its coordination trends toward three transition metals, Sc(III), Y(III), and La(III).

Solutions of 0.1 M $ScCl_3$, YCl_3 , and $LaCl_3$, respectively, in methanol were directly injected in the electrospray source (Finnigan MAT).

The solvent effects on complexation were assessed based on the appearance of the ES-MS spectra of Sc(III) solutions in methanol and acetonitrile, respectively. We found that more scandium-containing ionic species are present in higher abundances in the case of methanol solutions, leading to the conclusion

Figure 2 - ES-MS spectra of (a) Sc(III) and (b) Y(III) complexed with H_3L in methanol

A Transportable Actinide Mass Spectrometer (TAMS) System.

Michael S. Kahr, Jose' A. Olivares, and Kent D. Abney

Los Alamos National Laboratory, Los Alamos, NM 87545

An important analytical need exists for field instrumentation capable of providing isotopic analysis of uranium and plutonium samples. Currently, the time required for actinide isotopic analysis is weeks to months. Clearly this delay is too long to make appropriate decisions rapidly concerning nuclear material proliferation. This data could be obtained rapidly on site by employing a transportable field mass spectrometer system which has been developed by our group.

A compact transportable mass spectrometric system based on a commercially available quadrupole mass spectrometer system has been developed and evaluated. The system has been minimized for size and weight and is built into a commercially available rack which fits into a rugged suitcase designed to protect the contents for shipping. The system is controlled using a laptop computer. The vacuum system consists of a compact 45 L/Sec (N_2) turbomolecular pump which pumps the high vacuum chamber which houses the mass spectrometer. Backing the turbomolecular pump and for the purpose of evacuation of the gas manifold is a 1.13 cfm corrosive series two stage direct drive mechanical pump. To protect the pump and the operator, a soda lime trap is situated between the gas manifold and the mechanical pump. While corrosive gasses are pumped from the gas manifold, a solenoid valve isolates the turbomolecular pump.

The system employs the powerful fluorinating agent chlorine trifluoride. Chlorine trifluoride successfully and rapidly converts all uranium species of interest into uranium hexafluoride with reaction rates in the range of micrograms per second which depends on the surface area of the solid uranium sample. The uranium hexafluoride is ionized by electron impact in the mass spectrometer. Isotopic ratios are measured from the doubly charged uranium ion.

RECENT IMPROVEMENTS OF A NEW THERMAL IONIZATION CAVITY SOURCE FOR MASS SPECTROMETRY

Yixiang Duan, José A. Olivares, Ray E. Danen and Timothy J. Cleland

Los Alamos National Laboratory, CST-9, MS J514, Los Alamos, NM, 87545.

Thermal ionization mass spectrometry is one of the most powerful techniques for isotope ratio measurements. Traditional thermal ionization sources for mass spectrometry involve the use of resistively heated single, double, triple and flat ribbon-type filaments for surface ionization. Although the technique is sensitive, the sample utilization efficiency is very limited in the filament-type sources. Thus, research to improve the sample utilization efficiency has been widely explored by mass spectroscopists, including change of filament shape and geometry, improvement of ion transport, use of chemical ionization enhancers, and development of new types of thermal ionization sources.

One of the most significant improvements in sample utilization efficiency is the development of tube-type sources, which can provide orders of magnitude enhancement in efficiency. The first tube-type source was developed by Beyer et al. [1] in the early 1970's in USSR, and almost simultaneously by Johnson et al. [2] in Lawrence Livermore National Laboratory. In the tube-type sources, a refractory metal tube (called a crucible) was used instead of a filament to evaporate and ionize the samples. The high ionization temperature was achieved by using electron impact from a heated filament surrounding the crucible. The tube-type sources have much higher efficiency compared with the filament-type sources, and have been extensively used for coupling to large scale isotope separators. Last year we presented a prototype ion source design for mass spectrometry, which uses a tungsten crucible with a deep cavity for sample loading and enhanced surface ionization [3]. The crucible is heated by high energy electron bombardment. We named this ion source as a thermal ionization cavity (TIC). Although the advantages of the proto-type source are obvious compared with filament-type sources and traditional tube-type sources, there are still some potential problems which need to be considered to further improve its performance. Basically, the original TIC source design had two major constraints, sample loading and positioning were awkward and problematic.

Recent developments in our laboratories has lead to a series of modifications from the original design which makes the TIC source less complex and more compact and flexible. In the present work, we have designed an innovative TIC source which overcomes the major limitations of the previous model. In this new version of the source, a vacuum interlock system and translational stage have been manufactured from commercially available components. An adjustable insertion probe is set up to hold the crucible and to adjust the crucible's location in the heater region. As shown in Figure 1, a new interface has been specially designed and tested for coupling to a quadrupole mass spectrometer. With these modifications, the source is easier to operate and handle, while maximizing sample throughput.

The performance of the newly-developed source has been examined in this work. The experiment includes background examination, operating conditions for various elements from rare earths to actinides, precision, and ionization efficiency measurements, as well as diagnostic studies for the new source. The major background peaks were found for potassium and sodium at very low emission current, which mainly originates from the materials used for the crucible. The optimization work for different elements shows that the emission current used is element-dependent, mainly based on the elemental ionization potential and the available vapor pressure at a given temperature. The ionization efficiencies were measured for some elements with the quadrupole mass spectrometer, and compared with the results obtained from isotope separator system. For europium, the ionization efficiency measured with quadrupole MS is as high as 72%, which is the same to the value obtained from the isotope separator system. The diagnostic study of the new source shows that the crucible position is one of the most crucial parameters for sensitivity and performance. A typical examination result of sampling distance effect on europium peaks

shows a maximum signal peak at sampling distance of about 0.06" from the end of the shielding can. Other parameters, such as, emission current, bias voltage, and SEM voltage, were also found to influence the signal magnitude and even isotope ratio measurements. Stability tests demonstrate that the source can be run several weeks with a fixed emission current. This characteristic is definitely of benefit for the efficiency measurements and high precision analysis.

Finally, we would like to conclude that the source developed here possesses the characteristics of high efficiency, low complexity, easy adjustment, and flexible sample loading. The compact structure of the source makes it applicable to any type of mass spectrometer. Further miniaturization of the current source is under process to couple to a portable quadrupole mass spectrometer.

Preliminary Figures of Merit of a Plasma-Source Mass Spectrograph

Thomas W. Burgoyne, Gary M. Hieftje, and Ronald A. Hites
Department of Chemistry and School of Public and Environmental Affairs
Indiana University, Bloomington, IN 47405

Introduction

We have designed a mass spectrometer with an array detector (a mass spectrograph) that is "tailor made" for multielement analysis from a plasma source. It is compact (approximately 80 cm in length) and is designed to detect a complete atomic mass spectrum in two mass windows that straddle, but avoid, argon. We present three figures of merit of the current instrument: precision, detection limits, and resolution. These figures of merit are important characteristics that gauge a mass spectrometer's performance as well as indicate where weaknesses exist. These three figures of merit reveal some of the mass spectrograph's present and future strengths and weaknesses.

Brief Instrument Description

The instrument is based on the Mattauch-Herzog geometry which is compact, geometrically simple, and has a long linear focal plane. At the focal plane of this instrument sits a two-stage, 2.54-cm (diameter) array detector (12- μ m pixels) with an active phosphor diameter of 17 mm (Hamamatsu, Bridgewater, NJ). The location of the detector is such that the high-mass radius (R_H) is 10 cm and the low-mass radius (R_L) is 9 cm. Normal voltages on the detector are: grid = 0 V (post acceleration), front MCP = -3 kV, back MCP = 2 kV, and phosphor = +2 kV. At present, the detector is not shielded from fringing magnetic fields. The entrance slit is 0.55-mm wide and the present slit width produces a theoretical resolution of 145. The phosphor image is optically transferred by a two-lens system (the focal lengths of the first and second lenses are 250 mm and 180 mm, respectively) onto a charge coupled device (CCD) detector array. For all spectra recorded, the CCD was binned two pixels in the x-direction and four pixels in the y-direction.

Figures of Merit

Precision. Precision measurements were conducted with a glow discharge mass spectrum of copper and zinc in Naval Brass B (SRM 1107). For this mass spectrum, twenty images were captured with 10-second integration times and then averaged. The averaged peak intensities for both $^{63}\text{Cu}^+$ and $^{65}\text{Cu}^+$ revealed a large fluctuation in the signal. Although the source of these fluctuations was not identified, the relative standard deviations (RSD) of the $^{63}\text{Cu}^+$ and $^{65}\text{Cu}^+$ signals was 26% and 28%, respectively. The RSD of the ratio of these two signals is 1.9%, indicating a high degree of correlation in the fluctuations of the two isotopic signals. Also, this example represents a worse case; the RSD of the $^{63}\text{Cu}^+$ and $^{65}\text{Cu}^+$ ratio for the first 8 images (where no dramatic changes in signal have occurred) is 0.5%.

Detection Limits. Nickel and lead are present in Naval Brass B at concentrations of 980 ppm and 1800 ppm, respectively. A nickel mass spectrum was acquired as the average of 5 images taken with an integration time of 20 seconds and 1000 V across the MCP. A lead mass spectrum was acquired as the average of 5 images taken with an integration time of 10 seconds and 1300 V across the MCP. The calculated detection limits for nickel and lead are 8 ppm and 1 ppm, respectively. Although the detection limits are modest, they were attained with moderate integration times and detector gains. At more realistic detector voltages and longer integration times (60 s), detection limits should improve by two to three orders of magnitude.

Resolution. Resolution is currently disappointing and lies between 50 and 100, depending on peak definition. Similarly, abundance sensitivity is unacceptable. The main reason for this limited resolution is demonstrated in Figure 1 which shows an ICP mass spectrum of 100 ppm magnesium. The peak shape is far from an expected Gaussian distribution; similar peak shapes have been reported by others (1).

To better understand the origin of the peak shape, let us compare the measured and theoretical image widths. Each pixel on the CCD is 23 μ m wide; two pixels are binned in the x-direction. Using this and the

magnification of the light optics results in each pixel on the x-axis being equal to 63.9 μ m. At FWHM, the peak width for ^{24}Mg is 10 pixels or 639 μ m. We can calculate the theoretical peak width from measuring the distance between masses of 24, 25, and 26 and the theoretical mass dispersion (see Reference 2 for details). Performing this calculation, R_m for ^{24}Mg is 9.40 cm. The line-width (dy) on the array detector is given by:

$$dy = \frac{R_m \sqrt{2} S}{R_e}$$

where R_m is the radius of the ion trajectory in the magnetic sector, R_e is the radius of the ion trajectory in the electric sector (16.03 cm), and S is the slit width (550 μ m). Therefore, we calculate a theoretical peak width of 456 μ m. The calculated value is less than the measured value (a difference of approximately 3 pixels) and indicates that either ion focusing (in the mass spectrograph) or light focusing (from the phosphor to the CCD) can be improved.

Peak Shape. To further investigate the peak shape we placed a 350- μ m slit in front of the MCP. The imaged peak shape is almost identical to that in the acquired mass spectrum which suggests that the poor peak shape originates within the array detector or the CCD and not in the mass spectrograph (ion optics). At FWHM, the measured peak width is 8 pixels or 511 μ m wide, in good agreement with what one would expect, 495 μ m ($350\sqrt{2}$). Therefore, the peak width at FWHM is a good indicator of image width. Experiments have led us to believe that the poor peak shape is a result of the detector being affected by the fringing magnetic field of the magnetic sector. If so, magnetic shunts and shielding should alleviate the problem.

Conclusions

Some preliminary figures of merit of a plasma-source mass spectrograph have been presented. Precision, detection limits, and resolution were evaluated. The instrument's strength is its simultaneous detection capability, which was demonstrated by improving precision through ratioing techniques. Although detection limits only modest (due to the conditions under which they were taken), they can readily be improved. Lastly, the resolution was disappointing, and was attributed to a relatively wide entrance slit width and a poor peak shape. The former can be improved readily; in contrast, the exact cause of the poor peak shape is still to be determined, though it originates within the array detector.

Determination of elements of pharmaceutical interest in biological samples of human and animal origin by ICP-MS

E. Deseyve, B. Schmid and K. Michaelis, L.A.B. GmbH, Neu-Ulm, Germany

Due to the important role of elements in the function of the human body, their quantification is of growing interest. It is important to monitor the base levels and higher levels and to evaluate sources of uptake, either caused by different environmental background or by controlled pharmaceutical application of various elements. Of special interest in the pharmaceutical field are for example *Platinum* or *Ruthenium* in connection with cancer, *Bismuth* for the treatment of disorders of the gastrointestinal tract or iodized emulsified fat to enhance the contrast between normal and diseased liver tissues. Several very sensitive and selective ICP-MS methods for the quantitative determination of pharmaceutical relevant elements in different matrices were developed and validated. Determined elements were *Al*, *Se*, *I*, *Bi*, *Gd*, *Br*, *Pt* and many others. Data on *Iodine* and *Bromine* measurements are presented as examples.

Another very interesting example for the versatile field of ICP-MS applications is the use of stable element isotopes in studies on the uptake of elements after oral or intravenous administration. Data on the uptake of *Calcium* and *Zinc* after oral administration of enriched ^{42}Ca , ^{44}Ca and ^{70}Zn isotopes are presented.

ASSESSMENT OF INTERNAL STANDARDS FOR ARSENIC IN ICPMS

Thomas A. Hinner, Spiros A. Pergantis*, and Edward M. Heithmar, U.S. Environmental Protection Agency, National Exposure Research Laboratory, Characterization Research Division, P. O. Box 93478, Las Vegas, NV 89193-3478

To conduct valid exposure and risk assessments, the U.S. EPA needs accurate measurements of pollutants. Internal standards, if properly selected, can assist in obtaining accurate pollutant data. Because antimony, gold, selenium, and tellurium are similar to arsenic in their partial ionization in an inductively coupled plasma, they could provide more appropriate internal standards for arsenic than the highly ionized elements (such as germanium, indium, rhodium, scandium and yttrium) commonly used now as internal standards in ICPMS. The elements we evaluated as internal standards for arsenic included antimony, cerium, germanium, gold, holmium, indium, rhodium, scandium, selenium, tellurium, and yttrium.

Organics present in samples are known to affect the thermo-ionization of some elements in ICPMS; and they can still be present even after microwave digestion of materials in pressurized vessels [1,2]. Although Allain et al. reported [3] the enhancement of ICPMS signals for partially ionized elements by organics and cited the "difficulty in selecting an internal standard," they did not recommend any internal standard(s) for those elements that are partially ionized in an ICP. To study ionization effects in ICPMS, methanol provides a convenient carbon source that is miscible with aqueous solutions. When the methanol concentration was varied from zero to 3.2% (v/v) in 1% (v/v) nitric acid solutions containing arsenic and the candidate internal standards at 10 µg/L, the arsenic-to-internal-standard ratios varied more than 3 fold relative to the reference ratios (Fig. 1). The reference ratios were obtained, with no methanol (or any matrix element) present in the solutions, using a high-efficiency nebulizer (HEN) and optimizing the signal-to-noise ratio for arsenic. Only the arsenic ratios with selenium or tellurium differed less than 30% from the reference values in the presence of ≤ 3.2% methanol, but the ratio of the arsenic signal to the combination of Se+Te maintained the ratio within 5% of the reference value (Fig. 2). By using enriched ⁸²Se (with more than 96% isotope purity) rather than natural selenium, the conventional chloride correction for arsenic by the measurement of $As^{37}Cl^+$ ions is not confounded by the 7.6% abundance of ⁷⁷Se in natural selenium. Gold was not found to be a useful internal standard under the conditions of this study because of unacceptably high measurement variations.

While Se and Te served well as internal standards for solutions of differing carbon concentrations, these two elements were among the worst for two out of three solutions containing high concentrations of a matrix element (calcium, terbium, or uranium at concentrations between 238 and 636 mg/L). For these high-matrix solutions, germanium kept the arsenic ratio within 5% of the reference ratio for all three matrix elements, while Ce and Ho served well only for the Tb matrix, and the four elements with the lowest mass values (Sc, Se, Y, and Ge) held the ratios within 5% of the reference ratios for the uranium matrix (Fig. 3-6).

Internal standards should be selected with consideration of the range of sample matrices to be analyzed and the potential for endogenous levels of the internal standard elements in samples (i.e., Y contamination of the Ca matrix used in this study accounted for 66% of the total Y in the Ca matrix solution while the Tb matrix contributed 28% of the Y and 33% of the total In). The ratios involving Y and In were adjusted for these matrix contributions to the internal standard signals. When the sample matrix is uncertain or highly variable, the method of standard (analyte) additions could be the

most reliable form of "internal" standardization.

Metallic impurities have been shown to play a very important role in bulk micro defects in single crystal silicon. The major sources of these impurities are the quartz crucible and the polysilicon. Neutron activation analysis (NAA) has been used extensively for the analysis of these impurities in silicon. Unfortunately, at the current levels, the detection limits of NAA are at least one order of magnitude higher than what is needed for many of the critical elements. There is an interest in developing a method that can analyze elements, e.g., Fe, Cr, Ni, Cu, and Na, in polysilicon at the low part-per-trillion (ppt) range. While inductively coupled plasma mass spectrometry (ICP-MS) is known to be one of the most sensitive techniques for trace elemental analysis, detection limits need to be improved for analyses at such low levels. Ultrasonic nebulization (USN) sample introduction to ICP-MS results in an order of magnitude improvement in sensitivity compared with conventional pneumatic nebulization due to the better aerosol quality and transfer efficiency. Incorporating a membrane desolvation (MD) system results in better solvent removal, which reduces the solvent-related spectral interferences common in ICP-MS. Isotope dilution (ID) ICP-MS is known to be one of the most accurate methods for trace elemental analysis. ID-ICP-MS is relatively unaffected by both the sample matrix and instrument stability. The current work investigates the performance of an ID-ICP-MS system with USN/MD sample introduction for the determination of trace metal impurities in polysilicon.

A class-100 clean room facility was utilized for the handling and dissolution of the polysilicon materials. The polysilicon samples were etched prior to their complete dissolution to remove the first few surface layers containing elemental impurities due to handling which are not representative of the bulk. The dissolution procedure requires very high purity acids. It was observed that their substitution with even a small volume of slightly less pure acids resulted in higher levels of the elements of interest in the blank, which adversely affected the detection limits.

The USN/MD system was optimized to provide the highest ratio of analyte signal to argon oxide signal ($m/z = 56$), which interferes with the determination of iron. Parameters evaluated were nebulizer gas flow rate, sample pump rate, sweep gas flow rate into the MD, and sweep gas flow rate out of the MD. The ICP-MS was set up to monitor $^{52}\text{Cr}/^{50}\text{Cr}$, $^{56}\text{Fe}/^{57}\text{Fe}$, $^{60}\text{Ni}/^{64}\text{Ni}$, and $^{63}\text{Cu}/^{65}\text{Cu}$ ratios by peak hopping. Additionally, a $^{23}\text{Na}/^{50}\text{Cr}$ ratio was also obtained to calculate the sodium concentration using chromium as an internal normalization standard.

Results of two separate studies indicate that the sample preparation is of paramount importance. Results vary from samples prepared in one dissolution beaker versus another, and the background of the blanks limit the determination of sodium and iron. It was found that although instrument detection limits are acceptable, the reagent limits the current application of ICP-MS to polysilicon analysis.

Recent Results with the Three Aperture Gas Dynamic Interface for ICP-Mass Spectrometry

Ji-Feng Ying and D. J. Douglas, Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C. V6T 1Z1, Canada

Nearly all ICP-MS systems use an ion sampling interface consisting of a ca. 1 mm sampling orifice followed by a region at a pressure of a few torr. The centre-line flow of the plasma expanding into this region passes through a molecular beam skimmer into a region containing a first ion lens element [1]. Recent measurements of the ion beam profile from this interface by ion implantation [2] or current probe measurements [3] show that, even with a strong extraction field, an ion beam of ca. 1 cm diameter is formed. A mass analyzing quadrupole can accept only a much smaller beam so many of the ions in the beam are not transmitted by the mass analyzer. Measurements of the gas flow profile downstream of the skimmer from this conventional source show that, although its design is based on molecular beam techniques, only a highly attenuated and broadened beam of gas is formed [3]. These observations suggest that scattering of the ions by the locally high density of gas in the skimmer and space charge effects lead to a beam blow up which limits the sensitivity of the instrument.

Several years ago Tanner et al [4] described a three aperture interface which overcomes some of these limitations. The gas flow through the skimmer hits a flat top "reducer" where it forms a shock wave with a temperature near that of the source. Ions pass through a small aperture in the reducer in transition flow into the ion optics. In the original design a single turbomolecular pump was used for the optics and mass analyzer. This limited the gas and hence ion flux that could be introduced into this region. Here we have added a stage of differential pumping to the ion optics to allow increasing the reducer diameter.

Figure 2 shows the sensitivity of the system in counts s^{-1} per $\mu g\ ml^{-1}$ of element for reducer areas from $1 \times 10^{-4}\ cm^2$ to $1.6 \times 10^{-2}\ cm^2$ (diameters 0.011 cm to 0.14 cm). The sensitivity increases ca. $\times 10$ for reducer areas up to $6 \times 10^{-3}\ cm^2$ before leveling off. Figure 3 shows the suppression of

Figure 1. T=torch, sa=sampler, sk=skimmer, re=reducer, E=ezel lens, P=rf prefilter, Q=quadrupole, D=detector, rp=rotary pump, turbo=turbomolecular pump

analyte sensitivity from a $1000\ \mu g\ ml^{-1}$ Tl matrix. The suppressions increase as the reducer area is increased but remain fairly uniform with mass at least for reducer diameters less 0.04 cm. These increased suppressions likely derive from increased space charge defocusing of the ion beam as the ion current is increased. Measurements of the ion current profiles with a probe and the observation that 50% of the ion current is transmitted through a 1 mm aperture at the exit of the ion optics both suggest that a narrow (ca 1.5 mm) well defined ion beam is formed. Measurement of the total ion flux and of the ratio of V^+ to Ar^+ from $1\ \mu g\ ml^{-1}$ V solution both show that the Ar^+ flux is ca. 1.6×10^{-4} of that expected from the source conditions. This may be due to charge transfer of Ar^+ to background Ar in the region between the skimmer and reducer, or to preferential loss of the high ionization energy Ar^+ in the slightly cooler shock wave at the reducer. This loss of Ar^+ helps minimize space charge in the ion beam and leads to a "brighter" ion source; useful in the development of a high resolution quadrupole ICP-MS [5].

Figure 3

High Resolution and High Abundance Sensitivity Quadrupole ICP-MS

Ji-Feng Ying and D. J. Douglas, Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., V6T 1Z1, Canada

Molecular ions which can cause interference with atomic ions of the same nominal mass are a long-standing problem in ICP-MS. This has led to the application of double-focusing sector mass spectrometers to ICP-MS in order to obtain sufficient resolution to separate atomic from molecular ions. Sector instruments are expensive, complex and have not yet demonstrated the high scan speeds and rapid peak hopping possible with quadrupole mass filters. Here we have assessed the feasibility of a high resolution quadrupole ICP-MS by coupling an ICP ion source to a quadrupole which can be operated in alternate stability regions.

Figure 1 show the stability diagram for the linear quadrupole mass filter. The dark shaded regions labeled I, II, and III give trajectories simultaneously stable in the x and y directions transverse to the quadrupole axis (notation from [1]). It has been known for some time that operation in the second (II) [2] and third (III) [3] regions can give considerably higher resolution than conventional operation in the first region (I). The application of quadrupoles operated in these regions is under investigation here. The experimental apparatus, shown in Figure 2, is based on a three aperture interface described previously [4] (T=torch, sa=sampler, sk=skimmer, re="reducer", L=lens, Q=quadrupole D=detector).

Figure 1

Figure 2

Figure 3

Figure 4

With operation in region III, very high abundance sensitivity is possible and a limiting resolution at half height ($R_{1/2} = m/\Delta m_{1/2}$) of ca. 4000 is possible (data not shown). This limiting resolution however is not sufficient to separate many common atomic and molecular ion interferences. The effect of rod quality remains to be investigated. Operation in region II gives higher resolution. Figure 3 shows the mass spectrum of a solution of Mn, Fe, Ni and Co each present at 100 ng ml⁻¹. The sensitivity is 1.5×10^6 s⁻¹ per ug ml⁻¹ and $R_{1/2} = 3000$. The abundance sensitivity is estimated to be 10^7 at 1/2 mass unit. Figure 4 demonstrates separation of ⁴⁰Ar¹⁶O⁺ ($m/z = 55.99491$) from Fe⁺ ($m/z = 55.9349$) present at 12 ng ml⁻¹ in solution. Here $R_{1/2} = 5000$ and the sensitivity is 8.5×10^5 s⁻¹ per ug ml⁻¹ of Fe. This sensitivity approaches that of sector instruments operated at the same resolution (ca. 2×10^6 per ug ml⁻¹ of Fe [5]). The continuum background is high, ca 10^3 s⁻¹, but no attempts have yet been made to reduce this with stops in the ion optics or bends in the ion beam. Operation in the first stability region gives a sensitivity of 10^6 counts s⁻¹ per ug ml⁻¹ of element. These results suggest that, with continued development, a high resolution quadrupole ICP-MS with electronic switching of resolution while peak hopping to elements of interest will be possible.

Design and properties of a laser ablation/ICP-MS for bulk analysis and geological applications.

C.B. Douthitt, U. Greb, M. Hamester, L. Rottmann, E. Schroeder
Finnigan MAT GmbH, Barkhausenstr.2, D-28197 Bremen, Germany.

The coupling of a laser ablation (LA) microprobe to an inductively coupled plasma mass spectrometer (ICP-MS) produces an easy-to-use high sensitivity multi element analysis system. Its characteristics are ideally suited to the research in the earth sciences. Applications of LA-ICP-MS are the detection of distribution patterns of minor constituents in solid samples such as ceramics, alloys or geological structures. We report on the design, performance, and limitations of a laser ablation micro sampling system based on a frequency quadrupled Nd:YAG laser operated at 266nm. Details are given of the setup of the laser, its performance, its control elements, and the ablation chamber. Particular emphasis is given to the imaging video optics and microscope. A design of an imaging optics providing a magnification sufficient to image structures of less than 10 μm under real working condition is outlined.

Purpose

- * Design a micro laser ablation system and interface it to a high resolution ICP mass spectrometer
- * Determine the performance of the said system applied to glass samples containing trace elements in the low ppm range.

Method.

- * A laser ablation micro sampling system based on a frequency quadrupled Nd YAG laser operated at $\lambda=266\text{ nm}$ interfaced to a high resolution magnetic sector mass spectrometer
- * Adequate microscope imaging optics for proper sample selection

Results

- * Trace elements in transparent $\text{Li}_2\text{B}_4\text{O}_7$ glass samples have been detected and quantified from concentrations of some hundred ppm down to the ppb range. Good linearity of the calibration curves and acceptable standard deviations have been achieved with this system.

The combination of the laser ablation system with the high-resolution ICP-MS *ELEMENT* offers various benefits for the solid sample analysis

Figure 1 clearly shows that the LA-ICP-MS is also limited because of spectral interferences, very well known from solution ICP-MS. Fortunately, it is possible to separate these spectral interferences from the analyte peaks with the high resolution ICP-MS.

Fig. 1

Figure 2 shows the high correlation for 1, 5 and 10 ppm standards obtained from medium resolution measurements with laser ablation. The safe determination of the analyte peak besides the interference peak combined with these calibration curves shows the feasibility of satisfactory quantifications with LA-HR-ICP-MS.

The coupling of Resonant Laser Ablation (RLA) and quadrupole ion trap mass spectrometry (ITMS) is a powerful overlap of technologies [1-3]. RLA uses modest intensity ($<10^7 \text{ W}\cdot\text{cm}^{-2}$) laser pulses tuned to a resonant gas phase transition of a particular analyte to both vaporize and subsequently ionize desired analyte species from a solid sample matrix with the same laser pulse. The inherent selectivity of RLA makes it very suitable for stored ion mass spectrometry, because analyte ions can be created and stored without the complications of space charge induced by non-specific ionization modes such as simple laser ablation. Presented are recent developments in RLA ion trap research, including spectroscopic studies and improvements for the RLA process, which have lead to substantial improvement of the limits of detection for analytes in solid sample matrices. In addition, an investigation of the ion trapping efficiency for a laser ablation ion source within a quadrupole ion trap is presented. Finally, recent applications of RLA-ITMS by this lab are surveyed, including the use of RLA as a selective metal ion source for ion chemistry studies and metal ion CI investigations, and the application of newly developed methodologies (based in part on RLA) for the analysis of organophosphate environmental contaminants.

The use of pulsed dye laser radiation with narrower bandwidths has not only allowed further improvement in the selectivity of the ionization process, but has afforded spectral detail for some of the RLA transitions used in our laboratory. The $\text{Cr}(2+1)$ optical spectrum @ 473.17 nm has been measured in the past in best cases as being much broader than the laser linewidth limited case (typified by $\text{Cu}(2+1)$, not shown). This was suspected to be (in part) overlapping resonant transitions not resolvable by the relatively broad bandwidth lasers used. In a new series of experiments with a narrow ($<0.2 \text{ cm}^{-1}$) bandwidth pulsed dye laser, the entire multiplet from $j=1$ to 5 has been resolved for the $[3d^5 4d] e^7 D_j \leftarrow [3d^5 4s] a^7 S_3$ 2-photon transition of Cr(I) . This optical spectrum is presented in figure 1. This resolved multiplet demonstrates that overlap of several transitions was the main reason why the $\text{Cr}(2+1)$ optical spectrum always appeared broader than laser linewidth in earlier [1] work.

Figure 1: RLA optical spectrum for the $[3d^5 4d] e^7 D_j \leftarrow [3d^5 4s] a^7 S_3$ 2-photon transition of Cr(I) . The vertical axis represents the total ion signal for the chromium isotopic cluster.

The absolute detection limits for lead in copper were measured as ~ 9 attograms, based upon etch rates for copper thin films and RLA-ITMS analysis of trace lead in a NIST copper sample. These absolute detection limits are conservative since they are based upon mass removal rates that were obtained at higher fluence than typically used for RLA-ITMS and the mass spectral data for Pb showed a $S/N = 100$. A

preliminary investigation of ion trapping for ions generated by laser ablation directly within the storage volume of the ion trap is presented. For laser fluences greater ($\sim 7 \times 10^7 \text{ W}\cdot\text{cm}^{-2}$ or greater) than those used for RLA ($<10^7 \text{ W}\cdot\text{cm}^{-2}$), laser ablation of conducting samples inside the ion trap resulted in a suppression of the RF storage field during and shortly after the laser ablation event, acting to reduce or in some cases even eliminate the trapping capability for the laser generated ions. Although the phenomena presented does not pose a significant problem for RLA, trace analysis by non-specific ablation into a quadrupole ion trap may suffer from the described effects.

To further explore the utility of RLA for mass spectrometry, the selective generation of different metal ions from the same sample by RLA was applied to the investigation of gas phase ion chemistry. The facile switching between different types of metal ions without breaking vacuum was implemented by simply tuning the dye laser to a resonant transition for the desired metal, using the same laser dye. The metal ion chemistry of $M^+ + \text{acetone}$ ($M = \text{Cr}, \text{Fe}, \text{Ni} \text{ \& \; Cu}$) was examined as a test system. The chemistry of Cr^+ and Cu^+ was simple adduct formation, whereas Fe^+ and Ni^+ showed evidence of dissociative attachment reactions, as has been documented in the literature [4]. Figure 2 shows the ion molecule reaction products for Cu^+ and Fe^+ with acetone.

Figure 2: The gas phase ion chemistry of acetone (1×10^{-7} Torr) with copper and iron ions. In the above mass spectra, A = acetone.

A parallel application of this metal ion chemistry work was to use RLA to generate metal ions for use as CI agents for a variety of compounds. A survey of Cr^+ CI versus EI for a broad range of chemical compounds is presented, and in most instances, metal ion CI gave better signal-to-noise ratios and more abundant molecular or pseudo-molecular (adduct) ions.

This laboratory has been involved in a variety of projects that relate to the analysis and identification of environmental contaminants that have been "problem" analytical cases. Tri-butyl phosphate (TBP) has been one such problem compound. Conventional EI of TBP yields a base peak at $m/z = 99$, corresponding to loss of all the alkyl side chains. The metal ion chemistry of TBP and metal ion CI of gaseous TBP yields a base peak for the metal-TBP adduct species. The final study presented involves the use of a selective sorbent for TBP, a chemically modified zeolite sample, as a solid sample support platform for RLA-ITMS. The zeolite has been exchanged with silver ions, which are used as a cationization agent for the analysis of TBP.

Reduced Space Charge Effects in ICP/MS by Selective Elimination of Argon Matrix Ions

Charles J. Barinaga, Gregory C. Eiden, and David W. Koppenaal
Pacific Northwest National Laboratory*
PO Box 999, Richland, Washington 99352

The intense, matrix-related ion currents observed in ICP/MS are problematic as analyte spectral interferants and as significant contributors to space charge effects. Space charge effects downstream of the skimmer are thought to contribute significantly to the low efficiency, $\sim 1\text{E-}5$, of analyte ion transfer from the plasma to the mass analyzer and detector and to other unwanted effects, e.g. mass bias and interelement effects (see 1,2 and references therein). If some or all of these ions could be neutralized early in the sampling then spectral interferences and possibly space charge effects would be removed or minimized. Early work with a Plasma Source Ion Trap mass spectrometer (PSIT) (3,4) surprisingly indicated that most of these matrix ions weren't present or could be reacted away by holding them in the trap for several ten's of milliseconds. The reagent proved to be residual water vapor in the vacuum chamber. Unfortunately the water also reacted with certain metal ions to produce unwanted oxides and hydroxides.

Recently hydrogen and argon at relatively low pressures in the ion trap have been found to also be quite effective in reactively eliminating many of the significant matrix ions (5,6) either during the trapping process or by being held in the trap for a several milliseconds. Could similar effects be obtained in a conventional linear quadrupole ICP/MS where the maximum residence time for an ion is on the order of microseconds rather than milliseconds?

An older style (VG PQ-I) style sampling interface was modified so that the end of a small stainless steel tube could be placed in the intermediate vacuum chamber at the base of the skimmer or in the expansion region between the nozzle and skimmer at the outer base of the skimmer. This interface was installed on a VG PQ-II+ which was operated and tuned in standard fashion using a concentric, pneumatic nebulizer and 10 ppb standard solutions in 1% HNO_3 . The high purity hydrogen and argon were metered with needle valves. Mass spectra were obtained in both analog and pulse counting modes as the flow of gas was increased. The response of several different ions vs. increasing reagent gas pressure (H_2 and Ar introduced behind the skimmer) is shown in the panels below. All responses were normalized to $^{208}\text{Pb}^+$ which was assumed to have the least scattering loss. Ar reduced the intensity of all ions by reaction or scattering. H_2 reduced the level of most ions but not all, e.g. ArH^+ , and scattered the ions less than Ar did. H_2 between the nozzle and skimmer (not shown) increased the level of the matrix ions and depressed that of the analytes! Although no matrix ion was completely eliminated and no analyte ion intensity was improved in this preliminary attempt we are encouraged by the results from our ion trap work (companion paper WPC 56) and intend to examine better-suited collisions cells for the desired reaction chemistry.

SELECTIVE ELIMINATION OF ARGON IONS IN A PLASMA SOURCE ION TRAP MASS SPECTROMETER

GREGORY C. EIDEN, CHARLES J. BARINAGA, ORVILLE T. FARMER III, AND DAVID W. KOPPENAAAL
PACIFIC NORTHWEST NATIONAL LABORATORY, RICHLAND, WASHINGTON 99352

Several methods for minimizing the effects of the mass spectral background in a Plasma Source Ion Trap (PSIT) mass spectrometer are reported. The PSIT is an ion trap mass spectrometer (custom large electrodes in an unstretched geometry and Finnigan ITMS electronics) using an inductively coupled plasma (ICP) ion source.¹ The flux of Ar⁺ at the ion trap, while lower than the Ar⁺ flux at the detector in a conventional ICP/MS, is nevertheless significant. Chemical ionization by Ar⁺ in the trap (of H₂O, O₂, N₂, pump oil, etc.) can produce background at nearly every elemental m/z. The intensity of the chemical ionization background spectrum is in the range <0.005 to 1 ppb (background equivalent concentration) as shown by a comparison of the mass spectra in Figure 1. We have explored several methods to reduce the Ar⁺ in the trap or to mitigate its effect on the background. The background is nearly eliminated if the low mass cut-off of the ion trap is set above m/z 40 during ion injection, thereby preventing Ar⁺ from interacting significantly with background gases in the trap. Trapping of low m/z ions (m/z ~20 to 60) requires a low mass cut-off for efficient trapping so that Ar⁺ be removed by some other means. In this case, resonant ejection of Ar⁺ during ion trapping has been the method of choice; it is very effective in reducing the background spectrum. An alternative that we have recently reported is addition of H₂ to the buffer gas (normally pure He).² H₂ neutralizes Ar⁺ before significant chemical ionization occurs. Ar⁺ and H₂ react by electron transfer and H atom transfer;³ the latter reaction dominates under our conditions, producing ArH⁺ which reacts further with H₂ to form both H₂⁺ and H₃⁺. Ar⁺ is thus effectively converted to H₂⁺ and H₃⁺ which are rapidly ejected from the trap if the low mass cut-off is >3 amu. Reaction of H₂ with most analyte ions is minimal.²

Using neat H₂ as the buffer gas yields ~two-fold lower intensities in the background spectrum than Ar⁺ resonant ejection in He (using buffer gas pressures which yield similar analyte ion intensities). The H₂ chemistry allows direct detection of ³⁹K⁺ and ⁴⁰Ca⁺, and ⁸⁰Se⁺, ions normally obscured by intense plasma ion peaks. Low PSIT background also allows direct detection of other problematic ICP/MS ions, e.g., ²⁸Si⁺, ³¹P⁺, ³²S⁺, ⁵¹V⁺, ⁵⁶Fe⁺, and ⁷⁵As⁺ using either resonant ejection or H₂.

In Figure 1, we show mass spectra obtained using neat H₂ as the buffer gas at a low mass cut-off of 25 amu. The upper trace shows the spectrum for a 1 ppb multielement solution in 1% HNO₃; the lower trace shows the spectrum for a H₂O blank. Using reactive removal of Ar⁺ with H₂, many classically obscured ions (²⁸Si⁺, ³¹P⁺, ³²S⁺, ³⁹K⁺, ⁴⁰Ca⁺, ⁵⁴Fe⁺, ⁵⁶Fe⁺, ⁷⁵As⁺, and ⁸⁰Se⁺) can be directly analyzed, typically at sub-ppb levels. However, some ions react with H₂, e.g., Si⁺, K⁺, Cl⁺, O⁺. For analysis of such reactive ions, resonant ejection may be superior to H₂ chemistry for the removal of Ar⁺.

Figure 2 shows the mass spectra obtained for 0.1% HCl blank solutions using the PSIT or a conventional ICP/MS (VG PlasmaQuad II+). The PSIT spectrum shows far lower background between m/z 28 and 42 (m/z 40,41 were skipped in the PQ-II+ mass scan) and at m/z 54, 56, 80 and 84. In other m/z regions, e.g., m/z 47, 48, 65-74, 77, 79, the PQ-II+ shows lower background than the PSIT.

The ion trap can be operated at higher mass resolution by synchronizing the AC and RF waveforms applied to the trap electrodes and by reducing the scan rate of the RF voltage.⁴ Using larger than standard trap electrodes gives a lower mass range for a given RF trapping potential and thus a lower mass scan rate (~1900 amu/sec in this work), thereby increasing the mass resolution. As shown in the inset in Figure 1, we observe mass spectral peak widths in the large trap of ~0.05 Da (FWHM), versus 0.12 Da in a standard ion trap. The mass resolution at m/z 50 (m/Δm ~1000) is thus sufficient to partially resolve most hydrocarbon peaks from elemental peaks, even at low m/z, e.g., ⁴⁴Ca, ⁵¹V, ⁵⁶Fe, etc. A further decrease in the RF scan rate by less than a factor of two^{4a} will increase the mass resolution sufficiently such that most isobars of interest in elemental mass spectrometry can be resolved. In conclusion, the PSIT demonstrates orders of magnitude lower background for many classically interfered atomic ions and the prospects of higher mass resolution are excellent for making further background reductions.

Elemental and Isotopic Analysis of Geological and Environmental Samples by Inductively Coupled Plasma Quadrupole Ion Trap Mass Spectrometry (ICP-ITMS)
C.I. Frum, Harry Reid Center, University of Nevada, Las Vegas, NV 89154

Inductively coupled plasma mass spectrometry (ICP-MS) is generally acknowledged to be the most powerful technique for ultratrace elemental analysis. However, the high sensitivity and selectivity of the technique are significantly deteriorated when the signal originating from the analyte ion to be measured is overlapped by the signal due to an isobaric polyatomic interfering ion. An ICP ion source has been interfaced to a Finnigan ITMS with the purpose of carrying out interference free measurement of trace and ultratrace analyte concentrations in environmental and geological materials. Stored waveform inverse Fourier Transform (SWIFT) pulses are employed to carry out selective ion isolation, collision induced dissociation of polyatomic species, and matrix ion ejection with the purpose of reducing the space charge effects and thereby lowering the detection limits, increase the S/N ratio, and enhance the mass resolution.

The ions generated in an inductively coupled plasma are sampled by a sampler-skimmer interface, passed through an hyperbolic quadrupole and focused onto a quadrupole ion trap by a three cylinder ion lens system. The ITMS and the associated electronics are used to carry out the final mass analysis. The analytical performance of the method is significantly enhanced by using SWIFT pulses. Both the frequency amplitude and the time domain spectra are generated in a Labview program. The frequency magnitude spectrum in which notches have been created by assigning zero intensity to the secular frequencies of the ions to be isolated is converted to a complex, optimally phase modulated waveform. The complex waveform is transformed to the time domain using the Split-Radix Inverse Complex FFT algorithm. The pulse is downloaded in point mode to an arbitrary waveform generator, and then as a burst of pulses at an externally generated trigger signal during various stages of the scan function.

Broad band excitation technique using SWIFT pulses proves to significantly improve the performance of the method and greatly reduce the space charge effects. Mass spectrum of a 10 ppb mixture of Pb and In which is severely distorted by space charge effects is shown in Figure 1a while the spectrum of the same solution recorded using selective isolation and accumulation of In ions is shown in Figure 1b. Selective isolation of analyte ions by using SWIFT pulses is also possible in the low mass range where the presence of abundant plasma ions considerably affects the detection power of the method. Figure 2 which shows the isolation of Na ions exemplifies the utility of the SWIFT technique in this mass region.

The Lanthanides (Rare Earth Elements) are extensively used as geochemical tracers particularly due to their extremely coherent behavior. In Figure 3 the isolation of ^{142}Ce ion from a mixture containing all the lanthanide isotopes is shown. Barium, often found in large concentrations in geological samples, produces major isobaric interferences in the ICP-MS measurements La, Sm, and Eu. Barium oxide ions, $^{135,137}\text{Ba}^{16}\text{O}^+$, which are inevitably formed even in the dry plasmas, interfere on the measurement of both isotopes of Eu. In ICP-ITMS, BaO^+ ions are completely dissociated by the collision with the buffer gas present in the mass spectrometer. The small quantities of BaOH^+ which are formed in the trap by the reaction of the Ba ion with remnant water can be readily dissociated by using collision activation techniques as shown in Figure 4b. The measurement of ^{75}As , an environmentally important element, by conventional ICP-MS, in the presence of large quantities of Cl, is not possible due to the interference from $^{40}\text{Ar}^{35}\text{Cl}^+$ formed in the plasma. Complete dissociation of ArCl^+ by the collision with helium buffer gas is possible in ICP-ITMS even for Cl⁻ concentration exceeding 30,000 ppm.

Inductively coupled plasma mass spectrometry is unarguably the single most powerful instrumental method available for elemental analysis. Its benefits include good linear dynamic range, excellent limits of detection, easy to interpret spectra, and isotopic information. Most ICP/MS instruments are equipped with quadrupole mass filters having a mass resolution of about 1 amu. While suitable for many analyses, these instruments are rendered useless with samples where isobaric overlaps are present.

For example, the major isotope of calcium overlaps with the major isotope of argon, a plasma product and the major species observed in an ICP/MS spectrum. This severely limits the maximum obtainable detection limit for this element, since an isotope of much lower abundance must be used. The mass resolution required for this analysis is ~200,000 FWHM. The seemingly obvious solution to this problem is to use a mass spectrometer capable of higher resolution. Commercial ICP/MS instruments are now available with a double focusing sector as the mass analyzer. The dilemma with these instruments is a result of the tradeoff between high resolution and low limits of detection.

In many cases, an increase in resolution by a factor of two results in a concomitant decrease in signal by a factor of 10. In addition the maximum obtainable resolution of these "high-resolution" instruments is typically no more than about 25,000.

What is needed is a mass analyzer which offers good sensitivity and ultra-high resolution. We have taken the preliminary steps in creating such an instrument with this work. By coupling an inductively coupled plasma source with a Fourier transform ion cyclotron resonance mass spectrometer, we have obtained the highest mass resolution ever recorded to date.

The mass resolving power of FT-ICR for a particular mass is inversely proportional to an ion's mass-to-charge ratio. Since all elemental species are of relatively low mass, this makes FT-ICR/MS well suited for elemental analysis. The accompanying figure demonstrates one of the many advantages of FT-ICR/MS. By applying a resonant frequency pulse corresponding to 40 m/z, we have shown an ICP/MS spectrum with no argon ion present.

This spectrum shows the ejection of argon by using a "clean-up" shot. Note that argon is no longer the dominant feature in the spectrum, yet argon-hydride is still present.

Elemental Analysis Using an Electrospray Ionization Source Coupled With an FT-ICR Mass Spectrometer

K. Eric Milgram, Kevin L. Goodner, Clifford H. Watson, and John R. Eyer
 Department of Chemistry, University of Florida
 Gainesville, Florida

Since its inception, electrospray ionization (ESI) has been the ion source of choice for those interested in observing ions of high molecular weight species in the gas phase. Additionally, elemental mass spectrometry has been confined to inductively coupled plasma (ICP), microwave induced plasma (MIP), glow discharge (GD), and laser desorption (LD) sources. Gary Horlick and a few others have shown recently that electrospray ionization might be useful for those wishing to gain insight into the dynamics of elemental ions in solution.

Prior to our work, all of these elemental electrospray studies had been performed on quadrupole instruments. By exploiting the advantages of Fourier transform ion cyclotron resonance mass spectrometry we have been able to extend this work further.

This work was performed on a Bruker BioAPEX external source system equipped with a 2 Tesla superconducting magnet. The electrospray source was an Analytica source equipped with hexapole ion guide and a homemade heated metal capillary. The hexapole ion guide can be used to acquire ions over a variable time interval. The parameters we decided to evaluate were:

- 1) needle voltage
- 2) capillary temperature
- 3) capillary/skimmer voltage
- 4) hexapole holding time
- 5) signal vs. concentration

We immediately discovered that the signal was not a linear function of concentration, just as Horlick has shown. Additionally, increasing the needle voltage, capillary temperature, capillary/skimmer voltage, or hexapole holding time served to decluster the metal ions.

We were also able to perform CAD on some of the clusters so as to be able to further confirm the identity of the ions. The accompanying figure illustrates the dramatic effect capillary/skimmer voltage has on the distribution of ions in the mass spectrum. Notice that at lower capillary/skimmer voltages, there is very little bare lead in the spectrum, while at higher voltages, bare lead is the predominant species.

Capillary Potential = -90 V

Capillary Potential = -310V

Semi Quantitative Analysis of Complex Polyoxometalate Mixtures by means of Electrospray Ionisation Mass Spectrometry

Keith R. Jennings, Michael J. Deery and Oliver W. Howarth
Department of Chemistry, University of Warwick, Coventry, CV4 7AL

The structure of the species examined in this study (typically, $H_xPM_{12}O_{40}^{(3-x)-}$, where M = Mo(VI) or W(VI) or a combination of the two) is shown in Figure 1, and is known as an α -Keggin structure. The structure consists of four sets of three octahedral units of the type MO_6 which are fused at some edges and vertices. The vast majority of studies carried out on these ions have relied on x-ray crystallography and NMR techniques. There are, however, only a limited number of polyanions which crystallise without disorder and the available NMR nuclei in such complexes are mostly of low sensitivity. Previous studies have shown that intense reproducible spectra can be obtained by means of electrospray ionisation mass spectrometry (ESI-MS) from dilute aqueous solutions of polyoxometalate salts (1,2). This study aims to examine the behaviour of mixed metal species of the type $H_xPW_nMo_{12-n}O_{40}^{(3-x)-}$ by means of ESI-MS. The results obtained are contrasted with ESI spectra of alkali metal halide clusters in order to establish ideas, relating to equilibrium processes that may occur immediately before or after evaporation of the solvent droplets in the electrospray source region.

Figure 1 shows the mass spectra of the reaction mixture $HPW_{12}O_{40}^{2-} + HPMoO_{40}^{2-}$, acquired over a period of 45 minutes. Figure 1(a) and (d) show the mass spectra of the mixed metal species which were acquired immediately after the solutions were mixed and after a period of 45 minutes. It can be seen that the equilibration occurring in the system is a relatively slow process and it is reasonable to assume that no equilibration occurs in the solvent droplets formed during the electrospray process. If this were not the case, the mass spectrum acquired immediately after mixing the two separate W and Mo components would show one mass distribution (similar to Fig. 4(d)), as opposed to two. The ions in the mixed metal solution are therefore deemed to interchange metal atoms relatively slowly in the time scale of the experiment.

Figure 2 shows the ESI mass spectrum of LiF, acquired in the negative ion mode. A series of $(LiF)_n^-$ cluster ions are observed with n ranging from 6 to 30. The peak intensities decrease in an approximately exponential way with increasing n , although it is clear that certain values of n are favoured. There is no evidence to support the view that alkali halide clusters form in significant concentrations in aqueous solution and it is therefore assumed that they are formed either in a supersaturated solution formed by repeated droplet formation or in the gas phase, in contrast to the mixed polyoxometalate species discussed above. Essentially the same favoured values of n have been observed to form at higher energies by means of fast atom bombardment (FAB) MS (3). The $n=13$ cluster is likely to have a $3 \times 3 \times 3$ alkali halide cube. The subsequent preferences for $z=1$ ions with $n=16, 19, 22$ and 25 would then arise from the addition of 2, 4 or 6 rows of 3 alternating ions to the face of this cube, during the droplet evaporation process or in the gas phase.

ORGANOMETALLIC SPECIATION AND ELEMENTAL QUANTIFICATION USING GAS CHROMATOGRAPHY / MASS SPECTROMETRY

C.M. Barshick, D.A. Lake, S.A. Barshick, M.L. Mohill, and P.F. Britt
Chemical and Analytical Sciences Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6375

As an alternative to conventional techniques for inorganic analysis (e.g., x-ray fluorescence, glow discharge mass spectrometry, or inductively coupled plasma mass spectrometry), we have been investigating gas chromatography / mass spectrometry (GC/MS). GC/MS affords the opportunity to quantify both the inorganic and organometallic compounds in environmentally important media without any loss of speciation.

Classical organometallic analysis involves solvent extraction to separate the analytes of interest from an aqueous matrix, prior to chromatographic separation and mass spectrometric detection. New technology has provided a more convenient way of sampling organic compounds directly from aqueous media, solid phase microextraction (SPME). Using a 100 μ m polydimethylsiloxane SPME fiber, we have sampled several organomercurials from water by "extracting" the analyte until an equilibrium was reached between the fiber's stationary phase and the aqueous fraction. This was accomplished by inserting the fiber into a solution containing the sample in saturated sodium chloride for 15 minutes. The analytes were then thermally desorbed from the SPME fiber in the GC's injection port and analyzed by GC/MS.

Inorganic compounds, in general, are not very volatile, and most can't be analyzed directly by GC/MS, even with the aide of the SPME fiber. By converting the inorganic compounds into organic compounds, however, more volatile species can be made. Results in the literature indicate that this can be accomplished by an alkylation reaction [1]. A convenient alkylating reagent for mercury in aqueous media is methylpentacyanocobaltate (III), $K_3[Co(CN)_5CH_3]$. This reagent has been used to methylate inorganic mercury in high yields (80%), with short reaction times and under highly acidic oxidative conditions, to methylmercury chloride ($MeHgCl$) and dimethylmercury (Me_2Hg). Preliminary results indicate that only the Me_2Hg can be sampled with the SPME fiber. Figure 1 shows the results of a study done to assess the influence of reaction time on the formation of Me_2Hg from a National Institute of Standards and Technology (NIST SRM 3133, 10 mg/ml Hg in 10% HNO_3) elemental mercury standard. After 30 minutes, the reaction was observed to have gone to greater than 90% completion.

Preliminary results were obtained to assess the quantitative features of the methodology. Five 1 g soil aliquots obtained from the Army's Rocky Mountain Arsenal (previously determined by ICP-AES to contain only trace levels of mercury) were spiked with a 1000 ppm mercury standard solution to produce samples with 1, 10, 50, 100, and 500 ppm of mercury. The samples were allowed to dry overnight at room temperature. Prior to analysis, the soils were suspended in an aqueous solution of saturated sodium chloride at 50°C. A 1.0 mL aliquot of 0.39 M $K_3[Co(CN)_5CH_3]$ in 0.018 M KOH was added. The suspension was stirred for 25 minutes, the soil was allowed to settle for 5 minutes, and sampling with the SPME proceeded as described above. All of the peaks identified in the resulting chromatograms were integrated and plotted to determine if any correlation existed with the added mercury. We found that Me_2Hg showed the best correlation ($r^2 = 0.992$). The detection limit for mercury in soil was calculated to be 1 ppm. Table 1 shows two results, one from a second sample containing 100 ppm of elemental mercury whose concentration was determined from this calibration curve and one from a contaminated soil measured by a variation on the calibration curve method, standard addition.

Figure 1. Dimethylmercury product formation as a function of time.

Table 1. Quantitative results from the analysis of mercury in soil.

Sample	Known Hg Concentration	Measured Hg Concentration
ASTM Soil	100 ppm Spiked as NIST SRM 3133	99 ppm $\pm$ 15 ppm Calibration Curve
Contaminated Soil	8 ppm Headspace Analysis	11 ppm $\pm$ 1.7 ppm Standard Addition

Livermore, CA 94551-9900

Nickel is known epidemiologically to be linked to cancer and other health problems. Accelerator Mass Spectrometry (AMS) is well known for its ability to detect carbon-14 at levels that make biomedical tracer studies feasible. Turteltaub and Jones sought to define the possibilities and the limitations of using AMS to track nickel in biomedical systems. Fortunately, another group of scientists at Lawrence Livermore National Laboratory was interested in solving a difficult problem involving detection and quantification of nickel at ultra-trace levels. Therefore, we linked our study with those in the Environmental Health Directorate and others in the Center for Accelerator Mass Spectrometry who were seeking to measure the fast neutron fluence from the Hiroshima bomb by the measurement of ^{63}Ni produced by an n,p process in copper materials. Our similar need to detect trace amounts of a nickel isotope in a matrix of biological materials led us to work together to develop the method described here.

Nickel-63 has a half-life of 100 years. The estimated amount of ^{63}Ni in copper collected at the Hiroshima site is on the order of 1.5 femtograms of ^{63}Ni per gram of copper. Since 69% of copper is ^{63}Cu , we had to face the problem of achieving a separation of copper and nickel such that we could resolve the ^{63}Ni isotope from the copper atomic isobar starting with a ratio of about $10^{13}/1$. The AMS instrument was modified to use the characteristic X-rays emitted as the ions pass through a thin foil, a detection technique which allows a detector discrimination so that ^{63}Ni can be measured in an excess of 3000 to 1 of ^{63}Cu to ^{63}Ni . That required us to find a technique to reduce the copper isobar background about 10^{11} with no significant loss of the nickel-63. Normal chemical methods did not work since even high purity reagents contain picograms of copper per ml, amounts which would overwhelm the ^{63}Ni in the samples.

The solution to the problem was the development of a two stage process: the initial electrochemical separation of copper from the ^{63}Ni with the addition of a known amount of stable nickel carrier; and the subsequent separation of the nickel by the reaction with carbon monoxide to form a volatile nickel tetracarbonyl (copper does not form a volatile compound under these conditions). The nickel carbonyl is then subsequently thermally decomposed directly in a heated graphite sample holder for analysis by AMS. The final step is accomplished without mechanical handling and without the addition of reagents which would reintroduce copper.

The method has been validated on realistic test samples by the quantitative determination of ^{63}Ni produced by irradiation of two sets of copper wires exposed to neutrons from a ^{252}Cf fission source. The samples were prepared by exposure corresponding to about 1.2 and 12 times the fast neutron fluence predicted by the Dosimetry System model, DS86, for a location 1 meter above the ground and 100 m from the hypocenter at Hiroshima. Application of the method to ten samples ranging from 2 to 20 grams of Cu with the ^{63}Ni and 1.1 mg of stable nickel carrier resulted in nickel separation and total nickel recovery averaging 96.4% with an uncertainty of 4.5%. In addition to proving that the method avoids significant loss of total nickel, we proved that the isotope ratios can be measured quantitatively to determine the nickel isotope ions by AMS. Table I gives the results of AMS measurements of ^{63}Ni in the irradiated wires showing the measured amounts of ^{63}Ni to fit the 0 to 223 fg expected within the experimental errors of the method. We have detected 54 ± 11 fg of ^{63}Ni in 20 grams of Cu wire.

The techniques developed for the chemical isolation of ^{63}Ni are also applicable for ^{59}Ni , which has a half life of 1.1×10^5 years, and is a gamma emitter. The long half life means a very low decay rate which makes it a relatively low hazard from a radiation-safety viewpoint. On the other hand, it is active enough to have decayed away on the geological time scale of the environment. These factors combine to mean that ^{59}Ni is a better candidate than ^{63}Ni as a tracer for *in vivo* biomedical work with AMS. Initial studies have shown that a similar treatment using the nickel carbonyl method can separate nickel from the ^{59}Co isobar. We have demonstrated a minimum detection limit of 20 fg of ^{59}Ni . Currently, we are working both to refine the method further and to develop methods to separate nickel from various biological matrices.

Table I. AMS Measurements of ^{63}Ni in Irradiated Cu Wires

Expected $^{63}\text{Ni}/\text{Cu}$ (fg/g)	Cu wire mass (g)	Total Nickel (mg)	Measure- ment time (min)	Expected ^{63}Ni (fg)	Measured ^{63}Ni (fg)	Uncertainty (fg)
2.5	2.92	1.11	24	0	-9	± 18

TOWARD AN INSTRUMENT FOR HIGH PRECISION POSITION-SPECIFIC ISOTOPE ANALYSIS (PSIA)

Thomas N. Corso and J. Thomas Brenna, Div Nutritional Sci, Cornell University, Ithaca, New York, 14853 USA

High precision on-line compound-specific Gas Chromatography-Combustion Isotope Ratio Mass Spectrometry (GCC-IRMS) has been used for carbon isotopic analysis since the late 70's. Position-specific measurements for analysis of natural variability have been published but are generally limited to the most important problems because of laborious chemical degradation and separation steps required prior to IRMS. We report here a high-precision on-line pyrolysis-combustion IRMS system for carbon using GC separation and a continuous flow microreactor, specifically designed for automated position-specific isotope analysis (PSIA).

The interface is constructed using tandem GCs capable of analyzing complex mixtures as shown in the instrument schematic below.

In the first GC, a rotary valve is used to introduce exclusively the precursor molecule of interest to the pyrolysis furnace. Upon pyrolysis, the product fragments continue to a second GC for separation where they are subsequently combusted and introduced to a Finnigan 252 IRMS or to a Varian Saturn 3 ion trap mass spectrometer for structural analysis.

The test molecule was methyl palmitate of either natural abundance or labeled in specific positions with ^{13}C . A series of fragments correspond to the 17 carbons of methyl palmitate are observed as shown below

Routine precisions for the precursor and product molecules range from $\text{SD}(\delta^{13}\text{C}) = 0.14$ to 1.63% , with the average precision $\text{SD}(\delta^{13}\text{C}) < 0.4\%$. Labeling experiments with natural abundance, $[1-^{13}\text{C}]$, $[1-^{13}\text{C}, \text{Me}-^{13}\text{C}]$, $[16-^{13}\text{C}]$, and $[16-^{13}\text{C}, \text{Me}-^{13}\text{C}]$ methyl palmitate show no rearrangement whatsoever. The degree of fragmentation of the parent compound is selectable by setting the microreactor temperature. No strong dependence of fragment isotope ratio on pyrolysis temperature was observed. These data demonstrate that on-line pyrolysis can produce highly reproducible carbon isotope ratios of precisions required for natural abundance measurements, and that rearrangement induced by pyrolysis is negligible.

ISOTOPE RATIO MASS SPECTROMETRY USING THE CHEMICAL REACTION INTERFACE WITH GC AND HPLC INTRODUCTION

Yohannes Teffera, Josef J. Kusmierz, and Fred P. Abramson

Department of Pharmacology
George Washington University Medical Center
Washington, DC 20037

INTRODUCTION: The chemical reaction interface mass spectrometry (CRIMS) concept, developed by Markey and Abramson in 1982 (1), has grown into a sensitive and selective method for the analysis of labeled compounds (2). Its quantitative capability and high selectivity are analogous to tracer methods utilizing radioactivity. CRIMS has been successfully coupled to both GC and HPLC separation systems (2), and has been used on different types of mass spectrometers. Isotope ratio monitoring is an increasingly sophisticated method which yields highly accurate and precise data. While there are commercial GC interfaces for IRMS instruments, there are none for HPLC. This paper presents a new method for the continuous introduction of GC and HPLC samples into an IRMS using CRI.

EXPERIMENTAL: In the apparatus developed GC effluents are introduced into the CRI where they are converted to CO_2 by a micro-wave powered helium plasma, and passed into a Finnigan/MAT delta S mass spectrometer. The HPLC effluent is desolvated and converted into a particle beam prior to its introduction into the MS. Most aspects of the components of the system have been described before (3). Unlike CRI on conventional MS analyzers, limitations in the tolerated gas load of the IRMS required that a split be effected between the CRI and the MS to reduce the incoming gas flow as much as 1:10. The reaction gas used in all experiments was oxygen. The GC experiments were performed using a DB-5ms fused silica column. A mixture containing hydrocarbons (60-80 nmol C each), their deuterated analogs (25 nmol C each), and caffeine (30 nmol C) were separated with a temperature gradient of 130-240° at 6°/min after a 3 minute delay. HPLC experiments were conducted using a pair of ISCO Model 260D syringe pumps, a solvent system of 7:3 methanol: acetonitrile, and an Aquapore C-8 column. The $\delta^{13}\text{C}_{\text{PDB}}$ value of condensed phase internal standard testosterone was found by using a standard of heptadecanoic acid whose isotope ratio had been determined off-line.

RESULTS AND DISCUSSION: GC/CRI/IRMS was successfully used to separate and analyze the mixture of deuterated and undeuterated alkanes and caffeine. Using the known values of the deuterated standards, the $\delta^{13}\text{C}_{\text{PDB}}$ values of the unlabeled alkanes and caffeine were computed. The SD values in all cases were well below 1 ‰ (mean of SDs = 0.65). For HPLC/CRI/IRMS, an optimum working range of 0.5-10 μg was established. Within this range, signal was adequate and linear, measurements had good precision, and isotope ratios remained constant.

With this system we were able to distinguish the origin of biological compounds following HPLC separations. Chlorophyll a from spinach and from algae were taken as examples. Figure 1 shows two consecutive injections, one of spinach chlorophyll a and the next of chlorophyll a from algae. While the m/z 44 peak heights of the two chlorophylls are similar, the ratio plots are clearly different. Multiple injections of the two chlorophylls gave the results shown in Figure 2. The $\delta^{13}\text{C}_{\text{PDB}}$ value for the spinach was -54.12 ± 0.60 (mean $\pm$ SD, n = 14) while the algae chlorophyll was -29.98 ± 0.51 (mean $\pm$ SD, n = 13).

CONCLUSIONS: A new GC/IRMS method with precision close to those of established GC/combustion/IRMS instruments (SD<0.80 ‰) and a novel HPLC/IRMS method with optimum performance ranges of 0.5-10 μg have been developed. Using HPLC/CRI/IRMS, on-column

analysis of chlorophylls from spinach and algae gave different ratios with a precision of SD<0.658. These results appear to be better in precision and chromatography when compared to different HPLC/IRMS configuration that uses a moving wire or belt and CuO oxidation.

REAL-TIME MONITORING OF PLASMA PARTICLES

W. D. Reents, Jr. and J. Daugherty
Lucent Technologies, Bell Laboratories
700 Mountain Avenue, Murray Hill, NJ 07974 USA

Semiconductor device manufacturing relies on plasma processing for critical material deposition and removal. The enhanced concentration of reactive species in the plasma greatly increases the desired reaction rate. Simultaneously, gas phase particle generation is greatly increased leading to a significant danger of device failure if these particles deposit on the silicon wafer. Current techniques for monitoring these particles are limited in their size detection limit (>0.2 micron) with no ability to identify the particle in real time. It is crucial to track all particles potentially harmful to the semiconductor device (>0.02 micron), yet this information is unavailable.

We have interfaced our home-built particle analyzer for monitoring particles in a low pressure (0.1-10 torr) methane plasma. Particle size and composition are obtained in real time for particle sizes as small as 0.001 micron. A tuned cavity microwave source is used for particle generation. Particles are monitored 20 feet downstream.

Time-of-flight mass spectrometric analysis of individual particles give simple spectra as shown in Figure 1. The majority of particles are composed of pure carbon (60%) as shown in Figure 2. The particle size distribution, shown in Figure 3, has a mean of 0.0045 ± 0.0001 micron. The apparent noise in the particle size distribution of Figure 3 is statistical due to the data set size (390 particles). A Monte Carlo simulation gives a similar "noisy" distribution for the same size data set.

The chemical information shows a dominance of C^+ , with 60% of the particles composed only of carbon. CH^+ is the most common ion containing hydrogen representing nearly 10% of the particles. CH^+ is more prevalent than $C_2H_2^+$ which has the same C/H ratio. Conversely, CH_2^+ is less prevalent than $C_2H_4^+$.

There has recently been a surge of interest in metal complexes containing polycarbon ligands with extended unsaturation, spurred by their potential in the field of materials science. We have prepared a series of polyruthenium clusters featuring alkynyl ($-\text{C}\equiv\text{C}-\text{Ph}$) and butadiynyl ($-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{Bu}^t$) groups which are attached to the metal framework via metal-carbon σ - and σ - π interactions. The high degree of unsaturation provided by the hydrocarbonyl group allows for a rich and diverse chemistry. This study of ruthenium clusters using LSIMS and LSIMS-MS/MS assists in the characterisation of new polynuclear organometallic compounds and provides useful information on ligand dissociation and cluster fragmentation. In cases where absolute determination of structure by X-ray diffraction analysis is not possible, these techniques can allow the elucidation of molecular composition and assist in the identification of unknowns. The example given here is for the compound $\text{Ru}_5(\text{CO})_{13}(\text{C}\equiv\text{CPh})(\text{PPh}_2)$.

A study of possible ionization methods revealed that APCI resulted in a broad distribution of ions over a wide m/z range, whilst electrospray resulted in low intensity and irreproducible spectra. In contrast, LSIMS ionization in the positive ion mode using a *meta*-nitrobenzyl alcohol (mNBA) matrix resulted in intense spectra of the polyruthenium clusters. The LSIMS spectrum (Fig. 1a) shows considerable fragmentation and is greatly complicated by the wide isotopic envelopes (Fig. 1e) of the clusters due to the seven isotopes of Ru. In contrast, high energy MS/MS spectra (800eV, Xe CID, Micromass AutoSpec oa-TOF) are relatively simple and are dominated by the loss of ligands rather than by fragmentation of the polyruthenium structure, so that the isotopic composition of the precursor ion is less important.

The MS/MS spectrum (Fig. 1b) of the ion at m/z 1157 (the peak of highest intensity in the molecular ion distribution, Fig. 1e) shows a series of fragment ions ($\heartsuit$) due to the abundant loss of carbonyl groups from the precursor. A second series ($\clubsuit$) is due to the loss of $[\text{Ph}^n(\text{CO})]$ which suggests that the molecular species is the radical cation $\text{M}^{\cdot+}$. However, there is also evidence from the isotope distribution as well as from the low mass ions observed in the MS/MS spectrum of several polyruthenium compounds, for the formation of some MH^+ ions.

The MS/MS spectrum of the $[\text{M}-4(\text{CO})]^+$ ion (Fig. 1c) shows virtually the same fragmentation pattern as was observed for the molecular ion. Fig. 1d shows the MS/MS spectrum of the molecule stripped of carbonyls. The main fragment present is due to loss of C_6H_6 , with minor contributions due to isobaric precursor ions which are source-derived fragments containing carbonyl groups. No fragmentation of the Ru_5 cage was observed in any of the spectra.

In conclusion, it appears that both $\text{M}^{\cdot+}$ and MH^+ ions are produced by LSIMS. Although Ru-Ru bonds were not broken by collision energies of 800eV (Xe), MS/MS spectra are informative about ligand distributions. The ability of the AutoSpec oa-TOF to rapidly collect MS/MS data for several precursor ions helps in overcoming the ambiguities caused by the wide isotope distributions and extensive fragmentation in the LSIMS spectra.

Probing Silicon Substitution in Aluminum Phosphate Molecular Sieves by ToF-MS

S. L. von Heimburg, M. J. Van Stipdonk, E. A. Schweikert
Center for Chemical Characterization and Analysis
Department of Chemistry
Texas A&M University
College Station, TX 77843-3144
E-mail: EASGROUP@CHEMVX.TAMU.EDU

Zeolites and molecular sieves are being widely studied to increase the number and efficiency of the reactions they catalyze. One technique utilized in these studies is the addition of small amounts of another element into the zeolite or molecular sieve framework to change the catalytic selectivity. One example of this technique is the addition of silicon to aluminum phosphate, forming a "SAPO". The speed and selectivity at which a reaction is catalyzed by the molecular sieve are dependent on the pore size, the composition and the arrangement of atoms in the framework.

Previous studies of Desorption/Ionization Time of Flight Mass Spectrometry (ToF-MS) have shown that in the negative ion mode, secondary cluster ions are preferentially formed by the direct emission process, which allows this technique to be applied to the characterization of materials. Coincidence counting techniques are used in this experiment to increase the signal-to-noise ratio. A coincidence spectrum consists of the results of those primary ion impacts which produce the ion of interest. Several coincidence spectra plus the total spectrum can be acquired simultaneously.

We are currently investigating the substitution of silicon into the ALPO-5 framework using ToF-MS and MeV energy primary ions. We have collected mass spectra from samples with varying amounts of silica added during synthesis, and from these same samples which had been heated to higher calcinating temperatures. Figures 1 and 2 show the mass spectra of AlPO_4 and of SAPO with 2% silicon by weight respectively. The peak abundances measured in coincidence with PO_2^- were normalized to H^- and plotted. As the silica content increases in the unheated samples, the abundance of the silicate containing species and the abundance of alumina in the mass spectrum both increase, indicating the formation of silica and alumina on the surface. As the temperature at which the samples were heated increases, the abundances of the aluminum containing species and the abundances of the phosphate both decrease, and the abundance of SiO_2 increases, indicating the formation of a surface silicate layer. These results were confirmed by x-

ray photoelectron spectroscopy (XPS), a surface technique. The results were not confirmed by x-ray diffraction (XRD), a bulk technique, which showed the single-phase molecular sieve framework.

This experiment illustrates the importance of surface analysis in materials characterization. There exists a sharp contrast in the results of the surface and the bulk analysis methods. If only one of these types of analysis is used to characterize the material, an incorrect representation of the studied material may be made. Therefore, ToF-MS can be a compliment in near-surface analysis to other methods of materials characterization, such as XPS, XRD, and secondary ion mass spectrometry (SIMS).

Observation of doubly charged mercury cluster ions Hg_n^{2+} , $n=2-10$ by using secondary ion mass spectrometry

*H. Ito¹, T. Sakurai¹, T. Matsuo¹, T. Ichihara² and I. Katakuse²

¹Department of Physics, Faculty of Science, Osaka University, Toyonaka, Osaka 560, JAPAN
²Department of Earth and Space Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560, JAPAN

Mass spectra of doubly charged mercury cluster ($m/z=30-1065$) were investigated by secondary ion mass spectrometry. Positively charged ions were generated from an amalgam of mercury and silver by bombarding with xenon ion beam and mass analysed by a grand-scale sector type mass spectrometer. Hg_n^{2+} , $n=1-10$ and Hg_n^+ , $n=1-5$ were observed. It turned out doubly charged mercury clusters survived at least for 0.1 ms.

INTRODUCTION: It is known that bulk mercury shows metallic character. This fact might seem to be contradict that a mercury atom possesses $5d^{10}6s^2$ closed shell electronic structure. In case of the bulk, overlapping 6s and 6p bands produces metallic character of mercury bulk. In case of mercury clusters, the widths and gap of the 6s and the 6p band vary depending on a cluster size. Thus, the mercury cluster has a metal-to-nonmetal transition as a function of cluster size, accordingly. Mercury clusters and mercury cluster ions were investigated by mass spectrometric techniques [1-6]. Neutral mercury clusters were produced by using a pure-gas adiabatic beam expansion [1] or a supersonic molecular beam with a rare gas [2-6]. The neutral clusters were ionized by using an electron impact method [1-3, 4] or a photo absorption method [5, 6]. Mass analyses were performed by using a quadrupole [1] or a time of flight [2-6] mass spectrometer. It is important to study mass spectra of mercury clusters by the comparative production and ionization method. The purpose of present measurement are (1) to detect doubly charged cluster of even size and (2) to compare the abundance distribution of clusters produced by different production and ionization method. The detection of doubly charged clusters of even size are required to measure under higher mass resolving power. We report here mass spectra, $m/z=30-1065$ by using an ion bombardment ionization and a sector type mass spectrometer.

EXPERIMENTAL: Positively charged ions are generated from an amalgam of mercury and silver by bombarding with xenon ion. The primary xenon ions were produced by using a discharge type ion source[7], and were accelerated to 10 kV above target voltage. The spattered positively charged ions were mass-analyzed using a grand-scale sector mass spectrometer (radius of magnet, 1.25 m, flight path length 7.635 m), of which the field arrangement is QQHC (Q denotes quadrupole lens, H, homogeneous magnetic sector, C, cylindrical electric sector)[8]. Mass spectra were recorded by using 486 PC/AT compatible computer with an analogue to digital converter (Data Translation DT16-EZ, MA) by scanning the magnet current in a linear mode. The scanning of magnet current and filtering of analogue signal were performed by using a scanning unit and a filtering unit designed for a mass spectrometer (JEOL JMS-HM1000, Akisima, Japan), respectively. The β slit width was adjusted such that the ions accelerated to 5 kV $\pm$ 0.1% were able to pass through an electric analyzer. An voltage adjustment of a lens system in the ion source was performed by using a beam of Hg_2^+ .

Fig. 1. Mass spectrum, $m/z=30-1065$

SIMS, Double Focussing-Mass Spectrometer, Metal Cluster, Binding Energy, Ion Structure

RESULT and DISCUSSION: Figure 1 shows a typical mass spectrum, $m/z=30-1065$. The most abundant ions were singly charged mercury cluster, Hg_n^+ , $n=1-5$. An intensity of Hg^+ was saturated in Fig. 1. Doubly charged cluster ions, Hg_n^{2+} , $n=1-10$ and mercury-silver binary cluster ions, Hg_nAg^+ , $n=1-4$ can be seen. Multiply charged atoms Hg^{N+} , $N=2-6$ and Xe^{N+} , $N=2-4$ can be also seen. As an example of doubly charged mercury cluster, fig. 2 shows a mass spectrum of Hg^+ and Hg_2^{2+} . It is clearly seen that isotopic pattern of Hg^+ fits well to the isotopic composition of element shown in IUPAC and that isotopic peaks of Hg_2^{2+} are also clearly observed. Peaks are furnished with mass number and symbol of element. Figure 3 shows an expanded mass spectrum of fig. 1, $m/z=296-341$. Isotopic peak patterns of Hg_3^{2+} , HgAg^+ and HgXe^+ can be well seen.

It turned out doubly charged mercury clusters survived at least for 0.1 ms. This time was estimated from the flight time of the ions which was calculated by using the designed length from a source slit to a detector slit (7.635 m) and the acceleration voltage (5 kV). As an example, the calculated flight time of Hg_2^{2+} and Hg_3^{2+} are 0.11 ms and 0.16 ms, respectively.

In case of mercury cluster ions producing by using a secondary ion mass spectrometry, it is clear from observed data that there does not exist so-called critical size of doubly charged mercury clusters with regard to the coulomb repulsive forces.

We might conclude that the binding energy of Hg_2^{2+} is stronger than that of Hg_2^+ . The dissociation energy of Hg_2^+ was reported with 1.40 eV. The value, 1.40 eV happens to be the same to the repulsive energy of two point charge in 1 nm distance apart. The distance of 1 nm is longer than a mean bond length. If the binding energy of Hg_2^{2+} is equal to or less than 1.4 eV, it is impossible to observe Hg_2^{2+} . Because a coulomb repulsive force of Hg_2^{2+} will overcome a dipole interaction force of Hg_2^{2+} . As a result of competition between coulomb repulsive and dipole interaction force, Hg_2^{2+} will dissociate. However, Hg_2^{2+} was clearly observed, it suggests that the binding energy of Hg_2^{2+} was larger than 1.4 eV.

Researchers have long been interested in the direct analysis of coal surfaces with secondary ion mass spectrometry (SIMS). However, many of the results reported are ambiguous and difficult to interpret due to low mass resolution (R) of the instruments used in the past. Low mass resolution is a particular problem in the analysis of coal, in which both organic and inorganic ions are of interest.

In this work, we present data acquired with a high performance instrument with mass resolution (R) better than 7500 at Si (m/z 28). The instrument, a TOF SIMS (PHI-Evans) equipped with a 69Ga primary ion gun, was used to analyze the surface of polished coal planchettes. A series of coal samples was collected from the BRJ Area located in the desert region of northwestern China. Table 1, as an example, shows precise mass determinations of elemental ions derived from a coal sample (BRJ-9), as well as the measured elemental compositions obtained by comparison with the theoretical mass and with isotopic abundance patterns. One of the main results of this study is that the noble metal elements Cu and Ag, and others including Be, Na, Mg, Si, Ca and Zn, are definitely present in the coal; while elements such as K, Al and Fe are not detected. Elements of interest from the point of view of air pollution include F, S and Cl are also detected with negative ion mass spectrometry (data not shown here).

In addition, the chemical state of selected elements in the coal is also considered. For example, based on the precise mass determinations and comparison with known isotopic abundance, the ions at 143 Da and 145 Da, shown in table 1, are more reasonably interpreted as the protonated cluster ions $AgClH^+$ instead of ions of $AgCl$, which indicates that silver in the coal at least partly exists as organic salt of $AgCl$. The ions at 135/137 Da and 91/93 Da are more likely to represent the species $Ag(CH_2CH_2)$ and $Cu(CH_2CH_2)$, respectively, rather than the species $Ag(CO)$ and $Cu(CO)$. This suggests that a certain amount of silver and copper may be chemically adsorbed with the organic substance in the coal.

This work demonstrates that the application of high resolution secondary ion mass spectrometry to coal studies provides a wealth of chemical and elemental information that can not be obtained with instruments having only unit or near unit mass resolution.

This work was supported by Chinese Postdoctoral Funds

INTRODUCTION

In the field of forensic science, qualitative and quantitative data acquisition, and the time required to obtain the results are of equal importance.

Even though Ion Mobility Spectrometry (IMS) is a semi-quantitative technique, it has the advantage of an extremely rapid analysis time, unlike other techniques⁽¹⁾.

The objective of the present work is to point out an extremely rapid method for the quantitative determination of 2,4,6-TrinitroToluene (TNT), one of the most widely used military explosive, using a field-type detector based on the IMS technique

The recent modifications to the IMS instrument at our laboratory have increased its sensitivity and reduced background noise.

These improvements gave us the incentive to carry out the present work.

METHODS

Equipment

IMS: IONSCAN Model 250/350 (Barringer Instruments Ltd., Mississauga, Canada)

IMS Desorption time: increased from 6.6 s to 20.0 s to improve quantitative analyses

IMS Amplitude Threshold: reduced from 60 du to 30 du to improve detection of TNT samples at lower concentrations

Rapid Analysis Method for TNT

Standard solutions: 0.8, 2 and 3 ppm of TNT in acetonitrile and three analyses were carried out for each solution

Calibration curve of first approximation: to verify if the detected quantity fell in the linear range of 300 - 5000 pg and to calculate the value x in pg. The value x obtained using the calibration curve of first approximation is used to construct the Calibration curve of second approximation in which two standard solutions were considered containing $x + 300$ pg TNT/ml and $x - 300$ pg TNT/ml

RESULTS

- Statistical analysis of quantitative results: distribution, χ^2 test, method of least squares.
- Linear response between 300 pg and 5000 pg
- Accuracy between 0.2% and 1.0 %.

CONCLUSIONS

From the study carried out it was determined that it is possible to apply IMS for quantitative determination of TNT.

The same statistical treatment of the quantitative results obtained from the IMS has allowed the characterization of the interval of linearity within which an analytical method permitting a good precision, from a quantitative point of view, may be based. Even if the focus of the method has been on using TNT, it is now being looked into applying it to all the principal explosives of Military Air Force interest.

TRACE ANALYSIS OF EXPLOSIVES IN WATER BY GC/MS AND GC/MS/MS WITH A TEMPERATURE-PROGRAMMED INJECTOR

Jehuda Yinon

Department of Environmental Sciences and Energy Research
Weizmann Institute of Science, Rehovot 76100, Israel

The disposal of large quantities of explosives in an environmentally acceptable manner poses serious difficulties. For many years, obsolete explosives and ammunition were disposed of by burying them in the ground. Wastewater from explosives-manufacturing plants, containing explosives and their degradation products were discharged into rivers and streams. In order to assess the extent of the contamination of an area by explosives it is necessary to detect and analyze the explosives and their degradation products in groundwater and soil. Such analyses may reveal the degree of contamination in areas suspected to be contaminated by improper disposal of obsolete explosives or by wastewater from ammunition plants.

Although GC/MS is a well established technique for trace analysis of organic pollutants, including some explosives, it has never been recommended for the analysis of the more thermally labile explosives because of their decomposition in either the heated GC column or injector.

We have used GC/MS and GC/MS/MS with a cooled temperature-programmable injector to analyze picogram amounts of a series of explosives in water. The analyzed compounds included 2,4,6-Trinitrotoluene (TNT), 2,4,6,N-tetranitro-N-methylaniline (tetryl), 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (HMX) and pentaerythritol tetranitrate (PETN).

The instrument used was a Varian 4D GC/MS/MS-ion trap with a Septum-equipped Programmable Injector (SPI). The GC column used was a DB-1, 15 m x 0.255 mm, 0.25 μ m film thickness, column, programmed from 80°C to 250°C at 25°C/min. The temperature of the SPI injector was programmed from -5°C to 250°C, at a rate of 200°C/min. The injector was cooled with liquid CO₂. Helium flow rate was 1 mL/min.

The ionization mode used was electron ionization (EI). Ion trap temperature was 170°C.

Analyzed samples were prepared by spiking water with a mixture of explosives at various concentrations. Explosives were then extracted from water by liquid-liquid extraction with methylene chloride. After adding methanol, the methanol-dissolved extract was concentrated by a factor of 100 and injected into the GC/MS.

Fig. 1 shows the mass chromatograms of a mixture of explosives in water containing 10 ppb of each explosive. The explosives can be identified by at least one typical ion for each explosive. Identification is supported by MS/MS. Fig. 2 shows the GC/MS/MS-CID spectra at various CID voltages of the ion at m/z 223 of HMX.

Using Mass Spectrometry and a Direct Insertion Probe to Prescreen Soil Samples for Fuel Contamination

The largest point source of soil pollution is leaking underground storage tanks used for gasoline and diesel fuel. This has prompted legislation requiring the routine monitoring of these facilities for fuels and related compounds. Consequently, there is a need for rapid detection of contaminants and remediation for the soil surrounding these sites. In order to facilitate rapid assessment of a potentially hazardous site, it is desirable to utilize instrumentation and techniques which afford the most information regarding a site; allow for optimization in environmental assessment; and maintain a realistic time schedule for determination of contamination and resulting remediation. To address these issues a technique using a direct insertion probe (DIP), suitable for soil samples, coupled to a quadrupole mass spectrometer was investigated to analyze soil samples without any preparatory work.

When analyzing soil samples for fuel contamination, the primary obstacle¹ is the procedure used for extraction of target compounds from the soil matrix. The current USEPA approved method² for this type of analysis involves the use of halogenated solvents. This method takes a minimum of 3 to 4 hours to extract the compounds from the soil and prepare the sample, and creates an additional halogenated waste stream. The use of a quadrupole mass spectrometer and a purpose built DIP will significantly reduce the waste stream resulting from the extraction process. The goal of this project is to develop a technique whereby a standard mass spectrometer with a DIP suitable for soil samples can be used to detect, identify, and quantify components of petroleum products directly from the soil eliminating the need for any form of solvent extraction which saves time and money.

To facilitate the introduction of the soil sample into the MS, the original DIP was replaced with a probe designed and built at UTSA. This probe has an inner cavity designed to accept a 0.5 mL, 6 mm o.d., borosilicate culture tube (Kimble) replacing the capillary tube intended for pure samples. An end cap is used to hold the sample tube in place. The nichrome wire coiled around the tube cavity has an increased number of turns and is embedded in a high temperature ceramic coating to provide more even and efficient heating. A temperature profile run by the GC descriptor program controls the temperature and rate at which the sample subsequently is heated and thermal desorption of the analytes of interest occurs. A platinum temperature sensor was used to monitor temperatures using the GC descriptor.

Sea sand was used as a blank soil matrix into which known contaminants were spiked. Matrix samples were prepared in advance of the various batch runs. The sea sand was baked before use at 200 °C to reduce phthalate and hydrocarbon contamination. Each sample consisted of 0.50 g of sea sand loaded into a borosilicate culture tube followed by a plug of fused silica wool (Restek) inserted midway into the tube. The fused silica wool was used as a precaution to maintain the sand within the sample tube. These prepared blanks were then stored at room temperature. Varying amounts (1 µL to 20 µL) of Diamond Shamrock diesel #2 were injected into the prepared sample tubes.

The tube was loaded into the DIP and inserted into the mass spectrometer. With the spiked sample next to the ionizer of the MS, the DIP was held at a constant initial temperature of 60 °C for 1 minute, then ramped to 150 °C at a rate of 20 °C per minute, then ramped to 300 °C using a ramp of 10 °C per minute and finally held at 300 °C for 5 minutes. The mass spectrometer was scanned from 60 to 400 m/z at a rate of one scan per second.

The DIP-MS technology for soil sample analysis developed at UTSA was used to run samples of unweathered diesel fuel spiked into a baked sea sand soil matrix. The mass spectra display typical hydrocarbon background due to trace contamination from back-streaming of pump oil into the vacuum chamber overlaid with a slight presence of hydrocarbon ions desorbed from the soil matrix at 177 °C. The mass spectrum shows a series of 14 amu losses from 43 amu to 166 amu which represents the typical fragmentation pattern of straight chain alkanes at low concentrations, with additional m/z = 208, 236, 257. These ions have reappeared in other sample runs. Although these have not been sufficiently identified, their presence indicates that this method can be further developed for fuel analysis.

Another sample that had been spiked with 5000 ppm diesel fuel #2 standard purchased from ULTRA Scientific. The higher concentration level of the spike was reflected in the increase in the number of ion counts. The RIC has two primary features. The first indicates immediate volatilization of some components as the DIP was introduced into the vacuum chamber through the solids inlet. This accounts for some sample loss and indicates one obstacle in converting this technique from pre-screen to quantitation. The second feature represents thermal desorption of the diesel fuel contaminants. Further investigation will be necessary to fully characterize these features and to develop a temperature profile specific to desorption of fuel contaminants. Initial analysis of the chromatographic peak indicates the presence of alkanes. The mass spectrum shown is typical of straight chain alkanes at low concentrations. There is a clear series of 14 amu's from 182 amu to 43 amu.

A quadrupole mass spectrometer coupled with a DIP can be used to prescreen soil samples for fuel contamination. Further study of this technique should prove it out as a method for quantitative detection of fuels in soils. These investigations will involve the development of calibration curves for unweathered and weathered diesel fuels and gasoline. It is intended that these curves will serve as a base line for development of subsequent analysis on other soil types. Problems with losing contaminants upon entry into the MS vacuum chamber should decrease as the soil type (e.g. clay, loam soil matrix) affinity for contaminants increases. The increase in soil sample size is a benefit to rapid analysis. This technique can easily be adapted to field work as there is little preparation necessary. This technique holds promise in meeting the needs for sampling underground storage tank sites in the most efficient manner.

A quadrupole mass spectrometer coupled with a DIP can be used to prescreen soil samples for fuel contamination. Further study of this technique should prove it out as a method for quantitative detection of fuels in soils. These investigations will involve the development of calibration curves for unweathered and weathered diesel fuels and gasoline. The increase in soil sample size is a benefit to rapid analysis. On-line Postcolumn Photolysis LC-Electrospray-MS Analysis of Isomeric Triazine Pesticides in Food Samples. Dietrich A. Volmer¹ and Jon G. Wilkes, U.S. Food and Drug Administration, National Center for Toxicological Research (NCTR), Jefferson, AR 72079

1. Introduction. Since many agricultural chemicals react in the environment under the influence of sunlight to form new, potentially harmful transformation products, photodegradation studies of pesticides have received much attention. Most studies have been carried out in the laboratory under conditions designed to approximate those found in the field. In the present study, photolytic transformation has been induced by an on-line photolysis LC-MS approach; that is, by using a postcolumn photoreactor coupled to the system prior to MS detection. The kinetics of these reactions are largely dependent on irradiation wavelength, residence time in the photoreactor, presence of photosensitizers, solvent composition and pH. Hence, these parameters were investigated to evaluate their impact on the photolysis experiment. Moreover, in this study on-line photolysis was also used for a quite different reason; viz. to enhance structural information in LC-MS spectra. The most common ionization techniques - TSP, ESI and APCI - yield primarily molecular weight information. That is, little fragmentation is observed to confirm the structure of the analyte. In-source CID has been utilized as a means of producing structurally significant ions. It is, however, often unreliable and can suffer from a significant loss in sensitivity. Alternatively, on-line photolysis can be used to induce dissociations. After postcolumn irradiation and LC-MS ionization the formed phototransformation products appear as "fragment ions" in the mass spectrum since both the unreacted precursor compound and the photolysis products all co-elute. This offers a means of producing structurally significant ions. The present paper has two main objectives: (1) to examine the photochemical behavior of several pesticides in a photoreactor coupled on-line with an electrospray LC-MS/MS system, to identify phototransformation products, and to establish possible photolytic pathways; (2) to show the application of on-line photolysis LC-MS as an alternative approach for both trace and confirmatory analysis of pesticides in food samples by means of inducing photolytic dissociations.

2. Experimental. HPLC work was performed on a 15-cm x 3.2-mm (5- μ m) Ultracarb 5 ODS 30 column operated at a flow rate of 0.6 mL/min. The mobile phase consisted of a methanol-water gradient (20-95% methanol over 45 min). An additional postcolumn flow of 0.4% formic acid in methanol at 0.2 mL/min was applied. The photosensitizers acetone and benzophenone were added postcolumn to the mobile phase via a syringe pump. A photochemical reactor fitted with Teflon knitted-open tubular reactor coils (0.25-mm i.d. x 5-, 10- and 15-m length) and 8-W, 254- or 366-nm ultraviolet bulbs was connected after the analytical column, followed by a 1:4.5 split prior to MS analysis. Approximately 150 μ L/min of sample and eluent were admitted into the electrospray source of a Finnigan TSQ 7000 triple-quadrupole mass spectrometer. CID was accomplished in the Q2 unit using argon as collision gas at pressures between 1 and 1.6 mTorr and collision-offset voltages between 15 and 35 V.

3. Results. A series of N-heterocyclic compounds phenylureas and carbamates were chosen for this study. (a) *Role of Singlet Oxygen in the Degradation Process:* The acetone- and benzophenone-sensitized photodegradation of pirimicarb and metamitron was different from that in solutions without photosensitizer (see Fig. 1). Singlet oxygen is believed to have a role in the

degradation process in the presence of photosensitizer. Singlet oxygen is readily formed via the uptake of radiation by the photosensitizer which subsequently transfers the absorbed energy to ground state molecular oxygen. Singlet oxygen is a highly reactive electrophile. It readily attacks nitrogen-activated double bonds, e.g. the 5,6-double bond of the pyrimidine moiety of pirimicarb. The results were confirmed by MS/MS analysis of the degradation products formed. (b) *Phototransformation of Phenylureas:* On-line photolysis LC-MS analysis of phenylureas indicated a large number of transformation products. The major degradation pathway was loss of halogen and subsequent replacement by a hydroxyl group or hydrogen. Consequently, fenuron, which does not contain halogen atoms on the phenyl ring, did not undergo substantial photodegradation under the applied conditions. (c) *Photolysis LC-MS Analysis of s-Triazines:* Photolysis of triazines in the presence of solvent led to a number of phototransformation products. The chlorinated triazines readily underwent replacement of the chlorogroup by a methoxy or hydroxyl group, while in alkylthiotriazines the alkylthio group was replaced by hydrogen or hydroxyl. Moreover, isomeric triazines could be distinguished by their photolysis LC-MS spectra. The parameter f/I is an indicator for the ionization efficiency of the transformation products formed. For $f/I = 1$, the phototransformation products are ionized with the same efficiency as the original precursor compound as it was observed in our experiments for the investigated triazines. That is not surprising since the major degradation pathways do not involve loss of nitrogen atoms. Consequently, the ESI sensitivity was not substantially reduced in the photolysis mode. Thus, the system could be used for a very sensitive confirmatory analysis in sample extracts. (d) *[M+32]⁺ Ion Formation of N-Methylcarbamates:* All investigated N-methylcarbamates produced significant amounts of methylamine after photolysis. The proton affinity of methylamine is high. Consequently, carbamate-amine adducts were formed during photolysis and/or ionization. Addition of photosensitizers significantly enhanced photolysis; i.e., usually more than 90% of the precursor compounds were degraded.

ANALYSIS OF 23 TRIAZINE HERBICIDES USING ION TRAP GC/MS/MS.

Vincy M Abraham and Bert C Lynn Jr, Department of Chemistry, Mississippi State University and Mississippi State Chemical Laboratory, Mississippi State, Mississippi 39762

Triazines are a class of herbicides commonly applied in agricultural fields as pre- and post-emergent weed control agents. Because of serious health risks posed by these herbicides, it is important to improve the qualitative and quantitative detection of these toxic pesticides in complex matrices. In spite of extensive clean-up procedures prior to analysis, background matrix interference often prevents the detection and quantitation of the target compounds at trace levels. Triazines are often referred to as s-triazines, meaning they are symmetrical in structure. This structural similarity leads to poor chromatographic selectivity and resolution. Tandem mass spectrometry with optimized MS/MS parameters and multiple reaction monitoring has proven to be a good solution to this problem.

A Saturn 3 ion-trap GC-MS system (Varian, Walnut Creek, CA, USA) with Wave-Board technology was used for all experiments. The gas chromatograph was equipped with a DB-5MS fused silica capillary column, 60m in length and 0.25 mm id with 0.25 µm bonded film (J & W Scientific) and a 1078 injector. One µl splitless injections were made using a Varian 8200 autosampler. Helium carrier gas at a flow rate of 1.5 ml/min was maintained throughout the experiment. The GC program was at 50°C for 1 min and then ramped to 170°C at 20°C/min with no hold time, then to 270°C at 3°C/min and finally it was ramped to 300°C at 5°C/min and held at 300°C for 3 min. The injector temperature was maintained at 250°C and the transfer line temperature was at 300°C. The real world samples were obtained from Mississippi State Chemical Laboratory.

A GC/MS/MS method using Saturn 3 ion trap was developed for the analysis of twenty-three triazines in a single chromatographic run. Selected ion storage (SIS) in the EI mode was used to acquire the full scan spectra. In SIS, only the ions of interest are stored, reducing space-charging and improving mass resolution. Non-resonant collisionally induced dissociation MS/MS parameters were optimized using the Automated Method Development (AMD) Toolkit® software (Table 1). The CID parameters were optimized for selectivity and sensitivity. The product ions resulting from MS/MS parameter optimization were selected as quantitation ions. A five point calibration curve was developed and found to be linear over a concentration range of 20 pg/µl to 1 ng/µl.

Multiple Reaction Monitoring (MRM) was used to analyze triazine compounds that were chromatographically difficult to separate. The MRM allowed scanning across the chromatographic peaks using different CID parameters. These microscans were averaged to produce an analytical scan. The optimized CID parameters of the closely eluting compounds in a particular time-segment of the chromatogram were used to construct the MRM IPM files. In this experiment, 23 triazine herbicides were successfully analyzed in a single chromatographic run using MRM and MS/MS (Figure 1). The GC/MS/MS method thus developed was applied for the residue analysis of triazine contaminants in real world samples. The triazine analytes were routinely detected at ppb levels in the real world sample (picograms on column) and high signal to noise ratios were achieved.

IDENTIFICATION OF TRACE COMPOUNDS IN SOIL USING GC/MS IN CONJUNCTION WITH GC/AED TECHNIQUES

Dieter Drexler, Jeannine Jordan, Steven R. McGown

BASF Corporation • Agricultural Products Center • P.O. Box 13528
Research Triangle Park, NC 27709-3528

INTRODUCTION

The agrochemical industry performs a wide variety of residue analyses, studies and tests so that the safety of agrochemicals to the consumer and the environment can be ensured. During the development of crop protection agents, extensive metabolism studies of the active ingredient (AI) are performed, for example in soil. Soil samples are spiked with the AI and after a defined time, the soil is analyzed to study the behavior of the AI. One approach for these studies is the application of ^{14}C -radiolabeled compounds. This radioactive label makes it possible to keep track of the AI and/or degradation products using a ^{14}C -sensitive detector.

Soil extracts can then be screened by a GC/AED for GC-able compounds containing a ^{14}C -label or unique heteroatoms. The AED analysis can provide data about the composition of unknown molecules or verify the existence of the AI.

This information is critical in the identification of unknowns occurring in these soil extracts and simplifies any GC/MS analysis.

METHODS

A ^{14}C -labeled molecule, BAS 490 F, was chosen to illustrate this technique. The methylester of BH 514 was selected because it contains two Cl-heteroatoms.

The GCs used in the GC/AED and GC/MS were equipped with the same type of J&W DB-5MS columns. The same GC analysis conditions were utilized on each system in order to compare the retention times of the compounds.

RESULTS

The analyses of the purified spiked soil extract containing the compound BAS 490 F (AI) with the GC/AED showed multiple components eluting from the column (panel #1) in the ^{12}C -channel. The additional chromatographic information resulting from the nitrogen channel (N-channel) and the ^{14}C -channel indicated that the AI had been successfully extracted from the soil. The ^{12}C -, N-, and ^{14}C -channel were monitored simultaneously on the AED during a single injection. The retention time of the AI was verified with a ^{14}C -labeled reference solution.

This spiked soil extract was then diluted by factor 100 and analyzed with a Finnigan GCQ (panel #2). Utilizing the MS/MS capabilities to eliminate chemical interferences it was possible to trap m/z 174, which is a fragment unique to BAS 490 F in the negative ion mode, NICI. Mass 174 was subjected to collisionally activated decomposition, CAD, and fragmented again resulting in the MS/MS spectrum shown.

A purified soil extract containing the compound BH 514 - Methylester (AI) and a purified blank soil extract were analyzed on the GC/AED. The two heteroatoms, chlorine, on the ring in the AI can be utilized as labels for trace analysis. The chlorine channel (Cl-channel) was monitored for the soil blank and several natural occurring components were detected. The analysis of a reference solution of the AI showed that the AI elutes prior to these natural occurring components.

The analysis of the spiked soil extract indicated that there was a high chemical background in the ^{12}C -channel. The N-channel revealed less chemical interference but the data did not conclusively identify the AI. The AI was conclusively identified in the Cl-channel.

Expanding the region of interest showed the peaks detected on different element channels. Quantification of the AI was not possible in the ^{12}C -channel due to chemical interference, but the AI could be quantified utilizing the N- and Cl-channels. Obtaining data for the ^{12}C -, N- and the Cl-channel required two injections which were handled by the software easily. Two injections were necessary due to the different emission lines of the elements being monitored.

The soil extract was analyzed using GC/MS in the positive EI mode. Using MS/MS capabilities, the molecular ion m/z 255 of the AI could be trapped. This ion was then subjected to CAD and the resulting MS/MS spectrum recorded.

CONCLUSION

In conclusion, the GC/AED does not have the sensitivity of the GCQ, but it contributes valuable information due to the specific nature of the AEDs detection system. Simultaneous multielement analyses provides orthogonal information about the composition of the analyzed compounds. Specifically, the ability to detect ^{14}C -labeled compounds makes the AED a unique and useful tool to prescreen extracts in trace analysis studies. The use of the heteroatom channels yields element specific detection capabilities resulting in additional valuable data. Utilizing the AEDs element specific capabilities can result in faster trace analysis by the elimination of intensive sample preparation schemes. This is possible when unique heteroatoms or isotopes are present because the specificity of the AED alleviates the chemical noise problems normally encountered with other detection systems.

The GC/MS is a well known and long used instrument for the analysis and identification of unknown compounds. The specific information provided by the AED should be used in conjunction with a GC/MS system. The AED can provide the retention times and composition of labeled compound which improves the process of unknown identification. The Finnigan GCQ has GC/MS/MS capabilities which results in a reduction of the chemical background due to matrix. This ultimately increases instrument sensitivity, improves the resulting data, and confidence in unknown identification.

Pesticide Residue Analysis; A Comparison Between GC/MS and GC/MS/MS

Steve Schachterle and Carl Feigel, Varian Chromatography Systems, 2700 Mitchell Drive, Walnut Creek, CA 94598

Summary

GC/MS was compared with GC/MS/MS for the analysis of extracts from seven fresh fruits and vegetables spiked with a mixture of nineteen pesticides at the 10 ppb level (20 pg/ μ l). The pesticides included herbicides, fungicides, chlorinated insecticides, and organophosphorus insecticides.

Experimental

A Saturn 4D GC/MS with SilChrom trap was used in the EI mode.

Injections of 5 μ l were made into a 1078 injector operated in the temperature-ramped splitless mode.

The column was a Restek Rtx-5MS, 30 m $\times$ 0.25 mm with a 0.25 μ m film thickness.

Sample Preparation

Each whole fruit or vegetable was chopped and weighed before soaking overnight in methylene chloride. Water was removed, the extract was evaporated to dryness and reconstituted in hexane to give 1 μ l equivalent to 2 mg of the original produce. These final extracts were spiked with pesticides at the 10 ppb level. Internal standards were included at the 100 ppb level.

Results and Discussion

GC/MS provided identifiable spectra for some of the compounds, but for many, the spectrum was obscured by the chemical background. Figure 1 shows ethion and azinphos-methyl in apple extract by GC/MS. The ethion spectrum is easily identifiable, but the azinphos-methyl spectrum shows nothing but background.

GC/MS/MS provided unique spectra for all 19 of the pesticides tested in all 7 matrices. Figure 2 shows the same two pesticides in the same matrix as figure 1, analyzed by GC/MS/MS. In both cases, the spectra in the extract are identical with the ones from the standard.

Conclusions

GC/MS is a good screening technique, but may require more involved sample cleanup in order to identify pesticides at low levels.

GC/MS/MS is an excellent target compound technique, allowing identification and quantitation of pesticides at low levels, even in complex matrices.

Molybdenum Ion Trap for Analysis of Organochloride Pesticides

by
Ruidan Chen*, Stephen Palermo, and Peter Grosshans
Hitachi Instruments, Inc., 3100 North First Street, San Jose, CA 95134

The typical material for quadrupole ion trap electrodes is stainless-steel. However, when such an ion trap is used for organochlorinated compound analysis, the samples are likely to be degraded due to their interaction with the stainless-steel electrodes. To solve this problem a three-dimensional quadrupole ion trap made of Molybdenum was incorporated into a Hitachi GC-3DQMS system for the analysis of organochloride pesticides. Analyses of Organochloride Pesticide Mixture PPM-525-1 (from Ultra Scientific N Kingstown, RI) using both a Molybdenum ion trap and a stainless-steel ion trap were carried out under the same experimental conditions. Each sample ampule contains the following components at 100 ug/ml in methanol: alachlor, aldrin, atrazine, lindane, alpha-chlordane, gamma-chlordane, endrin, heptachlor, heptachlor epoxide (isomer A), methoxychlor, trans-nonachlor, and simazine. The original sample solution was diluted into 10 ug/ml with methanol. In each experimental run, 1 nl of the diluted sample solution (10 ng of each component) was injected into the GC.

Experiments were carried out using a HP 5890 II gas chromatograph (Hewlett Packard, Palo Alto, CA) and a Hitachi 3DQ Mass Spectrometer (Hitachi Instruments, Inc., San Jose, CA). XTI-5 column (Restek Corporation, Bellefonte, PA) is 15 m in length, 0.25 mm in ID, and 0.25 μ m in df. Initial time: 1 min; final time: 20 min. Initial temperature: 50°C; final temperature: 300°C. Heating rate: 20°C/min. He flow rate: 1 ml/min. Injector temperature: 250°C. Both stainless-steel trap and Molybdenum trap were used to acquire data (see the result section for details). For all the experiments, ion level 40 amu; scan range: 40 to 650 amu. Emission current: 15 uA; ionization time: 1 ms. Trap temperature: 120°C. 10 microscan co-adding.

To save space, we only present the mass spectra from Chlordane and Nonachlor in Figures 1 and 2, respectively. In each figure, the top spectrum is from the stainless-steel ion trap, the bottom spectrum is from the Molybdenum ion trap, and the one in the middle is the standard spectrum for that component from the NIST library. Results show that the Molybdenum ion trap performs generally much better than the stainless-steel ion trap, both in eliminating sample degradation and in reducing chromatographic tailing.

Generally, degradation of Chlorine-containing sample was observed in the stainless-steel ion trap. The greater the content of chlorine in the sample, the greater the degradation. The implementation of a Molybdenum ion trap into the 3DQMS greatly alleviated the interaction between chlorine-containing samples and the ion trap. Much better matching between the experimental results and the NIST standard spectra was achieved by using the Molybdenum ion trap. The tailing in chromatograms is also reduced due to the implementation of the Molybdenum ion trap. We suggest that Molybdenum ion traps be used for all routine analyses of chlorine-containing pesticides for more reliable results.

Determination of PCDD/F in Mixed Waste Compost from Small Static Piles

Brian D. Eitzer, William A. Berger and Mary Jane I. Mattina
Department of Analytical Chemistry
The Connecticut Agricultural Experiment Station
P.O. Box 1106, New Haven, CT 06504

One concern about the use of mixed waste compost is the presence of toxic compounds such as polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/F). These compounds are likely to be present in the feedstock and their concentrations could be changed by the composting process. During the summer of 1995 a portion of the organic waste generated at the Connecticut Agricultural Experiment Station was composted during a demonstration project. Organic waste materials were collected throughout the Station (primarily from lunchrooms and greenhouses) and composted in small static piles. As part of this project the concentration of PCDD/F was determined in samples taken from the piles both before and after the compost was generated. Results of these determinations are reported here.

Mixed wastes composed of food wastes (13-53%), plant material (13-23%), and spent potting media (34-64%) were shredded with a wood chipper and formed into three 24 ft³ compost piles. The piles were aerated by turning weekly. The temperature of each pile was monitored daily; when the temperature had returned to ambient it was assumed that the composting process had been completed (from 3-8 weeks). Each pile was sampled after being formed and upon completion of composting with the samples frozen at -4 C° until analysis.

Compost samples were Soxhlet extracted, taken through a multi-step clean-up procedure and analyzed by high resolution gas chromatography/ high resolution mass spectrometry on a Kratos Concept S. The MS was operated in the selected ion monitoring mode, using 5 groups of 10 ions each (1 group for each level of chlorination from tetra-, through octa-) at a resolution of 10,000. All of the 2,3,7,8 substituted congeners were individually quantified as compared to carbon-13 labeled standards. Homolog concentrations were determined based on the average response of all the 2,3,7,8-substituted congeners within a homolog.

Concentration of the average PCDD/F homologs for each pile are presented in Table 1 with the individual 2,3,7,8-substituted congener data in Table 2. As can be seen from these tables there were not any significant changes in concentration of PCDD/F which occurred during the composting process. Table 3 converts the overall average concentrations from all samples into 2,3,7,8-TCDD toxic equivalents for use in health risk assessment. It is useful to compare this number to the criteria for land application of sludge proposed by Goodman et al (*Environ. Toxicol. and Chem.*, 1995, 14, 1443-1450). They proposed that the mass of 2,3,7,8-TCDD + 0013 times the mass of 2,3,7,8-TCDF not exceed 1.3 mg/hectare. For a conservative estimate we used the average TEQ (including all congeners and 2,3,7,8-TCDF at a 0.1 equivalency factor) and an assumed compost loading of 50 tons per acre. Given these parameters the TEQ loading would be 0.3 mg TEQ/hectare well below the proposed limit.

ANALYSIS OF THERMALLY LABILE PESTICIDES BY GC/MS AND GC/MS/MS WITH TEMPERATURE PROGRAMMED INJECTOR

Adam Vincze * and Jehuda Yinon

Department of Environmental Sciences and Energy Research
The Weizmann Institute of Science, Rehovot 76100, Israel.

Carbamate and phenylurea pesticides are extensively used as insecticides, herbicides and fungicides. Presence of such compounds in the environment poses a potential health hazard because of possible contamination of food and water supplies. It is therefore of importance to have efficient methods for their detection and analysis. One of the most widely used methods of environmental analysis is GC/MS. Ion-trap GC/MS and GC/MS/MS are among the most sensitive of GC/MS techniques available. While the range of commercial ion trap mass spectrometers available is well suited for the purpose, thermal lability of the compounds in the two classes studied poses a problem because of their decomposition in either the heated GC column or injector. Some published protocols advocate on-column injection and sample derivatization. In order to simplify analysis and shorten its time, derivatization should be avoided. It is also important to obtain mass spectra as close to standard 70 eV EI mass spectra as possible.

We have used ion trap-GC/MS and GC/MS/MS with a cooled temperature-programmable injector and a 15-m capillary column of medium polarity to analyze and identify a series of carbamate and phenylurea pesticides. The investigated pesticides included Propham, Chlorpropham, Propoxur, Promecarb, Phenmedipham, Carbaryl, Isoprocab, Carbofuran, Aldicarb, Diallylate, Monuron, Linuron, Fluometuron, Metobromuron, Chlortoluron and Isoproturon.

The mass spectra were found to be in good agreement with 70 eV solid probe in-beam mass spectra. GC/MS/MS - CID mass spectra were also determined to support unambiguous identification.

Instrumentation used included a Varian Saturn 4D GC/MS/MS ion trap, a septum-equipped programmable injector (SPI), a DB-1, 15 m. x 0.255 mm ID, 0.25 µm film thickness, column. Typical temperature programs used were 80° to 200° C. at 15° C/min. for the column, and 0° to 150° C. at 150° C/min. for the injector. Injector coolant was liquid CO₂. The ion trap was kept at 170° C. Solid probe in-beam mass spectra were determined on a VG 70-11/250 mass spectrometer using a homemade vespel probe.

Fig. 1 shows the mass chromatograms and mass spectrum of the carbamate Diallylate. Fig. 2 shows the GC/MS/MS chromatogram of the phenylurea Isoproturon at various CID energies.

Analysis of pesticides and herbicides in drinking water using large volume injection GC/MS.

Jonathan Hughes¹, Neil Loftus¹ and Mark Powell².

¹Finnigan MassLab, Manchester, England.

²Acer Environmental, Laboratories and Sciences, Runcorn, UK.

Current environmental legislation in assessing the quality of drinking water in the UK requires selective and sensitive methods to achieve the lower detection limit set to 10ng/L for target compound analysis. Established sample preparation procedures often require considerable initial sample volumes to provide accurate determinations at the limit of detection. Conventional methods may demand large initial sample volumes of up to 2500mL which clearly results in time-consuming and labour intensive methods which may prove difficult to automate effectively. Large volume injection (LVI) into a GC/MS system offers a solution to improving productivity in a highly automated manner. Solvent volumes of the order of several hundred microlitres are injected into a true cold on-column injector exploiting the partially concurrent solvent evaporation technique. In practice the solvent is injected into a pre-column connected to a solvent vapour exit in front of the analytical column. The vapour exit valve is opened for a specific time dependent upon the nature and volume of the solvent. The solvent evaporation process is controlled by optimising the solvent injection rate, flow rate and temperature of the column specific to the solvent. This technique can be applied equally effectively to both volatile and non-volatile components without discrimination unlike PTV injection systems. LVI GC/MS was applied to the measurement of key markers of drinking water quality using positive electron impact ionisation in single ion monitoring and also with negative chemical ionisation in full scan acquisitions.

Methods

Test standard mixtures containing pesticide and herbicide components were extracted from drinking water samples using a solid phase extraction procedure on 1-5mL of sample and eluted with 500µL of ethyl acetate. Dependent upon the analysis, injection volumes of between 50-200µL were injected onto the MD 800 mass spectrometer (Finnigan MassLab) using the Ultra-Trace GC (CE Instruments). Speed of injection and carrier flow rates optimised for each solvent system were set using software which models evaporation by a given solvent. Positive electron impact ionisation data were acquired using single ion monitoring. In negative chemical ionisation detection full scan acquisitions were made using ammonia as the reagent gas, a source temperature of 200°C, emission of 100µA and electron energy set to 45eV.

In routine analytical applications, the pre-column length was optimised for efficient sample throughput using a 1m deactivated retention gap for injection volumes of 50µL.

Figure 1. LVI GC/MS analysis of pesticides in negative chemical ionisation following the injection of 200µL of solvent using a partially concurrent solvent evaporation technique. Chromatographic integrity is maintained throughout the analysis together with MS response.

The technique proved to be a reliable, quantitative tool applied equally effectively to routine EI+ and NCI detection without compromising the quality of the response. In the routine analysis of target compounds the regulatory detection limit of 10ng/L can be achieved without difficulty using 1-5mL of the initial sample increasing productivity significantly. Quantitative measurements from 5-5000 pg (equivalent to an amount injected onto the column from a 50µL sample volume) typically resulted in correlation coefficients greater than 0.999 for the target compounds.

Conclusion.

Large volume GC/MS is a practical tool in the routine analysis of target compounds in assessing drinking water quality. MS performance is not affected by injecting such volumes as the technique of partially concurrent evaporation is efficient and precise. Productivity can be increased significantly in this type of application as small initial sample volumes are used linked with an effective solid phase extraction procedure.

MS Analysis of Agrochemicals and Their Metabolites Using Capillary LC/FAB

Hideji Fujiwara and Robert C. Chott

Analytical Sciences Center, Monsanto Co., 700 Chesterfield Parkway North,
St. Louis, MO 63198

The application rates of agrochemicals in farm fields are generally decreasing due to environmental concerns. Therefore, the metabolism studies of agrochemicals are becoming more difficult since only minute amounts of metabolites are present in soil, crop, and other samples.

Some agrochemicals such as sulfonylurea herbicides and their metabolites, plant hormones (gibberellic acids, abscisic acid, etc.) are found to be more sensitive to fast atom bombardment mass spectrometry (FAB/MS) than electrospray ionization/mass spectrometry (ESI/MS).

A few years ago we developed LC/FAB on a double-sector mass spectrometer (VG ZAB-HF) using a microbore HPLC column with a mobile phase flow rate of 40 $\mu\text{L}/\text{min}$. This required post column splitting (4 - 10 :1) in order to maintain a good vacuum on the mass spectrometer. It was often difficult to obtain a good mass spectrum of a trace amount (less than 10 ng) of analyte since the majority of the sample was not introduced into the mass spectrometer.

In order to identify minute levels of agrochemicals and metabolites from biological fluids, we recently developed capillary LC/FAB using a Micro-Tech capillary LC column (Figure 1). The injector volume of the sample was 1 μL in a 5 μL injection loop. The capillary HPLC system consisted of an Applied Biosystem Inc. model 140A syringe pump, Harvard Apparatus model 2400-001 pump, Rheodyne model 8125 injector, and a VG dynamic FAB probe (M 416334D). The effluent of a Micro-Tech C18 ODS column (0.53 x 150 mm), which was connected to the Rheodyne injector, was directed into the mass spectrometer through a fused-silica capillary (50 μm I.d. X 150 μm o.d.). A glycerol solution (water-methanol-glycerol; 7:2:1 (v/v)) was added via another fused-silica capillary (200 μm x 340 μm o.d.) coaxial with the first so that the HPLC eluent and glycerol solution did not mix until reaching the ionization target.

The flow rates for capillary LC/FAB range from 10 - 15 $\mu\text{L}/\text{min}$ so that post-column split is not necessary. Reproducible LC chromatograms can be obtained. At flow rates of 10 - 15 $\mu\text{L}/\text{min}$ it is possible to obtain good chromatography using commercially available fittings and extra care to avoid excessive dead volume. Full scan mass spectra of typical metabolites (mw: 200 -1000) can be obtained with detection limits in the high picogram to low nanogram range.

Example

Capillary LC/FAB (positive-ion) traces (TIC: top; 541 ion: middle) of Alachlor-glutathione conjugate at 1ng level. The mobile phase of 1% HCOOH in water/acetonitrile was kept at 90% (v/v) acetonitrile at a flow rate of 15 $\mu\text{L}/\text{min}$. Capillary LC/FAB/Mass Spectrum (bottom) of Alachlor-glutathione conjugate at 1ng level.

**Identification of a Major Human Urinary
Metabolite of Metolachlor by LC-MS/MS**

Centers for Disease Control and Prevention (CDC)
U.S. Department of Health and Human Services
Atlanta, Georgia 30333 USA

Introduction

Metolachlor is a preemergence herbicide commonly used on soybeans, corn, and other crops. Herbicides are the most used class of pesticides accounting for more than 50% of total quantity used and more than 50% of total domestic sales. Metolachlor is one of the top three herbicides with 40 - 60 million pounds used annually. Recently, we have been involved in studies of herbicide exposure that required us to develop procedures to measure metolachlor metabolites, alachlor metabolites and other pesticide metabolites in urine. When we began the study, we found that neither alachlor nor metolachlor metabolism in humans was well understood, although alachlor metabolism had been studied in monkeys (Carr et al. 1986). This led us to try to understand the metabolism of alachlor in humans by looking for alachlor metabolites in urine of occupationally exposed subjects. We were able to identify a major human metabolite of alachlor, alachlor mercapturate (Driskell et al. 1996). In this study, we tested the hypothesis that metolachlor, which is structurally similar to alachlor, is metabolized in the same way as alachlor in humans, to metolachlor mercapturate. We synthesized metolachlor mercapturate to use as a standard to determine whether urine samples from subjects who had been occupationally exposed to metolachlor contained metolachlor mercapturate.

Experimental

To test the hypothesis that metolachlor like alachlor is metabolized to a mercapturate, we followed this regimen: (1) Synthesized metolachlor mercapturate to use as a standard; (2) developed an LC-MS/MS method for metolachlor mercapturate; (3) developed a solid phase urinary extraction method for metolachlor mercapturate; (4) analyzed for metolachlor mercapturate in urine samples from subjects exposed to metolachlor.

The urine samples were collected for the pilot Agricultural Health Study, an EPA sponsored study of pesticide exposure of agricultural workers. Many of the workers in the study had been exposed to metolachlor.

Results

We analyzed 86 urine samples for metolachlor mercapturate from agricultural workers and their family participating in the Agricultural Health Study. Nine of these samples had serum levels

of metolachlor above 200 ppt. We found metolachlor mercapturate in 10 of the 86 samples and in seven out of nine of the samples from subjects whose serum had metolachlor concentrations above 200 ppt. The urine metolachlor mercapturate concentrations ranged between 5 and 300 ppb.

We have shown that metolachlor like alachlor is metabolized to the mercapturate. It may be that there are other analogous metabolites. Five alachlor metabolites were identified in monkeys by following the fate of radioactively labelled alachlor: Alachlor mercapturate, alachlor cysteine, alachlor mercaptoacetate, secondary amide mercapturate, and alachlor O-glucuronide (Carr et al. 1986). In another study using radioactively dosed monkeys, alachlor mercapturate was found to be the major metabolite, accounting for about 40% of the metabolite concentration (Feng et al. 1994). We (Driskell et al. 1996) found that alachlor mercapturate made up between 25% and 62% of the total metabolite concentration in the human urine samples that we analyzed.

The mechanism for the metabolism of pesticides, drugs, and xenobiotics to thioether conjugates has been elucidated (Stanek et al. 1993). These compounds react with the tripeptide glutathione (GSH = γ -Glu-Cys-Gly). The products are then metabolized by the sequential loss of the glutamic acid residue, the glycine residue, and N-acetylation of the remaining S-substituted cysteine (Stanek et al. 1993). Other pesticides besides alachlor, including lindane, cyanatryn and atrazine and xenobiotics, including acrolein, benzene, vinyl chloride, and various allylic and benzylic halides are metabolized by the glutathione mechanism.

In this study, we have identified a major human metabolite of metolachlor, developed an LC-MS/MS method to measure it in urine, and shown that it is present in the urine of exposed individuals. We believe it will be useful as a marker for metolachlor exposure; we will investigate its usefulness by including it in future studies of pesticide exposure.

San Antonio, Texas 78249-0663

Introduction: Public perception concerning environmental contamination and hazardous waste production has shifted in the past few years. The emphasis in legislation has migrated from that of expedient waste disposal to focusing on the reduction of wastes produced, waste treatment, and remediation of contaminated sites. This change in attitude has necessitated an increase in the number of samples being tested for contaminants. Sample volume for hazardous constituent analysis is approximately half a million samples per year.

The approved method for environmental analysis of soils thought to contain semivolatile organic compounds is SW-846 Method 8270A. The standard procedure for extraction of nonvolatile and semivolatile organic compounds from soil-like media is Method 3540A. Prior to the extraction process samples may have to be oven dried, and the extraction may also have to undergo additional cleanup. This is a very time consuming process which results in the generation of a halogenated waste stream. This is a lot of effort for a soil sample that contains no target semivolatile organic compounds.

To reduce the number of negative samples analyzed, a technique was investigated using a direct insertion probe (DIP) coupled with a quadrupole mass spectrometer. The goal is to determine the feasibility of analyzing soil samples by loading a portion of a soil sample into a small tube at the end of the DIP. Then after insertion of the DIP a temperature program is run on the DIP in order to separate the target compounds in the soil sample. If no target compound were detected then no further analysis of the soil sample would be necessary. If target compounds were detected, the remainder of the sample could be analyzed using EPA approved methods.

Experimental: This work was undertaken on Finnigan 4600 and 4500 GCMS instruments with inlets for solids probes. Even though the original Finnigan probes were used initially in this work, they proved to be too difficult to load with soil, so a new probe was designed at UTSA in order to accommodate the soil samples. The UTSA probe is equipped with a heater and a Pt temperature sensor that plug into the Finnigan solids probe receptacles. Samples were prepared using baked sea sand as the soil matrix. The sea sand was chosen as the prototypical soil because of its relative inertness, ease of handling, and homogeneity. The baked sea sand (0.50 g) was loaded into the sample tube (6 mm od, Kimble) and spiked with mixtures containing known quantities of various EPA target compounds. For the PAHs Ultra Scientific mixtures EPA 2138N and 2139N were used. In later experiments actual PAH contaminated soil (Fisher Scientific) was used (0.10 g). The temperature program held initially at 40 °C for 1 min then ramped from 40 °C to 150 °C at a rate of 15 °C/min. The rate was then changed to 10 °C/min for heating from 150 °C to 290 °C. The temperature was held at 290 °C for 5 minutes.

Results: After initial experiments showed that most of the low molecular weight semivolatile target compounds boil off immediately after introduction into the vacuum chamber, we concentrated our effort on the higher molecular weight semivolatile target compound:

specifically PAHs. The first set of experiments were done using the Ultra Scientific EPA-2138N mix followed by the EPA-2139N mix. The final set of experiments involved using the PAH contaminated soil from Fisher. It contained a variety of PAHs found in the 2138N and 2139N mixtures as well as a couple of PAHs not contained in either mix. The two figures are examples of mass chromatograms from typical experiments.

The results from the spiking experiments indicate that using the direct insertion probe with a quadrupole mass spectrometer can determine the presence of PAHs in soil-like matrices. The PAH contaminated soil was more in the line of what might be typically expected when analyzing a soil sample. This method proved effective in determining the presence of PAH in the soil and using appropriate data handling routines was able to identify all of the individual PAH components in the soil.

Acknowledgments: The authors are grateful for support from UTSA through two Faculty Development Grants (SBHB), the Small Grants Program (CEC), and the Environmental Science Program at UTSA. Determination of Polyaromatic Hydrocarbons in Water Without Extraction Using High Pressure Liquid Chromatography - Mass Spectrometry

Introduction As a separation technique, high pressure liquid chromatography (HPLC) has recently gained popularity and advanced the development of environmentally friendly methods. For years gas chromatography was the method of choice for chromatographers. However, the use of HPLC has now surpassed GC as the most popular analytical method¹ as evidenced by the number of articles that exist in the recent research literature. A review by Furton et al², dealing with PAH determination, suggested that one hundred or more articles have appeared in journals in each of the last three years. Lee³ reviewed both GC and HPLC techniques, and Peltonen et al⁴ reviewed recent research into PAH analysis that included HPLC techniques. These review articles demonstrate the wide range of applications for the HPLC technique.

The work performed by Panlitzyn et al⁵ is an example of research that has the goal of lowering solvent waste. Their investigation utilized solid-phase microextraction (SPME) to determine nonpolar semivolatile PAHs. Within the study, they were able to achieve the detection limits that are established in EPA method 525. Separation and detection was performed utilizing GC-MS. Excellent results were obtained on the analytes investigated, but the fact that only nonpolar semivolatile compounds were tested, may signify a limitation of this procedure.

The HPLC technique was utilized for separation and UV detection of PAHs by Kettrup et al.⁶ They were able to detect and separate sixteen priority PAHs. By performing solid phase extractions (SPE) on the sample coupled with fluorescence detection, they were able to achieve sensitivity in the picogram range. They obtained 70 to 85 % recovery for thirteen of the PAHs. For naphthalene, acenaphthylene, and acenaphthene the recovery rates were much lower due to their volatility. To optimize the sensitivity for each PAH, the excitation and emission wavelengths were adjusted by a program to match the PAH being detected.

In our investigation of PAHs, we develop the use of HPLC coupled with electron impact mass spectrometry (MS) via a particle beam interface to separate and identify a mixture of these compounds from samples of water, without the usual work up of the samples. By directly injecting suspected contaminated samples of water into an HPLC this application of LCMS eliminates the secondary waste generated from sample extractions. Another advantage of this new procedure is that, unlike gas chromatography, HPLC can be accomplished at ambient temperature. This improves analysis of those PAHs that are thermally less stable, or are less volatile or nonvolatile. Therefore the HPLC method is not confined to a select portion of the compounds that can be separated by GC methods, but can be used to analyze a wide range of PAHs.³

Results Figure 1 is a chromatograph from an experiment utilizing a Milton Roy HPLC. There is clear separation of the seven compounds within the sample. This separation followed by MS detection, figure 2 a reconstructed ion chromatogram RIC, demonstrates that this technique is feasible for separation and detection of the PAHs. The lag time between detection of the PAHs by the LC and detection by the MS is approximately twenty seconds. Five of the seven PAHs in the matrix have positively been identified by the MS, figure 2. There is detection of the other two, pyrene and indeno [1,2,3-cd] pyrene, but their intensity is not as strong as that obtained for the other five analytes. This problem is being addressed by changing the experimental parameters.

This investigation is still in the preliminary stages and we are presently working on the experimental method to establish sensitivity of the method. Elution of the analytes through the HPLC has proved to be a

troublesome task. The gradient profile along with solvents and concentrations have been adjusted to obtain maximum sensitivity for the HPLC. The ionization energy that has demonstrated highest response to all PAHs in the mixture is 40 eV. This was determined by adjusting the electron energy and performing a series of direct flow injections. The most recent experiment utilized APCI, and was conducted on a Finnigan TSQ 7000. From this experiment it has been determined that EI is better suited for analysing PAHs.

Reduction of Interfering Ion Production in PCB Analysis with N₂-ECNCl

Paul Miyares, Gail Bradley and Christie G. Enke

Department of Chemistry

University of New Mexico, Albuquerque, NM 87131

In the analysis of PCBs by mass spectrometry, electron capture negative chemical ionization (ECNCl) with methane or ammonia moderating gas is often utilized. The high electron affinity of PCBs results in formation of the radical molecular anion through resonance electron capture of a thermal electron (< 0.1 eV). The CI environment also consists of medium energy electrons (1 to 15 eV) as well as reactive cationic and neutral species. Dissociative electron capture of the medium energy electrons leads to fragmentation resulting in $(M-Cl)^-$ and $(M-2Cl)^-$. Reactions between neutral analyte molecules and reactive cations such as CH_4^+ , NH_4^+ , or H_3O^+ result in products such as $(M-Cl + H)^-$ with m/z of M-34. The reaction of the molecular radical anion with oxygen will result in an oxygen-chlorine exchange product, $(M-Cl + H)^-$ with m/z of M-19. The chlorine loss fragmentations are considered interferences because they reduce the abundance of the molecular anion, thus reducing its peak intensity in the spectrum and the sensitivity. The presence of the M-34 and M-35 anions are critical interferants in PCB analysis by GC/MS because the chlorine-loss anion of one chlorine number PCB appears in the individual ion chromatogram of the next lower chlorine number PCB. Since PCBs differing by one chlorine number often co-elute in the chromatographic step of the analysis, this kind of interference prevents their separate detection and quantitation. In ammonia CI, the intensity of the M-34 peak can be as high as 60% of the molecular ion peak (base peak).

We have chosen to use ultrahigh purity nitrogen as the CI moderating gas. The ionization of nitrogen produces primarily one reactive species, thermal electrons. In addition, the nitrogen is passed through water and oxygen traps to reduce the presence of reactive impurities. A mixture of the coplanar PCBs combined with known co-elutants was analyzed by GC/MS using nitrogen CI, methane CI and ammonia CI. Also compared were the mass spectra of the individual compounds generated using each gas. The resulting spectrum obtained with nitrogen consisted of the molecular anion with essentially no fragmentation or ion/molecule reaction product. This suggests that any cationic species that may be present are non-reactive. For many of the lower chlorine number PCBs for example, Cl₄ and Cl₅, no M-34 anion is detected. The resulting individual ion chromatograms demonstrated that the coplanar PCBs could be analytically resolved from their known PCB co-elutants using N₂-ECNCl mass spectrometry.

Quantitative experiments were run to demonstrate the response factors, linear range and detection limits for this analysis. The response factors were found to be within an order of magnitude of each other. They were also found to be reproducible across a 3rd order of magnitude concentration range and across a 7 day time period. The detection limits for the individual coplanar PCB congeners ranged from 0.22 to 2.2 pg injected on column.

ABSTRACT

In the process of developing methods to reduce analysis run times, parameters were optimized for utilization of fast gas chromatography/high resolution mass spectrometry (FGC/HRMS) and fast gas chromatography/time-of-flight (FGC/TOF) mass spectrometry analysis of standards from environmental toxicant groups [polychlorinated biphenyls(PCBs), polyaromatic hydrocarbons (PAHs), chlorinated dibenzo-p-dioxins (CDDs), chlorinated dibenzofurans (CDFs) and phenols] and military storage site standards (explosives) that are also classified as a category of threat assessment analytes. Fast chromatography separations were accomplished with a commercial (ZOEX) prototype comprehensive, thermally modulated two-dimensional gas chromatography (C2DGC) system (the thermal modulator was not engaged for FGC/HRMS analysis) with capillary column lengths of 1 to 7 meters. HRMS analysis was accomplished on a Fisons Autospec.

GC/HRMS analysis run times (56 minutes) for a 24 component multigroup analyte mixture (CDDs, CDFs and PCBs) were reduced to less than 8 minutes by FGC/HRMS (2m, 0.1mm ID, 0.1µ film DB-1 column) with mass analysis distinguishing each mixture component except the two hexachlorodibenzo-p-dioxin (HxCDD) isomers that coelute under time-compressed conditions. Although peak tailing was observed for components at the back end of the chromatogram, FGC/HRMS analysis run times for multigroup analytes were reduced to 5 minutes with higher flow rates from a larger diameter (7m, 0.25mm ID, 0.25µ film) DB5 column. GC/HRMS analysis run times for a 27 component PCB mixture were reduced from 36 minutes to less than 11 minutes by FGC/HRMS. A 22 component mixture of coplanar PCBs was separated in 7 minutes by FGC/HRMS with two coeluting analytes identified by mass analysis.

Analyte group mixture separations by comprehensive two-dimensional gas chromatography (C2DGC) were initially accomplished in significantly shorter analysis times (relative to GC/HRMS) using a computer controlled component system with a thermal modulator external to the GC oven and a flame ionization detector (FID). Comprehensive 2DGC is defined by the criteria that in orthogonal separations, the total quantity of sample introduced passes through both linearly connected capillary columns and that the first dimension chromatogram can be reproduced with fidelity from 2DGC data. Components of a 13 component phenol mixture were separated in two dimensions in 5 minutes using a linear combination of two columns of variable polarity (DB-1 and OV-1701) connected at the thermal modulator. Two stage thermal modulation compressed analyte peaks into narrower bands with a resulting S/N increase of approximately two orders of magnitude. Thermal modulations for two-dimensional analyte group separations were also examined using a commercial computer controlled vertically mounted heating element where thermal modulation occurs inside the oven. Variable parameters include oven temperature programs, flow rates, capillary column lengths, film type and thickness and modulation rates and temperatures where applicable. Thermal modulation of 2,3,7,8-TCDD (the most toxic CDD congener) by C2DGC/HRMS resulted in a sensitivity increase to 335 attograms at a S/N value of 9:1 from 50 femtograms at a S/N value of 25:1 for GC/HRMS. A two-dimensional plot of a 24 component mixture of multigroup analytes (PCBs, CDDs, and CDFs) from C2DGC/HRMS analysis showed component separation in less than 7 minutes. The corresponding analysis run time for GC/HRMS was 56 minutes.

FGC/TOFMS (LECO FCD650) with an integrating transient recorder (ITR) and a time array detector (TAD) was utilized for analysis of environmental toxicant group mixtures to evaluate the high spectral acquisition rate (optimum rate of 200 spectra/second for maximum deconvolution) required for FGC and C2DGC of complex mixtures at higher time compression where spectral deconvolution can compensate for coelution. The FGC/TOFMS analysis run time for a 23 component mixture of PAHs and phenols was less than 4 minutes, a substantially shorter time than observed for GC/HRMS. A mixture of 13 threat assessment analytes (explosives) was also separated in less than 4 minutes, with the spectrum of each component subsequently identified by a library search. FGC/HRMS and FGC/TOFMS reconstructed chromatograms were compared with corresponding chromatograms from GC/HRMS analyses where time compressed separations were not employed. The accelerated throughput methods allow for rapid analyte screening for environmental toxicants with the additional potential benefit of sensitivity enhancement by coupling C2DGC with TOFMS.

Investigation of Arsine Generating Reactions by using Deuterium Labeled Reagents and Mass Spectrometry

*Witold Winnik[†], Spiros A. Pergantis[‡], Edward M. Heithmar, **William R. Cullen

*U.S. Environmental Protection Agency, NERL, P.O. Box 93478, Las Vegas, NV 89193-3478;

**University of British Columbia, Vancouver, Canada

Introduction Analytical methods that employ hydride-generation methodology coupled to element-specific detectors have been used extensively for the determination of hydride-forming elements such as As, Bi, Se, Sb, Ge, Te, Sn, and Pb at trace levels. However, a number of problems associated with the method still remain. Interferences caused by transition metals have been extensively reported. Variations in the hydride-generation efficiency for compounds of the same element, e.g. compounds of arsenic, have also been reported. In this study we have investigated differences governing the process of arsine generation for various arsenic compounds.

Experimental

Instrumentation A Finnigan-MAT TSQ 700 Gas Chromatograph (GC) / Mass Spectrometer (MS) was used for most of the experiments in this study. The instrumental operating conditions were as follows: electron impact (EI) ionization mode, electron energy 70 eV, tuning and calibration with perfluorotributylamine (FC43). A Varian 3400 GC system was equipped with a fused-silica column 0.18-mm I.D. x 20-m Crossbond[®] phenylmethylpolysiloxane (Restek Corp., USA) column. A GC ion-trap mass spectrometer (Finnigan-MAT Magnum[™]) was also used for some of the experiments.

Procedures Reactions were carried out in 2-mL glass vials with rubber septa. Unless stated otherwise, reaction conditions were as follows: 50 μ L of 100-ppm arsenic solution for each of the arsenic compounds investigated, along with 50 μ L of HCl (20% w/v) were added initially to the reaction vial. The vial was flushed with argon and sealed prior to the injection of 70 μ L of 2% w/v NaBH₄. Sampling of the headspace was accomplished by inserting a syringe needle through the cap septum and withdrawing a 2- μ L gas sample.

Discussion When arsenite was reacted with DCl and NaBH₄ in D₂O, the arsine detected was non-deuterated [M⁺ (m/z 78)]. Therefore it was proposed that hydrogen was transferred from borohydride to the arsenic atom without any further reaction of the arsine with the deuterated acid present in D₂O. To confirm this assumption, arsenite was reacted with HCl and NaBD₄ in H₂O. The generated arsine was deuterated, as indicated by its mass spectrum [M⁺ (m/z 81)]. When methylarsonic acid (MAA) was reacted with DCl and NaBH₄ in D₂O, the resulting methylarsine was a mixture of MeAsH₂, MeAsD₂, and MeAsHD (M⁺, m/z 92, 94 and 93, respectively). A time-series study clearly demonstrated the formation of MeAsD₂ (as evidenced by the increasing % relative intensity of the m/z 94 ion) and the disappearance of MeAsH₂ (decreasing % relative intensity of the ion at m/z 92) over time. Similar observations were made when MAA was reacted with HCl and NaBD₄ in H₂O, initially MeAsD₂ was detected, along with a smaller amount of MeAsH₂. The ratio of non-deuterated to deuterated methylarsine increased with time. The gradual conversion of MeAsH₂ to MeAsD₂, and vice versa, indicated that arsines once generated further reacted with acids present in the reaction mixture, thus allowing for hydrogen-deuterium exchange. When dimethylarsinic acid (DMAA) was reacted with DCl and NaBH₄ in D₂O, the resulting dimethylarsine was identified as Me₂AsD. When DMAA reacted with HCl and NaBD₄ in H₂O the resulting arsine was Me₂AsH. [M⁺

(m/z 106)] The products of these reactions formed rapidly and did not change over time.

Reaction [1] explains formation of Me₂AsD when generated from DCl and NaBH₄, and the formation of Me₂AsH when generated from HCl and NaBD₄. Protonation of MeAsH₂ similar to that of Me₂AsH in reaction [1] would be expected to be less favored, due to the lower basicity of MeAsH₂. This hypothesis is supported by the more gradual hydrogen-deuterium exchange indicated by the mass spectra. Apparently, protonation of AsH₃ does not occur to any appreciable degree. These conclusions were further supported by the results obtained from the following experiment. A mixture of arsines (AsH₃, MeAsH₂, Me₂AsH) was generated in one vial, a sample of which was immediately injected onto the GC/MS. Subsequently, a 1-mL gas sample was removed from the vial and then injected into the headspace of a second vial containing 200 μ L of HCl/H₂O. After 4 min, a gas sample was removed from the second vial and injected onto the GC/MS. The purpose of this experiment was to investigate any loss of arsines as a result of their dissolution in the HCl/H₂O solution. To a first approximation, if the protonation of the arsines varies in the order Me₂AsH > MeAsH₂ > AsH₃, then the solubility of the arsines in the aqueous acid should vary the same way. The results obtained from this experiment indicated a greater loss of Me₂AsH compared to MeAsH₂ and AsH₃. This was clearly observed when comparing the relative amounts of the arsines detected in the two chromatograms obtained from the arsine samples taken from the first and second vial. This experiment was conducted in triplicate, and a control was carried out in which the second vial only contained 200 μ L of H₂O. The control experiment demonstrated that the arsine solubility variations observed in HCl/H₂O do not occur in H₂O.

Table 1. Summary of arsine generating reactions carried out in this study. Boldface indicates reagents, underline indicates products identified by using mass spectrometry.

RAPID DETERMINATION OF THIOUREA IN WASTE WATER BY FIA-APCI-SRM-MS-MS

by Andrea RAFFAELLI, Sergio PUCCI, Raffaello LAZZARONI, Piero SALVADORI

Centro di Studio del CNR per le Macromolecole Stereordinate ed Otticamente Attive, Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via Risorgimento 35, 56126 PISA, Italy.

Thiourea

Molecular Formula: CH_4N_2S

Molecular Weight: 76.12 Da

Melting Point: 182 °C

Density: 1.405 g/cm³

Soluble in: Water, Alcohol

Insoluble in: Ether, Dichloromethane

Tox.Limit. Nitrif. Bacteria: 76 ppb

Thiourea is one of the most toxic substances for nitrification bacteria, with a toxicity limit of 76 ppb. Normally it is not present in waste water, but it can be a serious problem for industrial waste water treatment plants, in particular if the waste water comes from tannery factories. Thiourea

or some possible precursor can be used in some stage of the tanning process. For this reason, a fast and reliable method for its determination is strongly needed. The approach to this problem must face four main problems:

1. The samples of industrial waste water to be analysed contain a large number of different substances, some of which with a relatively high concentration.
2. Thiourea is very soluble in water and practically insoluble in organic solvents such as ethyl ether and methylene chloride so that its extraction with organic solvents is almost impossible
3. Thiourea is relatively unvolatile and its GC analysis is not very easy, at least using common apparatus.
4. Preliminary HPLC measurements caused the irreversible degradation of the HPLC column after a few injections due to the build-up of some components of the matrix onto the stationary phase.

The problem has been approached by liquid phase ionization tandem mass spectrometry. We tried both ionspray and atmospheric pressure chemical ionization. APCI gave the best results.

On the basis of the APCI-MS-MS (Fig. 1) product ion spectrum of thiourea, we developed an analytical procedure based on selected reaction monitoring. Two fragmentations were monitored for more reliable results: 77-60 and 77-43. The

Figure 1. APCI-MS-MS spectrum of thiourea.

Figure 2. FIA-APCI-SRM-MS TIC chromatogram of standard solutions of thiourea used for the calibration curve

samples were examined with a minimal pretreatment (elimination of solid particulate by centrifugation and extraction with ethyl ether to eliminate most of low-polarity organics).

The calibration was made by the analysis of standard thiourea water solutions in the range 10 - 5000 ppb. Figure 2 shows the ion chromatogram obtained by three injections for each calibration point. The relative calibration curve (Fig. 3) was absolutely linear in the range of concentration examined with a very good correlation factor ($R = 999931$). The detection limit was around 1-2 ppb.

The reliability of this analytical procedure was tested by the analysis of "spiked" samples and it was very good. It is also worthy to note that we never found thiourea levels above 50 ppb when the plant was working properly, and we never found thiourea levels below 100 ppb when something was wrong and there was an ammonia release from the plant. This means that the experimental amounts found were in a very good agreement with the toxicity limit known of 76 ppb. Moreover, we found values between 50 and 100 ppb when the plant was working not too bad, but a slight release of ammonia was still present.

Figure 3. Calibration curve for the analysis of thiourea in waste water by APCI-MS-MS.

ACKNOWLEDGEMENTS. The authors thank "Aquamo S.p.A.", S. Croce sull'Arno (PI), Italy, and "Consorzio Depuratore Castelfranco di Sotto", Castelfranco di Sotto (PI), Italy, for financial support and for providing us with real samples from biological waste treatment plants.

Real-time Field Analysis of Ground Water Samples using Membrane Introduction Mass Spectrometry (MIMS)

Dan A. Markham, J. R. Gilbert, R. J. West, G. M. Klecka, The Dow Chemical Company, Midland MI 48674 & M. Barcelona, C. L. Major, Jr., M. Henry, National Center for Integrated Bioremediation Research and Development

In recent years there has been a general increase in public awareness of environmental issues. Chief among these has been the impact of human activities on the quality of environmental resources. Early interest focused primarily on the pollution of air and surface water. More recently attention has shifted toward the quality of ground water. A variety of civilian and military sites have been identified that contain ground water contamination. The first step in returning these sites to their original water quality is to assess the amount, type, movement, and natural attenuation of the contaminants. This assessment is commonly referred to as site characterization. This information allows the selection of an appropriate remediation technique, but requires extensive knowledge of both the hydrogeology of the site, and the chemistry of ground water. Conventional technologies utilized a combination of laboratory and field devices to evaluate the ground water chemistry. Of particular interest is the expanding role that field portable analytical instrumentation is playing in site characterization.

Field studies were performed to determine the feasibility of conducting real-time, on-site characterization of fuel and solvent contaminated ground water. A field portable membrane introduction mass spectrometry (MIMS) system (Figure A) was developed from existing laboratory instrumentation. Application of the instrument in conducting real-time, on-site characterization of ground water contamination was recently evaluated at the National Center for Integrated Bioremediation Research and Development, located at Wurtsmith Air Force Base, Oscoda, MI.

In this series of studies we were able to perform real-time field analysis of volatile organic compounds in ground water down to the low parts per billion level using membrane introduction mass spectrometry. A laboratory MIMS instrument was successfully modified for field use, transported to a remote/field site, and able to function properly under field conditions. We were able to analyze up to 21 samples (3 - 4 replicate injections from 6 different wells) in a single day. Samples were analyzed for multiple components at a rate of one sample every ten minutes. In addition the instrument proved rugged enough to survive transport under vacuum for short distances. Cycle times for the instrument when moved to new locations ranged from 12 minutes when transported under full power, to 44 minutes when isolated and power cycled. The total time required from arrival at the site to the start of analysis was approximately one hour.

This technology has potential broad application in both the characterization and long-term monitoring of contaminated sites. Benefits of its application may include reduced costs for off-site sample analysis in addition to optimizing the location and depth of long-term site monitoring wells.

Increasing consciousness of environmental issues has generated a fast growing number of alternative techniques aimed at efficiently performing qualitative and quantitative analysis of chemical contaminants in water, air and soil samples. Membrane Introduction Mass Spectrometry (MIMS)¹ has emerged as a very efficient technique for the direct analysis of volatile organic compounds (VOC's) in water and air, showing outstanding speed and trace level detection capabilities. Rapid and direct (without extractions or pretreatments) analysis of VOC's in aqueous solutions are the most attractive features of MIMS, besides its superior detection limits normally at the low parts-per-billion (ppb) levels. Considerably lower detection limits have been recently achieved in MIMS, however, by applying a series of interesting trapping strategies. In the present work, it is described a very simple and efficient on-line pre-concentration MIMS system, that is a Cold Trap-MIMS system (CT-MIMS), that allows the detection of VOC's in aqueous solution at very low ppt levels using a simple quadrupole mass analyzer. Trapping uses no trapping material but liquid nitrogen cooling, followed by fast heating that thermally releases almost at once the condensed VOC's into the mass spectrometer. This lead to extraordinary enhancements of the detection limits, and several VOC's could be detected at very low concentrations typically at 10-20 ppt. The results show also excellent linearity and reproducibility for the system.

Figure 1 shows a diagram of the CT-MIMS system. The conventional MIMS system¹ is modified so that the membrane interface (A) connected by 1/4" stainless-steel tubing is placed about 15 cm distant from the ion source (B) of the mass spectrometer. Not being limited by the diameter of the inlet system, a larger spherical membrane (Silastic 500-3, 0.010 mm of thickness, Down Corning Co., 10 mm of diameter) was used to enhance the contact surface area and consequently the transmission of the analyte. The analyte solution is pumped through the membrane interface by a eight-roll peristaltic pump in the rate of 3 mL/min. via two stainless-steel tubing that are silver-soldered into the base of the membrane interface. An U-shape trap tube (stainless-steel tubing, 1/4" diameter, C) was inserted between the membrane interface and the ion source. Cooling of the trap is performed with liquid nitrogen, followed by fast heating (D). The heating system (D) uses a low-voltage (0.7 V), high current (82 A) transformer with the ends directly connected to the trapping tube. The own electrical resistance of the trapping tube is used for heating, which dissipates approximately 60 W. The system is also fitted with a timer that precisely controls the duration of the heating cycle. A high-transmission Extrel (Pittsburgh, PA) pentaquadrupole mass spectrometer² fitted with 3/4" quadrupoles was used. The instrument in its simple MS mode of operation showed ion transmission similar to most single quadrupole mass spectrometers, as evidenced by the observation of similar detection limits when applying conventional MIMS for a series of VOC's.

To determine the best cooling trapping period, a series of experiments were performed and the results are exemplified for toluene at 1 ppm in water in Figure 2. In these experiments, the m/z

91 fragment of toluene was monitored using a SIM scan mode. Since very fast heating is performed, a narrow and relatively concentrated "package" of trapped VOC's as well as water is released and reach almost at once the ion source. Very narrow peaks (6 sec.) are therefore produced which increasing intensities up to 15 min. of trapping. Signal intensity drops, however, after 15 minutes of trapping, most likely due to both saturation of the ionization capability of the ion source and the occurrence of ion/molecule reactions in the high-pressure conditions. Trapping periods greater than 25 min. lead to overpressure conditions and the consequent shut down of the instrument. Given that the same trapping period is used, a great signal reproducibility is observed after repeated cycles.

Figure 1

Figure 2

The voltage applied on the ends of the trapping tube and consequently the heating power dissipated was varied so that fast heating could produce the narrowest as well as the most intense peak possible. Too fast heating were shown to produce very narrow but not so intense signals. The best conditions were determined with a dissipation of approximately 60 W. Once these values are set, heating times controlled by the timer greater than 15 sec. practically do not affect the broadness and intensity of the signal and therefore very reproducible peaks were obtained. A variety of VOC's were then tested and similar gains around a hundred were obtained after 15 min. of trapping followed by 30 sec. of heating. This lead to extraordinary enhancements of their detection limits in the CT-MIMS system, which ranged typically from 10 to 20 ppt.

From the present experimental results and the high gains observed it is possible to anticipate that application of the CT-MIMS system with the very sensible ion traps mass spectrometers or with high-transmission, MIMS-dedicated single quadrupole mass spectrometers will lead to detection limits at the low ppq level, even lower than the extraordinary low limits that have already been obtained with conventional MIMS.

ANALYSIS OF VOLATILE ORGANIC COMPOUNDS FROM SOIL SAMPLES WITH PURGE-AND-MEMBRANE INLET MASS SPECTROMETRY

Timo Mansikka, Raimo Ketola, Marja Ojala, Tapio Kotiaho and Risto Kostiainen
VTT Chemical Technology, P.O. Box 1401, FIN-02044 VTT, Finland

INTRODUCTION

The contamination of soil with volatile organic compounds (VOCs) must be explored when making plans for example for residential areas. VOCs may easily be drifted from the contaminated area into the households by diffusion through the concrete. Before remediation, the area must be carefully surveyed. For this purpose rapid, selective and reliable analytical methods are required. Conventionally, a soil sample is taken from the area explored into a laboratory and analyzed by headspace (HS) or solvent extraction technique followed by gas chromatographic (GC) or GC/mass spectrometric (GC/MS) detection. VOCs are also collected directly from the soil into an adsorbent tube and the analysis is performed by thermal desorption/GC or GC/MS. The methods mentioned above have several disadvantages. For instance, quantitative analysis with headspace technique is highly dependent on the matrix and may lead to unreliable results. The sensitivity of solvent extraction is not high enough, since the extraction cannot be concentrated due to substantial evaporation of VOCs. A remarkable sample loss of VOCs with a low boiling point is observed during the collection of soil gas with adsorbent tubes.

Membrane inlet mass spectrometry (MIMS) is a powerful technique for the analysis of air or water samples. The procedure involves flowing the sample over a membrane, which selectively extracts VOCs from the matrix. The organics pervaporate through the membrane into the ion source of a mass spectrometer. The method provides linear dynamic ranges of about four decades and sensitivity below 1 ppb level. The articles published so far deal with analysis of water or air samples. In this study MIMS is applied to the analysis of VOCs in soil samples. The method utilizes a purge-and-membrane technique developed by Kostiainen *et al.* [1]. In this system (Fig. 1) VOCs are thermally desorbed from a soil sample followed by purging with helium into the MIMS.

EXPERIMENTAL

A quadrupole mass spectrometer (Balzers QMG 421C, Balzers Aktiengesellschaft, Liechtenstein) with a mass range 1-500 amu was equipped with an open cross-beam electron impact (70 eV) ion source. The membrane inlet was built at VTT Chemical Technology, Finland. A sheet polydimethylsilicone membrane (SSP-M100, Specialty Silicone Products Inc., Ballston Spa NY, USA, thickness 100 μ m) was utilized and it was operated at 70 °C. The purge-and-membrane/MS system is presented in Fig. 1. A sample at 70 °C was purged with helium (70 ml/min). The stream was directed over the sheet membrane into the MS. Temperature of the transfer line was maintained at 90 °C.

RESULTS AND DISCUSSION

An ion chromatogram of spiked soil sample (10 g) containing toluene and trichloroethene (5 mg/kg) was recorded. With the purge-and-membrane inlet/MS VOCs can be entirely purged from the sample within less than 10 minutes unlike the HS in which only a small fraction of the sample is used for the analysis. Hence, the analysis with purge-and-membrane inlet/MS is independent on the matrix. Recognition and quantitation of a multicomponent sample is possible with a Solver calculation program developed at VTT Chemical Technology. The limit values for VOCs in soil samples are between 0,5-500 mg/kg depending on the compound (The Finnish Ministry for Environmental Affairs). The sensitivity is easily achieved with the purge-and-membrane inlet/MS. The limits of detection ($S/N=3$) for VOCs studied are below 0.5 mg/kg level. The method developed is rapid and easy to use and it is suitable for on-site analysis. Furthermore, any harmful solvents do not need to be used in the analysis.

Membrane Introduction Mass Spectrometry for Monitoring of Aromatic Compounds in Exhaust Gases

G. Matz, W. Muenchmeyer*, G. Kibelka

Technical University Hamburg-Harburg, Harburger Schloßstr. 20, 21079 Hamburg, Germany

A. Walte*

WMA AIRSENSE Analysentechnik GmbH, Hagenower Str. 73, 19061 Schwerin, Germany

Benzene and some polycyclic aromatic hydrocarbons (PAH) are carcinogenic and occur in combustion processes. For the on-line assessment of these compounds new methods, based on a mobile membrane introduction mass spectrometer (MIMS) [1] have been developed. MIMS is a well known technique which is mainly used to monitor organic compounds in aqueous solutions, especially in fermentation and environmental processes [2]. Some work has been published on the determination of environmentally significant compounds directly from air, but little about monitoring of organics with high boiling points

The membrane inlet device is used as an interface between gaschromatographic probes and the MS (fig.1). Its advantages and drawbacks in the on-line analysis of high boiling compounds in exhaust gases is described.

A transportable MS (MEM, Bruker-Franzen) and a prototype of a new portable MS (EM640, Bruker-Franzen) were used in this study. The MEM has a flat silicone rubber membrane ($l=50\mu\text{m}$), while the EM640 prototype can be equipped with a hollow-fiber ($l=100\mu\text{m}$) or flat sheet silicone rubber membranes. Attached to the MS is a GC (DB5, 3-5m, 0.32mm) with a thermal desorption unit. Fast GC-MS methods have

Fig.1: High-vacuum valve with a flat silicone rubber membrane inlet

been developed due to the combination of short GC-columns with a MIMS. PAH mixtures and environmental samples like coke oven-, oil firing plant-, waste incinerator- and automotive emissions have been analyzed with the MIMS

The eluting compounds from the GC are pumped through a flow chamber (volume between GC-outlet and membrane) and the analyte diffuses through the membrane into the vacuum of the MS, where adsorption- and desorption processes on the surfaces take place, before ionization in the ion source. The transport of different PAH with boiling points from $T=218^\circ\text{C}$ (Naphthalene) to $T=525^\circ\text{C}$ (Benz[*g,h,i*]-perylene) into the MS has been investigated as a function of membrane temperature and thickness.

The measured analyte signal is a result of the distribution of analyte concentration in the flow chamber, permeation process through the membrane, and following adsorption and desorption processes at vacuum surfaces. This dynamic transport process is simulated by a numerical model and compared with the measured signals (fig.2). The numerical model used, is a combination of two slightly modified models: one describing the dynamic response of a membrane probe in flow injection MIMS [3], and the other describing adsorption/desorption processes on the vacuum surfaces [4].

Membrane inlets can be used for the analysis of aromatic compounds with boiling temperatures up to $T=525^\circ\text{C}$. Numerical and experimental results show that the main parameters

Fig.3 GC-Peaks of Benzo[e]-pyrene with different membrane inlet parameters

for decreasing the response time are membrane temperature, membrane thickness and the vacuum surface between membrane and ion source. In order to prevent the silicone membrane from thermal decomposition a maximal temperature of $T=250^\circ\text{C}$ was used for routine analysis. A spreading of eluting GC-peaks of PAH with boiling temperatures higher than $T=480^\circ\text{C}$ was observed. At a temperature of $T=250^\circ\text{C}$ there is nearly no effect in changing the membrane geometry (flat or tube) or thickness (20-50 μm), due to predominating ad- and desorption processes on the vacuum surfaces (fig.3).

On-site measurements of organic compounds at combustion processes show that membrane introduction prevents the MS from contamination and allows the on-line analysis of exhaust gases [5].

Detection of Semi-Volatile Organic Compounds by Trap-and-Release Membrane Inlet Mass Spectrometry

F.R. Lauritsen and M. Leth, Physical Biochemistry Group, Institute of Biochemistry, Odense University, 5230 Odense M, DENMARK

Recently, we presented preliminary results [1] on a novel procedure of conducting membrane inlet mass spectrometry, which allowed semi-volatile organic compounds (boiling point above 300 °C) to be measured at low ppb levels. In this procedure organic compounds were preconcentrated within the MIMS membrane, before they were thermally released into the ion source by heat radiation from the filament. In the original version of the system the membrane was kept cold during a sampling period by a continuous flow of water or sample liquid passing through the tubular silicone membrane. However, during an interruption of the liquid flow the membrane was heated resulting in the evaporation of semi-volatile organic compounds dissolved in the membrane. In the optimized version presented here a 25 second air-plug passes through the membrane inlet with a much faster temperature rise as a result.

The experimental setup was similar to the setup described earlier [1], except that a thermocouple was mounted inside the tubular silicone membrane. With this modification it was possible to monitor the temperature on the sample side of the membrane during the experiment. With an interruption of the liquid flow the temperature inside the membrane rose rapidly to 100 °C, where it stayed throughout the whole desorption period. Using an air-plug in the liquid stream passing through the inlet only a short delay in the temperature was observed at 100 °C, before it increased to approximately 300 °C after 30–40 seconds. As a result of the higher temperature inside the membrane a much sharper and more well defined desorption peak arises when the air plug is used.

Table 1 shows trap and release detection limits for a variety of less volatile organic compounds. With the exception of the highly hydrophobic phenanthrene and fluoranthene the detection limits improved by more than 50 times as compared to standard MIMS detection limits. One of the compounds (caffeine) was not detectable at all using standard MIMS. The data presented here suggests that the improvement in detection limit obtained with the trap-and-release MIMS technique becomes better the more polar the analyte. However, this requires further studies.

As a practical example of the potential of the new MIMS technique the caffeine content of various beverages was analysed. Figure 1 shows a comparison of a standard MIMS mass spectrum (Figure 1a) and a trap-and-release mass spectrum (Figure 1b) of a cup of tea. The tea was passed through the membrane inlet for 20 minutes before the standard MIMS mass spectrum was recorded. Ions at m/z 136, 121 and 107 characteristic for many simple monoterpenes was observed. In addition an intense peak at m/z 119 was assigned to Bergamot (a sesquiterpene) added to the tea as flavour component by the manufacturer. The important thing in the spectrum is the absence of m/z 194, the molecular ion of caffeine. In the trap-and-release mass spectrum recorded immediately after the standard MIMS spectrum this ion is very abundant despite the fact that the trap-and-release mass spectrum was recorded with a 10 times lower amplification. The ions at m/z 136, 121, 119 and 107 also improved in the trap-and-release experiment but only by a factor of 5.

Figure 1 Comparison of mass spectra of a cup of tea. (a) standard MIMS mass spectrum; (b) trap-and-release MIMS mass spectrum. Please note m/z 194 the molecular ion from caffeine and the change in scale.

TABLE 1: Comparison of detection limits for standard MIMS and trap-and-release MIMS

Compound	B.p. [°C]	Water solubility ^b	Ion monitored [Dalton]	Detection limit Standard ^c [ppb]	Detection limit Trap-and release [ppb]

REAL-TIME ANALYSIS OF VOCs IN GROUNDWATER USING AN IN-SITU SPARGER IN CONJUNCTION WITH A DIRECT SAMPLING ION TRAP MASS SPECTROMETER.

**Marcus B. Wise and Cyril V. Thompson, Chemical and Analytical Sciences Division,
Oak Ridge National Laboratory, Oak Ridge, TN 37831***

William M. Davis, Waterways Experiment Station, Vicksburg, MS 39180.

The use of direct sampling ion trap mass spectrometers for fast, in-field analysis of volatile organics in environmental samples significantly increases the ability to perform expedited site characterization in a cost-effective manner. Historically, this has been done almost exclusively through the analysis of discrete groundwater or soil samples collected from existing wells, or from drilling rigs during test boring or well placement. During the last year, an in-situ sparging device has been developed and tested in conjunction with a cone-penetrometer truck which provides a faster and much cheaper means of characterizing the groundwater at a site. Instead of drilling a test well, a hydro-punch is pushed into the ground by the cone penetrometer truck. The hydro-punch is a hollow pipe approximately 2 inches OD with a cone-shaped tip at the bottom. After reaching the water table, an outer sleeve is retracted from the hydro-punch which exposes a screened area that allows water to enter the interior of the pipe.

For analysis of VOCs, the in-situ sparger is lowered into the hydro-punch and VOCs are sparged into a direct sampling ion trap at the surface. A 150 ft length of 1/8 in OD Teflon transfer line connects the sparger to the mass spectrometer. The water in the hydro-punch is purged at a flow rate of 10-50 mL/min with helium. Water is continuously pumped through the sparging region and returned to the hydro-punch. This produces a steady-state signal in the mass spectrometer which is proportional to the concentration of the VOCs in the groundwater. Calibration is accomplished by placing the sparger in a beaker of water spiked with known concentrations of targeted analytes. Calibration is typically run before the sparger is inserted into the hydro-punch and again immediately after it is withdrawn. This provides a bracket for quickly estimating concentrations of target compounds. A full calibration curve can be run once or more throughout a day as needed.

Preliminary results of this technique are very encouraging. Very little difference is observed between the levels of VOCs measured by in-situ sparge vs. sparging of samples bailed from a well. Detection limits are in the low ppb range and reproducibility is +/-15% or better. The advantages include very fast results (<10 min), the ability to monitor multiple points in a single day, and no water samples are ever brought to the surface which have to be disposed of as hazardous waste. The in-situ sparger has also been used successfully to monitor VOCs in existing monitoring wells. During this study, approximately 4 wells per hour could be studied, including the time required to relocate the instrument at a different sampling point.

Upgrading the Perkin Elmer QMASS for Higher Sensitivity

*Roy, Laura; **Heller, Steve; Graves, Peter; Hamerly, Thomas

*Detector Technology, Inc., Sturbridge, MA

**Roy F. Weston, Inc., Holbrook, MA

Introduction

Instrument sensitivity has become increasingly important to the analytical chemist. Signal to noise and detection limits are restraints to advanced research and new discoveries. In order for the chemistry industry to grow, the instrumentation must improve. A developmental program was launched to design an improved detector for the Perkin Elmer QMASS mass spectrometer. The final design yielded increased stability and improved signal to noise. This improvement was accomplished by integrating a conversion dynode into the multiplier package resulting in a high energy dynode(HED) multiplier.

Methods

A conversion dynode is used in many instruments to increase the signal to noise ratio. The Perkin Elmer QMASS mass spectrometer does not have an external power supply for a dynode. To upgrade the Perkin Elmer system an internal power pack (patented # 5374827) must be used. This newly developed method allows for an easy dynode upgrade.

The power pack consists of a conversion dynode and DC/DC converter. The DC/DC converter uses the electron multiplier power supply as it's input. The converter then increases the voltage to -4.5 KV. This voltage is applied to the conversion dynode. By using a DC/DC converter integrated into the multiplier assembly no modification is needed to the Perkin Elmer instrument.

In the application of the standard multiplier, the -high voltage plays an important role in attracting ions to the multiplier's surface. A change in the multiplier voltage results in a change in the ion optics. When using a conversion dynode this problem is eliminated. The ions are attracted to the dynode. Because the voltage applied to the dynode is constant, the electromagnetic field is also constant. Therefore, the ion optic design has no dependence on the voltage applied to the multiplier. This explains the improvement seen in stability and life with the HED multiplier upgrade.

Results

These results were taken from a Perkin Elmer Autosystem gas chromatograph and QMASS mass spectrometer. The tests were performed at Detector Technology, Inc.

After installing the HED multiplier upgrade the system was tuned for maximum sensitivity. The multiplier voltage was adjusted to provide a threshold of 50 - 70. The peaks were kept to a 1 AMU width and tuned to the standard ratios using the sensitivity and resolution. The Autosystem was set up with a method to run Hexachlorobenzene (HCB). The baseline was set to approximately half of the baseline calculated in the tune. The threshold was set to zero.

A 1ul sample of HCB at a concentration of 10 pg/ul was injected into the column by the Autosystem. Mass 284 was analyzed. The signal to noise for this injection was 21.34. When injecting the same sample using the original equipment multiplier a signal to

noise of 6:1 was yielded. It was found that the signal to noise improved over time. We suggest allowing the system to pump for at least 24 hours to achieve maximum sensitivity. The parameters used were applicable for this case study. Instrumentation varies, and these parameters may need to be modified for individual systems.

Applications

Steve Heller is currently using the final design of the HED upgrade for ground water analysis. Steve belongs to a government Superfund sight through Roy F. Weston, Inc. He is testing for volatile compounds in a polluted ground water area. The following data was provided by Steve Heller.

The mass spectrometer is tuned to the manufacturer's specification. After tuning is completed a BFB solution is run. This test includes operation of the Perkin Elmer Autosystem GC as well as the QMASS mass spectrometer. Two microliters of BFB at a concentration of 25 ng/ul is injected into the column. The collected signal is analyzed at mass 95. The spectra at mass 95 is taken. Several peak ratios must be met to pass the BFB specifications. The HED multiplier passes all specifications. After the system passes the BFB requirements unknown samples can be run for 12 hours.

To analyze the ground water a purge and trap system is used. An inert gas is bubbled through a 25 ml sample at room temperature. The volatile compounds are transferred from the aqueous state to the vapor state. The vapors are trapped on a sorbent column. The sorbent column is then heated and backflushed with an inert gas. The volatile compounds are released onto the GC column. The collected signal is compared to the National Institute of Standard Testing(NIST) library. If the PPB detected is higher than the approved detection range, the ground water sample is diluted and re-analyzed. This information is used to assist the engineers in the quality of the clean up.

The system is calibrated using aqueous standards over the linear range of the instrument (2 to 20 PPB for most compounds). At least 5 calibration points are used. The initial 5 point calibration is checked daily using a mid point calibration check standard. The fit and purity are also calculated based on the quantitation ion and up to 10 secondary ions. Also, compound peaks are identified using the NIST library.

Conclusion

The main goal of this project was to design a multiplier to increase the sensitivity of the Perkin Elmer QMASS mass spectrometer. This was accomplished by adding an internal DC/DC converter and conversion dynode. The resulting detector yields improved sensitivity as well as increased stability. This upgrade is accomplished without making any modifications to the mass spectrometer hardware. The change in multiplier assembly allows for a quick and easy upgrade with little down time. The advanced technology of the DC/DC converter and conversion dynode allows the user to perform improved analysis on advanced topics while yielding library searchable spectra. In performing water analysis recalibrating the system may take up to 5 or 6 hours. Since the conversion dynode adds stability to the system, recalibration may not need to be performed as often. This detector upgrade with DC/DC converter and conversion dynode is available for Hewlett Packard MSDs as well as the Perkin Elmer QMASS.

Solid-Phase Microextraction with Fast GC/MS for Benzene, Toluene, Ethylbenzene and Xylenes Analysis

Deborah A. Grimm
Coordinated Instrumentation Facility
Tulane University

Casey C. Grimm
Food Processing and Sensory Quality
USDA-ARS-SRRC
New Orleans, LA

Solid-Phase Microextraction (SPME) is a technique that has recently been introduced as an alternative to other head-space techniques. SPME is performed by exposing a solid phase bound to a needle directly into the headspace or solution of the sample to be analyzed. During the extraction, components of the solution partition between the liquid phase of the solution, the headspace and the solid phase of the SPME fiber. The SPME capillary is then thermally desorbed in the injection port of a GC to transfer the analyte to the GC column for separation and subsequent detection.

Fast GC/MS is becoming a realistic option for the analyses of complex mixtures. Fast GC/MS offers higher sample throughput, maintaining the specificity of MS detection. In the development of Fast GC/MS, several obstacles have had to be overcome, including minimization of the solvent front on the GC column which interferes with the detection of the compounds of interest and contributes to poor GC resolution. By combining SPME with Fast GC/MS, it is possible to minimize this effect. However, the desorption times of the SPME must be held small to keep the injection bandwidths narrow.

A 200 ppm BTEX standard in methanol was diluted to 200 ppb, 100 ppb, 50 ppb, 25 ppb and 12.5 ppb. Three 2.0 ml water samples of each concentration in 5 ml vials were prepared. A SPME fiber possessing a 70µm film of polydimethylsiloxane was exposed to the headspace for five minutes, while sonicating the sample at 40°C. The SPME fiber was desorbed for 0.1 minute in the GC injection port (220°C) fitted with a 0.75 mm I.D. injection liner. The GC contained a 5m, DB-5, 0.1 mm I.D. capillary column. The data were collected using a modified Finnigan 4500 equipped with an HP 5890 GC. The GC oven was initially held at 50°C for 0.1 minute and then ramped to 100°C at 30 °C/min. The transfer line between the GC and MS was held at 100°C. The MS was scanned from 50 to 150 amu. Eight data points were collected/amu and two samples per point were averaged, for a scan rate of 16 Hz.

A typical chromatogram (TIC) is shown below. All components elute within one minute. Benzene responded poorly to the method and had the highest detection limit. There is sufficient chromatographic resolution to separate ethylbenzene from m,p-xylenes. The mass spectrum for ethylbenzene shown below and agrees very well with the NIST spectrum. Calibration curves were constructed for benzene, toluene, ethylbenzene, m,p-xylenes and o-xylene. The average response and RSD's from three replicate injections are shown in the table below. The correlation coefficient for a linear regression fit is also shown for each compound.

	12.5ppb	rsd	25ppb	rsd	50ppb	rsd	100ppb	rsd	200ppb	rsd	r2
Benzene	0	n/a	184	24	961	44	2891	24	11134	40	0.9826
Toluene	532	67	3618	7	8164	21	17215	18	46382	31	0.9939
Ethylbenzene	3668	55	12588	3	25811	19	51374	21	138887	32	0.9926
m,p-Xylenes	10379	43	32014	3	63116	19	121414	20	328607	32	0.9920
o-Xylene	4054	45	12437	6	26211	21	55009	21	138467	26	0.9957

It is demonstrated that the BTEX analysis can be quantitatively accomplished in less than one minute on standard samples from water. This work demonstrates the potential of combining SPME with Fast GC/MS for routine analysis of environmentally interesting compounds.

The RSD could be improved by controlling the SPME extraction conditions more rigorously. Use of an internal standard would also improve the RSD.

Trace Analysis in Complex Matrices: Problems and Practical Solutions

S.A. Barshick, J.E. Caton, B.A. Tomkins, W.H. Griest

Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

The objective of this project was to investigate sampling and analysis methods for trace detection in complex matrices. The detection of explosives and their metabolites in ocean water for the remediation and cleanup of unexploded ordnance was used as the example application. This application was chosen because the release of explosives from unexploded ordnance or from contaminated property into various bodies of water, and the subsequent identification of the biotransformation products of these explosives, is an environmental concern of the Department of Defense. To monitor explosives in ocean water, a method was investigated based on gas chromatography / ion trap mass spectrometry. The explosives used in this study were TNT, RDX, and the metabolites of TNT: 2-aminodinitrotoluene, 4-aminodinitrotoluene, 2,4-diaminodinitrotoluene, 2,6-diaminodinitrotoluene and tetranitro-4,4'-azoxytoluene.

Separation and detection were performed using a Finnigan MAT GCQ gas chromatograph / ion trap mass spectrometer. Separation was achieved using a DB-5MS column (10m x 0.25mm x 0.25 μ m) temperature-programmed from 60°C to 280°C with a constant linear velocity of 30 cm/s helium. Classical electron ionization (70 eV) and methane chemical ionization (100 mtorr) were used. Detection in the fullscan mode (60 - 450 amu) at 0.5 seconds per scan was used for data acquisition. Sample introduction was performed using solid phase microextraction (SPME) fibers. Sampling was achieved by immersing the fiber into an aqueous sample for 10 minutes. The fiber was then inserted into the injection port for thermal desorption "elution" of the analytes into the GC/MS for analysis. Derivatization was performed using the reagent heptafluorobutyrylimidazole to enhance the negative ion detection of the diaminodinitrotoluenes.

A conventional-length (30m) column was originally used for separation in this study. Using this column, the inability to detect the more thermally-labile analytes (RDX, diaminodinitrotoluenes, and tetranitroazoxytoluene) was observed. The use of a shorter (10m) column was shown to eliminate this problem. The detection of the tetranitro-4,4'-azoxytoluene by short column GC/MS is important to note because this compound and its isomers typically can only be detected using HPLC-based methods. Classical electron ionization was initially employed and resulted in extensive fragmentation, although this is useful for structure elucidation, detection sensitivity was limited for trace analysis. An enhancement in detection sensitivity was observed using negative ion chemical ionization, although the diaminodinitrotoluenes were not sufficiently electronegative to be detected in the negative ion mode, they were detected in the positive CI mode, Figure 1. Derivatization of the diaminodinitrotoluenes with the fluorinated reagent heptafluorobutyrylimidazole increased their electronegativity allowing their detection in the negative ion CI mode.

Complex matrices typically cannot be analyzed directly to obtain the selectivity and sensitivity required for most trace analysis applications. To circumvent this problem, solid phase microextraction techniques were used to pre-concentrate analytes selectively prior to analysis. The choice of SPME sorbent phase was shown to be important especially for the amino-metabolites, which were extracted better on the polar phases, and the azoxy dimer, which was extracted only on the non-polar phases. Rapid sample preparation and low ppb to ppt detection capabilities were demonstrated for TNT and the aminodinitrotoluenes in ocean water using SPME, Figure 2. Studies are on going to perform on-fiber derivatization of the diaminodinitrotoluenes using SPME.

Tandem Mass Spectrometry with a Benchtop GC/MS/MS System for the Analysis of Target Compounds in Complex Matrices

Steven T. Fannin, Gary Woffendin, James Edwards, Meredith Conoley

Finnigan Austin/Gas Chromatography Systems, 2215 Grand Avenue Pkwy, Austin, TX 78728-3812

Tandem Mass Spectrometry (MS/MS) is increasingly becoming the analytical tool of choice when analyzing target compounds in complex matrices. The availability of ion trap technologies affords the mass spectrometrists benchtop MS/MS capabilities, hence, lower costs and simplified instrumentation is possible. In general, MS/MS is characterized as a highly selective mass spectrometric technique, whereby target analytes are separated from the sample matrix or coeluting interferences. More specifically, MS/MS operates by first selecting ions at a specific m/z during the first stage of MS/MS, thereby separating the ions from the chemical background (the matrix). The selected precursor ions are then induced to dissociate, typically by collisional activation. The resultant unique product ion spectrum, free from background chemical noise, provides confirmation of the target analyte. Further, a product ion can be used for quantitative purposes. The increased selectivity of MS/MS results in the enhancement of the signal to noise (S/N), therefore, lower limits of detection are possible.

The work presented in this report exemplifies the selectivity and analytical utility of GC/MS/MS using a benchtop external source ion trap mass spectrometer (the GCQ GC/MS/MS system, Finnigan Corp., Austin TX). Tandem mass spectrometry with the GCQ operates by first isolating selected ions from the chemical matrix. The precursor ions are isolated by applying a waveform to the endcaps of the ion trap electrode assembly. This waveform ("isolation waveform") is applied with a notch capable of isolating ions at a single m/z . After the isolation event, a single frequency "excitation waveform" is applied to the endcaps at an amplitude defined by the user. Because the characteristic frequencies of motion of the precursor ions are in resonance with the frequency of the waveform, the ions gain kinetic energy. The presence of the helium "damping gas", inherent in ion trap operation, causes the ions to undergo multiple collisions. Collisional activation creates internally excited ions, thereby causing fragmentation (collision induced dissociation). Characteristic product ions are stored and sequentially ejected and detected in the usual manner (mass selective instability mode). A resonance ejection waveform is also applied to the endcaps to facilitate product ion ejection and improve mass resolution across the m/z range (10 - 1000 Da). Unique to the GCQ is the simplicity of MS/MS method development: The isolation and excitation waveform characteristics and ring electrode potentials ('q' values) are automatically calculated by the GCQ workstation. This greatly simplifies setup and application development.

As an example of the data presented in this work, figure 1 shows the analysis of carbamates by GC/MS/MS in a dog digestive tract GPC extract sample (dog poisoning incidents). The spike level in the extract was 50 pg/ μ L. This is equivalent to 50 μ g/kg in the sample. This data represents an excellent example of the selectivity of tandem mass spectrometry (enhancement in S/N), thereby providing lower detection limits.

Ion-Trap Analysis of Anthraquinone in a Complex Matrix by GC/MS/MS Resonant and Non-Resonant CID

Andrew A. Mosi*, William R. Cullen and Guenter K. Eigendorf
University of British Columbia, Department of Chemistry, Vancouver, B.C.,
Canada, V6T 1Z1

The analysis of trace level substances in complex matrixes is not only limited by the sensitivity of an analytical instrument towards the target substance, but also by its ability to discriminate between the analyte and matrix interferences. The work presented here demonstrates the use of GC/MS/MS on a Varian SATURN 4D quadrupole ion-trap as a sensitive and selective technique for detecting compounds of environmental concern that exhibit characteristic fragmentation pathways. Anthraquinone (AQ), and 2-methylantraquinone (2-MeAQ), oxidation products of anthracene and 2-methylantracene respectively, compounds present in the contaminated sediment analyzed here, were used as models to demonstrate the usefulness of this method. Collision Induced Dissociation (CID) of the molecular ions of AQ and 2-MeAQ (m/z 208 and 222) produced characteristic fragments which could be used for both identification and quantification. For AQ the two sequential losses of CO were monitored, for 2-MeAQ the loss of CH_3 can also be utilized. The collision energy and other CID parameters were optimized by performing series of ten sequential CID experiments using the Varian "Toolkit" software. Both Resonant and Non-Resonant techniques were compared using standard solutions of anthraquinone over a concentration range of 0.5 ppb to 100 ppm and using sediment extracts spiked with perdeuterated PAH internal standards.

By pre-selecting the molecular ions of AQ, methyl-AQ and dimethyl or ethyl-AQ (m/z 208, 222 and 236 respectively) these compounds were identified in a complex PAH contaminated sample (Figure 1) after CID experiments. Complete elimination of matrix interferences for the (M - 2 CO) ion chromatogram was achieved for AQ and using the (M-2CO-alkyl) fragments also for the alkyl-AQs. These latter compounds could not be identified in the sediment extract using standard GC/MS analysis.

Using non-resonant CID good characteristic mass spectra can be obtained for structural identification (Figure 2).

A New Approach to Organic Mixture Analysis Using Time-of-Flight Mass Spectrometry

Robert D. English, Michael J. Van Stipdonk and E. A. Schweikert

Center for Chemical Characterization and Analysis

Department of Chemistry

Texas A&M University, College Station, TX 77843-3144.

INTRODUCTION

The analysis of multi-component mixtures using mass spectrometry often relies on the tandem of MS/MS methods. This two-dimensional approach provides characteristic ion abundance patterns for each component of the mixture, providing for unambiguous assignment of mixture composition. We are currently evaluating a method to mixture analysis that uses only a single linear TOF mass spectrometer and coincidence counting data collection methods.

Our approach is to establish correlations between fragment and quasi-molecular ions from one component, while discriminating against secondary ions from other components. In this way, fingerprint patterns for individual components are obtained in one experiment without the need for a multi-sector instrument or stimulated dissociation. This result is realized by the use of event-by-event monitoring of single ion impacts and single ion counting detection methods in tandem with specialized data collection methods.

EXPERIMENTAL METHOD

The experiments were performed on a home-built Time-of-Flight mass spectrometer using a ^{252}Cf primary ion source. By performing the experiment in the event-by-event mode, coincidence counting methods can be used to highlight those primary ion impacts that produce at least a secondary ion of interest. The sum of those desorption events make up coincidence mass spectra from which the frequency with which two or more secondary ions are desorbed from the same ion impact can be measured. A series of coincidence spectra can be acquired simultaneously with a conventional mass spectrum (all secondary ions from all primary ion impacts) using software developed in house.

RESULTS

The relative intensity of a secondary ion in any particular coincidence spectrum can be adjusted by dividing it by the relative intensity of the same ion in the coincidence with H^+ spectrum. There is an equal probability among all

secondary ions (within 10% variance) for co-desorption with H^+ . Thus the H^+ coincidence spectrum can be used as an internal standard. A plot of the relative intensity ratios calculated using the data from the coincidence with PheH^+ , coincidence with ArgH^+ and coincidence with GluH^+ mass spectra acquired from the same equal mole mix sample of those three amino acids is shown in figures 1a, b and c respectively. The fingerprint patterns that are produced show that those ions, quasi-molecular and fragment, that originate from the same compound have ratio values much greater than unity.

Figure 1

CONCLUSION

Using a careful measure of the co-desorption frequency of secondary ions with each other and with H^+ from mixture samples of simple amino acids, fingerprint patterns can be derived that identify correlations between secondary ions that originate from the same component. These patterns in turn provide MS/MS type information.

The next phase of this work will center on developing statistical models to facilitate the application of this methodology to the analysis of mixtures with unknown composition. The advantage to this approach is that the coincidence spectra (up to 10 different spectra) are collected simultaneously with a conventional TOF spectrum relatively quickly in one experiment, without the need for multiple mass analysis stages.

Analysis of Commercial Vanilla Extracts Utilizing GC/FTIR/MS

Tania A. Sasaki and Charles L. Wilkins

Department of Chemistry, University of California–Riverside, Riverside, CA 92521-0403

Because of its desirable flavor and aromatic properties, the use of vanilla in commercial industries such as food, beverage, and confectionery industries, has become widespread. As a result, adulteration of natural vanilla extract has become a major concern in the commercial market. These concerns have become even greater because the ability to create synthetic vanilla flavors to replace the natural extracts has reached such a high level of quality that very few products exist in which these flavorings cannot be successfully used. This factor, along with the limited supply and therefore high price of authentic vanilla extracts, creates a real economic advantage to misrepresent inferior and synthetic products as natural vanilla.

Many classical methods are utilized for analysis and quality control of vanilla extracts, including UV spectroscopy and thin layer and paper chromatography. Although these methods can help control certain aspects of vanilla production and identify unsophisticated attempts at adulteration, they are of little or no value in some of the higher quality blended or synthesized mixtures.

In this paper, high resolution capillary gas chromatography was combined with both Fourier transform infrared (FTIR) and mass spectral (MS) detection in the analysis of four commercially available vanilla extract samples. Two of the samples (a and b) were pure vanilla extracts available in the United States (US), one was a commercial pure vanilla extract from Mexico (sample c), the other was a known imitation mixture from the US (sample d). The total ion chromatograms (TICs) of each sample are shown in Figure 1 and the peak identifications are listed in Table 1. Identifications were determined by searching the sample IR and mass spectra against their respective libraries.

	a	b	c	d
Benzaldehyde	1	1		
Phenol	2	2		
2-Methoxyphenol	3	3	1	
Substituted benzaldehyde	4,6	4,6		
Substituted ketone	5	5		
4-Hydroxybenzyl alcohol	7	7		
4-Hydroxy-3-methoxybenzoic acid	8	8		
4-Hydroxy-3-methoxybenzaldehyde	9	9	3	2
4-Hydroxybenzaldehyde	10	10		
1,3-Benzodioxole-5-carboxaldehyde				1
3-Ethoxy-4-hydroxybenzaldehyde				3
Benzoic acid			2	
2H-1-Benzopyran-2-one			4	

Table 1: Identification of compounds present in samples (a), (b), (c), and (d). Numbers correspond to peaks in Figure 1.

Figure 1: Total ion chromatograms of the four vanilla samples: (a) and (b) US pure vanilla extracts; (c) Mexican vanilla extract; (d) US artificial vanilla.

The principal polar aromatic flavor compounds of natural vanilla are 4-hydroxybenzyl alcohol, 4-hydroxybenzoic acid, 4-hydroxybenzaldehyde, 4-hydroxy-3-methoxybenzaldehyde (vanillin), and 4-hydroxy-3-methoxybenzoic acid (vanillic acid). Some common additives used to prepare artificial vanilla extracts are 2H-1-benzopyran-2-one (coumarin), 3-ethoxy-4-hydroxybenzaldehyde (ethyl vanillin), and 3,4-(methylenedioxy)benzaldehyde (piperonal).

From the identification of the compounds in the four samples, it was determined that samples (a) and (b) were both authentic extracts. Sample (c) was labeled as a pure vanilla extract. However, the presence of coumarin, a common adulterant, contradicted this claim. The presence of ethyl vanillin, a synthetic product found only in artificial vanilla products, confirmed that sample (d) was indeed an artificial solution.

**Identification of a Benzalkonium Chloride Contaminant
on a Paper Surface by Simultaneous TG-IR-MS**

Craig C. Lynch and Jeffrey M. McGuire
Hercules Incorporated
Research Center
500 Hercules Road
Wilmington, DE 19808-1599

The accumulation and deposition of materials other than fibers in the paper making process can be extremely detrimental. Deposits on the paper machine can cause spots, holes, and even sheet breaks, which all decrease productivity. In order to preserve machine runnability and paper quality, many mills maintain rigorous deposit control programs. These programs often include the use of microbiocides to eliminate microbiological deposits, and other additives to inhibit the formation of inorganic (scale) and organic deposits. However, as changes are made in the process, such as revisions in the sizing system or modifications in the retention system, deposits may occur. A rapid characterization of these deposits is essential in order to reduce lost production or off specification products.

Simultaneous thermogravimetry-infrared-mass spectrometric (TG-IR-MS) analysis is a relatively new technique, which when applied to the analysis of mill deposits provides a rapid means of identifying the source of these contaminants. In 1991, Buchanan, et al., developed a simultaneous TG-IR-MS system for the examination of lignite coal¹. We have designed and assembled a similar system in our laboratory using a TA Instruments Model 951 TGA directly coupled to the injection port of a commercial Hewlett-Packard GC-IR-MS system.

Figure 1 shows the thermogravimetric (TG) curve obtained from the TG-IR-MS analysis of the methylene chloride extract of an off-grade paper product used in liquid packaging cartons. The paper mill experienced a loss in sizing efficiency, and preliminary tests indicated that a residual surfactant might be present on the paper surface. The TG data shows the sample's volatility profile. The solid line is the direct weight loss profile, while the dashed line is the first derivative plot of the direct weight loss. As the curves indicate, a major portion of the sample weight is lost between 200°C and 400°C.

Figures 2 and 3 show the infrared and mass spectra of the volatiles evolved over this temperature regime. The spectra are an average of individual spectra acquired every second, and are indicative of an N,N-dimethyl substituted amine. Upon closer examination of the mass spectral data, tentative molecular ions were identified at m/z 297 and 373. By inspecting the extracted ion profiles for these two ions it was possible to determine at what temperatures maximum volatility was

achieved for these species, and thus obtain representative spectra of the individual species. The m/z 297 compound was unambiguously identified as N,N-dimethyl octadecylamine based on a comparison of the spectrum with a known library spectrum, and the m/z 373 species has been tentatively identified as N-methyl,N-benzyl octadecylamine based on interpretation of the IR and mass spectra.

From this information and the identification of a third species, chloromethyl benzene ($C_6H_5CH_2Cl$), the extracted contaminant was identified as an alkylbenzyltrimethyl ammonium chloride, $R(C_6H_5CH_2)N^+(CH_3)_3Cl^-$, where $R = C_{18}H_{37}$. This quaternary ammonium salt is representative of a class of surfactants known as benzalkonium chlorides with wide-spectrum antimicrobial activity. The observation of the amines and chloromethyl benzene have been rationalized as thermal decomposition products of the quaternary salt as shown below:

LASER DESORPTION FAST GC-MS IN SUPERSONIC MOLECULAR BEAMS

Shai Dagan* and Aviv Amirav, School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel

Phone: 972-3-6408253, Fax: 972-3-6424048, E-mail: amirav@post.tau.ac.il

A new laser desorption mass spectrometry analysis method was developed based on ultra fast GC-MS separation and quantification of the laser desorbed compounds, followed by supersonic molecular beam mass spectrometry.

The laser desorption was performed on a variety of untreated samples at ambient atmospheric pressure and near room temperature. Thus, relatively volatile compounds could be analyzed at their natural composition and phase. The major attribute of this novel laser desorption method is the ability to largely reduce or eliminate complex sample preparation steps that are usually required. It can be applied to a broad range of samples and matrices including solids, powders, liquids, sludge, surfaces and small particles.

An Excimer laser was used for desorption with a train of 20 pulses at 50 Hz (0.4 sec) with average pulse energy of 3-5 mJ at 308 nm. The desorbed sample was swept with helium (300 ml/min) into a 50 cm megabore (0.53 mm ID) column for ultra fast GC separation and quantification in about 1.5 seconds. After the short column, the sample expanded through a supersonic nozzle and was ionized by a molecular beam "fly-through" electron-impact ion source or by a rhenium oxide surface through hyperthermal surface ionization. The ions were then mass analyzed and detected by a conventional quadrupole mass analyzer.

The characteristics of ambient "open-air" laser desorption processes will be discussed and several applications will be described, including the analysis of 1) Caffeine in coffee powder; 2) Paracetamol and codeine in a solid tablet; 3) Methylparathion pesticide in liquid water; 4) Oil film on a stainless steel surface; 5) Aldicarb on an orange leaf; 6) Lidocaine in coagulated untreated blood.

SUPERSONIC MOLECULAR BEAM MASS SPECTROMETRY -

THE QUEST FOR ULTIMATE PERFORMANCE GC-MS AND FAST GC-MS

Aviv Amirav* and Shai Dagan, School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel

Phone: 972-3-6408253, Fax: 972-3-6424048, E-mail: amirav@post.tau.ac.il

Supersonic molecular beams are uniquely characterized by the supercooling of the molecular vibrational degrees of freedom, controlled hyperthermal (up to 30 eV) directional molecular kinetic energy, effective jet separation and high flow rate atmospheric pressure sample inlet capability. We have explored the use of these features for the enhancement of the various aspects of GC-MS. In this poster we shall describe and discuss the following features:

1. Faster analysis through the use of fast, very fast and ultra fast GC-MS without sacrificing the improvements listed below.
2. Lower detection limits achieved with hyperthermal surface ionization. Large quantity fast splitless injections are facilitated by the high column flow rate allowed.
3. Selective ionization of drugs and aromatic compounds is achieved with HSI and with the enhanced M^+ peak in EI that helps in the simplification of complex mixture analysis.
4. Broader range of thermally labile and relatively non-volatile compounds can be analyzed by fast GC-MS without peak tailing and decomposition.
5. Increased level of information is provided with EI due to the vibrational cooling effect on the enhancement of M^+ peak and isomer effects as well as a tunable degree of fragmentation at low electron energies.
6. Flexible sampling with 1) Laser desorption fast GC-MS; 2) A unique direct sample introduction device, 3) Dirty untreated sample insertion in a disposable vial for GC-MS analysis; 4) Simultaneous coupling of multiple columns without column diameter, length and flow rate restrictions.

Several demonstrations of each of these and other features will be shown

Fig. 1. Drug screening in untreated urine. 0.2 μ L of untreated urine was analyzed, demonstrating the capability of universal fast drug screening method in urine using fast GC-MS with SMB.

Fast Multidimensional (3D and 4D) MS² and MS³ Scans in a High-Transmission Pentaquadrupole Mass Spectrometer

Marcos N. Eberlin,* Valmir F. Juliano, Fábio C. Gozzo and Concetta Kascheres

State University of Campinas - UNICAMP, Institute of Chemistry
CP6154 13083-970 Campinas, SP Brazil

Claudimir L. do Lago

University of São Paulo - USP, Institute of Chemistry

Tandem (MS²) mass spectrometry is a very valuable analytical tool that has been performed in a variety of mass spectrometers. One of the most used mass spectrometers in the MS² field has been the triple quadrupole, which allows the efficient performance of the whole set of MS² experiments, while its tandem-in-space mode very much simplifies the acquisition of multidimensional spectra.¹ A more sophisticated implementation of multiquadrupoles is the recently introduced pentaquadrupole mass spectrometer (Q₁Q₂Q₃Q₄Q₅),¹ which employs an ion source, two rf-only reaction quadrupoles (q₂ and q₄), and three mass analyzing quadrupoles (Q₁, Q₃ and Q₅). Their on-line arrangement allows the study of reactions that occur in sequence in the two separate reaction regions by using three stages of mass analysis. Given, therefore the ability to mass-analyze ions before and after each of the reaction regions, a powerful and diverse set of MS³ experiments are available.^{2,4} The pentaquadrupole is also particularly useful for multiple-stage mass spectrometry experiments because it allows all types of MS³ experiments to be accessed and permits either ion/molecule reactions or CID to be performed in either of the two separated reaction regions. Also by scanning sequentially two or all three of the mass analyzing quadrupoles, a variety of three-dimensional (3D)² and a 4D mass spectrum³ can be acquired, each of them providing specific information about the processes under investigation. A variety of applications of several pentaquadrupole MS³ scans have been demonstrated, especially towards the investigation of gas phase ion chemistry processes.²⁻⁴

In this study³ a high-transmission Extrel pentaquadrupole mass spectrometer (Figure 1) was interfaced to an IBM compatible microcomputer and a variety of object-oriented programs in the Microsoft® Windows™ operating system were developed to operate and to increase the versatility of the instrument. A selective pre-scan routine and the complete control of all three mass-scanning quadrupoles made possible very fast acquisition of several types of multidimensional MS² and MS³ spectra, while the high transmission of the quadrupoles conferred excellent signal-to-noise level to the spectra. By performing an unrestricted third-order (MS³) experiment through scanning all of the three mass-analyzer quadrupoles, an entire MS³ data domain was acquired, and the results collected in the first 4D MS³ mass spectrum (Figure 2a). Data projection and data extraction procedures were applied to the 4D spectrum, each of which yielded spectra that provide very specific analytical information. The applicabilities of several other multidimensional mass scans were further demonstrated, particularly towards the study of gas phase ion chemistry processes. A consecutive MS³ neutral gain/neutral loss scan was for the first time applied (Figure 2b), and proved to be very selective for the detection of acylium ions in the gas phase. The application of a 3D MS² scan in

conjunction with the membrane introduction mass spectrometry (MIMS) technique, for fast and simultaneous qualitative, quantitative and structural analyses of VOC's in water was also demonstrated. It was therefore demonstrated that multidimensional mass scans can be acquired rapidly and with high efficiency of ion transmission in pentaquadrupole instruments. A powerful set of MS³ experiments that produces 3D and 4D mass spectra are therefore readily available for ion chemistry studies. This considerably enhances the applicability of multidimensional pentaquadrupole mass spectrometry.

Figure 1 - Diagram of the Extrel Pentaquadrupole Mass Spectrometer.

Figure 2 - (a) The first 4D MS³ spectrum obtained by sequential scanning of all three mass analyser quadrupoles, which contains the entire MS³ data domain for cyclopentanone ions and the two planes described by the equations $m/z(Q3) = m/z(Q1) + 44$, and $m/z(Q5) = m/z(Q3) - 44$ are shown. (b) MS³ consecutive 44 u neutral gain/neutral loss (NGNL) spectrum, which was extracted from the 4D spectrum along the line defined by the intersection between the two planes. Only the m/z 55 acylium ion (and its m/z 56 isotopes) responds to the 44u NGNL test.

RAPID CATALYST AND FEEDSTOCK SCREENING BY MOLECULAR BEAM MASS SPECTROMETRY (MBMS)

French, Richard; Milne, Thomas; Overly, Constance; Broce, Scott; Rejai, Bahman; Meglen, Robert;
National Renewable Energy Laboratory, Golden, Colorado

INTRODUCTION

The use of botanical sources of hydrocarbons have been explored since oil shocks in the 1970's. Crops rich in fatty acids, resins, and latexes have been considered. Pyrolysis with catalytic upgrading with Mobil's ZSM-5 was recognized as a means for producing gasoline (Weisz, Haag, Rodewald, *Science*, 206: 57-58, (1979)).

While common woods are of low cost and ready availability, the high oxygen content of wood makes the effective available hydrogen low. Thus the catalytic upgrading step tends to produce CO, CO₂, water, aromatics and coke rather than the alkenes and alkanes that are desired for the manufacture of transportation fuels or oxygenated fuel additives.

Efforts to produce hydrocarbons from wood at NREL seem to have reached a limit of about 14%(wt). Alkenes for producing light ethers have not exceeded about 8%. Variations on ZSM-5 have not produced substantial improvements.

Therefore, as part of the 1995 US Department of Energy Biofuels Program, hydrocarbon-rich feedstocks were sought to improve the yield of hydrocarbons from pyrolysis followed by catalytic upgrading. These consisted of oil seeds, oil seed plants, plants with potentially high levels of extractives, a commercially available extractive oil (tall oil), and wood. These were examined under consistent pyrolysis and catalytic upgrading conditions. The products were measured by molecular beam mass spectrometry (MBMS).

EXPERIMENTAL

Samples were ground to pass a 2mm mesh. Nominally 20mg portions were batch-fed in pseudo-random order into the pyrolysis zone. They were then catalytically upgraded over Mobil MCG-2. Fast pyrolysis was carried out in 70sccm He at 550°C while the catalyst was held at 525°C. The effluent was diluted in 2.5slm of helium and extracted into a free jet expansion. The adiabatically cooled sample gas was then ionized by electron impact at 23eV and analyzed with a quadrupole spectrometer.

The materials fed were the following: Buffalo Gourd Root, Chrysothamnous Nauseousus, Eucalyptus Globulus, Eucalyptus Teraticornis, Eucalyptus Europhylla, Guayule, Hemp Stalk (Mature), Hemp Seed (Sterile), Leucaena Pod, Milkweed Pod, Milkweed Stem, Pine Lighter Wood, Pine Stump, Rapeseed Plant, Chinese Tallow Seed, Jojoba Seed, Lesquerella Seed, Peanut Seed, Polyethylene/Paper, Soybean Seed, Sunflower Seed Kernel, Crude Tall Oil (Pine).

RESULTS

Pyrolysis produced three types of spectra--woody feeds with a standard lignocellulosic spectrum, pine products characterized by a prominent peak at $m/z=302$, and oil seeds with various fatty-acid series. Such series comprised a few prominent peaks near $m/z=300$ and $m/z=600$ and a low-mass series. Many woody species also had unique peaks indicating high levels of unique extractives.

With catalytic upgrading these all produced mixtures of aromatic and aliphatic hydrocarbons. These feeds were ranked based on the sums of $m/z=42$ and $m/z=56$ as alkene markers and the sum of $m/z=78$, 92, 106 as an indication of aromatic yields. These were compared to known gas and

liquid mixtures to provide reasonable lower limits of alkene and aromatic yields. On this basis, oil seeds produced high yields of 18-19% alkenes and 4-11% aromatics with jojoba and sunflower kernels showing the highest yield. Tall oil produced the highest aromatic yield--up to 18% with up to 17% alkenes. Typical woods (basswood and aspen) yielded about 3% alkenes and 3-5% aromatics by this method. Other feeds were close to the woods with rapeseed plant and pine lighter wood giving yields slightly higher than these standard woods.

CONCLUSIONS

The oil-seeds and tall oil produced at least several times the yield of hydrocarbons that wood did. Also, alkenes were a higher fraction of the product, making it a much more desirable feed for refinery use. Whole rapeseed plant and pine lighter wood showed significant but less dramatic improvements. The yields cited are conservative--only the major desirable species are reported in the total. There were additional products which could be processed by a refinery, but spectroscopic interferences and lack of resources prevented quantification. In light of these encouraging yields, some economic evaluation is warranted followed by optimization of conditions and further quantification of yields for the most promising feedstocks.

**Matrix-Enhanced Secondary Ion Mass Spectrometry:
A New Method for Molecular Analysis of Solid Surfaces**

Kuang Jen Wu and Robert W. Odom
Charles Evans & Associates, Redwood City, CA 94063

A new methodology, matrix-enhanced secondary ion mass spectrometry (ME-SIMS), is reported for the analysis of biomolecules. The technique applies secondary ion mass spectrometry (SIMS) technique to samples prepared in a solid organic matrix similar to sample preparations used in matrix-assisted laser desorption/ionization (MALDI). This process expands the routine operable mass range for static SIMS to reach ca. 10 000 Da and higher. Significant enhancement in ionization efficiency of the analyte molecules is also observed. Higher mass peptides, proteins and nucleic acids has become analyzable with this new technique. The experimental studies were conducted with a PHI-EVANS TOF-SIMS system with a pulsed 11kV Cs⁺ ion beam as a primary source. A direct comparison of the matrix enhanced effects is shown in Fig. 1. Figure 1(a) shows positive ion TOF-SIMS mass spectrum of porcine renin substrate (average MW = 1,759 Da) with 2,5-dihydroxybenzoic acid (2,5-DHB) as a matrix material. Matrix to analyte ratio in mixture solution was ~ 10,000 : 1 with 1 pmol of analyte loaded for analysis. The isotopic features are clearly resolved and mass resolution was measured to be $M/\Delta M = 4,500$ (FWHM). This measured isotope distribution is in good agreement with calculated pattern as shown in the insert. The mass spectrum obtained from a neat renin substrate residue on Si is shown in Figure 1(b). A factor of 50 increase in total secondary ion signal intensity was observed. Therefore, ionization yields of the analytes are greatly enhanced by the presence of the matrix, although the matrix molecules are no longer used for the absorption of laser energy as in MALDI. Fig. 2 shows a positive ion mass spectrum of an underivertized, custom synthesized, mixed-base single-stranded DNA 26-mer (MW= 8,083) using 2,5-DHB as a matrix materials. The "conventional" matrix for DNA, 3-hydroxypicolinic acid (HPA), dose not perform well for ME-SIMS applications. This result suggests that ME-SIMS shares some common matrices with MALDI, but discrepancy dose exist. HPA no longer produces strong nucleic acid ion signal, instead it is 2,5-DHB which generates most intense secondary analyte ions for oligonucleotides. A number of matrices were examined for their efficiency for ME-SIMS applications and the initial studies on matrices were focused on some MALDI matrices and their isomers. The results from our survey indicated that 2,5-dihydroxybenzoic acid provides the most enhancement to secondary analyte ion signals. The matrix-enhanced configuration enables conventional static SIMS instrumentation analyze higher molecular weight biomolecules and organic polymers.

Fig. 1 Positive ion TOF ME-SIMS spectrum of renin substrate with (a) 2,5-DHB as a matrix and (b) neat residue deposited on a Si wafer substrate. A total of 1 pmol analyte loaded.

Quantitation and Confirmation Seven Tetracyclines Residues in Kidney Tissues by APci LC/MS/MS.

David Kwok¹, Carl Alleyne¹, Pauline Chow¹, Larry Young¹, Man Sen Yong² and Brian Mon¹.
Organic Residues Laboratory, Health Protection Branch, Health Canada, Burnaby, B.C., Canada V5G 4P2¹; Bureau of Veterinary Drugs, Health Protection Branch, Health Canada, Ottawa, Ontario, Canada K1A 0L2².

Tetracyclines are a group of effective antimicrobials commonly used as veterinary drugs in food animals. To determine the presence of veterinary drug residues in animal tissues for the purposes of human health risk assessment and for regulatory diagnostic monitoring, an analytical program is underway to investigate specific food animals. This study involves the development and validation of an APci LC/MS/MS method for routine determination of six tetracyclines (minocycline, oxytetracycline, tetracycline, demeclocycline, chlortetracycline, doxycycline and methacycline) in beef kidney tissue with a LOQ of 10 ng/g.

Fortified beef kidney tissue was extracted by acetonitrile: citric acid / EDTA / phosphate buffer (40:60) using a tissue homogenizer. The extract was centrifuged at 5000xg for 3 min and the supernatant was placed on a rotary evaporator under vacuum at 35°C for 30 min to remove the acetonitrile. The aqueous extract was purified by C-18 solid-phase extraction using ethyl acetate / acetonitrile as elution solvent. Following evaporation of the elution solvent, the final extract was reconstituted with 100 µl of acetonitrile / buffer for LC/MS/MS analysis.

All HPLC experiments were performed on a HP1090 liquid chromatograph with a Zorbax Rx-C8 (5µ) 2 1x150mm column and a gradient mobile phase of ACN water containing pentafluoropropionic acid (PFPA) 0.3mM / triethylamine (TEA) 0.05mM / oxalic acid 10mM. A column flow rate of 300 µl/min was delivered directly into an APci source by heated nebulization using a nitrogen flow rate of 300 L/h

MS/MS analysis was carried out with a Quattro-II instrument using corona discharge atmospheric pressure chemical ionization (APci) and Argon as collision gas. The ion source and the collision cell operating parameters were optimized for MRM transitions monitoring two or three ions for each of the tetracyclines over a calibration range from 10 to 4000 ng/g. Quantitation of six tetracyclines, using demeclocycline as an internal standard, was found to be linear over the calibration range

Method validation was carried out with fortified beef kidney calibration samples at 10, 50, 100, 500, 1000 and 4000 ng/g, based on 5 g samples. Calibration curve for each drug was generated by (1/c) weighted linear regression with coefficient of determination ranging from 0.9985 to 0.9999. The back-interpolation errors for the range of calibration standards were typically within 10% of the expected nominal values. QC samples were fortified at 20, 60 and 250 ng/g (n=3 at each level). Quantitation precision and accuracy of the QC samples were within a relative error (%RE) of 11 and a CV of 15, respectively. Method absolute recovery was examined at fortified concentrations of 10, 50 and 100 ng/g for each drug with an overall mean recovery ranging from 70 to 90%.

Method specificity was examined for each residue using known blank beef kidney matrix. Positive confirmation for each drug was based on two or three specific parent-to-daughter transition ions. A representative LC/MS/MS MRM chromatogram of a 100 ng/g fortified beef kidney sample is shown in Figure 1.

This study demonstrates that APci LC/MS/MS is a highly specific and reliable technique for the quantitation and confirmation of six important tetracycline drug residues in beef kidney tissue over the concentration range from 10 to 4000 ng/g. The utility of this method was applied to a survey of the six tetracycline residues in 50 cull dairy cattle beef kidneys obtained from federally non-registered slaughterhouses in Canada. A 2% incidence of violative tetracycline residues was detected. In a separate study, the utility of this LC/MS/MS method for screening of multiple-classes of drug residues was further applied for the quantitation of 10 sulfonamides antibiotic residues from 10 to 200 ng/g fortified beef kidney.

Figure 1. Representative APci MRM chromatograms of six tetracyclines at 100 ng/g fortified beef kidney.

Ionspray-MS and MS/MS Analysis of Natural Products: Structural Characterization of 10 Aporphine-Benzylisoquinoline Alkaloids

Wu-Nan Wu and Michael D. Moyer, The R. W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477, USA

INTRODUCTION: Aporphine-benzylisoquinoline alkaloids exert antitumor, antimicrobial and hypotensive activities (1-3). Previously, structural characterization of these natural products has relied mainly on EI-MS, CI-MS and FABMS, however, these techniques require more than 10 µg of material (1-6). The objective of this study was to elucidate the structures of aporphine-benzylisoquinoline alkaloids in ng quantities using ionspray-MS and MS/MS techniques.

METHODS: Thalycarpine and 9 other aporphine-benzylisoquinolines isolated and derivatized previously from *Thalictrum* sp. (Ranunculaceae) (2-5) were studied. Acetate and dimethyl diiodide derivatives were synthesized using acetic anhydride/pyridine (2:1, v/v) and methyl iodide, respectively. Samples (20-50 ng/µL) were prepared in acetonitrile/water (50/50, v/v) with 5 mM ammonium acetate (pH 4), and analyzed using a Sciex API III mass spectrometer equipped with an ionsprayer via flow injection using nitrogen as a curtain and nebulizing gas and argon as a collision gas for MS and MS/MS analysis. The mobile phase for this system was acetonitrile/water with 5mM ammonium acetate buffer (pH 4.0; 50/50, v/v) at a flow rate of 0.1 mL/min.

RESULTS AND CONCLUSIONS: Structures and representative Q1 scan MS and MS/MS data for 10 alkaloids are presented (Figures & Table). Ionspray-MS analysis exhibited apparent protonated molecular ions and intense doubly charged ions (base peak) for the alkaloids in Q1 scan MS (Figures & Table). MS/MS analysis of each alkaloid revealed prominent daughter ions for structural elucidation of the aporphine-benzylisoquinoline alkaloid (Figures & Table). Detection of molecular ions and structural identification was accomplished using ng quantities of the alkaloids.

Studies of Sulfated Marine Toxins by MS and MS/MS Using a Hybrid Sector/Orthogonal Acceleration Time-of-Flight Mass Spectrometer

Jonathan M. Curtis, Tingmo Hu and Jeffrey L.C. Wright.

Institute for Marine Biosciences, N.R.C., 1411 Oxford St., Halifax, Nova Scotia B3H 3Z1

We have recently reported the isolation and structure of several water-soluble diarrhetic shellfish poisoning (DSP) toxins produced by two *Prorocentrum* species of marine dinoflagellates [Hu et al., J. Chem. Soc. Chem. Commun. 597 (1995), Tetrahedron Letts, 36, 9723 (1995)]. These water-soluble compounds are derivatives of okadaic acid containing a polysulfated acyl chain. The structures of DTX-5a and DTX-5b (Fig. 1) only differ by an additional methylene group and it was hoped that LSIMS-MS/MS experiments using a Micromass AutoSpec oa-TOF (Xe CID, 800eV) could locate this group as well as confirm other structural details. In addition, the fragmentation of these linear molecules was compared with that for a cyclic sulfated structure.

The presence of sulfate groups in the molecules is readily seen by the characteristic mass difference of 102 (+H-SO₃Na) in both the positive and negative ion LSIMS spectra. The negative ion MS/MS spectrum of DTX-5b is dominated by "backbone" fragmentation remote from the charge localized on the sulfates, making these types of molecules (ie linear, sulfated) ideal for MS/MS studies. Thus, comparison of the negative ion MS/MS spectra of DTX-5a and -5b reveals a series of ions shifted by 14 units thereby locating the additional methylene group between two fragment ions. The structure proposed from NMR data is supported by the observed fragmentation, and the presence of sulfate is confirmed by the fragment ions at *m/z* 80 and 97 (SO₃⁻ and HSO₄⁻).

A more spectacular illustration of the location of this variation can be seen in the MS/MS spectra of the [M+3Na-2H]⁺ ions (Fig. 1). In this case the charge (Na⁺ adduct ion) can reside at either end of the molecule resulting in fragmentation in both directions. With DTX-5a a major fragment ion at *m/z* 919 is formed whereas the equivalent ion for DTX-5b at *m/z* 933 is very weak and additional intense ions at *m/z* 107 and 79 are present. This can be explained by the formation of a 6-membered diene for DTX-5a (Fig. 1a) whereas for DTX-5b, the additional methylene group makes this less favourable and instead the competing reaction leading to cleavage at both ends of this short hydrocarbon chain occurs (with a hydride transfer) resulting in the fragments C₈H₁₁⁺ and C₆H₇⁺ (*m/z* 107 and 79).

In contrast to the linear structure of the Dinophysistoxins, the macrocyclic structure of the polar Prorocentrolide B (another *Prorocentrum* metabolite) [Hu et al., J. Natural Products (submitted)] poses more of a challenge to MS/MS. In this case, despite the presence of a sulfate group, fragmentation can be propagated through either of the two macrocycles, making interpretation ambiguous. Interpretation is facilitated by comparison of the MS/MS spectrum of the [M+2Na-H]⁺ ion with that of the [M+2K-H]⁺ ion where all the ions containing sulfate are shifted by 32. Also the [M+Na]⁺ ion (ie [M+(Na-H)+H]⁺) shows fragmentation directed by protonation at a nitrogen resulting in complementary fragmentation to that observed for the [M+2Na-H]⁺ ion.

Results from these experiments illustrate the versatility of the hybrid sector/orthogonal acceleration TOF arrangement (AutoSpec oa-TOF) which allows rapid and sensitive collection of high-energy MS/MS data. The ability to compare several adduct ions is invaluable for interpretation. The sulfated toxins described gave informative MS/MS spectra although this was much less so for the cyclic molecules.

Sulfonium Salt Reactions with LSIMS Solvents Induced by Primary Beam Bombardment

Michael C. Melnyk and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta GA 30332-0400; R.W. Johnson Pharmaceutical Research Institute, Princeton, NJ

An organic sulfonium salt (of the general structure $ABCS^+X^-$) contains a tricoordinate sulfur atom bearing a positive charge; A, B, and C are organic groups, and X is the counter ion associated with the cation. Sulfonium salts have been utilized as cationic photopolymerization agents, as intermediates in organic synthesis, agents in areas such as coating, inks and adhesives, photo polymers for the preparation of printing plates, fiber optic coatings, fiber-reinforced composites and for electronic encapsulation [1-3]. Nuclear magnetic resonance spectrometry has been the primary structural analytical method used to date.

Since sulfonium salts are non-volatile compounds, electron and chemical ionization are not appropriate for their spectrometric characterization. Fast atom bombardment (FAB) and liquid secondary ion mass spectrometry (LSIMS) sputter sample ions directly from a sample solution, and have been used to produce high quality mass spectra from a number of "onium" salts. Duffin and Busch [4] examined several sulfonium salts with positive ion LSIMS, and found the mass spectra to be easily interpretable.

Despite the ease with which LSIMS mass spectra for these compounds can be measured, general rules that support the structural interpretation of the mass spectra for these salts is still based on a relatively small number of examples. One purpose of the present work is to record mass spectra for a group of structurally diverse sulfonium salts, and to further establish the ground rules for spectral interpretation. Further, since sulfonium salts react with some of the matrices used for sample preparation in LSIMS [1], we wish to further explore this reactive chemistry.

Figure 1 is the positive ion LSIMS mass spectrum for sulfonium salt I. The strong signal at m/z 275 corresponds to the intact cation of the sulfonium salt. The isotope peak at $(C+2)^+$ represents the isotope of the sulfur atom. The fragment ion at m/z 197 (20% relative intensity) corresponds to a loss of 78 Daltons (Da) from the intact cation, attributed to the loss of neutral benzene. Simple cleavage by loss of a phenyl group would lead to an odd-electron ion. Instead, hydrogen transfer to the phenyl group occurs (presumably from the bridging methylene) and loss of a neutral benzene molecule preserves the even-electron character of the fragment ion. Mestdagh *et al.* [5] postulated that loss of 78 Da (neutral benzene) to form the intact cation of dialkylphenylsulfonium salt was due to a secondary fragmentation rather than a direct loss from the cation. Usually, both loss of 77 and loss of 78 are observed in the collision-induced dissociation MS/MS spectrum. Since this is not the case here, we suggest simply that the hydrogen transfer required for loss of 78 Da is particularly easy in this case. Loss of 32 Da from the fragment ion at m/z 197 to form the fragment ion at m/z 165 (not labeled) corresponds to loss of a sulfur atom. The signal at m/z 637 (note the multiplication factor) corresponds to the CAC^+ cation, configured as loss of methyl biphenylene. The ion at m/z 999 corresponds to the $CACAC^+$ cation. Other ions in the mass spectrum (unlabeled) are due to the *m*NBA matrix. The presence of both C^+ and CAC^+ provides a double check on the molecular mass of the cation, and identifies the anion by mass as well. The structures of the ion CAC^+ is still in question. Although it is simple to write $C^+A^+C^+$ as shown, this may not necessarily correspond to the most stable structure for this cluster ion. In particular, the loss of methylbiphenylene as a neutral molecule for CAC^+ and not from C^+ , indicates a structure in which the two cations may act in a concerted fashion to cause fragmentation.

Charge-remote fragmentation is a dissociation process that was first observed in the product ion MS/MS spectra of charge-localized parent ions. Recently, it was observed to occur in the mass spectra of carbocyanine dyes that contain a localized charge site proximate to a long alkyl chain [6]. For salt O, charge-remote fragmentation is also observed a successive losses of methylene groups along the long C_{11} alkyl chain, providing yet another example of such a process in a mass spectrum produced by energetic particle bombardment.

Another instance of reactive chemistry involving a sulfonium salt and the matrix used is evident in the analysis of sulfonium salt T. When *m*NBA was used as a matrix, the spectra generated followed the same pattern previously discussed, with the intact cation as the base peak in the mass spectrum. However, when TEA (triethanolamine) was used as a matrix, the spectra generated was different, and the most intense sample related ion in the mass spectrum corresponds to an adduct, formally $(C^+ + TEA + OCH_3)$ (See Figure 2).

The ground rules for spectral interpretation of the positive ion LSIMS mass spectra of sulfonium salts are established. The intact cation of sulfonium salts is a dominant ion in the mass spectrum. Only a minimal amount of fragmentation occurs. Clustering of the cation and anion is manifest in the appearance of the CAC^+ , the $CACAC^+$ and, for some salts, $CACACAC^+$ cluster ions. The structures of these cluster ions have not been definitively established. Most fragment ions observed in the spectra can be rationalized as simple cleavages and rearrangements form the intact cation. However, there are additional ions in the mass spectra that represent fragmentation from the cluster ions. These fragmentations often mirror those that occur from the cation itself, but in at least one instance, a concerted dissociation process that requires the involvement of both cations in CAC^+ was observed. We have documented a beam-induced alkoxylation reaction for one of the sulfonium salts analyzed, and a reaction of a sulfonium salt with triethanolamine is described. Sulfonium salts can be included in the short list of compounds that exhibit charge-remote fragmentation in the LSIMS spectrum, provided that the structure of the salt contains at least one long alkyl chain.

LIQUID IONIZATION MASS SPECTROMETRY FOR REACTION STUDY -FORMALDEHYDE OLIGOMERS IN A SOLUTION

T.Kaneko, P.Yang, J.Saito and M.Tsuchiya, Department of Physical Chemistry, Yokohama National University, Hodogaya-ku, Yokohama, Japan

An aqueous solution of formaldehyde (formalin) is used as raw materials for producing polymers. Since a small amount of methanol is added, the formalin contains poly(oxymethylene) glycols (POMGs) and also methylethers of POMG. Its composition varies with temperature and so on. Since proton affinity (PA) of solvent is smaller than PAs of POMGs and their related compounds, these analytes in a solution can be analysed by Liquid ionization mass spectrometry (LI-MS)¹⁻³⁾ without disturbance of solvent ions.

Experimental Paraformaldehyde (solid) was dissolved in water to prepare the primary aqueous solution (3% and 30% by weight). LI mass spectra²⁾ shown in this paper are all the average of mass spectra of 5~10 scans. The sample was kept at ambient temperature between scan numbers 1~15 and then, was heated up to about 200°C in final. Rapid (heater voltage increased to 10V in 20 s) and slow (same process in 50 s) heating rate were examined.

Results Most of ions observed for the primary solution were protonated molecules (MH⁺) of hydrated POMGs, $\text{HO}(\text{CH}_2\text{O})_n\text{H}(\text{H}_2\text{O})_m\text{H}^+$ (referred to as $\text{A}_n\text{W}_m\text{H}^+$ or n-m, $\text{A}_n = \text{POMG}$). In the case of concentrated solutions (POMG > 20%), an intense peak at m/z 60 and the small peaks corresponding to solvated monomethylethers of POMG, $\text{CH}_3\text{O}(\text{CH}_2\text{O})_n\text{H}(\text{H}_2\text{O})_m(\text{CH}_2\text{OH})_k\text{H}^+$ (referred to as $\text{C}_k\text{W}_m\text{M}_1$ or n-m-k, M: CH_2OH) were also observed (Fig.1), when the sample was heated (at scan numbers about 15~30). These peaks were observed at heating, indicating that these compounds were not contained in the sample. Dilution of sample with water was most effective to reduce the extra reactions (Fig.2). Water is also useful as a vapor matrix, which is vaporized near the sample holder, and gave different kinds of information about analytes and reactions.

A dilute solution of POMGs (3%) and its reaction products with methanol have been analysed without any treatments by LI-MS³⁾. Methanol reacted with POMGs (A_n) even at ambient temperature to form monomethylethers of POMGs (C_k) as shown in Fig.3, which are selected ion profiles of main ions and clearly indicates that the reaction took place within 5 min after methanol addition and almost completed in 15 min.

Liquid ionization mass spectrometry is useful to study reactions occurred in a solution and also in the ion source.

Soft Ionization Mass Spectrometry of Chromanols Produces Radical Cation Molecular Ions

Thomas R. Sharp

Analytical Research & Development
Central Research, Pfizer Inc., Groton, CT 06340 U.S.A.

Introduction: The soft ionization -- *i.e.*, FAB and APCI -- mass spectral behavior of chromanols, represented by the general structure shown at right, is dominated by the behavior of the substituted chromanol ring system. These compounds do not form $[M+H]^+$ in FAB and APCI experiments, as would be conventionally expected. Rather, they produce radical cation molecular ions. The oxidation state and nature of substitution of the chroman ring appears to play a role in determining whether an M^+ , an $[M+H]^+$ or an $[M-H]^+$ is formed.

Experimental: FAB mass spectral observations were done on a VG 70S magnetic sector mass spectrometer, using a *ca.* 8 KV xenon atom beam generated by a saddle field atom gun. The matrix routinely used was dithiothreitol-dithioerythritol[1]. Poly(ethylene glycol) was used as the accurate mass reference standard.

Results: The FAB mass spectrum of an example compound, CP-105,696, is shown in Figure 1. CP-105,696 ($C_{28}H_{28}O_4$, r.m.m. 428) is a leukotriene B_4 antagonist drug substance previously described in the literature[2, 3, 4]. CP-105,696 contains a 4-phenylbenzyl group attached at position 3 (R_1 of the above structure) and a cyclopentanecarboxylic acid group attached at position 7 (R_2). Rather than the conventionally expected $[M+H]^+$, the molecular ion species in the spectrum appears at m/z 428, corresponding to a radical cation molecular ion. FAB accurate mass measurements (see the table below) on this species yield a measurement consistent with the expected empirical formula of the radical cation.

Figure 1: FAB mass spectrum of CP-105,696 (r.m.m. 428).

Investigations of the structural features of this molecule causing this behavior focused, by elimination of other substructures, on the alcohol functional group at position 4. Change or removal of the sidechain attached at either position 3 or position 7 had no effect, as long as the sidechain did not contain a nitrogen atom. The presence of a nitrogen provides a convenient protonation site, and $[M+H]^+$ are formed. Esterification of the carboxylic acid at position 7 had no effect.

Conversion of the free hydroxyl at position 4 to a methoxyl group does not alter the behavior -- still producing an M^+ . Oxidation of the hydroxyl group to a carbonyl group causes the molecule to behave in the orthodox manner expected for FAB ionization, producing an abundant $[M+H]^+$.

Removal of the free hydroxyl group and introduction of a double bond into the ring, producing a 3-chromene ($C_{28}H_{26}O_3$, r.m.m. 410) complicates the situation. See Figure 2. The compound exhibits an abundant $[M-H]^+$ at m/z 409, and abundances at m/z 410 and m/z 411 too high to be attributable to natural isotope abundances. Accurate mass measurements are consistent with assignment of the m/z 410 species to be an M^+ and the m/z 411 species to be an $[M+H]^+$.

Figure 2: FAB mass spectrum of the 3-chromene analog of CP-105,696 (r.m.m. 410).

FAB Accurate Measurement Mass Results

compound	rmm	m/z	assignment	observed	composition	expected	agreement
chromanol	428	428	M^+	428.1992	$C_{28}H_{28}O_4$	428.1988	1.0 ppm
methoxyl	442	442	M^+	442.2142	$C_{29}H_{30}O_4$	442.2144	0.5 ppm
chromene	410	411	$[M+H]^+$	411.1933	$C_{28}H_{27}O_3$	411.1961	6.8 ppm
		410	M^+	410.1866	$C_{28}H_{26}O_3$	410.1882	3.9 ppm
		409	$[M-H]^+$	409.1806	$C_{28}H_{25}O_3$	409.1804	0.5 ppm

Discussion: Even though, formally, the m/z 428 species produced by FAB has the same elemental composition and overall electronic content as the m/z 428 species produced by electron ionization (EI), they are "structurally" different species. Under EI (not discussed here), the molecule eliminates H_2O by neutral loss, producing an m/z 410 species. Under FAB, a radical cleavage occurs, producing an m/z 411 fragment (Figure 1).

If we envision valence electron ejection and proton attachment as two competing reactions, the results suggest that loss of a valence electron for the chromanols is a much easier process than attachment of a proton. The presence of apparent $[M+H]^+$, M^+ and $[M-H]^+$ species in the spectrum for the chromene (Figure 2), however, suggests that proton attachment can compete more favorably with electron ejection. Proton attachment leads to subsequent ejection of H_2 to produce the chromenyl cation[5]. A driving force for this latter fragmentation would seem to be formation of the fully aromatic chromenyl (benzopyrilium) cation, in which a formal positive charge resides on the ring oxygen.

COMPARISON OF LSIMS AND ESI MEASUREMENT OF MASS SPECTRA FOR METAL-CONTAINING COMPOUNDS

Robert J. Geiger, Michael Bartlett and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400; Department of Medicinal Chemistry, University of Georgia, Athens, GA

In the study of the mass spectra of inorganic and organometallic compounds, softer ionization techniques have been used extensively, and liquid secondary ionization mass spectrometry (LSIMS) has been one of the more successful of these. (1-4) Positive and negative ion LSIMS mass spectra of metal-containing compounds contain significant intensities of cluster and adduct ions, and there is some debate about whether the occurrence of these ions is evidence for the presence of the corresponding species in the solution prior to energetic particle bombardment. By comparing LSIMS and Electrospray mass spectra for a particular compound, it may be possible to determine the origin of cluster and adduct ions.

Electrospray ionization (ESI) has been used to delineate the extent of beam-induced reactions such as oxidation, reduction, and adduct ion formation in LSIMS. ESI/MS provides a method of transferring pre-existing ions from solution to the gas phase (1) In this work, LSIMS and ESI are used to acquire positive ion mass spectra for a variety of metal acacs to investigate fragmentation patterns, sample-matrix interactions, and cluster ion formation. More importantly, we use LSIMS and ESI to determine if the cluster and adduct ion formation occurs in solution prior to ionization or by a beam-induced reaction. Our main focus is to study these LSIMS high mass ions that have been formed by the reaction of the primary beam between the sample and the solvent.

Positive ion LSIMS mass spectra were acquired on a VG70-SEQ mass spectrometer of EBQq geometry. ESI mass spectra were obtained from a 100% methanol solution. ESI/MS experiments were performed on a VG-Quattro II mass spectrometer. To give ESI generated ions the chance to react with TEA, a small amount of TEA was added to the methanol solution.

Plaziak *et al* (5) describe the use of TEA for the generation of negative ion LSIMS mass spectra for several of the same transition metal acetylacetonate (L) studied here. An intriguing aspect of Plaziak's work was the variety of sample/solvent interactions reported. Adduct ions were observed that contain a mixture of (L) and TEA ligands. Plaziak suggested a beam-induced formation of polymeric species to account for these adduct ions. We have calculated structures of these ions, consistent with the recorded LSIMS spectra, by Insight II molecular modeling program.

In our study, we focused on the mass spectra of Ga and In acetylacetonates. A peak for the lone Ga metal (m/z 69) is present in the ESI but not in the LSIMS spectrum. The base peak (m/z 267) present in both the LSIMS and ESI spectra corresponds to the $\text{Ga}(\text{2L})^+$ ion. The high mass ions in the LSIMS spectrum correspond to the addition of matrix molecules to the $\text{Ga}(\text{L})_2^+$ ion. The high mass ions in the ESI spectrum are not the same as those observed in the LSIMS mass spectrum. They do not correspond to the addition of TEA to sample-derived ions, nor to adducts with methanol. There is no evidence for sample/TEA interaction as apparent in the LSIMS mass spectra.

The lone In ion (m/z 115) is present in the ESI but not in the LSIMS spectrum. The base peak (m/z 313) in both the LSIMS and ESI spectra corresponds to the $\text{In}(\text{2L})^+$ ion. We observe a very intense ion at m/z 835 in the LSIMS spectrum and not in the ESI. The ion at m/z 835 corresponds to the $[\text{3In}+2(\text{TEA-3H})+2\text{L}]^+$ complex, and a suggested structure for the adduct ion at m/z 835 is shown in Figure 1. The higher-mass region of the ESI mass spectrum again does NOT contain ions that evidence cluster ion formation between TEA or methanol and the sample-derived ions.

Plaziak *et al* suggested that the presence of cluster ions in the LSIMS mass spectra of these compounds was due in part to the presence in solution of the cluster ions. If these ions were indeed present, the ESI mass spectra should provide some evidence for them. However, they are totally absent from the ESI mass spectra. We must conclude that such cluster ions are NOT present in the solution. We suggest that the products of beam-induced reactions are formed exclusively in this selvedge region. The intensity of the ion at m/z 835 in the LSIMS (TEA) mass spectrum reflects a relatively high stability. However, this ion is not formed at all in the ESI mass spectrum, despite the presence of all the components. The LSIMS sputtering process must surmount the activation energy for formation of this ion, while ESI ionization does not.

In potential uses of these ions in surface modification studies, the need is for novel ion structures prepared with relatively high ion currents. ESI is clearly not the method of choice here. Although very sensitive, only a limited ion current is available from the ESI source, and the absence of the selvedge limits the diversity of ions that can be formed. LSIMS, on the other hand, can generate a very high ion current and a number of unique ions that include both cluster and adducts of unique composition and geometry. Note that the mass spectra of indium acetylacetonate had not been previously reported anywhere in the literature -- and this investigation uncovers ions of unique character.

Using the measured ion current in the mass spectrum, and other parameters of the mass spectrometer, calculations show that a small amount of material (3.2×10^{-5} ng/s) could be deposited on a collector surface. With soft landing (the deceleration of ions onto the collector surface) the spacing between metal centers, the extent of bonding to oxygen or nitrogen, and the oxidation states of the metal atoms are all controllable. The impetus for study of these novel metal-containing ions is the desire to understand their inherent chemistry, but more importantly, the promise that these novel ions can ultimately be used in the preparation of unique surfaces and materials.

MIXED-METAL IONS IN THE MASS SPECTRA OF GA AND IN ACETYLACETONATES

Sharon W. Lemire and Kenneth L. Busch

School of Chemistry & Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400

Metal acetylacetonates (acacs), $\text{Met}_x(\text{C}_5\text{H}_7\text{O}_2)_y$, are attractive subjects for mass spectrometric analysis due both to their volatility, and to their well-studied gas-phase chemistry. To support vapor deposition studies, means to create mixed-metal ions from these compounds are being sought. Mixed-metal acacs have been observed in spectra acquired by EI¹, and by SIMS². In these studies, mixed-metal cluster ions, $\text{MetMet}'(\text{acac})_n$, $n = 3$ to 5, were observed from mixtures of two $\text{Met}(\text{acac})_3$ compounds, but neither $\text{Ga}(\text{acac})_3$ nor $\text{In}(\text{acac})_3$ was included.

Single-metal cluster ions involving a ligand-exchange reaction between the matrix molecules, *m*-NBA and triethanolamine (TEA), and the acac ligands have been observed in the LSIMS/FAB mass spectra^{3,5}. Saraswathi³ suggested bidentate coordination of (*m*-NBA - H), either through the two nitro-group oxygens, or through the combination of a nitro-group oxygen and the alcoholic oxygen. A structure proposed by Bartlett⁴, in which *m*-NBA acts as a bridging ligand between the metal ions, agrees with the latter suggestion.

EI, DCI and LSIMS mass spectra of various mixtures of $\text{Ga}(\text{acac})_3$ and $\text{In}(\text{acac})_3$, are discussed here. The impetus behind this research is the prospect of forming novel mixed-metal species for use as precursors in chemical vapor deposition (CVD) processes. The volatility of metal acacs renders these compounds good candidates for CVD, and mixed-metal species may ultimately be used to prepare surfaces with unique properties by this technique. *In situ* mass spectrometry has been used to determine the CVD processing window for pure copper acac precursors⁶.

Solutions of each $\text{Met}(\text{acac})_3$ were made in DMSO:AcCN, in TEA:DMSO:AcCN, and in *m*-NBA. In EI, the mass spectrum of the mixed-metal acacs was obtained from neat $\text{Ga}(\text{acac})_3$ and $\text{In}(\text{acac})_3$, mixed *in situ*, from single-metal DMSO and TEA solutions mixed *in situ*, and from premixed DMSO and TEA solutions. Mixed-metal mass spectra were obtained by DCI from the single-metal DMSO solutions, and by LSIMS from the single-metal TEA and *m*-NBA solutions. In both cases, the solutions were mixed *in situ* on the probes. All mass spectra were acquired under standard operating conditions. For EI, the probe temperature was ramped from 50 to 200°C at 50°C/min. (solids), and from 100 to 400°C at 100°C/min. (solns.). The DCI probe was ramped from ambient to 400°C at 8 mA/second.

Among individual metal acac species investigated, only Schildcrout⁷ has included $\text{Ga}(\text{acac})_3$, and no reference to the analysis of $\text{In}(\text{acac})_3$ has been found. Table 1 summarizes the mixed-metal ions observed in the EI, methane DCI, and LSIMS mass spectra of the mixtures. The mixture of $\text{Ga}(\text{acac})_3$ and $\text{In}(\text{acac})_3$ produced EI and DCI mass spectra containing ions consistent with the mixed-metal ions observed for mixtures of transition metal acacs^{1,2}. The presence of specific $\text{Met}_x(\text{acac})_y^+$ clusters, where $y = 2$ to 5, is determined by the available oxidation states of the metal atom⁷. For the proposed mixed-metal formulas of the ions observed in EI and DCI, the measured isotopic envelopes (assessed from the DCI spectra), and the exact mass measurements are in excellent agreement with the calculated values. The ion at m/z 595 has two possible mixed-metal formulas that could not be differentiated either by isotopic-envelope or exact-mass measurements.

The LSIMS mass spectrum of the mixture also contained mixed-metal ions with two metals and three or five ligands, but the acac ligands were progressively replaced by up to two (*m*-NBA - H) for Met_2L_3^+ (L = ligand), and up to three for Met_2L_5^+ . The number of acacs replaced by (*m*-NBA - H) here is consistent with that previously observed for individual metal acacs^{3,4}. The presence of these additional ions in LSIMS, and the absence of the proposed mixed-metal ions from the mass spectra of the individual complexes, further supports the formation of mixed- rather than single-metal ions.

No ions that could be attributed to mixed-metal species were observed in the EI mass spectra of either the DMSO or the TEA solutions, whether the samples were premixed or mixed *in situ* on the probe. This result, and the observation of such species in the spectrum of the neat mixture, is consistent with the suggestion that these mixed-metal ions are formed from ion/molecule reactions in the gas phase⁷. In LSIMS, the fact that mixed-metal ions are observed with *m*-NBA, but not with TEA, also suggests that such species are formed in the gas phase. These results suggest that the sample concentration at the surface of the TEA film is less than that at the surface of *m*-NBA, so that formation of mixed-metal ions would be less likely. Overall, the evidence strongly suggests the formation of mixed-metal species in the gas phase.

Practically, loss of structural integrity due to ion/molecule reactions can cause errors in the structural determination of the original molecule. In the area of gas-phase reaction chemistry, however, these reactions may provide a means of producing ion structures that are not otherwise attainable and that may lead to novel applications. The fact that Ga and In acacs form mixed-metal species containing mixed oxidation states may be useful for applications requiring such species. For example, surfaces coated with mixed-metal species may be found to possess unique catalytic or electrical properties. By regulating experimental conditions, it should be possible to orchestrate the extent of mixed-metal ion formation. This possibility could find utility in the area of vapor-phase deposition of mixed-metal species. The replacement of acac ligands by matrix molecules in LSIMS may also provide a unique synthetic route. By careful selection of the matrix, such compounds may be engineered to provide specific metal-to-metal spacing, oxidation states and/or heteroatom connectivity. Deposition of such an engineered compound on a surface might impart unique properties to that surface.

Generation of Metalloporphyrins in the source under Fast Atom Bombardment

M. Rosário Marques Domingues, M. Graça O. Santana Marques, F. M. L. Amado and A. J. Ferrer Correia
Department of Chemistry- Mass Spec. Lab., University of Aveiro, 3810 Aveiro, Portugal

Metalloporphyrin complexes are, as it is well known, very important in life biochemistry. They have many practical applications, namely as catalysts. We have found that the formation of metalloporphyrins in a mass spectrometer source under FAB, without previous synthesis, produces molecular ions with high relative abundances, allowing their characterisation and the study of their gas-phase fragmentations by MS/MS.

There are two previous reports of the formation of metalloporphyrins under FAB: of Zn(II) and Mn(II) complexes of porphyrin dimers and of Zn(II) with porphyrin monomers^{1,2}. Formation of complexes during Laser Desorption Mass Spectrometry, with the production of short lived molecular ions, was also reported³. We have studied the formation in the source, under FAB, of complexes of the following compounds, tetraphenylporphyrins **1** to **4** and tetraphenylchlorin **5**, with different metal centres. The metals used were Mg(II), Zn(II), Ni(II), Cu(II), Cd(II), Pb(II), Co(II), Fe(II) and Fe(III). The procedure involves the addition, on the probe tip, of a porphyrin solution to the matrix, 3-nitrobenzyl alcohol, saturated with a metal salt.

In the case of Zn(II), Cu(II), Cd(II) and Pb(II) the molecular ion MetP⁺ of the metalloporphyrin was observed for all the porphyrins tested. We were unable to detect the formation of metalloporphyrins for Mg(II), Ni(II), Fe(II) and Fe(III) and, for Co(II), metalloporphyrin formation was only observed in the case of compound **1**. Zn(II), Cu(II) and Pb(II) metalloporphyrins were produced with a good yield, and in all the spectra the molecular ions MetP⁺ of the metalloporphyrins, have higher relative abundances than the protonated molecular ion [PH₂+H]⁺ of the corresponding free porphyrins, PH₂, (Figure 1). However, for Cd(II) and Co(II), [PH₂+H]⁺ ions have higher relative abundances than the corresponding MetP⁺. The ratios of the relative abundances of MetP⁺ ions and [PH₂+H]⁺ ions are presented in Table 1.

Figure 1 - FAB mass spectrum of compound **1** + Zn(II)

Table 1 - Bar graph of the ratios of MetP⁺ and [PH₂+H]⁺ relative abundances

The present process of metalloporphyrin production is rapid, requires minimal amounts of reagents and, due to both the high abundances and relatively long lives of the molecular ions, allows the study of their gas-phase fragmentation by MS/MS.

Mixtures of Tetraspirocyclohexyl Calix [4] Pyrrole as a New Reference Compound For Positive Ionization Fast Atom Bombardment High Resolution Mass Spectrometry

Longfei Jiang and Mehdi Moini
Department of Chemistry and Biochemistry
University of Texas at Austin, Austin, TX 78712

Recently, we introduced two calibration/reference compounds for both low and high resolution mass spectrometry (HRMS), 1) perfluorophosphazines (Ultramark 1621) for positive and negative chemical ionization (CI) and fast atom bombardment (FAB) in the mass range of 800-2100 Da, and 2) a commercially available mixture of perfluoropolyethers (Fomblin) for negative FAB high resolution mass spectrometry in the mass range of 180-4000 Da. Another commonly used calibration/reference compound in the FAB positive ionization mode is polyethylene glycol (PEG). These reference compounds, however, have some limitations. For example, the intensity of the PEG peaks diminishes very rapidly at high masses (>1300 Da), or in some cases at resolution of approximately 10,000 its peaks cannot be separated from the peak of the unknown. The disadvantages of Ultramark includes its limited mass range, and in some cases, it tends to suppress the peaks of the unknown, and/or it produces memory effect when used as an internal standard.

A new calibration compound is, therefore, needed when one encounters the disadvantages mentioned above. We hereby introduce a new reference compound for positive FAB that fills the gaps mentioned above. This compound is tetraspirocyclohexyl calix [4] pyrrole. The advantages of the new calibration/reference compound are that: 1) it covers a wide mass range of 200 - 3000 u, 2) its exact masses are different from those of PEG and therefore can be used as an alternative to PEG when the peaks of PEG interfere with those of unknown, 3) its peaks are separated by approximately 80 mass units, ideal for HRMS, 4) it works well with glycerol and nitrobenzyl alcohol, and 5) it behaves similarly to PEG and does not suppress sample peaks in the manner that Ultramark does in some cases. The disadvantages of this compound are that: 1) it is not commercially available (however, it is very easy to synthesize.), and 2) it does not work in the negative ionization mode.

All experiments were performed on a VG ZAB-2E high resolution mass spectrometer (VG Analytical Ltd., Manchester, UK) with the OPUS data system. The tetraspirocyclohexyl calix [4] pyrrole was prepared by the following procedure: 1) Mix and stir 0.811g N-methyl pyrrole, 0.98g cyclohexanone, and 20 ml CH₃CN at 0°C in a round bottom flask, 2) add 10 drops HClO₄ at 0°C, and allow the mixture to warm up to room temperature, 3) after 24 hours, a precipitate will have formed. Remove the solvent in a vacuum (Gale, P.A., Sessler, J.L., Král, V., and Lynch, V. Submitted for publication.)

The chemical structure of tetraspirocyclohexyl calix [4] pyrrole is shown in Figure 1.

Figure 1. Schematic of the chemical structure of tetraspirocyclohexyl calix [4] pyrrole

The mass spectrum of tetraspirocyclohexyl calix [4] pyrrole in the mass range of 300 - 3000 Da is shown in Figure 2. The accurate masses and elemental compositions of this series are listed in Table 1. Exact masses were examined by high resolution mass measurement of several of its peaks using PEG as the reference compound.

Figure 2. FAB Mass spectrum of tetraspirocyclohexyl calix [4] pyrrole using NBA matrix. Mass numbers denote the ¹²C isotope peaks of the isotope clusters.

Clemson, SC 29634-1905

Introduction:

Glow discharge (GD) sources have been extensively utilized for the direct analysis of metals, alloys, and semiconductors. The inherent ability of the radio frequency (rf) powered glow discharges to sputter and atomize nonconductors facilitates the analysis of polymeric and composite materials. From a recent study, the rf sputtering process was demonstrated to bring substantial amounts of polymer fragments into the gas phase for subsequent ionization in the glow discharge plasma. A series of bulk polytetrafluoroethylene (PTFE) based polymers were studied to assess their fingerprint mass spectra and to distinguish each sample by differing base peaks and relative peak intensities. The use of this rf-GDMS system for thermally stable PTFE samples produced stable fragment ion currents (< 5 %RSD), excellent discharge stabilization times (< 3 min), and promising depth profiling possibilities. The preliminary observations of molecular species observed by rf-GDMS for both fluorocarbon and hydrocarbon polymers are reported in this presentation.

Experimental:

The VG GloQuad is a quadrupole-based instrument which has a three stage differentially pumped vacuum system. Two turbo pumps produce a final stage vacuum of $10\text{E-}7$ mbar. Two detectors are utilized, a Faraday cup for high ion currents typical of matrix species and an electron multiplier for minor and trace components. For this presentation, a novel direct insertion probe (DIP) and sample holder introduce flat samples to the VG GloQuad ion volume that is housed within the spectrometer chamber.

Results and Discussion:

Polycarbonate (PC) and polytetrafluoroethylene (PTFE) samples, with each having a thickness of 1 mm, were studied by the use of this rf-GD source. One of the advantageous features of rf-GDs is their excellent stability. The surface regions were sputtered under the same operating conditions of 25 W power, 0.10 mbar Ar flow, and 10 mm anode plate. Selected fragment ions of these sheets were monitored in a peak jumping mode for twenty minutes. The internal stability of each of the respective sample polymers are listed in table 1. All fragments have signal variations of less than 5 %RSD. A preliminary evaluation of the role of discharge parameters was also performed. Scanning electron micrographs of a sputtered and a non-sputtered region of PC revealed the effect of sputtering on the structure of the surface region. An rf-GDMS depth profile analysis of a 1 μm copper layer on a 1.5 mm thick PTFE substrate (20 W power, 0.075 mbar Ar discharge gas pressure) was also reported. All of the results obtained herein suggest that the implementation of this rf-GDMS system is a viable technique for the analysis of polymeric materials.

PTFE			PC		
Fragment	Intensity	%RSD	Fragment	Intensity	%RSD

Measuring Cationization Effects on the Molecular Weight Distribution of an Ethoxylated Polymer by Time-of-Flight Secondary Ion Mass Spectrometry

Paula A. Cornelio Clark*, Scott D. Hanton, and David M. Parees,

Air Products and Chemicals, Inc., 7201 Hamilton Blvd., Allentown, PA 18195-1501.

INTRODUCTION:

All synthetic polymers consist of molecules with a distribution of chain lengths, characterized by the number average molecular weight (M_N), the weight average molecular weight (M_W), and the polydispersity (PD) (1). The molecular weight distribution (MWD) governs many polymer properties, therefore, it is important to characterize the distribution quantitatively.

The repertoire of mass spectral techniques applicable to measuring MWDs has increased steadily (2). In previous work, we compared the MWDs for Surfynol®4XX (XX = 20, 40, 65, and 85) using Fast Atom Bombardment (FAB), Matrix Assisted Laser Desorption and Ionization (MALDI/I), Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS), and Electrospray (ESI). The increasing XX values indicate increasing amounts of ethoxylation on a backbone of 2,4,7,9-tetramethyl-5-decyne-4,7-diol. In this study, the MWD of Surfynol®465 (S465) generated from sodium and from silver cationized oligomers was measured by ToF-SIMS.

EXPERIMENTAL:

Sample solutions of S465 (Air Products and Chemicals, Inc.) were prepared in methanol (1 mg/mL). In one preparation, 10 μ L of solution (saturated with either NaCl or AgNO₃) were streamed across a silicon substrate angled at 45°. In the second preparation, 10 μ L of solution were streamed across a silver foil (cleaned with nitric acid and Barnstead E-pure 18 megohm-cm water) angled at 45°. The ToF-SIMS data were collected on a PHI-EVANS TFS® Surface Analyzer using a 15 kV, bunched ⁶⁹Ga⁺ beam, operated at a repetition rate of 5 kHz. The data were collected using 10 kV post-acceleration. Primary ion doses did not exceed 10¹² ions/cm².

RESULTS & DISCUSSION:

The Na⁺ and Ag⁺ cationized oligomer distributions for S465 on silicon are shown in Figure 1. The M_N , M_W , and PD values for samples prepared on silicon and silver are summarized in Table 1. We find the measured molecular weight of S465 depends on the metal cation and the supporting substrate. We measure a higher molecular weight for Na⁺ cationized oligomers than for Ag⁺ oligomers. In addition, we measure higher molecular weights for cationized oligomers generated from the silver substrate than from cationized oligomers generated from the silicon substrate. We speculate that Na⁺ complexes the oligomers through an ion-dipole interaction with the O atoms on the ethoxy chains of S465, while Ag⁺ complexes the oligomers through interaction with the acetylenic backbone of S465 (3). We

propose two explanations for the higher molecular weights measured from the Na⁺ cationized oligomer distribution: 1) A minimum ethoxylate chain length is required for Na⁺ chelation. Thus, the Na⁺ cationization mechanism may discriminate against the very low molecular weight oligomers and produce higher average molecular weights. 2) The Ag⁺ cation may face steric hindrance to the triple bond as the ethoxy chains extend. This may result in lower average molecular weights.

We find cationized oligomers generated from the silver substrate yield higher molecular weights than the cationized oligomers generated from the silicon substrate. The silver substrate preparation appears to yield better oligomer separation, which increases oligomer-metal interaction and leads to higher molecular weights.

Figure 1. ToF-SIMS spectra of Surfynol 465/Si: Na⁺ (top) and Ag⁺ (bottom) cationized oligomer distributions.

Table 1
Molecular Weight of S465 by ToF-SIMS

Substrate	Cation	M_N	M_W	PD
Si	Ag ⁺	559	571	1.02
Si	Na ⁺	638	658	1.03
Ag	Ag ⁺	653	676	1.03
Ag	Na ⁺	705	730	1.03

Note: The precision of the M_N and M_W data is ± 7 amu, based upon $n = 9$ measurements.

Time-of-Flight Secondary Ion Mass Spectrometry of Substituted Polystyrenes

Yeonhee K. Lee and Seunghye Han

Advanced Analysis Center, Korea Institute of Science & Technology, Seoul, Korea

Polystyrene is a linear polymer and is a thermoplastic with many desirable properties. It is clear, transparent, easily colored, and easily fabricated. The major application field for polystyrene is packaging and insulating materials. The family of styrene polymers includes polystyrene and polymers of derivatives of styrene. Many styrene derivatives have been synthesized and studied.

Secondary ion mass spectrometry in combination with time-of-flight mass analyzer (TOF-SIMS) has been widely used to characterize the synthetic polymers (1). Beside desorption of intact oligomer ions, fragmentation of the polymer chain was observed. TOF-SIMS spectra of different molecular weight polystyrenes, poly(α -methylstyrene), poly(4-methylstyrene), poly(4-tert-butylstyrene), poly(4-chlorostyrene), poly(vinyl benzylchloride) poly(4-vinylbiphenyl), and poly(vinylnaphthalene) were obtained using TOF-SIMS.

TOF-SIMS spectra show typical oligomer distributions of molecular weight (MW) 700 and 2180 polystyrenes. The results from TOF-SIMS are in good agreement with Gel Permeation Chromatography (GPC).

Figure 1 shows the positive ion TOF-SIMS spectra of MW 2180 polystyrene, poly(4-methylstyrene), and poly(α -methylstyrene), respectively. As can be seen in the figures, poly(4-methylstyrene) have different fragment patterns from poly(α -methylstyrene). The low mass region of the spectra was used to identify the substituted polystyrenes.

Fig.1 Positive ion TOF-SIMS spectra of MW 2180 polystyrene, poly(4-methylstyrene), and poly(α -methylstyrene).

Recent studies using matrix-assisted laser desorption coupled with a time-of-flight mass spectrometer demonstrate the soft ionization feature and very high mass capability of this technique (2,3). Using dithranol and silver trifluoroacetate (AgTFA) as the liquid matrix and cationization agent respectively, 1 μ l of sample solution was dripped onto a sample holder. The typical MALDI spectra of 700 polystyrene and 2180 polystyrene were obtained. The molecular weight distribution of polystyrene in MALDI spectra is a little higher than values obtained in TOF-SIMS. The higher molecular weight polymers are more difficult to analyze as evidenced by the very low signal intensity of molecular ions.

Fig.2 MALDI Spectrum of MW 200,000 polystyrene using dithranol matrix.

2-Nitrophenyl octyl ether (NPOE) matrix was tried also. No signal was obtained for MW 200,000 polystyrene in NPOE. The highest molecular weight polystyrene from which molecular ion peak could be obtained in this work was a 200,000 polystyrene in dithranol. (Figure 2) The structural characterizations of polystyrene standards and substituted polystyrenes were done using TOF-SIMS and MALDI-TOFMS.

Mass discrimination effects in an ion detector exemplified by MALDI mass spectrometry of polymers

JAN AXELSSON, ELAINE SCRIVENER, DAVID M. HADDLETON, and PETER J. DERRICK

Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry, CV4 7AL, United Kingdom

ABSTRACT Recent attempts to employ matrix-assisted laser desorption/ionisation (MALDI) mass spectrometry for polymer characterisation have claimed successful matches with more traditional methods such as size-exclusion chromatography. The resulting mass spectrum is, however, not only extremely sensitive to ionisation conditions such as laser power, but is also sensitive to the mass and velocity dependent detector signal. The dependence on the detector is best illustrated for a polymer distribution, because oligomers of similar mass are expected to exhibit similar ionisation efficiency. Because of the different detection efficiencies for different oligomer masses the number distribution measured with mass spectrometry is distorted, so that the higher mass oligomers are discriminated against.

EXPERIMENTAL A 337 nm nitrogen laser Kratos Kompact MALDI III (Kratos Analytical Ltd, Manchester, UK) time-of-flight (TOF) reflectron mass spectrometer was employed using both 5 kV ("low mass" mode) and 20 kV ("high mass" mode) extraction voltages. Data was averaged over 20 to 50 laser shots for 20 kV extraction potential, and over 100 to 500 shots for 5 kV extraction potential. The laser beam was rastered over the 3 mm long sample to minimise sample deterioration. We found excellent reproducibility for the first 500 laser shots (M_n varied from 1911 to 1980 u).

Samples of poly(methyl methacrylate), PMMA, were prepared on a stainless steel slide employing the following procedure: A 0.5 µl droplet of 2,5-dihydroxybenzoic acid (0.1 M in 5:1 acetone:deionised water) was deposited onto each sample spot and left to dry for five minutes. A 0.5 µl droplet of 10^{-3} M PMMA (in 5:1 acetone:deionised water) was then dropped on top of the dried matrix, and again air-dried for five minutes. No salts were added; ionisation was from Na^+ cations present in solution.

PMMA

THEORY The dependence of the detection efficiency can be described by employing theories for secondary electron emission from the first dynode surface in an electron multiplier. For any selected extraction voltage this mass and velocity dependence is transformed to a mass dependence. The mass dependence will act so that an ensemble of heavier ions will exhibit a mass-spectral peak of lower intensity than would the same number of ions of a lighter ion species.

From experimental data of low velocity secondary electron emission¹ (around and below 30 km/s), the secondary electron yield can be described by

$$\gamma_L = a \cdot m \cdot \exp(B \cdot \sqrt{U/m}), \quad (1)$$

and for velocities above approximately 30 km/s, the secondary electron yield^{2,3} may be described by

$$\gamma_H = k \cdot m \cdot \left[(13.9 \cdot 10^3)^2 \cdot U/m - v_t^2 \right] = k \cdot [C \cdot U - D \cdot m]. \quad (2)$$

Here, U is the extraction voltage, m the ion mass in u, and v_t the extrapolated threshold velocity for electron emission. The parameter values $B=3.59$, $C=1.93 \cdot 10^8$ and $D=2.56 \cdot 10^8$ were calculated from a least square fit spectra of the theoretical formulas (1) and (2) to data from two PMMA ($M_n=1520$) spectra acquired at $U=5$ kV (equation 1) and $U=20$ kV (equation 2). The value of D is not very sensitive for the goodness of this fit.

Since the detected signal is proportional to the number of emitted secondary electrons, the detector effects in a measured spectrum can be corrected for by multiplying the signal by one of the correction functions (figure 1):

$$\begin{aligned} 1/\gamma_L \quad M/Z &= 1000 \text{ u } (v=30 \text{ km/s}) \text{ to } 4000 \text{ u} \\ &\quad (v=15 \text{ km/s}) \text{ for } U=5000 \text{ V} \\ 1/\gamma_H \quad M/Z &= 400 \text{ u } (v=100 \text{ km/s}) \text{ to } 4000 \text{ u} \\ &\quad (v=30 \text{ km/s}) \text{ for } U=20000 \text{ V.} \end{aligned}$$

The proportionality constants a and k are set to 1.

RESULTS Figure 2 shows the distinctly different spectra of PMMA ($M_n=1520$, polydispersity 2.06) acquired with different extracting voltages. The most probable peak is shifted by 468 u. However by multiplying the spectra with the correction function, the most probable peak in the spectrum acquired at 5 kV is shifted from 1024 u to 1492 u, which coincides with the peak for the spectrum acquired at 20 kV. The 20 kV spectrum does not change significantly when multiplied by the correction function, which illustrates the importance of choosing an extracting voltage which minimises the distortion of the spectrum.

This distortion for the lower extracting voltage can be easily understood examining figure 1. Comparing a mass range from 1000 to 4000 u, the correction function increases nine-fold for 5 kV but only 1.5 times for 20 kV. Thus, if one wants to avoid using a correction function, the extraction voltage should be set so that the correction function varies as little as possible.

Fig. 1 The correction function with which to multiply a measured spectrum in order to correct for the mass and velocity dependence of the secondary electron yield. Thick line and filled circles represent the valid range.

Figure 2. Bar graph showing peak areas from PMMA 1520 spectrum acquired at 5 kV (top) and 20 kV (bottom). The circled line represents the same data multiplied by correction function.

For 5 kV extraction voltage, PEG ($M_n=1500$) with a polydispersity of 1.04 only displayed a small 40 u shift (to be compared with the 468 u shift for PMMA of polydispersity of 2.06). Thus, the distortion of a measured polymer distribution is much more severe for polydisperse samples such as the PMMA studied.

Polymer Analysis by Time-Lag Focusing MALDI TOF MS

David C. Schnemer, Randy M. Whittall and Liang Li*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

MALDI has a demonstrated usefulness in the area of polymer analysis. In the typical operating mode (DC, or continuous extraction), MALDI appears capable of generating signal intensities that are independent of mass and, subject to detection limitations, is able to provide accurate molecular weights [1]. The significantly higher mass resolution attainable with TLF MALDI provides the ability to determine structural information for a greater mass range than in normal DC operation.

In TLF MALDI, the pulse voltage is selected to provide the highest resolution, but this optimum resolution applies only over a limited mass range. It is a fair question to ask if the application of TLF introduces any mass dependent biasing of the signal intensities as well. With the analysis of two polystyrene samples (a polydisperse and a high mass polymer), it will be shown that the pulse voltage does not bias the molecular weight determinations. Furthermore, the analysis of the polydisperse sample also demonstrates that the detector does not introduce measurable mass biasing over a 13 kDa mass range.

Samples were dissolved in freshly distilled THF. Retinoic acid was prepared to a concentration of 150 mM in THF. The polystyrene solution and matrix solution were premixed to give a final analyte concentration of 50 to 300 μ M. To 100 μ L of this mixture, 1 μ L of silver nitrate solution (saturated in ethanol) was added. One μ L of the final mixture was added to the sample probe.

High resolution data were collected on the previously described TLF MALDI instrument, modified for operation up to 30 kV [2]. The first extraction plate was redesigned and a grid was placed on the repeller side. The lower resolution spectrum of polystyrene was collected on a Hewlett Packard G2025A MALDI TOF system. The polymers were purchased from Aldrich. Retinoic acid (also from Aldrich) was used as the matrix without further purification.

Figures 1A and 1B display spectra of a mixture of polystyrene 3250, 5000, 7000, 9250 and 13000 collected under TLF MALDI conditions with a 1 μ s time-lag. In Figure 1A, the spectrum shown was collected under conditions which maximizes the instrumental resolution at 4 kDa. The spectrum in Figure 1B was collected under conditions which maximizes the instrumental resolution at 11 kDa. However, Table 1 demonstrates that the number average (M_n) and weight average (M_w) molecular weights are constants regardless of pulse voltage selected. This is due to the fact that relative peak areas remain constant. The pulse voltage can dramatically influence the shape of the distribution, however. In Figure 1A, the resolution begins to decrease significantly at higher mass, requiring a drop in peak height to maintain the peak area.

Table 1 M_n and M_w values determined for a blend of polystyrene 3250, 5000, 7000, 9250 and 13000

TLF Pulse Optimized at: (Da)	Observed M_n	Observed M_w
4000	7420	8540
11,000	7390	8420
20,000	7470	8510
25,000	7260	8330

The above mass determinations demonstrate an average relative standard deviation of 1.6%.

If the individual components of the polymer blend are run in TLF MALDI, the spectra can be normalized and summed together with consideration of the fraction of the individual components to come up with a theoretical distribution. The individual components and the blend were analyzed using the same pulse voltage. The number average molecular weight and polydispersity of the blend can be compared to those obtained from the theoretical distribution (Table 2). If mass discrimination were to occur with such a polydisperse sample, then one would expect a significant difference in the results between the two cases. Table 2 shows that mass discrimination does not occur in a simple multichannel plate detector in the mass range from 2 to 15 kDa.

Table 2 Comparison of the M_n and polydispersity of a polystyrene blend with the values calculated from the individual components.

	M_n	Polydispersity
Calculated	7420	1.155
Experimental	7390	1.152

Figure 2 shows a comparison of TLF and continuous extraction MALDI using polystyrene 45,000. The polystyrene oligomers are partially resolved under TLF conditions with a resolution of 620 fwhm. The M_n and polydispersity of the polystyrene in the two extraction schemes is listed in the figure. The manufacturer reports an M_n of 45,550 and polydispersity of 1.053 for this sample.

THE EFFECTS OF SAMPLE PREPARATION AND DELAYED EXTRACTION ON THE MALDI ANALYSIS OF SYNTHETIC POLYMERS.

(1) Introduction.

Over the past four years the Matrix Assisted Laser Desorption/Ionization -MS analysis of synthetic polymers has been increasingly used [1]. In spite of this there is still a degree of uncertainty about the accuracy and reliability of the technique for polymer analysis.

The aim of this poster is to present the results of two series of investigations carried out into the analysis of synthetic polymers by MALDI. The first series of experiments involved the analysis of polyethyleneglycol (PEG) and polypropyleneglycol (PPG) with dithranol as the matrix, at a range of concentrations of the polymer, matrix and added salt (NaCl).

The second series of experiments utilized delayed extraction of laser desorbed ions to investigate the ionization process. Over the past year, delayed extraction has come to the fore as a method of increasing the resolution of MALDI-TOF spectra. In this investigation however, the motivation behind the use of delayed extraction was to enhance the yield of molecular ions and thus increase the signal intensities of polymer molecular weight distributions.

(2) Experimental.

A home built linear coaxial reflectron time-of-flight mass spectrometer was used for both sets of experiments [2]. For the concentration studies, a constant accelerating voltage of 10kV was used for single stage ion extraction. However, for the delayed extraction experiments, a pulsed high voltage switch (+/-6kV, Behlke GmbH) in conjunction with a delay generator was used, again with single stage extraction.

(3) Results (a) Sample Spot Concentration.

Figure 1 shows a series of spectra obtained at different PPG concentrations, with all other parameters (i.e. dithranol and NaCl concentration and laser energy) kept constant.

It can be shown by normalizing the data that a variable polymer concentration affects only the intensity of the polymer distribution and not the shape.

Further experiments were carried out with variable matrix and salt concentrations, and it was found that most intense polymer molecular ions were obtained with as high a matrix concentration as possible relative to the polymer concentration. It was also found that adding an alkali metal salt to a concentration of $\sim 1\text{g/L}$ led to much more reproducible signals rather than relying on the presence of alkali metal contaminants. Over the mass range studied, there were no significant changes in the shapes of the polymer distributions at different concentrations of either the matrix, polymer or salt.

(3) Results (b) Delayed Extraction of Synthetic Polymers.

Pulsed extraction has been increasingly been used recently to improve the resolution of laser time-of-flight mass spectrometers [3]. In this present work, delayed extraction was used to increase the polymer molecular ion signal obtained during MALDI of synthetic polymers. It was found that laser desorption/ionization within a field free region increases the probability of cationization of polymer neutrals by metal ions.

Figure 2 illustrates the normalized behaviour of a range of PPG oligomers at a series of delay times of up to $3.5\mu\text{s}$. It can be seen that there is an increase by about a factor of 3 in polymer molecular ion intensity at delays of $\sim 750\text{ns}$, compared with extraction into a DC field.

A further consequence of delayed extraction is that higher laser energies may be used, without either resolution degradation or detector saturation. Figure 3 shows several spectra obtained at a constant delay of $1\mu\text{s}$, but at a range of laser energies. It can be seen clearly that there are several series of fragment peaks extending from the intact molecular ion region down to very low mass. Furthermore it can be seen that at $135\mu\text{J}$, there is a shift in the apparent position of the polymer molecular ion distribution.

(4) Conclusions.

Delayed extraction for polymer analysis has several advantages including: (i) Increased molecular ion yield; (ii) Improved resolution; (iii) Possibility of fragmentation, hence increased information about polymer composition; (iv) Information on the time dependence of molecular ion formation in MALDI

²ICI Research and Technology

The direct study of synthetic polymer samples by mass spectrometry has largely been restricted to those which contain polar functional groups, such as polymethyl methacrylate (PMMA) and polyethylene glycol (PEG).^{1,2} These polymers are known to interact favourably with alkali metal cations, via the functional group. Conversely, the interaction between non-polar polymers such as polystyrene (PS) with alkali metals is not as favoured, primarily because of the absence of basic functional groups containing heteroatoms (N, O). However, previous experiments carried out by means of matrix assisted laser desorption/ionisation (MALDI)³ have shown that silver cations interact favourably with polystyrene, probably by binding to the electron rich phenyl ring along the polymer chain. At present, little work has been focused on the analysis of synthetic non-polar polymers by means of electrospray ionisation mass spectrometry (ESI-MS).⁴ The present work aims to establish which metal cations interact effectively with polystyrene in the gas phase, by means of ESI and MALDI MS.

All MALDI experiments were carried out in a VG ToFSpec time-of-flight instrument.

MALDI samples were all prepared in the following way: 10mg of dithranol, polymer sample and metal salt were each dissolved in 1 mL of THF. The three solutions were then mixed together in the ratio 10:1:1, matrix:polymer:salt. ESI experiments were performed in a VG Quattro II tandem quadrupole instrument and sample preparation involved preparing polystyrene 1700 to a concentration of 5 mg mL⁻¹ in 50:50 THF/DMF and adding 0.5 mg of metal salt to 100 mL of the mobile phase (50:50 THF/DMF).

Figure 1 shows the ESI spectrum of polystyrene 1700. The main distribution of peaks corresponds to the attachment of one lithium cation to the polystyrene chain, i.e. $[H(CH_2CHC_6H_5)_n, C_6H_5 + Li]^+$. The ESI spectrum in Figure 1 is interesting because of the presence of a second intense series of peaks, which corresponds to the attachment of a lithium salt cluster to the polystyrene chain i.e. $H(CH_2CHC_6H_5)_n, C_6H_5 + (LiCl)Li^+$. These PS + salt adduct ions were observed in the ESI spectra for each metal salt added to the mobile phase. Other metal cations which were found to bind to polystyrene to give reproducible MALDI and ESI mass spectra were Na⁺, K⁺, Ag⁺, Cu⁺ and Co⁺. The MALDI mass spectrum of PS + Cu⁺ is shown in Figure 2, and the ESI and MALDI spectra of PS + Ag⁺ are shown in Figures 3 and 4 respectively. Zinc (II) was found to give reproducible adducts of polystyrene in MALDI spectra, but not ESI spectra and the reverse was true of NH₄⁺. The most reproducible MALDI and ESI spectra were obtained when silver trifluoroacetate and potassium iodide, respectively, were used in the sample preparation. A summary of these results is given in table 1.

Studies of the Cationization Behavior of Small Oligomers in the Matrix-Assisted Laser Desorption/Ionization Experiment

Yansan Xiong, Robert Goldschmidt, and Kevin G. Owens*, Department of Chemistry, Drexel University, Philadelphia, PA 19104

Matrix-assisted laser desorption/ionization (MALDI) has successfully been used by a number of laboratories to analyze a variety of industrial polymers. In attempting to understand in detail the MALDI behavior of a series of small polyethylene glycol ($n=1-4$) and polypropylene glycol ($n=1-4$) oligomers, a series of factorial design^{1,2} experiments were performed. A factorial is a type of experimental design where the investigator chooses a fixed number of levels of each of the experimental factors (i.e. variables) and runs experiments with all possible combinations. Running the experiments in this carefully controlled manner enable the results to be interpreted, even if there is significant interaction between two or more of the factors investigated. Here a 2^3 factorial was performed to evaluate the effect of the quantity (in nanomoles) of each component of a mixture (polyethylene glycol ($n=4$), EG4, and polyethylene glycol ($n=4$) dimethylether, EG4DM) and of the matrix (2,5-dihydroxybenzoic acid, DHB) on the experimental results. The results that were evaluated are the peak area ratio of EG4DM/EG4 and the peak area/mole ratio for EG4DM/EG4.

For the peak area ratio, the correction factor, quantity of EG4DM, quantity of EG4, interaction between EG4DM and EG4, and the lack of fit were found to be significant factors. The peak area ratio should depend upon the number of moles of each component present- the more analyte that is present, the larger the measured peak area. The significant interaction and lack of fit is harder to understand. However, as the experiment was constructed with a ratio of 10:1 in the number of moles of each of the samples present in the mixture, we would expect the peak area ratio to be 0.10 and 10.0 for the $+1/-1$ (EG4DM/EG4) and $-1/+1$ corners of the design, respectively. That the ratio was 0.21 and 4.97, respectively, indicates that the response in our experiment does not track with the quantity of analyte in the sample. Note that the number of moles of each analyte are equal at both the $-1/-1$ and $+1/+1$ corners of the design as well as at the centerpoint, where the experimental responses are found to be nearly constant at 1.15. That the response stays constant suggests that the MALDI response of each component of the mixture is independent of the total amount of analyte present in the sample, as we would expect. That the responses do not equal the expected results at the $-1/+1$ and $+1/-1$ corners of the design is discussed further below.

A second way to evaluate the data is to look at the peak area/mole ratio as the experimental response. Under ideal circumstances, we expect that this ratio would remain constant under all conditions (i.e., that there are no significant factors). Unfortunately, it is found that the peak area/mole ratio depends on the quantity of EG4DM and EG4 present; there are no significant interactions or lack of fit in the model. That the peak area/mole ratio depends on the quantity of material present is somewhat counter-intuitive, as it indicates that the MALDI response depends upon the relative amount of the two analytes present.

There are at least two possible reasons for deviations from our expectations for the MALDI responses:

- incorporation of the two analytes within the crystal matrix may differ, resulting from solubility differences of the two different analytes in the solid solution. Desorption of the small volume of the matrix/analyte crystals may then result in the preferential observation of signal from one analyte over the other.
- the quantity of cationization reagent present is limited, yielding a decreased peak area/mole response as the quantity of either analyte increases.

We expect that the solubility of the two analytes, as measured by their log P values, should be different. Indeed, EG4 is significantly more water soluble than EG4DM. As we are crystallizing the samples from a methanol solution, we might expect that the EG4DM would be better incorporated into the relatively more non-polar DHB crystals as they are forming, leading to a possible segregation of the two analyte materials. If there is segregation, we might expect the outer regions of the crystals to be enriched in the more water soluble EG4 materials, leading to preferential MALDI signal from the EG4 material. The fact that our results show that the peak area ratio is either 5:1 or 1:5 (EG4DM/EG4) suggests that this segregation is not the likely reason for the discrepancy. Whichever material is in excess exhibits a deficit in the MALDI response. When the two analytes are in equal concentration (even under the $+1/+1$ conditions) the peak area ratio is approximately 1.2. A lack of cationization reagent, however, would explain the observations. A study was therefore conducted to identify and quantify the sources of salt (sodium) in the matrix/sample solutions.

The quantity of sodium in each of the analytes and DHB matrix was determined using flame atomic absorption spectrometry (AAS). The largest contribution of Na to the sample comes from the DHB matrix material itself; there is negligible contribution from solvents, samples or sample containers used in the experiment. For the $+1/+1$ experiment (EG4DM/EG4) the total quantity of Na present is 0.22 nmoles; the total amount of sample present is 12.8 nmoles. These results suggest that the samples, as prepared, are limited in the amount of cationization reagent present. This possibility was further evaluated by the addition of Na cationization reagent (in the form of the sodium salt of the DHB matrix) to the sample/matrix solutions. Analysis of this data indicates that at a level of 7 μ l NaDHB solution added, the ratio of EG4DM/EG4 levels off at a value of 11.1. The total amount of Na added here is ~6 nmoles; the quantity of sample present is 3.0 nmoles. Additionally, the observed mass spectra show increased signal levels (i.e. peak areas) as the amount of Na present in the sample is increased, further suggesting that Na is the limiting reagent in these experiments.

Relative alkali ion affinities of a number of crown ethers and their acyclic analogs were reported by Liou and Brodbelt³. These results indicate that relative cation affinity of EG4DM (4-glyme) to EG4 (4-glycol) is 10:1. In the MALDI results presented here, we observe a ratio of approximately 1.2:1 for a 1:1 molar sample of EG4DM/EG4, suggesting that the MALDI cationization process may be operating far from equilibrium conditions. To further understand these results we measured the EG4DM/EG4 peak ratios as the ion acceleration voltage was varied. The results show that the peak area ratio increases as the accelerating voltage is decreased. A decrease in the acceleration voltage should allow for an increased time of reaction between the cationization reagent and both the analyte and matrix molecules in the expanding plume. Even at 2500V acceleration the reaction time is estimated to be quite short, and may only be significantly altered if operated under field free (i.e. delayed extraction) conditions. The shape of the curve also suggests that we might approach a value of 1.0 for the EG4DM/EG4 ratio if the acceleration voltage is further increased. This also suggests that the relative cation affinities of the various reactants are leveled under high voltage extraction conditions. This would be advantageous for the quantitative analysis of mixtures of materials of differing cationization efficiency.

Nebulised Spray Deposition of Synthetic Polymer Samples for MALDI Analysis

J. S. Cottrell, Thermo BioAnalysis Ltd., Paradise, Hemel Hempstead, Herts HP2 4TG, UK.

J. L. Dwyer, X. Liu, and J. N. Willis, Lab Connections Inc., 5 Mount Royal Ave., Marlborough, MA 01752.

Introduction: Matrix Assisted Laser Desorption Ionisation (MALDI) is the most widely adopted ionisation method for synthetic polymer analysis by MS. However, comparisons between traditional analytical techniques and MALDI sometimes show substantial discrepancies which are difficult to account for by known artefacts of the instrumentation. One source of error in MALDI could be the drying and crystallisation of the solution of matrix and analyte on the sample target:

- If the sample is truly incorporated into the crystal lattice of the matrix, then it might be expected that some kind of sieving due to size exclusion processes would occur during crystallisation.
- The use of liquid matrices should alleviate this problem, but could introduce artefacts due to variation in surface activity, (c.f. FAB).
- The solubility of a synthetic polymer will vary as a function of chain length. Thus, when a droplet of solution containing a distribution of oligomers dries slowly, systematic depletion or enrichment of certain oligomers in certain regions must be expected.

Strategy: The diameter of the area irradiated by the laser beam in MALDI is of the order of 100 microns, while the sample deposit may be 2 mm or more across, and several tens of microns thick. This makes it impractical to analyse material from all parts of the deposit and average the results.

We have investigated nebulised spray deposition as a method of minimising discrimination effects during MALDI sample preparation. By using an aerosol spray process to disrupt the solution into droplets which are small relative to the volume of material ablated by a single laser shot, under conditions which encourage these droplets to dry in isolation, we aim to create a deposit in which each laser shot samples a mixture of oligomers which more closely represents the composition of the bulk solution.

Experimental: Mixtures of PEG 1500 and PEG 4600 were prepared in weight ratios 2:1, 1:1, 1:2, 1:4, and 1:8. The final composition of the solution was 1 mg ml⁻¹ total PEG and 10 mg ml⁻¹ DHB in 1% acetonitrile. This mixture was sprayed onto polished stainless steel sample targets using an LC-Transform interface (Lab Connections Inc., Marlborough, MA 01752). The carrier solvent was 50% aqueous methanol. Sample application conditions were:

Sample volume	2 µl
Carrier solvent volume	40 µl
Carrier solvent flow rate	50 µl min ⁻¹
Nozzle gas pressure	40 psi
Nozzle gas temperature	95°C

The sprayed deposits and conventionally loaded samples were analysed on a Vision 2000 reflectron instrument (Thermo BioAnalysis Ltd., Hemel Hempstead HP2 4TG, UK). For each deposit, 50 spectra were acquired from randomly chosen locations. Each spectrum represents the sum of 30 laser shots. All acquired data were included, no rejection of outliers being permitted.

Qualitative Observations:

1. The laser threshold was extremely consistent across all areas of the sprayed deposits. The laser threshold for the conventional deposits depended strongly on the crystal morphology.
2. As a consequence, data acquisition from the sprayed deposits was significantly quicker, and required little operator judgement.
3. When the laser was fired repeatedly at a single spot on a sprayed deposit, the signal dropped off after approximately 100 shots, even though there was no sign that the material had been significantly depleted. In the case of a conventional deposit, the signal seems to persist until the irradiated portion of the crystal had been completely destroyed.

Quantitative Observations:

The scatter on the number average molecular weights (M_n) for the relatively narrow PEG 1500 and PEG 4600 distributions were pretty good for both spray and conventional loadings. A typical standard deviation was around 1.5%. In contrast, the scatter on the total distribution for all PEG peaks was of the order of 5% for the spray deposits and 15% for the conventional deposits. Plotting the average and standard deviations for each of the datasets generates a quantitation curve. The error bars, ± 1 standard deviation, are much tighter for the spray deposited samples and the trend line, constrained to pass through the origin, becomes a much more convincing fit

Analysis of Synthetic Polymers by MALDI-TOF Mass Spectrometry

Anne-Mette Hoberg, David M. Haddleton and Peter J. Derrick, Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry CV4 7AL, United Kingdom.

Introduction

Correct molecular weight information is of great importance for the characterisation of synthetic polymers. Matrix assisted laser desorption/ionisation time-of-flight (MALDI-TOF) mass spectrometry can provide absolute molecular mass information rapidly and probably with more accuracy than conventional methods such as gel permeation chromatography (GPC). However, the molecular weight distributions obtained by the two methods can be significantly different.

In this work we approached the problem by looking at factors that could affect the mass distribution in MALDI-TOF mass spectrometry of poly(methyl methacrylate) (PMMA).

Experimental

The PMMA samples were narrow GPC standards with polydispersities near to unity. Matrix films of 3-indoleacrylic acid were produced from a 10^{-1} M solution in acetone/water (5:1) doped with sodium chloride. The matrix was allowed to dry before sample application. All polymer samples were prepared as 10^{-3} M in acetone or tetrahydrofuran, and applied on top of the pre-prepared matrix films unless otherwise specified. Mass spectra were obtained by averaging data over 200 laser shots. All spectra were recorded in positive ion mode. The acceleration potential used was +20 kV in all experiments.

Fractionation by gel permeation chromatography

PMMA 2010 and PMMA 4700 were both fractionated by GPC. MALDI-TOF analysis was performed on a Kratos Kompact III instrument. A laser intensity just above threshold for ion formation was used in all experiments. Sample concentrations were in the range from 10^{-5} - 10^{-3} M.

Laser intensity versus ion formation in linear and reflectron MALDI-TOF analysis (Fig. 1)

Laser intensity and its influence on the polymer mass distributions of PMMA 2010 obtained by the MALDI-TOF Kompact III mass spectrometer were investigated in linear and reflectron mode. The experiments were performed using the same sample spot in order to avoid spot-to-spot variations.

Fragmentation studies in reflectron MALDI-TOF mass spectrometry (Fig. 2)

The experiment was performed using a Kratos Kompact IV MALDI-TOF mass spectrometer. The reflectron of this instrument has a near-quadratic potential distribution which allows time-focusing of fragment ions near to the detector. An area from m/z 1485 - m/z 1585, including the most intense peak in the MALDI mass spectrum of PMMA 2010, was selected using a beam blanking and pulsing system. The laser power was increased step-wise for every spectrum collected. The experiment was performed using the same sample spot and the same laser trace across the spot.

Conclusions

Fractionation of the polymer improves the signal-to-noise ratio in the high mass region of the mass distribution. Threshold was found to increase with increasing oligomer mass.

The shape of the mass distribution of unfractionated PMMA, was found to be strongly dependent of the laser intensity when the TOF mass analyser was operated in linear mode. An increase in laser intensity introduced numerous ion peaks in the linear mass spectra of high-mass oligomers. This effect was not observed in reflectron mode. These results indicate that the polymer ions in the high-mass region undergo a laser-induced fragmentation during the MALDI-TOF process.

Fragmentation of poly(methyl methacrylate) was observed in reflectron MALDI-TOF analysis at laser powers 4-5 times the laser power needed for ion formation. This laser-induced fragmentation causes loss of about 88 mass units from the polymer chain.

Mass Analysis of Large, Anionic, Spherical Dendritic Macromolecules

C. A. Haney¹, J. H. Sanford¹, C. B. Gorman¹, B. Parkhurst¹, K. Chen¹, L.B. Martin², J. Mark³

¹NC State Univ. Dept. Chemistry, Raleigh, NC

²Micromass Inc., Beverly, MA 01915

³PerSeptives Biosystems, Framingham, MA 01701

Introduction

There is interest in using dendritic molecules as information bearing units (IBUs) as it relates to computing elements. These molecules can be tailored to serve as switchable, organizable IBUs. As a first step in designing functional IBUs, synthetic and analytical methodologies must be established for their routine production and characterization. The molecules of interest in this study are spherical in shape with an unusual iron-sulfur core.

The mass spectral analysis of these dendrimers is difficult. Generally the samples consist of a complex mixture depending on the generation being analyzed. There are reports of dendrimer analysis using FAB¹, electrospray^{2,3}, and MALDI⁴⁻⁶

The dendrimers in this study are built around a dianionic iron-sulfur cube. In the first generation, the core is connected by an iron sulfur linkage to a benzamide which is connected to a pair of benzyl-ether linked ligands. In the second and third generations, the benzyl-ether linked branched pairs continue to extend with the molecule becoming more spherical in shape. The counter ions are tetrabutylammonium cations.

The iron sulfur core of these dendrimers is unstable in air. The core is readily oxidized and the dendrimer "rusts"; the corresponding color change to red is useful in identifying degraded samples.

MALDI-TOF ANALYSIS OF POLY (ETHYLENE TEREPHTHALATE) (PET) OF VARYING STRUCTURE

Hilary T Yates, Jim Scrivens, Tony Jackson

ICI Research and Technology Centre, Wilton, Cleveland, England, TS90 8JE

Michael Deery

Department of Chemistry, University of Warwick, Coventry, England, CV4 7AL

The introduction of matrix assisted laser desorption/ionisation (MALDI) has greatly extended the capability of mass spectrometry in the role of direct analysis of polymers. The current work is focused on poly (ethylene terephthalate) (PET) which is commercially a very significant material for the chemical industry. PET samples have been studied at various points throughout the polymerisation process, this being possible by the extraction of aliquots in real time from a working process vessel. Subsequent analysis by MALDI of these varying time samples has provided a measure of the molecular weight change and in addition, characterisation of end groups other than those of the major series. This analysis had previously been attempted by field desorption mass spectrometry which had proven largely uninformative due to the extent of the thermal effects associated with ionisation of linear PET. Analysis by MALDI, in contrast, has provided good molecule ion information with ionisation occurring predominantly by sodium attachment. In the course of this study it had been observed that when addition of both sodium and potassium had occurred, a shift in distribution to higher molecular weight was observed in the latter case. As a result of this finding, the effect of ionisation by addition of other alkali metal cations has also been investigated.

Figure 1
UV-MALDI-MS
of Linear PET

The MALDI spectra obtained from linear PET (3mer to ~25mer) with lithium, sodium, potassium, rubidium and caesium salts respectively added during sample preparation, are displayed in Figure 1. It can be deduced from these data that the effect of increase in cation size is progressive with the oligomer distribution being observed to shift to higher molecular weight in moving down the alkali metal series. This effect has not previously been reported and in equivalent studies by this group on poly (methyl methacrylate) and polystyrene, has not been observed. In order to establish a possible role of oligomer end group in the above findings, an equivalent set of experiments was performed on a sample of the cyclic polymer. The resulting spectra are displayed in Figure 2. These data also clearly illustrate a shift of distribution to higher molecular weight with increase in cation size. In both sets of results, minor series of varying end group or cycle structure, have also been observed to demonstrate the same molecular weight shift with changing cation.

One proposed explanation for the above findings is that the ability of an oligomer to be attached to by a cation is related to the rigidity of the chain, this being both molecular weight and structurally dependent. It is predicted that a PET oligomer is more rigid than one of PMMA of equivalent molecular weight. As a result of this, a higher oligomer would provide a more favourable site for interaction with a larger cation. In order to investigate this more fully, it is recommended that this study be extended to include more polymer types over a wider range of molecular weights. It is also recommended that the current work be supported by computer modelling to enable simulation of varying oligomer/cation combinations.

DESORPTION BEHAVIOR AND DISTRIBUTIONS OF FLUORINATED POLYMERS IN MALDI AND ELECTROSPRAY IONIZATION

Laurence Latourte¹, Richard B. Cole², Jean-Claude Blais¹, Jean-Claude Tabet^{1*}

1. Laboratoire de Chimie Structurale Organique et Biologique, CNRS, E.P. 103, Université Pierre et Marie Curie, 4 Place Jussieu, 75252 Paris Cedex 05, France

2. Department of Chemistry, University of New Orleans, New Orleans, LA 70148, USA

Fluorinated compounds have already been studied by secondary ion mass spectrometry [1-3]. We report here preliminary results on the desorption of fluorinated polymers using: matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization (ESI). The studied fluorinated compounds can be divided into two types depending upon whether fluorine atoms are contained in the polymeric repeating unit, or only in the end groups. Compounds with high fluorine content are insoluble or only sparingly soluble in conventional solvent systems, making them difficult candidates for mass spectrometry studies. In both MALDI and ESI methods, signal intensities were observed to vary, as were distributions of oligomers, in response to changing experimental conditions.

In MALDI, varied parameters include target preparation (solvent, matrix and additives) and laser irradiance. Among eleven tested MALDI matrices, 2,5-dihydroxybenzoic acid produced the highest analyte ion yield allowing determination of repeating units and the polymer distribution parameters: $\overline{M}_n$, $\overline{M}_w$, and D . Use of a polar solvent to dissolve the fluorinated analyte produced a higher signal response than use of a non polar solvent. In addition, $\overline{M}_n$ was determined to be higher with the polar solvent. A laser irradiance of about $5 \times 10^9 \text{ W/cm}^2$ generated the highest intensity signal. Shown in Figure 1 is the positive ion MALDI mass spectrum of a fluorinated polyacrylate polymer bearing a fluorocarbon chain in the repeating unit, obtained under these optimal conditions.

In ESI, the solvent, and the temperature in the spray region were systematically varied. Solvent polarity was shown to exert a significant influence on the distribution of detected fluorinated species. A minimum aqueous content in the employed solvent vastly improved signal intensity compared to purely organic solvent systems. A very high aqueous content, however, may impair the desorption of longer chain fluorocarbons, owing to intermolecular aggregation of fluorocarbon chains. Increasing the temperature and the flow rate of drying gas in ESI shifted observed distributions toward lower molecular weights for a mixture of homologs of varying fluorocarbon ($-\text{CF}_2-$) chain length. Shown in Figure 2a and 2b are the negative ion ESI mass spectra of a polyacrylate polymer bearing perfluorinated carbon chain end groups of varying length. Prepared from a single starting solution containing $\text{CH}_3\text{OH}:\text{H}_2\text{O}:\text{CHCl}_3$ (3:1:1) with 2% triethylamine, the sample used to obtain the mass spectrum shown in Fig. 2a was diluted 1:1 with CHCl_3 (thus reducing the polarity), while that used to obtain the mass spectrum shown in Fig. 2b was diluted 1:1 with 50% aqueous methanol (thus increasing the polarity). The lower polarity solution resulted in the appearance of a higher relative intensity of short-chained fluorocarbons, while the higher polarity solvent promoted the desorption of longer chain fluorocarbons. These observations are in agreement with electrospray theory [4] which contends that, other factors being equal, analytes of higher solvophilicity tend to desorb to a lower extent than their solvophobic counterparts.

Introduction:

The knowledge of the amount of cyclic oligomers which are formed during the polymerization reaction of high mass polyesters is essential for obtaining high quality industrial polymers. However, direct and unambiguous characterization of cyclic oligomers cannot be obtained with conventional method such as SEC or NMR¹. Cyclic oligomers have been analyzed by mass spectrometry techniques. With conventional gas phase ionization methods (EI and CI), the identification of cyclic oligomers is difficult in the case of high molecular mass oligomers or oligomer instability². Furthermore, with Fast Atom Bombardment (FAB/MS), cyclic oligomers are subject to hydrolysis and fragmentation³. So, soft ionization techniques such as matrix-assisted laser desorption ionization (MALDI/MS) and electrospray ionization (ESI/MS), which offer the advantage of limited fragmentation, are particularly interesting for the characterization of synthetic linear and cyclic polymers⁴.

Our purpose was to optimize the sample preparation for the analysis of polyesters, in particular aliphatic and semi-aromatic cyclic polyesters, by ESI/MS and MALDI/MS. Modification of the ionization efficiency by cationization with various metal ions has been studied.

Methods:

The MALDI/MS experiments were carried out on a built in-house linear TOF mass spectrometer (1.36 m flight path, 20 keV ion energy) equipped with a nitrogen laser (337nm, 3ns pulse duration). Several matrices, which have been used earlier for the analysis of synthetic polymers, have been tested (2,5-dihydroxybenzoic acid, α -cyano-4-hydroxycinnamic acid, 5-chloro salicylic acid, 2-(4-hydroxyphenylazo)-benzoic acid, trans-3-indole acrylic acid, 1,4-di-(2-(5-phenyloxazolyl))benzene, 1,8,9-anthracenetriol, and 2,4,6-trihydroxyacetophenone).

The ESI/MS mass spectra were acquired on a R10-10 quadrupole mass spectrometer equipped with a Analytica of Brandford ESI ion source. As solvents stream, acetone, carbon tetrachloride, chloroform, dichloromethane, methanol and water have been tested. Sodium acetate or other metal salts were added.

Results:

In MALDI, a discrimination of cyclic oligomers relatively to linear oligomers has been observed, specially for the semi-aromatic polyesters. In the latter case, only 5-CSA (5-chloro salicylic acid) allows the observation of cyclic and linear oligomers as shown in figure 1.

The ESI mode with MeOH/CHCl₃ (1/1 v/v) and addition of sodium acetate, seems to be more effective for the analysis of the cyclic polyesters pure or mixed with linear oligomers. No segregation between the linear and the cyclic oligomers is observed and the lower mass oligomers can be readily analyzed (fig 2).

In order to improve the cationization efficiency, different salts have been added. It appears that the semi-aromatic cyclic polyesters exhibit a strong cation affinity for alkali metal

ions, Ag⁺ and Cu²⁺. However, cationization by Na⁺ is always prominent for both ionization modes.

Figure 1: Positive-ions MALDI mass spectrum of the semi-aromatic polyester (matrix: 5-CSA). Protonated and cationized cyclic and linear oligomers are observed.

Figure 2: Positive-ions ESI mass spectrum of the aliphatic polyester (MeOH/CHCl₃, 1/1 v/v; sodium acetate and polyester concentrations: 10⁻⁵ M)

Sequencing Copolymers Using Thermal Degradation - Photoionization Mass Spectrometry

David L. Zoller and Murray V. Johnston
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716

The sequence of monomers within a copolymer chain largely determines its physical properties. Using current techniques, obtaining microstructural information for a copolymer (i.e. number average sequence lengths) can be a long, arduous task. Thermal degradation mass spectrometry is a potentially quick method of copolymer analysis. However, the mass spectra are often difficult to interpret due to the complex distribution of ions formed. Vacuum ultraviolet photoionization makes interpretation easier by minimizing fragmentation due to the ionization process. For several butadiene copolymers, we are able to correlate copolymer microstructure with the photoionization mass spectrum.

Copolymers are analyzed by placing ~1 mg of sample into a pyrex vial which is inserted in the end of a thermal probe. The probe is inserted directly into the source region of a re-TOF mass spectrometer. In order to separate lower molecular weight additives, copolymer samples are first heated just below the copolymer degradation temperature. After the additives are completely evolved, the copolymer is degraded using a 20°C/min heating ramp controlled by a temperature programmer. Thermal degradation products are ionized by a single VUV photon (10.5 eV) and then mass analyzed.

Figure 1 shows the mass spectra of random and block styrene-butadiene copolymers ($M_w > 100$ kDa) averaged from 425-430°C. Comparisons are made relative to the butadiene trimer (B3) which is displayed with equal intensity in both mass spectra. Peaks due to mixed oligomers (S1B1, S1B2, ...) have much higher relative intensity for the random copolymer than the corresponding peaks (*) for the block copolymer. The dominant peaks in the block copolymer mass spectrum are due to pure butadiene (B3, B4) and pure styrene (S2, S3) oligomers. Therefore, the mass spectra confirm the copolymer microstructures.

Figure 2 shows the 8-mer distribution for three different acrylonitrile-butadiene copolymers ($M_w > 100$ kDa). The mass spectra are averaged from 280-320°C for each sample. Peaks further to the left correspond to 8-mers with higher acrylonitrile (m/z 53) content. Peaks further to the right correspond to 8-mers with higher butadiene (m/z 54) content. As the acrylonitrile content in the copolymer is increased, the 8-mer distribution shifts further to the left.

Figure 3 shows the calculated number of acrylonitrile units in the weight average peak for each oligomer length. Three acrylonitrile-butadiene copolymers with different compositions are displayed. The 95% confidence limits show a significant difference between the three copolymers. If the mass spectrum is representative of the copolymer, the slope of the regression line should be equal to the mole percent of acrylonitrile in the sample. Table 1 shows the slopes are consistent with the different acrylonitrile contents.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometer Study of Industrial Polymers

Boris Rozynov, Robert Liukkonen and Martha Sarpong.

Aspen Research Corporation, 436 West County Road D, New Brighton, Minnesota 55112-3522.

(1) Introduction.

Recently, considerable effort has been directed at the analysis of Industrial Polymers by MALDI-TOF MS. Results often depend upon successful desorption and ionization of the analyte [1,2].

(2) Experimental.

The MALDI-TOF MS was on a linear Hewlett-Packard G2030A MALDI-TOF MS system.

The polymer samples being studied include: (I) Non-polar polymers e.g. natural rubber, polyisoprene, poly(methyl-styrene-co-butadien), polylactic acid, poly(ethylene terephthalate), polysiloxanes; and (II) Polar polymers - polyglycols, polyacrylic acid and poly(acrylic acid-co-methyl acrylic acid).

(3) Results.

Table 1 summarizes the molecular-mass specification for PEG 1800 with a wide range of matrices. Mn and D show good agreement with GPC data regardless of the matrices specific nature. Figure 1 shows a spectrum of PEG 1800 obtained from 2,2,2 - trifluoro-toluic acid.

The proper matrix selection for small polar polymers is more important for the limit detection than for the accuracy of molecular-mass determination. The common industrial polymers (polyacrylic and polylactic acids and poly(ethylene terephthalate)) analyzed from the common matrix - 2,5 - hydroxybenzoic acid demonstrates the mass of the repeat unit (Figure 2).

The analysis of the heavy nonpolar industrial materials is greatly dependent on the chemical nature of polymers and matrices. Some halogenated matrices (see Table 1) have been useful. Figure 3 shows spectrum of PS18600 obtained from the mixture of 2,2,2 - trifluoro-toluic acid, dithranol and citric acid in THF doped with AgTFA. The spectra of commercial Russian poly(methylstyrene-co-butadienes) and natural rubber (Figures 4 and 5) are obtained using 5-cl-salicylic acid with AgTFA. For high molecular-mass polymers the MALDI-TOF MS instrument measures the molecular-mass average, but cannot resolve oligomer repeat unit.

(4) Conclusion.

Because of its simplicity, ease of use and speed, MALDI-TOF MS shows promise for rapid screening of materials and processes but usually requires method development.

CHARACTERIZATION OF ETHYLENE AND PROPYLENE OXIDE COPOLYMERS

M.P. Lacey, T. Keough, Y. Pan, M.P. Armstrong* and M.D. Fritz*, The Procter and Gamble Company, Miami Valley Laboratories, P.O. Box 538707, Cincinnati, OH 45253-8707 and *The Procter and Gamble Company, Ivorydale Technical Center, 5299 Spring Grove Ave., Cinti., OH 45217

Ethylene and propylene oxide polymers have interesting and unique properties that make them useful ingredients in a number of consumer products. By tailoring the EO/PO ratio, molecular weight, block size and order, they can exhibit a wide range of physical properties.

Kalinoski and coworkers (1,2) have previously described MALDI and ESI methods to determine the average molecular weights of a wide range of polyoxyalkylene block copolymers. In this presentation, we describe a method combining NMR, MS and partial chemical digestion to more fully characterize these kinds of polymers

NMR Methods - EO/PO compositions are calculated from the integration of the OCH_2 and OCH_2 resonances at 3-4 ppm and the CH_3 resonances at 1.1 ppm in a typical 1-D proton NMR spectrum. This composition can also be calculated from a quantitative 1-D carbon-13 spectrum, but quantitative proton data acquisition is more efficient.

To distinguish a regular (EO/PO) diblock copolymer from a reverse (PO/EO) diblock copolymer, C-13 DEPT experiments are used. This NMR experiment differentiates carbons by the number of directly attached protons. As a result, end-group carbons with an odd number of protons (PO, 61.2 ppm) are plotted 180° out of phase from carbons with an even number of protons (EO, 61.2 ppm), and the terminal groups are easily distinguished.

Alkyl EO/PO copolymers are easily identified by COSY NMR spectra. The alkyl peaks do not overlap with the PO CH_3 peaks, allowing accurate average alkyl chain length and EO/PO composition to be calculated

MS Methods - MALDI spectra of EO/PO copolymers were obtained using α -cyano-4-hydroxycinnamic acid as a matrix. A crystal of potassium iodide was added to the sample solution and 5-10 pmoles of polymer were loaded onto the probe tip. Average molecular weights are easily determined, but no polymer structural details are evident due to the complexity of the copolymer's distribution.

GC/MS was used to analyze a mixture generated by partially digesting a known alkyl copolymer. The sample was partially digested with acetyl chloride and ferric chloride (3) (30 minutes, 60°C). The resulting mixture was separated with a 30 meter DB-5MS column (J&W Scientific, Folsom, CA) and analyzed using electron ionization. From this experiment, we determine

1. Whether the sample contains alkyl, EO and PO components
2. The precise alkyl chain lengths
3. Which block is connected to the alkyl chain (if present).

To determine average segment length of the EO or PO blocks, one must use both NMR (composition) and MALDI (molecular weight) data as shown in Table 1 below. Note that this approach solves for average segment lengths. We cannot distinguish asymmetric blocks as in standard "D."

Unknown Sample - The MALDI spectrum of an unknown sample revealed the presence of both an EO homopolymer and a PO homopolymer. FAB analysis of the same sample confirmed the presence of the PO homopolymer and also showed the presence of another complex oligomeric series that had molecular weights consistent with alkyl ethoxylates

The MS/MS analysis of the $\text{M}+\text{NH}_4^+$ ion at m/z 656 using oa-TOF is shown in Figure 1. We were quickly

able to establish that the sample was not a simple alkyl ethoxylate - the mass differences between the product ions pointed out that the sample was in fact an alkyl EO/PO block copolymer with the structures shown on the spectrum. In this sample we had expected to find an EO/PO triblock copolymer. Instead, we found a mixture of EO and PO homo-polymers and an EO/PO diblock copolymer. These identifications were made without prior chromatographic separation.

Table 1. Results from EO/PO Standards

Polymer	NMR		MS		Average Structure	
	%EO	%PO	Mn	Mw	Observed	Manuf. Spec.

A NANOSPRAY ION SOURCE FOR SHEATHLESS CE-MS AND NANO LC-MS

*Schultz, Gary A., Alexander IV, James N. and Poli, Janet B.,

Rohm and Haas Company, 727 Norristown Rd Spring House, PA 19477

A FISIONS Quattro I electrospray ion source has been modified to produce stable electrospray ion currents at flow rates as low as 50 nl/min. The original skimmer cone lens used as the counter electrode in the FISIONS NanoSpray ion source has been replaced with a spherical cone lens. This improvement provides a greater range of XYZ positioning of the probe tip that results in a stable ion signal, a 3x signal increase and also less fragmentation under identical operating conditions compared to the original nanospray skimmer cone lens.

Spherical Cone Lens

CE and LC capillary columns coupled to a tapered 50 μ m i.d. x 300 μ m o.d. x 2.5 cm stainless steel capillary using a teflon sleeve. This probe is mounted on an XYZ stage.

We showed that the practice of coupling fused silica capillaries to stainless steel capillaries using a teflon sleeve at the MS interface does not introduce bandbroadening to a CE or nano LC separation. Stainless steel tubing of 50 μ m i.d. x 300 μ m o.d. was shown to generate stable electrospray ion currents at flow rates down to 50 nl/min

The electrospray stability has been previously shown to be enhanced by tapering of the tip of the capillary. Preparation of tapered stainless steel capillaries by electrochemical etching or micro-latheing is less time consuming (and therefore less costly) compared to tapering and vapor depositing Cr and Au to fused silica capillaries. Stainless steel capillaries are more durable and more easily coupled to the high voltage power supply and it has been our experience that the analyte signal is greater from tapered stainless steel capillaries

Sheathless CE-MS

Capillary Electrophoresis Electrospray Ionization Ion Trap Mass Spectrometry/Mass Spectrometry

Teng, Siu; Schnute, W. C.; Jardine, Ian; Schwartz, Jae

Finnigan Corporation, 355 River Oaks Parkway, San Jose Calif., 95134

Recent development has shown capillary electrophoresis (CE) to be a powerful and unique separation technique. The selectivity, and perhaps more importantly, the specificity of CE can be enhanced by its use as an inlet device by coupling via an electrospray ionization (ESI) device to a mass spectrometer (MS) detector.

The applicability of CE-ESI/MS and CE-ESI/MS/MS techniques have been demonstrated on various types of mass spectrometers, including magnetic sector, ICR, quadrupole, time of flight, and ion traps.

Sample loadability and concentration sensitivity in CE still limits its use as a separation technique prior to MS detection. The attainment of sufficient signal to noise requires the boosting of signal via pre-concentration methods or the lowering of the inherent noise level via the use of MS.

CE-ESI/MS/MS offers advantages over LC-ESI techniques. These include high separation power, minute sample amount with low volume analysis and low solvent consumption, high sensitivity, and now can be performed on relatively low cost benchtop instrumentation.

This is the structure of the antibiotic Tetracycline (445.4 mw). In acidic conditions (such as the beer samples tested), the compound will have several epimeric structural configurations. These epimers make the analysis of total tetracyclines in food products or other complex mixtures or biological matrices difficult by non-mass spectrometric detectors. Under the conditions of the experiment, Tetracycline introduced into the ESI source via CE shows a strong cluster of ions at 445.4

(the $M+1$ ion) and successive loss of 2 hydroxyls for 427.4 and 410.4. Successive fragmentation requires substantially more energy, and its epimers and tautomers exhibit the same first stage losses described.

The CE units used were a Thermo Capillary Electrophoresis Crystal 310, and a Beckman P/ACE 5000 equipped with a UV detector. The columns were uncoated 75mm I.D. fused silica capillaries 85 cm in length. Run buffer was 5 mM ammonium acetate in a mixture of methanol/water at 1:1. Tetracycline

Mass Spectrometer Conditions:

Scan Range:

MS mode - 10 to 500

MS/MS isolation of 445 ($M+1$)
product scan - 50 to 500

MS/MS Relative Collision Energy 30%

Capillary Temperature 220°C

Instrument was Auto Tuned and Calibrated

CE Run Conditions:

Constant voltage mode, 20kV

Ambient Temperature

Interface Sheath Liquid:

1% acetic acid MeOH/H₂O 1:1

1 to 3 mL per minute

Sheath Gas: N₂ at 30mL/min

(Sigma, St. Louis, Mo.) in the buffer solution was diluted to 100 pg/nL. The method of injection was the application of pressure for 5.0 seconds at 50 mBar which was used throughout the experimental runs. The volume injected using this technique corresponds to approximately 5.9 nL/s. The mass spectrometer used was a Finnigan LCQ ion trap equipped with an external electrospray ion source (ESI).

The ESI source was adapted with a CE interface option to allow direct insertion of the CE capillary into a spray from a liquid sheath supplied by the LCQ's integral syringe pump. The sheath liquid forms a carrier for the CE sample, as well as serving as an electrical liquid junction for the CE unit.

The same sample (in beer matrix) was run in a MS/MS set-up mode, where the relative collision energy (RCE) applied to the isolated protonated molecular ion (445) was increased stepwise. Generation of the first order product ions (427 & 410) resulting from the loss of hydroxyls increased with subsequent loss of the parent. Further fragmentation to second order products and beyond are not present in the full scan product spectra.

The beer sample was run again, with the RCE set at 30% and monitoring 410 ion production. The absence of background, either inherent or from sample matrix background is almost totally absent in this run. Typical signal to noise calculations have no meaning with this type of analytical response.

Analysis time is short, and column regeneration and reloading can occur in just a few minutes. We have also been able to demonstrate, that even though CE inlets in normal operation (without pre-concentration) still have very small injection volumes, sensitivity levels can be enhanced by maintaining signal strength and dramatically lowering background and ambient noise levels.

There are several issues that still need to be addressed:

The resolution of the CE still remains to be improved for separation of the tetracyclines.

Automation by means of methods and automated procedures.

Optimization of instrument parameters for sensitivity and overall performance.

Quantitative comparisons of linearity and minimum detection and quantitation levels.

FAST CAPILLARY ELECTROPHORESIS SEPARATIONS WITH TIME-OF-FLIGHT MASS SPECTROMETER DETECTION.

J. Fred Banks, James Boyle, Thomas Dresch, Erol Gulcicek, Patrick Haren and
Craig Whitehouse

Analytica of Branford, Inc. 29 Business Park Drive., Branford, CT 06505

The development and wider acceptance of capillary separation methods have placed greater demands on the hardware used for mass detection. Because of the high efficiencies, narrow peaks and potential for high sensitivity, capillary electrophoresis greatly challenges conventional types of mass spectrometers, i.e. quadrupoles and magnetic sectors. To solve this problem, a time-of-flight (TOF) mass analyzer has been developed which gives improved scan speed, sensitivity and m/z range.

The peaks eluting from a CE column may easily be 1-2 s wide, perhaps less. Thus, when using a standard quadrupole instrument with a maximum scan speed of 1000 m/z per second, it is probable that only 1 scan could be completed during the elution of a CE peak. This is clearly inadequate. The TOF instrument, however, can scan the complete m/z range at 10 to 100 times faster than this. Also, conventional quadrupoles are limited in scan range to 2000 m/z (sometimes greater). The TOF analyzer overcomes this limitation as well. As an example of TOF mass detection of CE separations, Figure 1 below shows the TIC from the CE separation of 240 fmol each of a peptide mixture using both -300 and -450 V/cm. An absolute sensitivity limit of 10 fmol has been established. An amine-coated column was used for this separation. Note that at -450 V/cm, the peaks migrating through the CE column are only about 2 seconds wide. Figure 2 shows the TIC from a CE separation of a mixture of proteins under the same conditions used above. Here, only 28 fmol were applied to the CE column.

Figure 1

Figure 2

CE/MS with an ESI/Ion Trap/Reflectron Time-of-Flight Mass Detector

Jing-Tao Wu, Mark G. Qian, Michael X. Li, Lin Liu, and David M. Lubman
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109

INTRODUCTION CE/MS has generated considerable interest in recent years because of its enormous capability to combine the high separation efficiency of CE with the identification capability of MS. A variety of mass detectors have been used as CE/MS detectors, among which time-of-flight mass spectrometers (TOFMS) are of particular interest. Compared with other mass analyzers, TOFMS has several unique advantages, including its high ion transmission efficiency and high acquisition speed. These features are especially important when TOFMS is used as an on-line detector for CE.

In the work reported herein, an ion trap storage/reflectron time-of-flight mass spectrometer (IT/reTOFMS) has been coupled to CE for the analysis of protein digests. The IT/reTOF uses a quadrupole ion trap as a front-end storage device, prior to mass separation and identification by the reTOFMS. With the IT/reTOFMS, a high duty cycle (>99%) can be reached with a sampling frequency exceeding 10 Hz.

EXPERIMENTAL SECTION An IT/reTOFMS similar to that described in previous work was used in these experiments. The capillary electrophoresis apparatus used in these studies was constructed in-house. The CE columns used in the experiments were prepared from 41 μm i.d. $\times$ 105 μm o.d. fused silica capillaries, whose inner walls were coated with 3-aminopropyl-trimethoxysilane. Acetic acid or ammonium acetate were used as the running buffer, with a concentration of 10 mM and a pH ranging from 3 to 4.9. A sheathless microelectrospray CE/MS interface was used in these experiments. A 250 MHz high speed transient recorder was used to collect the signals from the detector. A sampling time window width of 150 μs , which corresponds to a mass range from 0 to about 1500 Da was used for all studies in this work.

RESULTS AND DISCUSSION Figure 1 shows the total ion electropherograms of a five peptide mixture obtained at different spectral acquisition speeds. At a relatively low spectral acquisition speed of 2 s/spectrum (Figure 1a), peak 4 & 5 are only partially resolved, while peak 2 & 3 are not separated to the base line. When the spectral acquisition speed is increased to 1 s/spectrum, as is shown in Figure 1b, peak 2 & 3 are separated to the base line level while peak 4 & 5 are still not completely resolved. At a spectral acquisition speed of 0.5 s/spectrum (Figure 1c), however, all the peaks are resolved. A spectral acquisition speed of 0.25 s/spectrum further improved the separation (Figure 1d).

Figure 2 shows the total ion electropherograms for cytochrome c tryptic digest obtained with sample injections corresponding to about 50 fmol, 12 fmol and 3 fmol of the original protein. A detection speed of 4 Hz was used in these experiments. One unique feature of coupling MS with CE experiments is that the mass detector can identify unresolved or partially resolved peaks, as illustrated by peak 1 marked in the total ion electropherograms of cytochrome c digest shown in Figure 2. The mass spectrum reveals that the peak actually contains three partially resolved peaks, and they can be identified without ambiguity.

For CE/MS experiments using conventional scanning mass spectrometers, mass resolution is usually compromised for sensitivity. In the case of the IT/reTOF, mass resolution is not sacrificed for sensitivity since it is not a scanning device. Figure 3 shows the UV trace and total ion electropherogram of bovine β -lactoglobulin A digest. Lactoglobulin A is a relatively large protein

with several fragments of similar masses. One example includes fragments No. 2 and No. 9 which have calculated MH^+ masses of 673.4 and 674.4, respectively. In the total ion electropherogram, these two fragments correspond to the peaks marked as 1 & 2. Because of the high resolution of the mass detector, these two peaks can be identified clearly.

Figure 1. Effect of spectral acquisition speed on separation. Peaks 1 through 5 are: neurotensin, angiotensin III, angiotensin II, and angiotensin I.

Figure 2. Total ion electropherograms of bovine cytochrome c digest at different sample injection amounts. Peak 1 actually contains three unresolved fragments with measured m/z values of 1698.0, 1457.1, and 1584.4, respectively.

Figure 3. UV trace and total ion electropherogram of bovine β -lactoglobulin A digest. Peak 1-fragment IPAVFK(m/z 674.6). Peak 2-fragment GLDIQK(m/z 673.6).

CONCLUSIONS The IT/reTOF has proved to be a rapid and sensitive detector for CE. It can provide a detection speed for even the fastest separation over a broad mass range with a detection limit in the low fmol range for protein digest analysis. Further, the high mass resolution of the IT/reTOF makes it capable of identifying unresolved peaks and discriminating between fragments with a mass difference of 1 Da or less.

MODULAR SUBATMOSPHERIC PRESSURE MICROELECTROSPRAY INTERFACE FOR CE-MS

Frantisek Foret, Dan Kirby and Barry L. Karger
Barnett Institute and Department of Chemistry, Northeastern University, Boston, MA.

The combination of capillary electrophoresis - electrospray mass spectrometry is attractive for the analysis of biologically important molecules such as proteins, peptides and/or nucleic acids. At present the routine use of this technique is limited in part by relatively time consuming optimization of operational conditions.

This study is aimed at developing a new simple to operate CE/ESI/MS system by incorporating the following features in the interface:

- miniaturized electrospray needle with a 3 - 25 μm id tip
- normal pressure in the CE system (easy coupling to any CE instrument)
- use of short, standard diameter CE capillaries with or without electroosmotic flow
- on-line optical detection
- easy replacement of both CE capillary and the ESI tip
- rugged system with no capillary alignment

The design is shown schematically in Fig. 1. The electrophoresis separation capillary (21 cm x 75 μm id) is coupled to the electrospray needle via a liquid junction in the electrode reservoir equipped with an optically controlled voltage divider. The electrospray needle is formed by a narrow (10 - 25 μm id) fused silica capillary with either a sharpened or drawn end. The needle is enclosed in the subatmospheric chamber and the liquid flow rate is controlled by regulating the pressure in the chamber. Since the internal volume of the electrospray capillary is less than 25 nl, the contribution of the system to band broadening is negligible. The decoupling of the electrospray needle and electrophoretic capillary allows the use of a variety of compositions of the buffer for the separation and for electrospray ionization. At the same time the low pressure in the electrospray chamber helps efficient desolvation of the electrosprayed droplets. For easier monitoring of the CE separation and possible programming of the MS data acquisition, a fiber-optic based detector cell is attached 15 mm from the exit of the electrophoretic capillary. This allows use of a short separation capillary (minimum required length <10 cm). Since the electric current driving the electrophoretic separation is generally much higher than the electrospray

current, the power supply normally used for the electrospray is substituted by the optically controlled voltage divider. Besides instrument simplification, this voltage divider allows for simultaneous switching of both the CE and ESI voltages. The experimental data obtained with CE-ESI/MS analysis of peptide mixtures demonstrates that the interface allows simple "turn key" operation with sensitivity (base peak monitoring) comparable to the UV detection. Further, it is likely that sensitivity improvement could be obtained through higher ion transmission efficiency by increasing the diameter of the MS sampling orifice.

Towards the Development of a Practical Microspray Interface for CZE-ESMS*

K.P. Bateman^{1,2}, P. Thibault¹, R.L. White², ¹Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, Nova Scotia, Canada, B3H 3Z1; ²Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J3

The use of microspray (or nanospray) as an ion source for mass spectrometry provides increased sensitivity compared to conventional electrospray [1,2]. To date, microspray has been used for electro-infusion analysis [3] with a limited number of applications to CZE-MS using microsprayers [4,5]. One of the problems associated with such CZE-ESMS interfaces is the production of capillaries with the tapered and metalized tips required for microspray operation.

Mix of 10 peptides 200g each
Buffer 0.1 M HCOOH, -28 kV, one piece tapered capillary

1 Leu-Enkephalin	6 Angiotensin I
2 Glu-Fibrinogen	7 Val ¹ Ile ⁶ Angiotensin III
3 Substance P 3-11	8 Adrenocorticotrophic Hormone 4-10
4 Cholecystokinin 10-20	9 pGlu ¹ -Myelin Basic Protein 4-14
5 Substance P 1-9	10 Adrenocorticotrophic Hormone 11-24

Figure 1. Effect of capillary coating on separation efficiency.

A series of cationic coatings was studied with respect to separation efficiencies and flowrates. Figure 1 shows the microspray CZE-MS analysis of a mixture of 10 peptides using three different capillary surface coatings. The Polybrene and BCQ (or MAPTAC) coatings provided similar results

Two approaches were employed for the production of the microspray CZE interface: (1) one-piece columns tapered at one end which are then coated with gold; (2) small tapered and gold coated tips which are butted to the CZE column. Infusion experiments indicated that stability and sensitivity of the ion source depends on the flowrate of liquid emerging from the microsprayers. In CZE-ESMS experiments, the flowrate is dictated by the electroosmotic flow and the flow resistance associated with the inner diameter of the microsprayer tip. If the inner diameter is too small, the flow will be restricted and analysis time will be extended. On the other hand, sensitivity can be compromised when the tip dimension is too large and the Taylor cone cannot be stabilized. Investigation of sensitivity versus flowrate for a variety of tip dimensions was undertaken and the results indicated that tips of 20 μ m i.d. provided the best compromise between flowrate and sensitivity.

in terms of separation efficiency and analytical performance. Covalently bonded coatings (BCQ or MAPTAC) were found to be more convenient than the dynamic Polybrene coating.

Figure 2. Microspray CZE-MS analysis of tryptic digest of *Phaseolus vulgaris* lectin.

The analysis of glycopeptides from CNBr and tryptic digests of glycoproteins using the microspray CZE-MS interface developed was also investigated. Figure 2 shows the analysis of the tryptic digest of *Phaseolus vulgaris* lectin using microspray CZE-ESMS. Formation of characteristic oxonium ions from the carbohydrates using high orifice voltage allowed for identification of the glycopeptides. Microspray CZE-MS-MS of glycopeptides provided structural information on the composition of the carbohydrate moiety.

The Composite Liquid Junction CE/MS Interface: Refinements and Improvements

Timothy Wachs, Robin Sheppard, and Jack Henion, Analytical Toxicology, Diagnostic Laboratory, Cornell University, 927 Warren Drive, Ithaca, NY 14850

Continuing studies of the Composite Liquid Junction Interface (ref. 1) for coupling capillary electrophoresis to API mass spectrometers have identified at least three areas for improvement and enhancement: (a) addition of pneumatic nebulization, (b) reduction of chemical noise, (c) adaptation for LC/MS with sensitivity enhancing make-up solutions, and (d) design features and materials. Due to significance of the self-aligning nature of this interface, we have chosen now to refer to it as the "Self-Aligning Liquid Junction" interface.

The good signal-to-noise ratio and sensitivity of the composite liquid junction interface can be further enhanced by conversion to a miniaturized pneumatically assisted electrospray (Ion Spray) self-aligning liquid junction interface. This enables one to use a wider range of make-up solution compositions and flow rates, particularly if the interface is used for LC/MS in addition to CE/MS. In general, Ion Spray provides better spray stability than electrospray with aqueous solutions as well as at higher flow rates. The voltage necessary to electrospray aqueous solutions can be very near the onset of a corona discharge which can significantly increase the amount of chemical noise. The use of Ion Spray with lower voltage requirements reduces this problem. Because of the potential back-flow of the make-up solution from the composite liquid junction into the CE capillary, the distance from the junction to the sprayer tip should be kept to a minimum. The precludes using a separate Tee for the addition of the nebulizing gas. Size was kept to a minimum by incorporating the nebulizer into the same Rheodyne nut that was used to hold the alignment capillary. (See Fig.1) In practice, the signal to noise ratio that was obtained for a CE separation of Nickel-EDTA complex was better than that obtained with a similar sheath-flow interface. The position of the CE capillary with respect to the sheath flow is critical for signal-to-noise ratio, but was not adjustable on-line for the interface used (ref. 2).

A series of experiments was performed to determine what solvent type and composition results in the best sensitivity for both negative and positive ions. Previous work that we have done (as well as others) indicates that in some cases acetonitrile results in a better S/N ratio and fewer background peaks in the positive ion mode. Since CE and LC of highly polar compounds are often carried out with highly aqueous buffers, studies were done by infusing an analyte in water through the inlet of the liquid junction interface and an organic solvent with buffer was added via the make-up. Varying the flow rates varies the percent organic. Data were corrected for dilution factors.

For negative ionization of a bisphosphonate drug, CGP 42446, both acetonitrile and *n*-butanol gave the best sensitivity at typical LC eluent conditions (66% organic). Methanol gave comparable sensitivity, but only when the concentration was above 90%. Thus, all three solvents would be acceptable for CE make up, but methanol would not be as good for LC make-up. Isopropyl alcohol was inferior to all of the other three solvents. Sensitivity for the bisphosphonate continued to increase with methanol concentration until about 95%, and then showed a sharp decline. With

acetonitrile, however, sensitivity peaked around 50%. Two other anions were also studied, Acid Red-88 and naphthalene sulfonic acid, each show different responses to solvent and concentration. Thus for ultimate sensitivity, a careful selection of both solvent and composition should be made. Attention should also be given to the miscibility of the selected solvent with water. Unlike direct coupling with nano-spray, both sheath-flow and liquid junction coupling can optimize the response by varying the composition of the solution.

Experiments with the basic drug, reserpine, in the positive ion mode, show less variability with solvent than those detected in the negative ion mode. Methanol did show a slight drop-off at high organic concentration but not as pronounced as in negative ion mode. Although a series of compounds was not studied in the positive ion mode, attention should be given to the nature of the compound if ultimate sensitivity is desired.

The polar bisphosphonate drugs show little retention even on polar reversed-phase LC columns. In order to obtain any retention, 100% aqueous buffer is needed. The resultant sensitivity by electrospray or even Ion Spray is poor. The self-aligning liquid junction was found to be an ideal way to add a make-up buffer (in this case acetonitrile with ammonium acetate.) Flows of 50 μ L from a microbore column could easily be coupled to a flow of 50 to 100 μ L of make-up buffer. Sensitivity was enhanced by several orders of magnitude in the case of the LC/MS determination of the bisphosphonate CGP 42446.

The development of an on-probe capillary separation interface

Michael Morris, Steve Lane, Bob Boughtflower, Clare Paterson and Tim Underwood
Micromass UK Limited, Tudor Road, Altrincham, Cheshire WA14 5RZ, UK.
Glaxo Wellcome, Gunnels Wood Road, Stevenage, Hertfordshire SG1 2NY, UK

Introduction

Capillary electrochromatography (CEC) was first developed in 1974 (1) as an alternative to using hydrostatic pressure to effect a solvent flow through a packed capillary column. Electrically-driven flow in capillary columns results in a much flatter solvent front as compared to the Poiseuille flow of a pressure driven system, resulting in enhanced chromatographic performance with the possibility of using smaller particle sizes and longer columns.

Renewed interest in CEC was initiated by the work of Knox and Grant (2) culminating in the coupling of CEC to mass spectrometry using both continuous-flow fast-atom bombardment (3) and electrospray (4) ion sources, but with considerable loss in chromatographic performance in the post-detector unpacked region of the capillary column. It has also been demonstrated that there may be a significant improvement in chromatographic performance if the capillaries are packed through into the ion source of the mass spectrometer (5). The objectives of this work were to develop a CEC-MS interface that eliminated the need for long inter-connecting columns by using short, packed capillary columns that terminated at the electrospray needle.

Methodology and Instrumentation

Uncoated fused silica capillaries (43 cm x 50 µm i.d. x 375 µm o.d.) were slurry-packed with a 3 µm ODS-Hypersil packing material using a method that has been described previously (6). The columns were terminated at each end by integral sintered tips that prevented the ejection of the packing material under pressure-driven flow. The columns were equilibrated with a mobile phase of 80% MeCN/5mM sodium tetraborate at pH 9.

A schematic diagram of the probe interface is shown in Figure 1. A standard CE-MS triaxial probe on a Micromass Platform mass spectrometer was modified to allow the shortest possible length of capillary column to be used. A potential of 3.5 kV was applied to the electrospray needle. A high potential (up to 30 kV) was applied to the sampling needle shown in the probe body from a Brandenburg 3807 high voltage supply (Brandenburg, Thornton Heath, UK). The mass spectrometer was scanned in centroid mode from m/z 50 to 600 in 1 second so as to minimise any loss in chromatographic integrity.

Figure 1: Schematic diagram of the CEC-MS interface

Results

Figure 2 shows the reconstructed ion chromatograms for a preparation of fluticasone propionate. As can be seen from the upper trace, the fluticasone propionate migrates in 11.09 minutes, but is closely followed by an impurity of molecular mass 482 Da migrating at 11.61 minutes. The mass spectral data acquired suggested that the impurity was the fluticasone S-methyl ester.

While the principles of CEC-MS using this system have been demonstrated, the mass spectrometric performance has been compromised by the requirements of the buffer systems required for the generation of electroosmotic flows with conventional packing. Additional work is currently being undertaken to evaluate various column packing materials and solvent systems to try and enhance the mass spectrometric performance while not compromising the chromatographic separation.

Figure 2: Reconstructed ion chromatograms for fluticasone propionate and an impurity

Conclusions

A prototype probe has been developed to facilitate capillary electrochromatography using a mass spectrometer as the detector. Rapid analyses have been demonstrated without the need for an expensive commercial CE or CEC instrument. The electroosmotic flow of through the CEC column (50-100 nL/min) is also compatible with current nanoflow electrospray interfaces and it is anticipated that coupling to such an interface may offer an increase in sensitivity over the current sheath-flow system. The formation of bubbles that has previously been observed in CEC-MS couplings was found to be less frequent in this system where the packed column terminated in the ion source of the mass spectrometer.

Comprehensive RPLC-CZE with on-line Electropray Mass Spectrometry of Peptides

Kenneth C. Lewis, Gregory J. Opiteck, and James W. Jorgenson

Department of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599

Douglas M. Sheeley

GlaxoWellcome, 5 Moore Drive, Research Triangle Park, NC 27709

Peptide standards and tryptic digests of ribonuclease B are separated by comprehensive two dimensional reverse phase liquid chromatography (RPLC) and capillary zone electrophoresis (CZE) and detected on-line by electropray mass spectrometry. A 1 mm by 33 mm C8 RPLC column is coupled to a 29 μm i.d. by 15 cm CZE column by a transverse flow gating interface. A new rugged microelectrospray needle was developed that combines high ionization efficiency, low flow rates, and a sheath flow. The result is a system combining the separation capabilities of both RPLC and CZE with on-line mass spectrometric detection, all in about 15 minutes.

Figure 1 shows the total ion current of a CZE-MS separation of three peptide standards (360 fM injected) in under 30 seconds using the same conditions as during the 2 dimensional separations. The separation occurs at pH 11 so all of the peptides are negatively charged and migrate against the electroosmotic flow (EOF). Long injection times were used to widen the CZE peaks to insure detection with the API 100 mass spectrometer scanning at 2000 amu/second.

Figure 2 shows a base peak chromatogram of a RPLC-CZE-MS analysis of peptide standards. Separation is effected by both RPLC and CZE, and while neurotensin is not separated from angiotensin by RPLC, CZE clearly separates them. Although undesirable, the observed shifts in migration time for neurotensin and angiotensin due to under sampling and column overloading are not detrimental because the MS identifies the analytes.

The detection limit is elucidated from the analysis of the mixture of standards using angiotensin as the model peptide. One standard deviation for angiotensin in the RPLC dimension is 45.5 seconds. Therefore, 68.3 percent of the peptide elutes in 91 seconds, and since angiotensin is present in the initial sample at a concentration of 500 μM , the concentration eluting from the RPLC column between $-\sigma$ and σ is 75 μM . The observed dilution due to the interface is a factor of about 1.5. Therefore the concentration injected on the CZE column at the RPLC peak maximum is 50 μM . This translates to 175 femtomoles injected on the CZE column and yields a S/N ratio greater than 40 in the mass spectrum (figure 3).

A Novel Electrospray Interface for High Resolution, On-Line CIEF-MS

D. P. Kirby*, J. M. Thorne, W. K. Goetzinger, F. Foret, P. Vouros and B. L. Karger
Barnett Institute and Department of Chemistry
Northeastern University, Boston, MA

Capillary isoelectric focusing in combination with MS detection offers a means for the separation and structural characterization of peptides, proteins and other amphoteric substances and is analogous to 2D SDS PAGE. With CIEF-MS, the first dimension is based on *pI* and the second on MS-derived molecular weights. Of great practical importance for on-line MS analysis, this CE mode concentrates samples as part of the separation. One method of performing CIEF-MS has recently been described.¹

Interfacing CIEF with ESI-MS presents operational challenges because of the different chemistries required for focusing, mobilization and ESI detection. Ideally, on-line operation should require no interruption of the system to exchange buffers and must preserve the high resolution, high sensitivity capabilities inherent in CIEF analyses. A CIEF-ESI-MS approach meeting all these requirements is demonstrated here. We use a modified coaxial liquid sheath interface to allow the separation capillary to be positioned accurately with respect to the liquid sheath tube during ESI operation. Such active capillary positioning can be accomplished, for example, with the modification of the Finnigan ESI-MS source shown in Figure 1. To focus, the capillary is moved inside the liquid sheath tube, which thus becomes a micro-reservoir supplied through the liquid sheath path. After focusing is complete, the capillary is extended outside of the liquid sheath tube to its predetermined, stable ESI position.² The liquid sheath path is then used to exchange focusing buffer for mobilization/detection buffer. This procedure is highly versatile, requires no interruption of the system during the analysis, and readily lends itself to automation.

Analysis of model protein systems and comparison with CIEF-UV data indicates that analyte resolution is maintained with the interface. More importantly, the use CIEF-MS to perform two dimensional analysis is demonstrated. Table 1 lists the array of parent masses found with the on-line analysis of a mixture of hemoglobin variants. Each major peak (HbC, HbS, HbF and HbA) contained ion distributions of multiple species which were deconvoluted to give the parent masses in Table 1. In addition, high quality spectra were obtained from minor peaks, such as those at migration times 12:53, 13:42, 14:19 and 15:34 in Table 1. The expected α , β^A , β^C , β^S , and γ^G chains were easily and accurately identified from a combination of migration and mass information. Other masses are currently unassigned, but clearly the quality of the data is more than adequate to allow their identification.

Analysis Of Peptides And Proteins By On-Line CE-Electrospray MS and Off-Line CE-Nanoelectrospray MS Yiping Sun and Mark D. Bauer, The Procter & Gamble Co., Miami Valley Laboratories, P.O. Box 538707, Cincinnati, OH 45253-8707

Introduction

HPLC is one of the most commonly used separation techniques for biomolecules. However, capillary electrophoresis is rapidly becoming an important complementary method with several advantages over HPLC: high separation efficiency, small sample consumption and short analysis time. Electrospray mass spectrometry (ES/MS) is a powerful technique for the structural characterization of biomolecules. The direct coupling of CE to the mass spectrometer has been a challenging task. In this study, we report the on-line coupling of CE (Beckman P/ACE 5000) to electrospray MS (PE Sciex API-III) with a home-built coaxial interface (1). The use of the system for peptide and protein analysis is demonstrated. Nanoelectrospray (nES) is a new technique for characterizing biomolecules in small volumes (0.5-2 μ l) at low picomole levels (2). In nES, signals from a single-sample loading typically last more than 30 minutes, which permits optimization of instrument parameters and MS/MS sequencing of different peptides in a digest. nES is also more tolerant to buffer and salt solutions than conventional ES. These unique features of nES make it attractive as an off-line technique for the analysis of fractions collected from CE. In this study, applications of this method to analyze peptides are also illustrated.

Experimental

Capillary electrophoresis--A Beckman P/ACE 5000 (Schaumburg, IL) was used for CE-UV, on-line CE-ES/MS and off-line CE-nES/MS. All untreated fused-silica capillaries were obtained from Polymicro Technologies (Phoenix, AZ). The UV detector was set at 214 nm.

On-line CE-ES/MS--The Beckman system was coupled to a Sciex API-III triple quadrupole MS (Thornhill, Canada) with a home-built coaxial interface (Fig. 1). The background electrolyte (BGE) was CH₃CN/H₂O/HCOOH (50:45:5). A make-up flow (CH₃OH/H₂O/HCOOH=50:50:0.1) was delivered at 8 μ l/min by an ISCO μ LC-500 pump. The CE was operated at 30 kV at the cathode. The voltage on the electrospray needle was maintained at 4 kV. A peptide mixture of angiotensin-I, substance-P, bradykinin and angiotensin-II (0.25 mg/ml each), a protein mixture of myoglobin (1 mg/ml) and insulin (0.5 mg/ml), and tryptic α - and β -casein (1 mg/ml) in BGE, were analyzed with a 50 μ m x 110 cm column and a 10 sec pressure injection.

Off-line CE-nES/MS and CE-nES/MS/MS--A peptide mixture (0.33 mg/ml each of angiotensin-I, substance-P and met-enkephalin) was injected to a column (75 μ m x 97 cm) for 10 sec. Each fraction was collected into a small eppendorf tube containing 100 μ l BGE, and freeze-dried. Samples were re-dissolved in 4 μ l of make-up solvent. 2 μ l of each sample was analyzed by nES/MS and nES/MS/MS and the other half was analyzed by Edman sequencing.

Results and Discussion

Peptide mixtures, tryptic digests of proteins and protein mixtures were successfully analyzed by the on-line CE-ES/MS system. Fig. 2 is the total ion current trace for CE-ES/MS of a four-peptide mixture containing angiotensin-I, bradykinin, angiotensin-II and substance-P. About 5-10 pmoles of each peptide was injected onto the CE column. The Sciex instrument was scanned from m/z 1400-400. These four peptides were well separated and each peak gave a good mass spectrum. The same system has also successfully analyzed protein digests such as tryptic α - and β -casein and a protein mixture containing myoglobin and insulin. It should be pointed out that using 1% NaOH to regenerate CE column between each run in on-line CE-ES/MS resulted in a significant loss of sensitivity and affects ion stability. 1% NH₄OH can be used to minimize such problems. Although the on-line CE-ES/MS works well, there are some limitations: the column has to be long enough for the coupling of the Beckman CE to the Sciex API-III, and MS and MS/MS sensitivity needs to be improved. Matthias Mann and Matthias Wilm, at EMBL, Germany, developed the nanoelectrospray technology for the characterization of biomolecules in small volumes (0.5-2 μ l) at low picomole levels (2). It would be an ideal off-line technique for sequencing peptides collected from CE. Fig. 3 shows the electropherogram of CE-UV from the peptide mixture (angiotensin-I, substance-P and met-enkephalin) and the nES mass spectrum of peak "a" collected from off-line CE. The peak at m/z 649.2 and 433.2 corresponds to the doubly- and triply-charged ions of angiotensin-I. Although these peaks are weak, their nES/MS/MS sequencing data are very good (Fig. 4). All three peptides were successfully collected and sequenced by nES/MS/MS using only half of the

material from CE. The signal from each peptide lasted more than 30 min in nES/MS/MS. Peaks a and b in Fig. 3 were also successfully sequenced by Edman degradation using the other half of the material.

Conclusions

On-line coupling of CE (Beckman P/ACE 5000) to ES/MS (PE Sciex API-III) with a home-built coaxial interface was demonstrated. Peptide standards, protein digests and protein mixtures can be analyzed by the on-line system loading low picomoles of materials. However, sensitivity needs to be improved, especially for protein analysis. On-line coupling of CE to the Finnigan LCQ will be evaluated. nES/MS and nES/MS/MS and Edman sequencing are useful off-line techniques for sequencing peptides collected from CE.

Acknowledgment

The authors gratefully acknowledge Dr. Matthias Wilm and Dr. Matthias Mann (European Molecular Biology Lab, Germany) for the installation of a nanoelectrospray source on our Sciex API-III instrument. We thank Dr. Feng Wang (P&G Pharmaceuticals) for Edman sequencing of peptides.

A Comparison of Membrane Interface Designs for Electrokinetic Chromatography / Mass Spectrometry

John A. Masucci (1,2), Gary W. Caldwell (2), and Joe P. Foley (1)

(1) Villanova University, Villanova, PA 19085

(2) The R. W. Johnson Pharm. Res. Institute, Spring House, PA 19477

Substantial research combining mass spectrometry (MS) with capillary electrophoresis (CE) has been conducted since the first report by Smith and coworkers in 1987. Non-volatile buffers and additives have been generally avoided as these are less compatible with electrospray ionization (ESI).

Considerable interest has been shown in the analysis of small neutral molecules, or other analytes which require separations based on differences in hydrophobicity, chirality, etc. These separations, referred to as electrokinetic chromatography (EKC), provide excellent separation selectivity and efficiency. EKC combined with MS has not been extensively investigated due to the incompatibility of the nonvolatile buffer additives with ESI.

The need for coupling EKC with MS has led us to develop a new interface which permits the use of nonvolatile buffer additives such as surfactants, cyclodextrins and/or biopolymers. The interface utilizes a semi-permeable membrane that selectively transmits the small analyte molecules to the mass spectrometer but retains the larger buffer additive(s). The interface also allows separate selection of EKC and ESI buffers for independent optimization of separation and detection conditions. Applications of this type of interface include micellar, chiral and affinity CE analyses.

Our initial design which placed the membrane within a junction "T" did not prove to be satisfactory for optimal performance since a small positive inlet pressure was required to counteract the back pressure within the "T". An improved design, which places the membrane at the "Tip" of the electrospray probe, did not have these limitations and was much easier to implement.

Experiments were performed utilizing a Beckman P/ACE 2200 CE unit with VG TRIO 2000 single quadrupole ("T" design) and Finnigan TSQ 700 ("Tip" design) triple quadrupole mass spectrometers. The EKC/MS interfaces were constructed from modified versions of the VG triaxial flow and the Finnigan CE/MS probes. The interfaces utilize a 75 μ m ID fused silica capillary (80 cm length) onto which was attached a 1 or 3 mm length of cellulose hollow fiber (200 μ m ID), with an additional fused silica length to waste. For infusion experiments, a flow of buffer (100mM acetate pH 8.4) at 1-2 μ l/min. was established through the membrane interface probe. Make-up flow of 5-10 μ l/min. of 1:1 water : CH₃CN with 0.1% TFA was used in both designs. Initial EKC/MS experiments were performed using 60 sec injections of a mixture of 0.5 mg/ml adenosine and 2.0 mg/ml myoglobin. A membrane transmission of 8% was consistent with microdialysis efficiencies. Factors such as flow rate, molecular size, and concentration also affect transmission of compounds through the membrane.

Studies on Acyl-CoA with MALDI-TOF and CID MS/MS

Fong-Fu Hsu and Michael L. Gross

Department of Chemistry, Washington University, 1 Brookings Drive, St. Louis, MO 63130

Three soft ionization methods i.e., FAB, ESI and MALDI were used to study the CID tandem and PSD mass spectra of acyl-CoA thioesters, a class of compounds which have been implicated as substrates in a number of metabolic reactions at the cellular level as well as in the pathogenesis of the vascular complications of diabetes mellitus. We explored both high energy CID MS/MS by using FAB and ESI, and PSD with MALDI-TOF to study the utilities of mass spectrometry in the structural identification of acyl-CoA.

In the positive-ion mode, the CID MS/MS of the precursor ion $[M + H]^+$ for FAB and ESI yields similar tandem mass spectra and the fragment ions produced can be easily elucidated (Table 1 and Scheme 1). The amount required for obtaining a FAB CID tandem mass spectrum is 400~1000 pmol, depending on the compound. The total amount consumed for CID in the ESI is 200 pmol.

The PSD MALDI generated from loading 100 pmol gives a mass spectrum with less fragmentation. Common ions that bear the long-chain fatty acid fragment were observed as $(M - 506)$.

In the negative-ion mode, both FAB and ESI give similar CID mass spectra as MALDI PSD (figure 1) but only MALDI PSD exhibits superb sensitivity. Abundant fragment ions (Table 2) related to the structure of the acyl-CoA can be seen by a loading of 10pmol of sample. Major fragmentations involve the bond cleavages at the phosphate to form the complementary ion pairs constituting the molecules (Scheme 2).

The three mass spectrometric methods used in this study all yield similar CID tandem mass spectra, demonstrating the utilities of mass spectrometry in structural elucidation of acyl-CoA's. Results obtained from positive-ion and negative-ion CID MS/MS are complementary. Abundant fragment ions related to the structural information were observed in both positive and negative modes. But MALDI-TOF is 50~100 times more sensitive than FAB and 20 times more sensitive than ESI. The ease of use and the superb sensitivity exhibited by PSD MALDI-TOF make it a powerful tool in studying compounds requiring tandem mass spectrometry.

Electrospray Ionization Mass Spectrometry Characterization of Phosphatidylinositol Phosphates

Clay, Keith L. and MacMillan, Denise. National Jewish Center Immunology and Respiratory Medicine. Denver, CO

Phosphatidylinositol phosphate (PIP) species are becoming increasingly recognized for their importance in signal transduction pathways. Research in this area, however, is impeded by the difficulty of measurement of these molecules and by the presence in the cell of isomeric forms which have different biological activities. LC/MS with negative ion ESI has been evaluated for utility in the measurement of the intact PIP species.

Negative ion LC-ESIMS yields $(M-H)^-$ ions of the PIP species which can be used, in combination with chromatographic retention time to measure relative amounts of the various species. The native PIP species, however, have poor chromatographic characteristics and are recovered only with poor and variable yield in the isolation procedures used. Product ions observed by CID of the $(M-H)^-$ ion from native PIP species in the negative ion ESIMS/MS experiment consisted of the parent ion and ions corresponding to losses of the phosphate moieties with additional ions arising from the carboxylate anions of the fatty acids in the PI. This information was sufficient to determine the molecular species of the PIP with regard to fatty acyl groups and to number of phosphate groups. None of the ions from the native molecule was informative with respect to isomeric characterization.

Methylation of the phosphates to their dimethyl esters was very useful in characterizing these molecules. Isolation and purification of the methylated species was much more reproducible than with the native species. In addition, the methylated species gave ions which are of potential utility for isomeric characterization. The tetramethyl derivative of PI-4,5- P_2 gave a product ion spectrum with an ion at m/z 457 which arises from cleavage of the glycerol-phosphate bond with charge retention on the tetramethyl-triphospho-inositol moiety. This ion could also be generated by collisional processes in the ion source. Product ions arising from CID of the m/z 457 ion indicate that this analysis will be successful for isomer determination, an experiment which will be completed when appropriate standards are available. Synthesis and analysis of the isomeric PIP species of biological interest will allow definitive characterization of the PIP isomers with ESIMS/MS.

ESI-MS/MS Analysis of Ozonides of Polyunsaturated Fatty Acids in Phospholipids.

Kathleen A. Harrison and Robert C. Murphy

National Jewish Center for Immunology and Respiratory Medicine, Denver, CO 80206.

Ozonolysis has been used for many years as a tool to locate the position of carbon-carbon double bonds in fatty acids. Ozone adds to double bonds in polyunsaturated fatty acids very rapidly and nearly quantitatively. The initially formed molozonide (1,2,3-trioxolane) rearranges to the more stable Criegee ozonide (1,2,4-trioxolane) via carbonyl oxide and aldehyde intermediates. Oxidation or reduction of the Criegee ozonides results in carboxylic acids or aldehydes, respectively, which mark the original unsaturated carbon atoms. Ozone is also known to react with phospholipids containing polyunsaturated fatty acids. The direct mass spectral analysis of intact lipid ozonides has been limited by their chemical reactivity (1). We have investigated electrospray ionization mass spectrometry and collisional induced dissociation tandem mass spectrometry as a means for the direct analysis of intact ozonides of polyunsaturated fatty acid-containing phospholipids.

Experimental. Ozone adducts were produced when 100-200 ng of phospholipid, as a dry thin film on a glass capillary, was reacted for 8 minutes with ozone at room temperature. Ozone was generated by passing oxygen gas through a tesla coil fitted with a glass sleeve. For ESI-MS analysis ozonized lipids were dissolved by addition of 25-50 μ l of 85:15 methanol:20mM ammonium acetate to the glass capillary. 2-5 μ l of this solution was introduced to the Sciex API III mass spectrometer by flow injection analysis, using 85:15 methanol:20mM ammonium acetate mobile phase at 50 μ l/min. The orifice potential was 45v. For tandem mass spectrometry analysis collisional induced dissociation was performed in the second "quadrupole" collision cell using 18-20 eV collision energy and collision gas thickness of 200-220 $\times 10^{13}$ atoms Argon/cm².

Results and Discussion Electrospray mass spectra of intact ozonides of several phosphatidylcholine molecular species were obtained. Protonated molecular ions were observed along with ions that would correspond to decomposition products of the intact ozonides. These lower mass ions appeared to be mainly the result of the ionization of discrete species present in the reaction mixture rather than "front-end" CID product ions as their abundance relative to the protonated intact ozonide species was not changed greatly by increasing the orifice potential of the Sciex API III. For polyunsaturated fatty acid-containing phosphatidylcholine molecular species, ions corresponding to mono-, di-, tri-, and tetra-ozonides were observed depending on the number of carbon-carbon double bonds in the original molecule. ESI-MS/CID/MS analysis of these ozonide species allowed us to determine the position of the carbon-carbon double bonds in the phosphatidylcholines and to propose fragmentation mechanisms which should aid the understanding of the CID behavior of ozonides. The ESI-MS/CID/MS fragment ions obtained from several phosphatidylcholine monoozonides are shown in Table 1.

Table 1. Positive ESI-MS/CID/MS fragment ions obtained from protonated molecular ions of phosphatidylcholine monoozonides. (A/B/C:D PC represents a phosphatidylcholine molecular species having fatty acids with A carbons and B double bonds esterified to the sn-1 position of the glycerol backbone and C carbons and D double bonds esterified to the sn-2 position.)

molecular species	no. isomers	m/z, MH+	m/z, fragment ions
16:0/18:1 PC	1	808	650,666,621,537,184
16:0/18:1 2H9-PC	1	817	659,675,630,546,193
16:0/18:2 PC	2	806	650,666,621,537,184 661,706,690
18:0/20:4 PC	4	858	633,673,713,578,593,565,184
16:0/5-HETE PC	4	846	701,683,661,643,650,594,184

These spectra represent a mixture of all the possible isomeric ozonides as no purification of the ozonized phosphatidylcholines was performed prior to mass spectral analysis. Only one ozonide isomer can be formed from 16:0/18:1 PC. The major fragment ions correspond to 16:0/9:0 ω -aldehyde PC and

16:0/9:0 ω -carboxy PC. These fragments mark the original C9,10 double bond position of 16:0/18:1 PC. These ω -aldehyde and ω -carboxy type of fragments likely arose from homolytic cleavage of the peroxide bond of the ozonide followed by rearrangement of the electrons. Confirmation of the structure of the ω -carboxy fragment as such was obtained using negative ESI-MS/CID/MS. The MS/MS product ion spectrum of the acetate adduct of 16:0/18:1 ²H₉-PC ozonide, m/z 875, is shown in Figure 1. The carboxylate anions corresponding to the 9:0 ω -aldehyde fragment and the 9:0 ω -carboxy fragment appear at m/z 171 and m/z 204. In the MS/MS product ion spectrum of the non-labeled analog, these ions appeared at m/z 171 and 201. The shifts of 17u and 14u indicates that this ion has formed an ω -methyl ester with one of the choline methyl groups, as has been documented for ω -carboxyl containing phosphatidylcholines (2).

Figure 1. Negative ESI-MS/CID/MS of acetate adduct of 16:0/18:1 ²H₉-PC ozonide.

The other MS/MS fragment ions produced from 16:0/18:1 PC ozonide at m/z 621 and 537 also appear to arise via homolytic cleavage of the peroxide bond followed by homolytic fission of either the adjacent carbon-carbon bond or the C2,3 carbon-carbon bond. Addition of an double bond allylic to the ozonide enhances the formation of these latter types of fragments by resonance stabilization of the odd electron ion. This was observed for 16:0/18:2 PC ozonide with the abundant ion at m/z 661 arising from homolytic cleavage of the C11,12 bond of the 12,13-ozonide isomer. Similarly, such resonance stabilized odd electron ions were also observed from the monoozonide isomers of 18:0/20:4 PC at m/z 633, 673, and 713. The non-resonance stabilized fragment at m/z 593, corresponding to fragmentation of the C4,5 bond was much less abundant. 16:0/5-hydroxyicosatetraenoyl PC (16:0/5-HETE PC) also produced allyl radical ions and their corresponding dehydrated products (loss of 18u). Allyl radical ions were not formed from the ozonides of the conjugated double bonds at C6 and C8 as no resonance stabilization would be gained.

The positive ESI-MS/CID/MS product ion spectra obtained from some fully ozonized phosphatidylcholines are tabulated in Table 2. Formation of ω -aldehyde and ω -carboxy fragment ions dominate these spectra. The double bond positions in the original PC molecular species can be easily determined from these diagnostic fragment ion sets.

Table 2. Positive ESI-MS/CID/MS ω -aldehyde and ω -carboxy fragment ions obtained from protonated molecular ions of phosphatidylcholine complete ozonides.

molecular species	no. ozones	m/z, MH+	m/z, diagnostic fragment ion sets
16:0/18:1 PC	1	808	650, 666
16:0/18:2 PC	2	854	738, 754, 650, 666
18:0/20:4 PC	4	1002	886, 902, 798, 814, 710, 726, 622, 638

Differentiation of Steroid Isomers by Controlled Fragmentation in APCI-MS.

Per J.R. Sjöberg and Karin E. Markides

Dept. of Analytical Chemistry, Uppsala University, P.O. Box 531, S-751 21 Uppsala, Sweden

Constitutional and Stereo isomers of steroid molecules are normally not possible to differentiate in atmospheric pressure ionization mass spectrometry using their quasi-molecular ion $(M+H)^+$ mass and few fragmentation ions.

In this study, controlled up-front collision (increased orifice potential) or MS/MS with a low and a high pressure collision cell were performed. With these techniques it was possible to differentiate between steroid isomers using atmospheric pressure chemical ionization (APCI) interfaced to a triple quadrupole mass spectrometer.

Slow continuous supercritical fluid extraction and a micro LC heated nebulizer interface were used for analyte introduction.

Energy resolved spectra were recorded and differences in relative intensities of fragment ions were observed in both up-front collision and MS/MS mode. Furthermore, differences were also observed when the collision energy was fixed and the collision gas thickness was manipulated.

Different quasi-molecular ions $(M+H)^+$, $(M+H+CH_3OH)^+$, $(M+H+CH_3CN)^+$ were formed depending on type of solvent used for sample introduction. MS/MS experiments were performed to study the positive influence of quasi-molecular ion selection on the relative intensities of fragment ions.

Number and position of hydroxyl groups as well as stereo selective pattern influence the fragmentation in both ionization modes in a process that has no concentration dependence.

Up-Front Collision Induced Dissociation

LC/ESI/MS AND LC/APCI/MS ANALYSIS OF TRIACYLGLYCEROLS

I. ZANELLA, M.-M. FLAMENT, S. GIRAULT and M. BECCHI
SCA, CNRS, B.P. 22, 69390 VERNASION, FRANCE

The triacylglycerol (TAG) composition is very important for the physical and biological characteristics of edible oils and for some seed oils used as precursors in chemical synthesis. Several authors recently reported the development of HPLC coupled with atmospheric pressure ionization interface mass spectrometry for qualitative analysis of TAGs :

- electrospray ionization (ESI) was used after silver silica HPLC (1).
 - Atmospheric pressure chemical ionization (APCI) was investigated with propionitrile/hexane mixture in positive ion mode (2)
 - ESI/MS/MS was also investigated with direct injection (1, 3).
- We have completed these studies by evaluating :
- the significance of mobile phase composition in positive ion LC/APCI/MS and the possibility of studying negative ions, specially for saturated TAGs,
 - the use of ionic buffers in LC/ESI/MS.
- To conduct our different assays we chose reference materials from SIGMA and studied Castor oil from *Ricinus communis* L., a seed oil used in the manufacture of plastic formulation (Rilsan 11). This oil contains unusual hydroxylated unsaturated TAGs.

EXPERIMENTAL

Liquid Chromatography : Varian 9010 or Hewlett-Packard 1090,

Spherisorb ODS2 5 μ m 250 x 2,1 mm

CH₃CN/CH₂Cl₂/CH₃OH (55/10/35 ; v/v/v) at 250 μ l/min,

CH₃CN/CH₂Cl₂ (90/10 $\rightarrow$ 5/95 (1 min) ; v/v) at 250 μ l/min and 2-propanol post-column added at 60 μ l/min

CH₃OH/CH₂Cl₂/2-propanol + 20 mM CH₃COO NH₄ (40/25/35 ; v/v/v) at 250 μ l/min.

Sample cone : + 5 and + 20 V in positive mode; - 5 V in negative mode

ESI-MS Hewlett-Packard MS Engine 5989 with an Electrospray Source 59987 A

Temperature 300°C ; Capillary Exit 380V

RESULTS

POSITIVE ION LC/APCI/MS ANALYSIS

- The best Castor oil HPLC separation of TAGs was obtained by adding methanol to the usual dichloromethane/acetonitrile mixture because of the presence of hydroxylated TAGs.
- The choice of dichloromethane/acetonitrile mixture as LC mobile phase is important for APCI/MS analysis :
- we obtained protonated molecular ions [M+H]⁺ for hydroxylated TAGs associated with abundant [M+H-H₂O]⁺ fragment ions instead of mainly [M+H-H₂O]⁺ fragment ions and minor [M+H]⁺ using propionitrile/hexane solvent mixture.
- we also obtained more abundant [M+H]⁺ protonated ions for unsaturated TAGs. Even with saturated TAGs we observed very little but detected quasi molecular ions ([M+H]⁺ or [M+Na]⁺), that was not the case with propionitrile/hexane solvent mixture. In all cases saturated TAGs APCI mass spectra showed base peak corresponding to the diglycerol ion formation.

- The best way to characterize TAGs was to use cationization with ammonium acetate buffer : for all types of TAGs we produced abundant [M+NH₄]⁺ cationized molecular ions.
- We studied the effectiveness of adding a protic solvent to the propionitrile/hexane or dichloromethane/acetonitrile mixtures to enhance the ionisation/protonation process. For this purpose different amounts of 2-propanol were post column added but no significant improvement was noticed.

NEGATIVE ION LC/APCI/MS ANALYSIS

Negative ion APCI TAGs mass spectra mainly showed molecular ions [M-Cl]⁻ when dichloromethane is in the mobile phase. The presence of dichloromethane is essential in [M-Cl]⁻ ions formation. As no result had been obtained using propionitrile/hexane, addition of dichloromethane to this mixture allowed quasi molecular ions [M-Cl]⁻ formation.

LC/ESI/MS ANALYSIS

- TAGs needed to be cationized for electrospray ionization. LC/ESI/MS total ion chromatogram of Castor oil TAGs showed great discrepancy for individual TAG response. In our experimental conditions quantitative analysis is not possible. Individual ESI response of TAG would probably be less affected using a sheath liquid (triethylamine) to provide the necessary ionic buffer, as was already shown (1).
- ESI mass spectra were very simple : we only observed cationized molecular ions [M+Li]⁺, [M+Na]⁺ and [M+NH₄]⁺ with AcOLi, AcONa and AcONH₄ respectively, without any fragmentation. Even saturated TAGs could be characterized with their cationized molecular ions. We also used formic acid, and in this case we observed [M+Na]⁺ ions with minor fragment ions corresponding to fatty acyl residue losses, i.e. diacylglycerol ions.

CASTOR OIL TAGs studies showed that APCI in positive or negative ion mode gave quantitative response, that was not the case with ESI. Post column addition of ionic buffer using a sheath liquid would be better to control individual ESI response of TAGs. LC/MS results confirmed already described structure of Castor oil TAGs : RRR, RRL, RRO, RRP and RRS ; and allowed identification of new ones : RR (diglyceride), RRDH, RREnOH, RRLn and RREn.

ESI Mass Spectrometric Profiling of Bacterial Phospholipids: Effects of Environmental Conditions

Gavain Sweetman¹, Primrose Freestone², Mirella Trinei², Istvan Toth² and Vic Norris²
¹MRC Toxicology Unit, Hodgkin Building and ²Dept of Microbiology and Immunology, Leicester University, P.O. Box 138, Lancaster Road, Leicester, LE1 9HN, UK.

The phospholipid composition has been linked to environmental changes¹, cell cycle regulation², and protein content and activity³. Mass spectrometrists first used GC-MS⁴ and FAB-MS⁵(-MS⁶) for lipid analyses. Now ESI⁷ has become the method of choice. We have additionally used in-source CID to simultaneously fragment all the phospholipids and release the fatty acid side chains⁸, thus enabling the precise characterisation of the phospholipid species present.

The membrane phospholipid composition of *E. coli* grown under environmentally stressed conditions have been analysed using ESI-MS and in-source CID. The conditions varied from low/ high salt concentrations (osmotic potential) to anaerobiosis and minimal media.

The *E. coli* (K12 strain W3110, IN(rmD rmE)) were grown on two different media: M9 minimal media, which contains salts and glucose and no extra carbon source, and LB, which contains bacto tryptone 10 g/l, bacto yeast extract 5 g/l and normally 0.085 M NaCl. LB was also made up with no NaCl and 0.4 M NaCl.

E. coli grown aerobically were cultured at 37°C with shaking, and were harvested at an OD₆₀₀ of between 1.6 and 2.0. For the anaerobic conditions the flask was filled to capacity and tightly stoppered. The cells were grown without shaking, to prevent oxygenation, and harvested at an OD₆₀₀ of 0.5. The harvested cells were washed with PBS and distilled water prior to overnight freeze-drying. Two extractions were made using 400 ml of chloroform/ methanol (2/1 v/v) and the solvent was evaporated to dryness under a stream of nitrogen.

The samples were reconstituted in 1 ml of methanol/ chloroform (2/1 v/v) and infused into the ion source of a VG Quattro BQ (VG Organic, UK) at a flow rate of 5 µl/min, using a Harvard apparatus syringe pump. The samples were analysed using negative ion ES-MS. Each sample was analysed with both low (intact phospholipid detection) and high (fatty acid side chains detection) voltage settings for the sample cone.

Low voltage: Sample cone 66 V, scan m/z 600-900 in 2 s.

High voltage: Sample cone 135V, scan m/z 100-400 in 2 s

The displayed spectra are the result of combining all the spectra from a 2 min acquisition.

The different head groups on the phospholipids give different ionisation efficiencies using ESI-MS⁸. This is manifest in the data by apparently equal amounts of PE and PG species when their expected ratio is 3:1 (PE:PG).

Phospholipid extractions of *E. coli* grown on low and high salt media showed very little change from the extractions of control *E. coli*.

Growth in anaerobic conditions produced a much more profound change in phospholipid composition. The obvious features are the increase in the proportions of PE33:1 and PG33:1 in the intact spectrum and a general increase in the populations of fatty acids containing odd numbers of carbons, especially 17:0 which became the dominant species.

The *E. coli* grown on the M9 media produce a marked change in phospholipid composition compared with controls. The phospholipid composition is dominated by 4 main species (PG33:1, PE33:1, PG35:1 and PG36:2). The changes in fatty acid composition was characterised by increases in 17:1 and 19:1, decreases in 18:1 and 16:1 and an absence of 15:0.

Figure 1 *E. coli* grown in low salt (left) and anaerobic conditions (right) Top - intact phospholipids, Bottom - fatty acid side chains PE - phosphatidylethanolamine, PG - phosphatidylglycerol, xx:y - number of carbons: number of double bonds

We are currently evaluating the significance of the phospholipid compositional changes for the anaerobic growth and growth on M9 media. The broad similarities between the compositions suggest that there may be common factors that are influenced by the altered growing conditions.

ESI is a very useful tool in the analysis of phospholipids extracted from bacterial sources. The additional capability of in-source CID enables precise identification of the phospholipids present. This technique is very sensitive and both analyses can be performed on extracts from less than 4x10⁷ cells (actual sample consumption of 5x10⁶ cells for each analysis. Data not shown).

Altering the osmotic potential of the growth media did not cause any significant changes in the phospholipid composition of *E. coli*. However, growth in anaerobic conditions and growth on minimal media both caused a significant increase in lipids containing an odd number of carbons.

Characterization of a Novel Glycolipid Biosurfactant Bearing Acyloxyacyl Groups in *O*-Ester Linkage to Trehalose.

Todd D. Williams, Wynn-Steven Esch, Martha D. Morton, Clarence S. Buller
The University of Kansas, Lawrence KS 66044

DISCUSSION

A species of *Corynebacterium* isolated from soil secreted a novel glycolipid biosurfactant during growth on *n*-hexadecane, but not during growth on glucose. The surfactant was a glucose trisaccharide substituted with succinate, hexanoate, and two β -hydroxy acids bearing secondary hexanoate acyl chains (Figure 1).

Characterization required a combination of NMR and MS. The surfactant isolated from culture was initially determined to contain the glucose disaccharide trehalose [α -Glc_p-(1 $\leftrightarrow$ 1)- α -Glc_p] or possibly a glucose trisaccharide, with no evidence of phosphate or nitrogen substituents. ¹H-NMR, ¹³C-NMR, FAB and exact mass FAB experiments established a molecular formula of C₅₈H₉₈O₂₆. NMR established 18 carbons in carbohydrate. No unsaturated carbon-carbon bonds were detected in NMR data. 3-Hydroxyoctanoate, 3-hydroxydecanoate, succinate and hexanoate were found in a molar ratio of about 1:1:1:3 using GC/MS analysis of fatty acid methyl esters prepared by transesterification. Although the presence of six acyl groups was consistent with the molecular formula, NMR data indicated that only four hydroxy groups on the nonreducing trisaccharide were involved in ester linkages. Thus it was postulated that the 3-hydroxy acids bore secondary hexanoate chains in ester linkage, and this was confirmed by 2D-COSY, HMBC and HMQC NMR experiments and also by the detection of carboxylated anions of appropriate mass in FAB/MS and FAB-MS/MS spectra.

FAB spectra provided evidence that smaller amounts of homologous glycolipids differing by ± 2 methylene groups also co-purified in the preparation. These data suggested that the biosynthetic *O*-acyloxyacyl synthetase system may display low or random selectivity from a pool of acyloxyacyl precursors.

EXPERIMENTAL

Preparation of Glycolipid. After batch culture growth on *n*-hexadecane to the point of substrate depletion, cell-free culture supernatants were acidified with H₂SO₄ to pH 4.00, then centrifuged, yielding a wet gel precipitate. One-step purification of glycolipid extracted from the gel precipitate was achieved by preparative TLC on Silica Gel in CHCl₃/MeOH/H₂O = 65:24:4. Acid hydrolysis, alkaline deacylation and transesterification in MeOH-HCl were by standard protocols (Kates, 1986).

GC/MS. EI spectra were acquired on a Nermag (Paris, France) R10-10. GC injections were made onto a 15M DB1 capillary column (J&W Scientific, Folsom, California). The GC program: 60°C for 3 min. then to 250°C at 8°C/min.

FAB MS and FAB MS/MS. FAB spectra were obtained on an AUTOSPEC-Q (VG Analytical Ltd, Manchester, UK). Sample in CH₂Cl₂ was added to mNBA as the matrix. CAD experiments were by linked scans at constant B/E (60% precursor attenuation w/Ar. Exact mass determinations were carried out using voltage scans and polyethylene glycol.

NMR. Spectra obtained on a Bruker AM-500 in CD₃OD, CDCl₃ or D₂O. ¹H spectra were referenced against the residual proton impurity in solvent. ¹³C spectra referenced externally against DSS. ¹H - ¹H correlation spectroscopy (COSY) performed with solvent suppression of the residual water peak and double quantum filtered in a 256 x 2048 point matrix. ¹³C - ¹H heteronuclear.

Figure 1. Because loss of acyl groups predominated in FAB MS/MS spectra, the relative positions of the two acyloxyacyl groups could not be unambiguously assigned.

CHARACTERIZATION OF SEED OILS FOR POTENTIAL TECHNICAL USE BY HPLC, ESI MASS SPECTROMETRY AND MS/MS

Ernst Pittenauer, Thomas Aichinger, Karl de Hueber and Josef Bailer
Federal Office and Research Center for Agriculture, Institute for Agricultural Ecology,
Spargelfeldstraße 191, A-1220 Vienna, Austria

Introduction. Seed oils, especially edible oils, containing primarily triacylglycerols (TAGs) play an important role in animal and human nutrition. Besides, a growing interest has been arising for TAGs obtained from seed oils as a renewable agricultural raw material for non-food use within the European Union. Seed oils for potential technical use often constitute plant storage lipids containing specific fatty acids to a high percentage (>50-60 %). Often not only the fatty acid composition of such lipids based on fatty acid methyl ester analysis is of interest but also the structure of intact TAGs for certain technical purposes [1]. Due to the complexity of seed oils, non-aqueous reverse-phase (NARP) HPLC is needed to separate major components of such mixtures before further mass spectrometric analysis

Experimental. Seed oils were either commercially available or obtained using an Autoprep 44 SFE apparatus (Suprex, Pittsburgh, PA). NARP-HPLC was performed using an HP 1090 LC (HP, Waldbronn, Germany) fitted with two Spherisorb TAG columns (PhaseSep, Deeside, UK) in series. Analyte elution was done under isocratic conditions with $\text{CH}_3\text{CN} : \text{tetrahydrofuran} = 2 : 8$ (or 3:7). All mass spectrometric measurements were performed on a Finnigan MAT 95S (Finnigan MAT, Bremen, Germany) double focusing instrument (BE) fitted with a second generation API source for ESI (or APCI). All analytes were introduced in the continuous infusion mode. (analyte solvent: $\text{CHCl}_3 : \text{CH}_3\text{OH} = 7 : 3$ / 10 mM ammonium acetate or sodium acetate). For structural elucidation of individual TAG species either "in-source" CID or CID/linked scanning in the first [daughters at $B/E = \text{const.}$, neutral loss at $(B^2/E^2) (E_0 - E) = \text{const.}$] or second field-free region [daughters at $B = \text{const.}$, $E = f(t)$; parents at $B^2/E = \text{const.}$] was utilized.

Results and Discussion. Initial experiments on the characterization of TAGs were performed on a triple quadrupole instrument by positive-ion ESI-MS and MS/MS [2]. For evaluating the usefulness of a high performance magnetic sector instrument in TAG analysis several pure TAGs were analyzed by in-source-CID (i. e. low-energy CID), CID/linked scanning at $B/E = \text{const.}$ as well as by a combination of both techniques to establish their fragmentation behavior. All major fragment ions of $[\text{M}+\text{NH}_4]^+$ adduct ions already known ($[\text{M}-\text{RCOO}]^+$, $[\text{RCO}+74]^+$ and $[\text{RCO}]^+$) are observed in low- as well as in high-energy CID-spectra. Additionally, high-energy CID-spectra exhibit a complete series of odd-electron charge-remote fragment ions of the fatty acid alkyl side-chains allowing unequivocally the localization of double bonds at least in cases where all three fatty acids are identical (see Fig. 1.). Such TAGs are frequently found in oils, where one specific fatty acid occurs in high percentage. Limitations for CID/linked scanning are given due to the fact that for TAG species in such oils (e.g. erucic acid in Crambe oil, see Fig. 2) differing only by one double bond (i. e. a mass difference of only 2u in the mass range m/z 800-1100) the precursor ion mass window is not sufficiently narrow to have single species selection often resulting in mixed CID-spectra of neighboring TAGs. This problem is simply circumvented by prior NARP-HPLC analysis with fraction collection resolving TAGs differing by only one double bond. Another useful CID/linked scanning approach detecting TAG's containing the same fatty acid is given by neutral loss scans at $(B^2/E^2) (E_0 - E) = \text{const.}$, where the link mass is composed of $\text{R}_x\text{COOH}+\text{NH}_3$ ($x = \Sigma$ carbon atoms - 1)

Conclusion. "In-source" CID and various types of CID/linked scans in combination with NARP-HPLC represent powerful tools for structural characterization of TAG mixtures. Extension of the described analytical strategy to on-line LC-MS is actually in progress.

LC/MS/MS Analysis of Peanut Phospholipids

C.A. Haney¹, M. Ruan¹, J.H. Sanford¹, J.A. Singleton²

¹Dept. of Chemistry, NC State Univ. Raleigh, NC

²Dept. of Food Sci., NC State Univ. Raleigh, NC

Our previous work on the characterization of peanut phospholipids has focused on the FAB / MS and LC / FAB / MS analysis of the isolated lipid classes.¹⁻² In this paper, we present the results of the LC / MS / MS experiments on the peanut phospholipid fractions.

Characterization of plant phospholipids requires identification based on class separations plus separation of the individual species in each class.^{3,4} Characterization of phospholipids is difficult; phospholipids represent a minor portion of the total lipids (0.5 to 3.0%) and the separations are complicated.⁵ Class separations are generally carried out with normal phase HPLC while species separations are performed on reversed phase chromatography. Characterization of the fatty acids generally involves hydrolysis, derivatization, and GC / MS analysis.

FAB / MS has been proven to be an excellent choice for the analysis of phospholipids; significant fragment ions are observed in both the positive ion and negative ion spectra.⁶⁻⁷ FAB / MS / MS provides additional structural information and is particularly useful in characterization of the fatty acids both for location of unsaturation and positional substitution on the glycerol backbone.⁸⁻¹⁴ In the analysis of phospholipids isolated from living species, the FAB / MS / MS is complicated by the presence of numerous molecular species differing only by degree of unsaturation of the fatty acid.¹⁰ Precursor mass selection on double focusing instruments is unspecific at these small mass differences making chromatographic separation of molecular species necessary for accurate FAB / MS / MS characterizations.

Electrospray, FAB, thermospray and particle beam have all been used successfully for characterizing phospholipids. MS / MS analysis of phospholipids has been shown using FAB and electrospray ionization of unseparated molecular species for screening purposes.¹²⁻¹⁴

The results presented here demonstrate the selectivity of combined HPLC separations with MS / MS for individual phospholipid molecular species. Structural information about the phospholipid is readily available from full scan MS and CID MS / MS experiments. Ions are observed which define the fatty acid substituents as well as their position of substitution on the glycerol backbone. The class of phospholipid is available from both characteristic low mass ions and neutral losses. Prior to the HPLC / MS / MS experiments these positions could not be assigned with certainty.

IDENTIFICATION OF VERTEBRATE TYPE STEROID HORMONES IN THE SHRIMP *P. JAPONICUS* BY MS/MS AND MS/MS/MS

Ana M. Cardoso, Cristina M. F. Barros, A. J. Ferrer Correia
Departamento de Química, Universidade de Aveiro, 3800 Aveiro-PORTUGAL

INTRODUCTION

The physiological role of "vertebrate type" steroid hormones (Progesterone and male and female sexual hormones) in Arthropods (Insects and Crustaceae) is still unclear.¹ Their recent identification in several species of Crustaceae,² by unequivocal methods (GC-MS), and titre variation during important physiological processes are important perquisites to establish these compounds as invertebrate hormones.¹

We are studying the process of ovary maturation in the shrimp *Penaeus japonicus* in which Progesterone, 17- α -Progesterone and various oestrogen have been implicated.³ The identification of these compounds is usually done by GC/MS and involves several liquid chromatographic purification steps followed by HPLC separation in small groups of steroids, derivatization and GC/MS analysis. On the other hand Tandem Mass Spectrometry is considered to be an alternative technique to GC/MS with the advantage that much less sample pre-treatment is normally required. In this communication we describe the application of this technique to the identification of steroids in a complex mixture.

EXPERIMENTAL

Liophilized gonads of the shrimps were treated with methanol, and the solution filtered. The residue was solubilized in an aqueous solution and passed through a Lipidex⁴ chromatography column and introduced directly into the mass spectrometer. Tandem mass spectrometry analyses were performed in a VG AUTOSPECQ of EBEqQ geometry. The samples and standards were introduced with a direct insertion probe and ionized by EI at 70 eV electron energy and source temperature of 200 °C. First-generation product ion spectra (MS/MS) were obtained by adjusting the magnetic field strength to select the precursor ion (molecular ion) with subsequent scanning of the second electric sector to detect the product ions formed in the 3rd FFR. Second-generation product ions (MS/MS/MS) were obtained by adjusting the magnetic field strength to select the precursor ion (molecular ion), followed by adjustment of the second electric sector to select the first-generation product ion formed in the 3rd FFR, which was then subjected to collision activation with argon in the rf-only quadrupole (65 eV collision energy). The product ions thus formed were analyzed in the quadrupole mass filter.

CONCLUSIONS

From the comparison of the MS/MS spectra of pure steroids and the shrimp sample we can positively identify **Testosterone**, **17 α -Hydroxyprogesterone** and **Pregnenolone** in the extract (exemplified in Fig. 1 for 17 α -Hydroxyprogesterone). For Progesterone, due to the presence of other substances at the same mass-to-charge ratio than the molecular ion, the MS/MS spectra of the sample and standard are quite different. Although we could detect a few peaks due to fragmentation of progesterone, no positive identification based on MS/MS spectra, was possible for this steroid. With MS/MS/MS we increased enormously the selectivity of the analysis because we selected a reaction (314 $\rightarrow$ 191) and analyzed the fragment ions of an ion ($m/z = 191$) which can only be produced by fragmentation of ion $m/z = 314$ in the 3rd FFR of the mass spectrometer. The comparison of the MS/MS/MS spectra provided a positive identification for **Progesterone** in the shrimp *Penaeus japonicus*.

Nonenzymatic Formation of Biologically Active Eicosanoids During Lipid Peroxidation

Lisa M. Hall and Robert C. Murphy

National Jewish Center for Immunology and Respiratory Medicine, Denver, CO

Enzymatic oxidation of arachidonic acid leads to the formation of various products such as prostaglandins, leukotrienes, and hydroxyeicosatetraenoic acids which play important roles as lipid mediators. Recently, nonenzymatically formed compounds isomeric to prostaglandins and leukotrienes, termed F2-isoprostanes, were identified in rat liver after treatment with CCl_4 .¹ One compound, 8-epi $\text{PGF}_2\alpha$, was found to have potent biological activity in models of renal function.² Nonenzymatically formed compounds isomeric to leukotrienes, termed isoleukotrienes, have also been generated during free radical oxidation of 1-palmitoyl, 2-arachidonyl phosphocholine.³ Several isoleukotrienes were found to be biologically active as assayed by the ability to increase intracellular calcium in human neutrophils. We have now expanded the investigation of free radical generated eicosanoids with the *t*-butylhydroperoxide (*t*BuOOH) treatment of red blood cell ghosts to initiate lipid peroxidation.

Lipid peroxidation products have typically been measured by the production of thiobarbituric acid reactive substances (TBARS). These substances arise from the breakdown of oxidized phospholipids to malonyldialdehyde which can then react with thiobarbituric acid forming a complex which has an absorbance at 532nm. This measurement, however, does not yield any information about the initial oxidized products which may possess significant biological activity. We have employed the following approach to investigate the initial oxidized products which result during lipid peroxidation. Following incubation of red blood cell ghosts with *t*BuOOH, the oxidized phospholipids were extracted and then hydrolyzed to free carboxylic acids prior to separation by reverse phase HPLC. Elution of specific products from the HPLC was monitored by UV absorption and electrospray ionization mass spectrometry (Figure 1). Their biological activity was assayed by the ability to increase intracellular calcium in human neutrophils. The chemical structures of the most abundant eicosanoids from peroxidation of RBC ghosts were investigated using tandem mass spectrometry following collision induced decomposition (CID) of the carboxylate anions formed during electrospray ionization. The most abundant product with relevant biological activity was identified as 5-hydroxyeicosatetraenoic acid from the carboxylate anion at m/z 319 (Figure 2). Another abundant product was identified as 5-oxoeicosatetraenoic acid (5-oxoETE) from the carboxylate anion at m/z 317 (Figure 3) and this metabolite was found to have substantially more potent biological activity in the neutrophil calcium assay. This is the first characterization of 5-oxoETE formed in a lipid peroxidation model system. We suggest that this eicosanoid may be important

from the standpoint of its biological activity as well as being a novel marker of lipid peroxidation and free radical injury.

Quantitative and Qualitative Analysis of Albumin in Human Serum Reference Materials

David M. Bunk

Analytical Chemistry Division, National Institute of Standards and Technology
Gaithersburg, MD 20899

To support the standard reference material program at NIST, we are interested in applying ESI mass spectrometry to the determination of proteins used clinically as markers of health status. Unlike the spectrophotometric and immunological methods commonly used in clinical analyses that measure the protein concentration indirectly, mass spectrometry can provide a direct and selective measure of the analyte concentration. Development of this capability will permit the characterization and accurate quantitation of clinically important serum proteins in reference materials, which can then be used to assess the accuracy of the routine methods used in diagnostic assays.

In the exploration of the merits of quantitative ESI-MS of proteins, a quantitative determination of human serum albumin (HSA) in fresh-frozen reference serum produced by the College of American Pathologists (CAP) was performed. Because of the complex nature of the sample matrix, LC/MS with a C_8 reverse phase capillary column was used for the determination of the albumin. The fresh-frozen CAP serum was spiked with an internal standard prepared by derivatizing the protein with a biotinylating reagent. An initial experiment was performed to ascertain the reproducibility of the analyte/internal standard signal ratio from LC/MS. Fifteen replicate injections of the same serum sample spiked with biotinylated HSA (bHSA) yielded an RSD for the HSA/bHSA ion signal ratio of less than 3%.

For the quantitation of HSA in fresh-frozen serum, four standards were prepared along with three bHSA-spiked serum samples. Using the data from all four calibration standards, the HSA concentration in fresh-frozen CAP serum was determined to be 42.0 ± 1.6 g/L (RSD = 3.8%). Using only two calibration points, those producing HSA/bHSA ion signal ratios that bracket the HSA/bHSA ratios observed for the serum samples, a more precise HSA value was obtained: 41.5 ± 1.0 g/L (RSD = 2.3%). The data and results for the 2-point calibration are shown in Table I. The LC/MS quantitation results show no appreciable bias, either from sample-to-sample or from day-to-day. In addition to the HSA determination by LC/MS, a spectrophotometric assay was also performed. The result from the bromocresol purple (BCP) dye-binding spectrophotometric assay of HSA in fresh-frozen CAP serum ($[HSA] = 42.3 \pm 0.8$ g/L) is in excellent agreement with the mass spectrometric result. Overall, the LC/MS method for HSA quantitation demonstrated excellent precision and accuracy, paving the way for more application to clinically relevant proteins.

Freeze-dried serum from CAP was also examined. Freeze-dried sera are more commonly used in clinical laboratories because of their longer shelf-life and greater portability as compared to frozen serum. Upon examination by LC/MS, the albumin in freeze-dried serum was found to be distinctly different from that in frozen serum. The molecular mass profile of the albumin in freeze-dried serum was larger and exhibited more heterogeneity than that in frozen serum. Immunoaffinity chromatography was used to extract the albumin

from the freeze-dried serum; the extracted albumin along with an HSA standard were subjected to digest by CNBr, followed by LC/MS analysis of the digest fragments. Pronounced $\Delta M = +161$ u adducts were found on fragments [124-298] and [447-548] from the freeze-dried serum albumin but were only marginally present in the digest of the albumin standard. This $\Delta M = +161$ u adduct suggests more extensive glycation of the HSA from freeze-dried serum as compared to the HSA standard.

This assumption of advanced glycation was tested by subjecting the extracted HSA to glyco-affinity chromatography. Separation of glycated albumin from non-glycated was accomplished on a glyco-affinity support containing aminophenylboronic acid ligands, which reversibly bind to *cis*-diol groups of glycated proteins. The fraction of the HSA extracted from freeze-dried serum which was retained by the glyco-affinity column had a higher molecular mass and a broader mass profile than the unretained fraction which was, in turn, lower in mass and less heterogeneous than the extracted HSA prior to glyco-affinity chromatography. The results from the affinity chromatography demonstrated that the albumin in freeze-dried serum is substantially more glycated than either the HSA standard or the HSA in fresh-frozen serum.

Structural Characterization of Human Renal Dialysate Protein by mPC-CE-MS/MS

Stephen Naylor^{1,2}, Andy J. Tomlinson¹, James M. Londowski³, and Rajiv Kumar³

¹Biomedical Mass Spectrometry Facility, Department of Biochemistry and Molecular Biology,

²Department of Pharmacology and Clinical Pharmacology Unit, ³Nephrology Research Unit, Department of Internal Medicine, Mayo Clinic, Rochester, MN 55905, USA

A heat labile protein (8-25 kDa) was isolated from the supernatant of sclerosing hemangioma cells derived from a patient with oncogenic osteomalacia and hypophosphatemia. The same protein was also found to be present in the dialysate of patients with end-stage renal failure. The protein inhibits renal epithelial phosphate transport but not glucose or alanine uptake. Approximately 200 liters of dialysate from six end-stage renal disease patients were concentrated down to 600 mL using a cellulose acetate dialyser and subsequently subjected to a series of chromatographic separations. Individual fractions were at each stage of chromatography subjected to bioassay, measuring phosphate uptake in opossum kidney cells. Finally, a reversed phase HPLC fraction which displayed inhibition of phosphate uptake was subjected to capillary electrophoresis-MS/MS analyses.

The active HPLC fraction containing the intact protein was subjected to on-line membrane preconcentration-CE-MS (mPC-CE-MS). A major response was observed at $M_r = 11,729$ Da (shown in Figure 1). Subsequently the protein was subjected to lysine-C endopeptidase digestion (100 mM Tris:HCl, pH 8.4 @ 37° C for 8 hours). The entire digest was then analyzed by mPC-CE-MS, and this is shown in Figure 2. A number of peptides were then analyzed by mPC-CE-MS/MS and a representative product ion spectrum is shown in Figure 3. The sequence data was analyzed using a Sequest program of Yates and the protein was determined to be β_2 -microglobulin, a common kidney component.

This work demonstrates the practical efficacy of mPC-CE-MS(MS) in the rapid characterization of an unknown biologically active protein. At present studies are ongoing to determine if, indeed, the high levels of β_2 -microglobulin are responsible for disabling phosphate uptake in patients.

THERMAL *IN SITU* METHYLATION OF BIOMOLECULES FOR MASS SPECTRAL ANALYSIS

Michael B. Beverly, Franco Basile, Christy Abbas-Hawks, Kent J. Voorhees, and
Ted. L. Hadfield¹

Colorado School of Mines, Golden, CO 80401

¹Armed Forces Institute of Pathology, Washington, D.C. 20306

Recent efforts by the U.S. Army to develop an automated biological agent detector has renewed interest in traditional sample pre-treatment and volatilization, like pyrolysis, prior to mass analysis of the resulting biomarkers. The high polarity and low volatility of cellular components (ie. fatty acids, nucleic acids) represent a challenge if GC-MS or Py-MS is to be used. Derivatization of the sample with a methylating agent prior to analysis can overcome most of these problems. Curie-point pyrolysis/triple quadrupole mass spectrometry with tetramethylammonium hydroxide (TMAH) has been used to conduct *in situ* methylation of the acidic bacterial biomarkers, dipicolinic acid (DPA), nucleic acid bases, and fatty acids¹.

DPA in whole cells of sporulated *B. anthracis* reacted *in situ* during pyrolysis with TMAH to form the dimethyl ester derivative of DPA, dimethyl-2,6-dipicolinate (mDPA)², Figure 1. Nitrogen bases of *B. neotomae* DNA reacted *in situ* during pyrolysis with TMAH to form the methylated bases, Figure 2. Figure 3 shows a comparison of Py-*in situ* fatty acid methylation with TMAH from whole bacteria to a fatty acid methyl ester (FAME) extract Py-mass spectrum.

The feasibility of using Curie-point Py-MS with *in situ* methylation as a rapid method for detecting DPA in sporulated bacteria has been shown with *B. anthracis*. The simplicity of this approach over other methods has been shown by the application of *in situ* pyrolysis methylation in the detection of taxonomically important bacterial fatty acids^{3,4}, and nucleic acid nitrogen bases. The information generated by Curie-point Py-MS with *in situ* methylation by TMAH will facilitate the goal of developing a rapid chemotaxonomic assay for microorganism identification. *In situ* derivatization with TMAH afforded no appreciable sample loss, rapid sample analysis (less than 10 minutes), and an increase in structural information.

Introduction

The measurement of glycated hemoglobin is widely accepted as a valuable indicator for long-term diabetic control [1], and it has been shown that there is a significant reduction in the development of diabetic complications when glycated hemoglobin levels in diabetics are maintained as close as possible to those found in non-diabetics [2]. Several procedures and numerous commercial instruments, mainly based on separation techniques, have been developed for measuring glycated hemoglobin but can yield significantly different results unless carefully calibrated against a reference 'standard'

Glycated hemoglobin is the result of the non-enzymatic binding of glucose to the N-terminal of one of the globin chains [3], and, in some instance, the condensation linking of glucose to a lysine ϵ -amino group. For several years electrospray mass spectrometry has been recognised as one of the tools available for the characterisation of variant hemoglobins [4]. Since glycated hemoglobin chains are separated from the non-glycated forms by 162 Da, the separation of the different species according to mass is a relatively simple exercise.

Methodology

Blood from a sample population of 78 diabetic patients was diluted by a factor of 500 in a solution of 50% aqueous acetonitrile containing 0.2% formic acid. The samples were analysed by flow-injection analysis (10 μ L injections into a mobile phase of 50% aqueous acetonitrile flowing at 10 μ L/min) using a Micromass Quattro II mass spectrometer. The instrument was operated in positive ion mode and for each sample 10 $\times$ 8 s scans were summed from m/z 980-1300. Following baseline subtraction the data were transformed onto a true molecular mass scale using standard software routines. Internal mass scale calibration was performed using the multiply-protonated molecules of the normal α -chain.

Results and discussion

The following assumptions were made in the analysis of the data

- Each globin chain and its glycated form have equivalent sensitivity
- There is no contribution from multiple alkali metal adducts of the unglycated chains at the mass of the glycated chains
- Minor hemoglobin components (e.g. δ -chain, acetylated and pyruvylated chains) may be ignored
- The data sets were corrected to adjust the α -chain and β -chain intensities to be equal as both components should be present in equi-molar amounts in a denatured sample

Figure 1 shows a comparison of the transformed data from three patients showing glycated hemoglobin levels of 5%, 7% and 12%. The increases in the relative intensities of the glycated α - and β -chains (15288 Da and 16129 Da) relative to the non-glycated forms (15216 Da and 15867 Da) are clearly observed. It is the accurate determination of the relative glycation of the globin chains to the free chains that is used to assess the total glycated hemoglobin present in the sample.

Figure 1: Typical mass spectra from patients showing three degrees of hemoglobin glycation

Conclusions

An electrospray ionisation mass spectrometric procedure has been developed for the determination of glycated hemoglobin. Whole blood samples from 78 diabetic and 50 normal subjects (glycation range 4-20%) were diluted 1 in 500 in an acidic denaturing solvent and introduced directly into the ion source of a mass spectrometer. The resulting mass spectra were then processed to estimate the percent glycated hemoglobin present in the sample. The total analysis time including plotting the spectra and computation of the percentage glycation was approximately three minutes. The procedure gave good precision with better than 3.1% CV for inter- and intra-batch analyses. The mass spectrometric results were compared with those from established analytical procedures based on affinity chromatography and gave good overall agreement. The relative glycation of the α - and β -chains was determined directly and shown to be constant (0.64:1) over the glycation range studied. Only single glucose attachment to both the α - and β -chains was observed.

Characterization of Glycated Hemoglobin by Electrospray Ionization Mass Spectrometry.

KP Braun *, JG Pavlovich[§], D Goldstein[¶], R Little[¶], J England[¶], JK Noffsinger[‡], and CM Peterson*. *Sansum Medical Research[‡] Foundation, Santa Barbara, CA; [§]UC Santa Barbara; [¶]Univ. Missouri, Columbia; [‡]Primus Corp., Kansas City, Kansas

Glycated hemoglobin is formed in vivo by the nonenzymatic attachment of glucose to hemoglobin. Hemoglobin A_{1c} is a stable minor hemoglobin variant separated by charge that is composed primarily but variably of glycated hemoglobin, and is used clinically as a measure of long term glycemic control in diabetic patients. However, the structure(s) of the quantified species has not been elucidated, and the available methods lack a reference standard. We used electrospray ionization mass spectrometry (ESI-MS) to determine both the location and extent of glycation of analytical samples as quantified by various chromatographic methods. We compared these spectra to those obtained of a highly purified material that has been proposed as a reference standard for glycated hemoglobin (HbA_{1c}) measurements.

Glycation occurs on both the α and β globin chains of all HbA_{1c} samples analyzed. Higher HbA_{1c} values are consistent with additional glycation, primarily on the β globin chain. The relative proportion of glycated to nonglycated globin chains is significantly different for the samples separated by different methods. Samples obtained after affinity chromatography contained approximately equal proportions of glycated to nonglycated α and β chains. Samples obtained after a combination of affinity and cation exchange chromatography had quite different proportions; essentially no nonglycated β chains were present in the sample, and considerably fewer glycated α chains were present.

Glycation analysis by ESI-MS provides a useful measure of the relative glycation of hemoglobins in diabetic patients. ESI-MS also has potential utility for the structural characterization of various hemoglobins that could serve as clinical references and standards.

Each whole blood sample was analyzed by positive ion electrospray ionization mass spectrometry (ESI-MS) on a VG Fisons Platform II - 8102 mass spectrometer with electrospray attachment and a DEC pc XL560 computer with 540MB hard drive and MassLynx operational software and BioLynx analysis software.

Samples were prepared for initial analysis by desalting using ultrafiltration or dialysis and a 30 kDa cutoff membrane. Samples were concentrated to a volume of 1 mL. A 20 μ L aliquot of sample was introduced to the instrument via a 100 μ L sample loop. Source temperature was set at 55°C and All samples contained 0.1% formic acid to aid ionization. Intact globin chains and single chains attached to heme were observed using this method.

To observe intact heterodimers (α and β chains attached to heme), neutral solvent conditions (H₂O) were employed. The source temperature was set at 90°C, and the capillary and skimmer were set at 2.8 kV and 2 V, respectively. Sample (approximately 50 μ M) was infused onto the system at a flow rate of 20 μ L/min.

Under acidic sample conditions, α and β chains were observed. Patient samples also contained glycated α and β chains. The relative abundance of glycated α as well as β chains correlated with the hemoglobin A_{1c} as measured in clinical HPLC assays. Most important clinically was the observation that in patient samples with high clinical HPLC measurements of hemoglobin A_{1c}, multiple glycation of the β chain was observed. These findings represent a major step forward in the characterization of the glycated hemoglobin species quantified in current clinical assays.

Analysis of the *Haemophilus influenzae* proteome using 2-D and tandem mass spectrometry

Lara G. Hays, [Andrew J. Link](#), John R. Yates, III

Department of Molecular Biotechnology, University of Washington, Seattle, WA 98195

Introduction *Haemophilus influenzae* is a gram-negative bacterium responsible for several human diseases including respiratory infection and meningitis. The 1.83 Mb genomic sequence has recently been completed and 1,743 protein coding regions were predicted. We are using two-dimensional gel electrophoresis (2-D) and tandem mass spectrometry to identify and characterize the proteome or protein content of the cell. We are correlating the predictions from the genome to the authentic gene products expressed under in vivo conditions. 2-D is employed to fractionate and display the proteome, and the relative abundance, isoelectric point, and molecular mass of each protein are precisely measured. The enzymatically digested proteins from the 2-D gel are analyzed using micro-column HPLC and automated tandem mass spectrometry. The amino acid sequences represented by the tandem mass spectra are aligned with the genomic sequence to identify the proteins. Protein processing events that the genomic sequence alone does not predict such as proteolysis and covalent modifications are being identified using the 2-D and mass spectral data. We have identified the most abundant proteins in the proteome and compared the observed physical properties of the proteins to the predicted values. This approach has also been used to identify differences in the proteome of antibiotic resistant and sensitive strains. The differences may be used as biomarkers for identifying antibiotic resistant strains with mass spectrometry as a diagnostic tool.

Methods *Haemophilus influenzae* type strain 33391 bacteria were grown overnight and harvested. Cells were lysed by sonication and proteins solubilized with urea. Insoluble proteins and cellular debris was separated by centrifugation. The first dimension isoelectric focusing was performed with gel strips focusing on pH ranges of 3-10 and 4-7. The second dimension was run on 10% SDS-PAGE. Gels were transferred to PVDF membrane by electroblotting. Proteins were detected by staining with Coomassie Brilliant Blue. Protein spots to be analyzed were cut out, wet, blocked and washed. About 3 spots were pooled for each sample. Spots were digested overnight with the enzyme trypsin. The resulting peptides were subjected to reverse phase micro-column LC/MS/MS. The peptides were eluted off a 10-15 cm reverse phase micro-column using a 0-80% B in 15 minutes (A: 0.5% acetic acid in water; B: 80:20 acetonitrile:water with 0.5% acetic acid). MS/MS were collected using a Finnigan MAT TSQ700 with an electrospray ionization source. Peptide spectra generated were searched against an *H. influenzae* protein database (1,743 sequences) using SEQUEST software. This allowed for identification of proteins in each spot.

Conclusions The analysis of the *Haemophilus influenzae* proteome has been successfully started. Using 2-D electrophoresis and tandem mass spectrometry, the proteins are being identified. 2-D electrophoresis of *Haemophilus influenzae* extracts produced membranes showing 100+ spots with reasonable intensity. We have analyzed 86 of these *Haemophilus influenzae* proteins by tandem mass spectrometry and positively identified 50. The analysis of the MS/MS data by SEQUEST also included searching for modified peptides. We looked for oxidated methionine, phosphoserine, phosphothreonine, phosphotyrosine and phosphohistidine. Modifications found included oxidated methionine and phosphothreonine. The insoluble pellet that remained after

removal of the extract was analyzed by SDS-PAGE. An antibiotic sensitive and resistant strain were run. This produced two significant bands for each strain. The difference in molecular weights of these proteins leads to a possible biomarker. Analysis by tandem mass spectrometry identified both proteins for the antibiotic sensitive strain and one protein for the antibiotic resistant strain.

Identified Proteins Sorted by Function

<u>Amino Acid Biosynthesis</u>	<u>Biosynthesis of Cofactors, Prosthetic Groups and Carriers</u>	<u>Fatty acid and Phospholipid Metabolism</u>	<u>Central Intermediary Metabolism</u>	<u>Cellular Processes</u>	<u>Other</u>
Cysteine synthetase (cysK)	Biotin sulfoxide reductase (bisC)	acetyl-coenzyme A carboxylase (accA)	glycerol kinase (glpK)	replicative DNA helicase (dnaB)	hslUV operon heat shock protein (hslU)

Characterization of Heterogeneity in MHC Class II Peptides using MALDI

Michelle D. Beeson, and Jan Pohl

Microchemical Facility, Winship Cancer Center, Emory University 1365-B Clifton Road, Atlanta, GA 30322

J. Bruce Sundstrom, Kim Jollow, and Aftab A. Ansari

Department of Pathology, School of Medicine, Emory University 1365-B Clifton Road, Atlanta, GA 30322

The rejection of transplanted tissue and organ allografts is mediated by the cognate interactions of antigen receptors on host T lymphocytes with antigenic complexes of peptides, resulting from processed forms of antigens, and major histocompatibility complex (MHC) molecules. These MHC molecules are expressed on the cell surface of donor tissues. It has been proposed that the heterogeneity of antigenic peptides associated with monomorphic MHC molecules of donor origin determines the diversity of allospecificities displayed on donor tissue and thereby dictates the strength of the alloimmune response. The heterogeneity and mass of the expressed antigenic peptides provides insight into the alloimmune response. The study of antigenic peptides associated with MHC Class II molecules has been hampered by the small amounts of biologically derived material that is obtained for biochemical analysis. Previous studies have relied on microbore HPLC to characterize the heterogeneity of MHC peptides, which provides insight into the heterogeneity of the expressed peptides, but not the masses. Methods for obtaining mass spectra of MHC Class I peptides using electrospray and MALDI have been developed. However, electrospray spectra from the complex mixture of biological material obtained can be difficult to interpret. Recent improvements in the sensitivity of matrix-assisted laser desorption/ionization (MALDI) have facilitated the study of MHC Class II complexes using MALDI. Additionally, interpretation of the complex spectra is simplified using MALDI.

In this study we report on the application of MALDI for the determination of mass and sequence diversity among peptides from MHC Class II complexes immunoprecipitated from an Epstein Barr Virus transformed Human B cell line. After purification using an immuno-affinity column, the MHC Class II peptides were further separated using microbore HPLC. The resulting microbore HPLC chromatogram is in Figure 1. The individual fractions were collected, dried, reconstituted in the MALDI matrix solution (α -cyano-4-hydroxycinnamic acid) and analyzed by MALDI. Analysis of the fractions indicated that some fractions contain multiple species. Figure 2 contained a MALDI analysis of a representative fraction. From this preliminary data, we have determined that HPLC analysis does not provide an accurate representation of the heterogeneity of MHC Class II peptides. MALDI, used in addition to microbore HPLC, facilitates the characterization of the MHC Class II peptides, in addition

to providing information on the peptide masses. Future work includes improving the MALDI and N-terminal sequencing of the expressed peptides.

Characterization of Acetaldehyde Modified N-Terminal Peptides of the Hemoglobin Beta Chain. Karen P. Braun¹, James G. Pavlovich², Dane R. Jones³, and Charles M. Peterson¹

¹Sansum Medical Research Foundation, 2219 Bath St., Santa Barbara, CA, 93105;

²Chemistry Dept., University of California, Santa Barbara, 93106; ³Chemistry Dept., California Polytechnic State University, San Luis Obispo, 93407.

Acetaldehyde is the first oxidation product of ethanol *in vivo*. Our earlier showed that with sufficient acetaldehyde, 5 of the 6 possible sites of the peptide pentalysine were modified as a Schiff base¹. However, we were unable to deduce unequivocally which site was unmodified. Lysine residues as well as the amine terminal valine residues in hemoglobin have been implicated as target structures for acetaldehyde adducts resulting from ethanol consumption. Hemoglobin adducts of acetaldehyde have been used clinically as a marker of ethanol consumption but the chemical nature of these adducts remains undefined. As part of our continuing structural characterization of acetaldehyde-protein adduct formation, we studied the peptides Val-His-Leu-Thr-Pro and Val-His-Leu-Thr-Pro-Val-Glu-Lys, from the amine terminus of the β globin chain of hemoglobin, *in vitro*. Both peptides have at least one potential site for adduct formation. In the octapeptide, the N-terminal amine group of Val as well as the ϵ -amine group of the lysine sidechain can potentially be modified by acetaldehyde. We employed electrospray ionization mass spectrometry, carbon-13 nuclear magnetic resonance, and Raman spectroscopy and characterized stable Schiff base acetaldehyde adducts of these two peptides at both reactive sites. The identification of stable Schiff base adducts with the N-terminal peptides of the β -chain of hemoglobin as well as with ϵ amino groups of lysine provides another possible means of monitoring ethanol consumption. The functional implications of these stable Schiff bases remains undefined.

Acetaldehyde adducts were formed by the addition of appropriate volumes of 100 mM acetaldehyde stock solution in water to 1 mM solutions of the appropriate peptide in either water or phosphate-buffered saline (PBS). The mixtures were incubated at 37°C for 1 hour and chilled on ice until purified by reversed phase hplc.

Electrospray ionization (ESI) spectra were obtained using a mass spectrometer (VG Fisons Platform II) equipped with liquid chromatography/mass spectrometry (LC/MS) electrospray ionization source in positive ion mode. Capillary and high voltage lens settings were 2.75 and 0.75 kVolts, respectively. Formic acid (0.2%) was added to each sample to aid in ion formation. A 20 μ L injection of sample was eluted into a 20 μ L/min stream of 50% acetonitrile in water with 0.2% formic acid. Drying gas was maintained at 70°C. Data were acquired over a range of 100-1100 m/z.

The pentapeptide spectrum shows a molecular ion for the native peptide at 566.7 m/z, and the acetaldehyde monoadduct at 592.7 m/z (Panel A). The peak at 608.7 is due to an impurity in the peptide, presumably a hydroxylation of one of the residues. The difference in mass (26 m/z) is consistent with a Schiff base structure for the adduct.

The analysis and characterization of acetaldehyde adducts with blood proteins is a vital component of the ongoing study of the biological effects of alcohol consumption. The modification of blood proteins by acetaldehyde has far-reaching implications for the explanation of some of the physiological consequences of drinking alcohol. Stable Schiff base products may serve not only as markers of ethanol consumption, but also may explain some of the myriad clinical sequelae of ethanol abuse. Further study should reveal preferred binding sites for acetaldehyde in teetotalers, social drinkers, and alcohol abusers.

INTERACTION OF NITRIC OXIDE WITH BIOLOGICAL PEPTIDES

W. Rodney Mathews and Rachel Laskey,
Pharmacia & Upjohn, Structural, Analytical and Medicinal Chemistry,
Kalamazoo, MI 49001

INTRODUCTION

Nitric oxide (NO) is an important biological messenger molecule involved in regulation of immune function, neurotransmission and vascular function. In addition to these physiological roles, NO has been implicated in a variety of human pathologies. The toxic properties of NO have been suggested to be due, at least in part, to the chemical reactivity of this radical species. For example, reaction of NO with superoxide anion results in the production of peroxynitrite anion, a powerful oxidant. The reaction of NO with oxygen also increases its chemical reactivity. Subsequent reactions of these reactive products of NO with biological targets such as DNA, membrane lipids, and proteins may play an important role in the toxicity of NO. We have investigated the reaction of NO (and ONOO) with several biologically active peptides including bradykinin, angiotensin II, and endothelin. These peptides are normally found circulating in the plasma and are likely targets for NO generated by vascular endothelial cells. These peptides were reacted with NO (and ONOO) and the products analyzed by HPLC and a variety of MS techniques.

METHODS

Reaction of peptides with NO, ONOO. Peptides were dissolved in water at 0.1 mg/ml and bubbled with NO (99%) for 20 seconds, and incubated for up to 20 min at room temp. At the end of the incubation, the samples were purged with nitrogen for 5 min and aliquots corresponding to 10 µg starting material were analyzed by RP HPLC. ONOO⁻ was synthesized from H₂O₂ and nitrite using a quenched flow reactor.

HPLC. Modified peptides were subjected to reversed phase HPLC on an ODS column eluted with a linear gradient of 100% A (0.05%TFA/water) to 80%B (0.04% TFA/ACN).

Mass Spectrometry. Low and high resolution FAB MS data was acquired using a VG 70SE with glycerol as the matrix. ESI and tandem FAB MS was carried out by RH Robins and JE Kupstas-Guido at Pharmacia & Upjohn using a Finnigan TSQ-70B.

Bioassays. Bradykinin (Bk) was assayed for stimulation of calcium flux using cardiac valve endothelial cells loaded with fura-2. Endothelin-1 (Et-1) and angiotensin II (A-II) were assayed on isolated rings of rabbit aorta.

RESULTS

Bradykinin. The reaction of Bk with NO was monitored by HPLC. Reaction of Bk with NO resulted in the formation of two new peaks. These new peaks were collected and analyzed by MS. FAB MS revealed that the first peak had a molecular weight 17 daltons less than Bk and the second peak had mass 1 unit greater than Bk. When analyzed by tandem MS, all of the N-terminal sequence ions (a, b, and b-NH₃) were shifted (-17) and (+1) relative to Bk for peak 1 and 2 respectively while C-terminal ions and internal ions were identical to the expected ions for native Bk. These results indicate that the two peptides were modified at the N-terminal. This is consistent with the observation that both peptides failed to give any sequence information when submitted to gas phase Edman sequencing. Reaction of Bk

with NO resulted in a loss of biological activity. Both peaks were inactive when tested for the ability to stimulate calcium influx in cardiac endothelial cells. When Bk was exposed to ONOO⁻, no reaction was detected by HPLC.

Angiotensin II. The reaction of A-II with NO was monitored by HPLC. Two new peaks were collected and analyzed by MS. The results were similar to those seen with modified Bk, i.e the molecular weights were determined to be (+1), and (-17) with respect to native A-II and the tandem MS results confirmed that the modifications were located at the amino terminal. Reaction of A-II with ONOO⁻ resulted in the generation of two new peaks, the first was identical to the (+1) product observed after reaction with NO, the mass the second product (+46) is consistent with reaction of ONOO⁻ with the tyrosine residue to form nitrotyrosine. After reaction with either NO or ONOO, the ability of A-II to contract vascular smooth muscle was significantly reduced.

Endothelin-1. After reaction of Et-1 with NO, the peak corresponding to Et-1 disappeared however no new peaks appeared. Similarly no products could be detected by MS (FAB or PDMS) either before or after HPLC. The ability of Et-1 to contract rings of rabbit aorta was abolished by reaction with NO. The loss of HPLC, MS and biological activity following reaction of Et-1 with NO are most likely due to reaction of NO with the -S-S- groups resulting in formation of insoluble products.

CONCLUSIONS

Reaction of biological peptides with NO resulted in the formation of several new products and loss of biological activity. The α-amino group appeared to be a major site of reaction. A potential reaction scheme is shown below. In the presence of O₂, NO forms nitrous acid which reacts with the α-nitrogen forming an unstable diazonium intermediate. Decomposition of the diazonium intermediate results in loss of N and formation of alcohol (+1) and alkene (-17) products. NO was also observed to react with protein disulfides, however these products could not be analyzed. Peroxynitrite but not NO reacted with peptide tyrosine residues to produce nitrotyrosine.

Membrane Preconcentration-Capillary Electrophoresis-Tandem Mass Spectrometry (mPC-CE-MS/MS) - A Strategy for Sequencing MHC Class I Peptides

Andy J. Tomlinson¹, Richard Gallagher², Peter J. Derrick², Geoffrey W. Butcher³, Simon J. Powis⁴ and Stephen Naylor^{1,5}

¹Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN 55905, USA. ²Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry, UK. ³Department of Immunology, The Babraham Institute, Cambridge, UK. ⁴Department of Biochemistry, University of Dundee, Dundee, Scotland. ⁵Department of Pharmacology and Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN, USA.

Small peptides (~8-10 amino acid residues), that bind to class I major histocompatibility complex (MHC) molecules are essential components of the immune system. These peptides are proteolytic products of endogenous or exogenous proteins that result from cell malfunction or infection. Their presentation to cytolytic T-lymphocytes (CTLs) leads to the destruction of such cells. Therefore, structural characterization of these small peptides could potentially yield improved control of many disease states or infections. This task is formidable since:

*Each MHC class I molecule can bind >10,000 unique peptides,
Peptides are present in low concentration (typically <picomolar),
Only a small number of peptides are antigenic,
Most peptide sequences are currently unknown.¹*

In the current study, we consider all aspects of the challenges to analytical chemistry that have to be overcome to successfully sequence biologically-derived MHC class I peptides including:

*Minimization of analyte losses during extraction and analysis,
Improving CE CLOD by use of membrane preconcentration,
Peptide sequencing of <50 fmol by mPC-CE-MS/MS.*

We have developed a strategy for structural characterization of MHC class I peptides.² Peptides are isolated by two dimensions of chromatography. First reversed phase HPLC, then membrane preconcentration-CE (mPC-CE). Antigenic peptides can be detected by a CTL assay after each stage of chromatography. When CTLs are not available our strategy can be used to detect and characterize peptides that are extracted from normal and diseased cell lines. Antigenic or novel peptides are sequenced by mPC-CE-MS/MS.

In the rat, the transporter genes TAP1 and TAP2 (Transporter associated with Antigen Processing) appear to be necessary for efficient MHC class I antigen presentation. Furthermore, the TAP2 gene in MHC recombinant rats and TAP2 infected cell lines has been found to be polymorphic. This has led to the hypothesis that different peptides are likely to be associated with RT1.A^a-TAP2^a and RT1.A^a-TAP2^u MHC class I molecules. The objectives of these studies was the development of methodology that will enable us to test this hypothesis. RT1.A^a-TAP2^u peptides derived from PVG.R1 rat spleen cells were analyzed by

preparing a cell lysate from ~10 rat spleens and extraction of MHC class I molecules using an immunoaffinity column. After washing, the column was treated with 0.5% TFA to release the extracted MHC class I molecules and bound peptides. The column eluant was reduced to dryness and resuspended in TFA. Peptides were isolated using a 10 kDa. mw cutoff filter and reversed phase HPLC. These fraction were analysed by mPC-CE-MS, which is a technique that enables the analysis of large sample volumes (>100 µL) in narrow bore capillaries.³ Following the removal of acetonitrile from HPLC fractions, samples are diluted with CE separation buffer (to 150 µL) to reduce peptide losses, and 50 µL was analyzed by mPC-CE-MS. The results of these studies indicated the complexity of MHC class I peptide fractions; in excess of 70 peptide responses were detected in a single HPLC fraction. However, the power of mPC-CE-MS is such that it affords the separation of isobaric peptides (Figure 1). Individual peptide responses are sequenced by analysis of the remaining 100 µL of sample using mPC-CE-MS/MS (Figure 2). Peptide sequences are deduced from such spectra by searching protein databases using the Sequest algorithm developed by Yates *et al.*⁴ In our experience this powerful strategy will be further improved as protein databases become more complete. In this example, no rat proteins were returned for the data shown in Figure 2, using the Owl protein database. Manual interpretation of these data has yield a tentative partial sequence of KTXPE or TKXPE (X = L or I). Complete sequencing of this peptide is in progress.

RAPID ANALYSIS OF BASIC AMINO ACIDS BY TANDEM MASS SPECTROMETRY

Donald H. Chace and Steven L. Hillman, Duke University Medical Center
MS Facility, Box 14991, Research Triangle Park, North Carolina 27709

INTRODUCTION

The rapid analysis of neutral amino acids in filter paper blood spots using tandem mass spectrometry has been described at this conference previously (ASMS 93-95) and in several journal articles¹⁻³. A neutral loss of 102 dalton scan function was used to selectively detect α -amino acids in one minute or less. Both liquid secondary ionization and electrospray ionization have been used in these analyses with quantitative results that compare well (ASMS 95). Several inherited metabolic diseases are detected using tandem MS of amino acids including phenylketonuria (elevated phenylalanine), maple syrup urine disease (elevated leucine, isoleucine, valine), and homocystinuria (elevated methionine). Additional neutral loss scan functions (NTL 119, NTL 161) were investigated to detect and quantify several basic amino acids that are elevated in these disorders. Stable isotopically labeled internal standards were developed to quantify amino acids such as ornithine, citrulline and arginine.

EXPERIMENTAL

Ornithine, citrulline, and arginine standards were obtained from Sigma Chemical Co. Isotopically labeled standards, $^2\text{H}_6$ -ornithine, $^2\text{H}_2$ -citrulline and $^{13}\text{C}_1$, $^2\text{H}_4$ -arginine were obtained from Cambridge Isotopes. For quantitative studies, whole blood was fortified with these basic amino acid standards and spotted on neonatal screening filter paper (S&S Type 903). The metabolites present in two, 3/16" blood dot punches were extracted with methanol containing the internal standards and derivatized to butyl esters using procedures described previously¹⁻³. All tandem mass spectrometric analyses were performed using a Micromass (formerly Fisons/VG Organic) Quattro I using fast ion bombardment (FIB). Product ion and neutral loss spectra were acquired in MCA mode using Mass Lynx software.

RESULTS AND DISCUSSION

Product ion spectra for the butyl esters of ornithine (m/z 189), citrulline (m/z 232) and arginine (m/z 231) were obtained. The collision-induced dissociation for these basic amino acids was such that a common neutral loss of 119 selectively detected ornithine, $^2\text{H}_6$ -ornithine, citrulline and $^2\text{H}_2$ -citrulline. A NTL 161 scan function for arginine and $^{13}\text{C}_1$, $^2\text{H}_4$ -arginine resulted in the enhanced sensitivity and specificity of this analysis. Citrulline can also be detected as a de-ammoniated fragment ion (-17) at m/z 215 using a NTL 102 scan function (this scan function detects the neutral and acidic amino acids as described previously^{1-3,4}). A profile of an extract of filter paper blood spots from a normal patient is shown in Figure 1 while a profile for a newborn diagnosed with citrullinemia is shown in Figure 2. Three scan functions were acquired for each of these profiles: a NTL 102, NTL 119, and NTL 161. The NTL 102 scan function is described in previous publications and abstracts presented at ASMS and is presented in the top panels. Citrulline is detected as a de-ammoniated fragment at m/z 215 in newborn with citrullinemia. Endogenous levels of citrulline are not detected using this scan function. A more specific scan function (NTL 119) for citrulline is shown in the middle panels. A clear elevation in citrulline is observed relative to the internal standard in the patient with citrullinemia. Ornithine is also detected using this scan function but is not elevated in this disease. A specific scan function for arginine is observed using the NTL 161 scan function. Endogenous levels of arginine are easily measured, bottom panels. Arginine is not elevated in either of these patient profiles. Linearity data (standard curve), and extraction efficiencies of the analysis for ornithine and citrulline were obtained. The analysis of each amino acid showed good correlation (>0.99) for amino acid enrichments of 0 to 500 μM . The overall extraction efficiency for ornithine was 40% while citrulline was 86%.

SUMMARY

A rapid analysis of basic amino acids of importance in neonatal screening has been described. With the addition of ornithine, citrulline, and arginine, the number of diseases screened using tandem mass spectrometry will expand. This assay, because it incorporates isotope dilution mass spectrometry, can also be used to rapidly quantify these basic amino acids in biochemical investigations. MS/MS in newborn screening applications continues to demonstrate its versatility, sensitivity, and selectivity. Its role in the expansion of metabolic disease screening in newborn screening programs will likely be an important one (see editorial by Larry Sweetman, March 1996 issue, Vol 42 No 3, Clinical Chemistry).

Enhancing Sample Loading in CE-MS Using a Membrane Preconcentration-CE Cartridge (mPC-CE)

Stephen Naylor^{1,2}, Linda M. Benson¹, and Andy Tomlinson¹

¹Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology, ²Department of Pharmacology and Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN 55905, USA

A major perceived limitation of CE-MS is the limited loading capacity of conventional CE capillaries. Typically only 1-2% of the total volume of a capillary can be injected (1-200 nL), otherwise compromised CE performance can occur. Ultimately this limited loading leads to poor concentration limits of detection. We recently reported¹⁻⁷ the use of on-line membrane preconcentration-CE-MS as a means of overcoming this major limitation. The device (Figure 1) consists of a Teflon cartridge containing a membrane impregnated with a suitable adsorptive phase (e.g., C-18 for peptides, C-2 for proteins) sandwiched between two pieces of capillary tubing. The cartridge can readily be inserted or removed from the inlet end of the CE-MS capillary. A common protocol to use the mPC-CE cartridge is (1) activate it using a MeOH/H₂O wash, (2) install onto CE capillary, (3) measure flow rate, (4) apply sample by pressure injection to load and adsorb analytes onto the membrane, (5) wash membrane with separation buffer to effect on-line sample cleanup, (6) elute analytes with suitable organic phase, (7) turn on CE voltage and effect CE-MS analysis.

In order to ensure that no compromise in CE performance is observed, conventional CE chemistries such as analyte stacking (for small organic molecule analysis) Figure 2 and transient isotachopheresis (for biopolymers such as peptides and proteins) Figure 3 are concomitantly carried out. It should be noted that by using a pressurized bomb system, 100-150 μ L sample volumes can be loaded onto the mPC-CE cartridge in <5 minutes. This approach has been used in the analyses of drug/xenobiotic metabolite mixtures, MHC class I peptides and proteins derived from human body fluids such as urine, aqueous humor, plasma, and cerebrospinal fluid and brain dialysate. Using this method CLOD of fg/mL are achievable.

Kyotorphin, the dipeptide Tyr-Arg, is a neuropeptide physiologically synthesized in the brain by a specific enzyme, kyotorphin synthetase,¹ from the two amino acid constituents. In a clinical trial, administration of Arg solution has shown potential benefits for treating various chronic pain conditions due to the presumed Tyr-Arg synthesis in the brain and spinal cord,² and based on the kyotorphin-stimulated release of opioid peptides as analgesic agent, specifically methionine enkephalin (Tyr-Gly-Gly-Phe-Met), from enkephalinergic neurons. Regarding previous *in vitro* studies³ on the mechanism of action, the use of excised tissue and also the application of analytical techniques with poor molecular specificity may be of concerns. Our study was aimed at supporting the role of kyotorphin as a Met-enkephalin releaser *in vivo* in rats by using cerebral microdialysis in combination with mass spectrometry⁴ as a high-specificity analytical technique for the peptides involved.

The animals were stereotactically implanted with a guide cannula reaching the globus pallidus of the brain – a site with high enkephalin-like immunoreactivity. After their recovery from surgery, a microdialysis probe (CMA/12, CMA/Microdialysis, Acton, MA) fitted with a polycarbonate membrane was inserted through the guide cannula into this specific brain location, and kyotorphin was delivered to the freely moving animal through the membrane by perfusing the probe with a 5 nmol/μl solution of the dipeptide in artificial cerebrospinal fluid (CSF) at 2 μl/min flow rate. Under these conditions, about 8% of the perfused peptide entered the extracellular space of the selected brain region. In control experiments, the probe was perfused with artificial CSF only. Aliquots (100 μl) of the effluent collected, that contained the undelivered kyotorphin (in the related experiments) and also the compounds dialyzed from the brain, were desalted by using reversed-phase 1-ml Supelclean LC-18 octadecylsilica cartridges (Supelco, Bellefonte, PA) to remove inorganic contaminants interfering with ESI mass spectrometric analysis. The samples were lyophilized, dissolved in aliquots (100 μl) of deionized water immediately before LC/ESI-MS, and 10 μl of solution was analyzed. Capillary-bore reversed-phase (15 cm x 0.3 mm i.d., 5-μm octadecylsilica, LC Packings, San Francisco, CA) liquid chromatography coupled with electrospray ionization (ESI) mass spectrometry (Quattro, Fisons Instruments, Altrincham, UK) was applied using gradient elution.⁵ Selected-ion monitoring (SIM) of the molecular ion ([M+H]⁺) of Tyr-Gly-Gly-Phe-Met (m/z 574) was performed. The effluent collected during the control experiment contained about 2 pg/μl of Met-enkephalin, which was determined by external standards (injecting Met-enkephalin solutions of known concentration and using the integrated areas, A, under the chromatographic peaks). The dialysates collected from the kyotorphin-perfused probes showed a more than five-fold increase (to 11 pg/μl) in Tyr-Gly-Gly-Phe-Met concentration, compared to control samples (Fig. 1).

In conclusion, *in vivo* cerebral microdialysis combined with LC/ESI-MS has been useful in demonstrating specific peptidergic interactions in localized regions of the brain.

Figure 1. LC/ESI-MS SIM profiles (*m/z* 574) for (a) 1.1 pg/μl Met-enkephalin, (b) microdialysis with artificial CSF, and (c) with 5 nmol/μl Tyr-Arg in rat globus pallidus. (Int. scale: 100=3.53E5).

**Anatomical Features in Biologic Tissue Determined by
Secondary Ion Mass Spectrometry**

Carl A. McCandlish, John M. McMahon, and Peter J. Todd
Chemical & Analytical Sciences Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee 37830

Phosphocholine ions m/z 184 and m/z 86 are almost always abundant in secondary ion mass spectra (SIMS) of animal tissue, and have been previously identified by tandem mass spectrometry (MS/MS). The parent compounds of these ions, mainly phosphatidylcholine and sphingomyelin, are major constituents of animal membrane, particularly in the brain. Often emission of the m/z 184 is heterogeneously distributed across a tissue section. We have taken advantage of this differential emission to correlate secondary ion images with known physiological features. We hypothesize that the distribution of this ion emission corresponds to the density and composition of the membrane. For example, the distribution of neurons and associated cell axons detected in tissue stained with cresyl violet corresponds to the observed distribution of m/z 184 emission. Cresyl violet is a conventionally used anatomical marker that distinguishes neuronal and axonal distribution in brain sections.

Rats and mice were anesthetized with metofane and perfused intracardially with buffered saline (pH. 7.3) followed by a 2% formalin solution (pH. 7.3). Following perfusion, the brain was removed from the skull and later sectioned (50 microns) coronally using a Series 1000 Vibratome Sectioning System. Sections were mounted onto copper slides for SIMS imaging. Images were obtained by 200X200 raster of a 10 keV Cs^+ primary beam over a field of view of 1 cm dia., and measuring the intensity of secondary m/z 184 for each spot on the raster. Alternate (reference) sections were mounted onto glass slides for staining with cresyl violet. Imaging of stained sections was performed by video mounted on a low power microscope.

An example of heterogeneity in secondary ion emission from brain sections is illustrated in Figure 1. A few of the major cell nuclei and axonal tracts are labeled for reference in Figure 1B. A clear relationship is obvious between the m/z 184 secondary ion image and the schematic shown in Figure 1B, which was actually obtained from an adjacent section of the same specimen and stained with cresyl violet. Analysis of m/z 184 ion images indicates that areas of greatest ion intensity are brain nuclei which are cell-rich, whereas areas which have little or no emission are acellular fiber tract sites. That is, emission seems to be greatest from cell bodies, and least from axons, which serve for communication between cells, and when bundled together, between major neurological features. We tentatively attribute this behavior to the fact that phosphatidylcholine resides mainly on the outer membrane of cells, and so is exposed more during the sample sectioning.

The difference in m/z 184 emission could arise from differences in tissue composition, but could also arise from slight changes in the topography of the sample. We addressed this question by examining one of the largest fiber tracts in the brain called the corpus callosum. The corpus callosum is known to be the primary neural axon pathway permitting communication between the

two hemispheres of the brain in all higher vertebrates, including man. The corpus callosum, unstained, was dissected from the surrounding tissue of a section mounted to a copper slide. The results from a secondary ion image of the unstained corpus callosum showed little m/z 184 emission. These results support the notion that the observed secondary ion yield of m/z 184 is not an artifact of tissue preparation or experimental design. Rather, there is a real difference in surface membrane chemical structure and, with that, differences in secondary ion emission.

Another important result is the indication that imaging by SIMS delineates brain structures in a way consistent with known histochemistry. As an emerging tool for biomedical research, it is first necessary that results obtained by SIMS be consistent with known physiology and histochemistry. The correspondence between alternate optical and secondary ion images suggests that successive ion images could be used to produce a 3-D image of the brain. Generation of such an atlas will be necessary for developing the sensitivity and specificity of SIMS, e.g. for trace chemical analysis.

Figure 1A. Secondary ion image (m/z 184) obtained from mouse brain. The variation in secondary ion emission may be caused by the relative exposure of phosphatidyl-choline at the sample surface. Remarkable correlation exists between the secondary ion image and the optical image obtained from a stained section.

OCCURRENCE AND LEVELS OF DIHYDROXY C-18 FATTY ACIDS IN GENERALIZED PEROXISOMAL DISORDERS

James E. Evans, Jacqueline M. Street and Barbara A. Evans
The E. K. Shriver Center, 200 Trapelo Rd., Waltham, MA 02254

Peroxisomes are subcellular organelles that play an important role in a number of lipid and "reactive oxygen" metabolic pathways. The generalized peroxisomal disorders are a group of inherited metabolic diseases in which these organelles are absent or greatly reduced in number and size. Numerous biochemical abnormalities are present due to greatly diminished activity and abnormal subcellular distribution of more than 60 identified peroxisomal enzymes. These include several important enzymes that help regulate levels of reactive oxygen species such as superoxide dismutase, glutathione peroxidase and catalase.

We have reported the excretion of mono-, di- and trihydroxy C-16 and C-18 fatty acids conjugated to glucuronic acid in the urine of a patient with a generalized peroxisomal disorder (1). These were first detected as intense ions at m/z 489 and 505 in negative ion FAB-MS analyses for bile acids in urine from patients. Further investigation revealed that a large number of such conjugated hydroxy fatty acids were present in patient urines. The most prominent species was 9,10-dihydroxy-12-octadecenoic acid glucuronide. We postulate that these compounds result from impaired metabolism of reactive oxygen species or from a block in the metabolism of hydroxylated fatty acids in patients with these disorders.

This report concerns our investigation of the levels of erythro and threo 9,10-dihydroxy-12-octadecenoic and 9,10-dihydroxyoctadecanoic acids in urine and plasma from patients and normal controls.

Urine samples (1 ml) were lyophilized and then methanolized, to free glucuronide and lipid bound hydroxy fatty acids, by heating at 90° for 2 hr with 3 ml of 10% acetyl chloride in methanol-chloroform (1:2). One ml of water was mixed with the sample, the phases separated and the upper phase discarded. The lower phase was washed with 2 ml of 50% methanol. Following acetylation with pyridine-acetic anhydride, the samples were dried and redissolved in isooctane for analysis. Ammonia CI GC-MS was performed on a 30 m X 0.25 mm DB5-MS column with H_2 carrier gas. SIM is used to detect $[M+NH_4]^+$ ions at m/z 432 and 430 for the methyl ester-diacetyl derivative of the saturated and monounsaturated C-18 fatty acids. Concentrations were calculated with respect to external standards of erythro-9,10-dihydroxyoctanoic acid.

Because of the limited volumes available for analysis of plasma samples (0.1 ml), they were analyzed by NCI-GC-MS as their pentafluorobenzyl ester-diacetyl derivatives to achieve higher sensitivity. They were hydrolyzed by addition of 2 ml of 0.5 N HCl in acetonitrile and heating at 100° for 45 min. Since hydrolysis is expected to have converted epoxy fatty acids to dihydroxy fatty acids, values obtained are for the sum of these. Following pentafluorobenzylation with PFBzBr and triethylamine in acetonitrile, the products are extracted into chloroform and washed with water before evaporation and acetylation. SIM is used to measure the $M-181$ ions at m/z 399 and 397 as above.

RESULTS

Levels of Dihydroxy C-18 Fatty Acids in Generalized Peroxisomal Patient and Control Plasmas

	ng/ml			
	Erythro-18:0	Threo-18:0	Erythro-18:1	Threo-18:1
Patient 1	277	444	33	200

Normal control 9	44	38	2	3
Normal control 10	1	9	1	6
Mean	10	19	1	19

CONCLUSIONS

- Elevated urine levels of all four dihydroxy C-18 fatty acids measured were found in all four patient samples examined. Threo-9,10-dihydroxy-12-octadecenoic acid showed the highest elevation (64 fold vs. controls) and highest levels in the patient samples.
- Elevated plasma levels of threo-9,10-dihydroxy-12-octadecenoic acid were found in 4 of 5 patient samples examined. The mean of the patient group was 2.3 fold higher than controls. Levels of the erythro isomer and saturated forms of this compound did not appear to differ from those of controls.
- These elevations of hydroxylated fatty acids may be explained by several mechanisms:
 - They may arise through nonenzymatic oxidation of unsaturated fatty acids by "reactive oxygen species" that may accumulate because of altered activity of peroxisomal enzymes including catalase and peroxidase. Enzymatic processes that utilize reactive oxygen species as substrates could also be activated by increased levels.
 - Peroxisomes may metabolize hydroxy fatty acids and a block in this may result in increased levels. Such a block has been demonstrated for prostaglandin and thromboxane metabolism in peroxisomal diseases.
- Measurement of hydroxylated fatty acids may provide a useful diagnostic tool for peroxisomal diseases.

ACKNOWLEDGMENT

We are grateful to Ann Moser for providing plasma samples from patients used here.

Cardiac Troponin-T Analysis by Immunoaffinity Purification and MALDI Mass Spectrometry

Robert L. Fitzgerald¹, Kenneth D. Harris², Wendy L. Frankel¹ and David A. Herold¹ (¹VAMC-San Diego, Dept. of Pathology, UCSD, CA 92093, ²Scripps Research Institute, La Jolla, CA)

Introduction: Troponin T is a part the troponin protein complex located on the thin filament of the contractile apparatus of striated muscle and is involved in regulation of muscle contraction. Identification of cardiac troponin-T (cTnT) in serum is useful for detecting myocardial infarctions (MI) and for risk stratification of unstable angina patients. Cardiac troponin-T is a sensitive marker of myocardial damage, but its specificity for MI is less than that of creatine kinase MB isoenzyme. The decreased specificity may be due to the ability of cTnT to detect minor myocardial damage or may be caused by a cross reacting substance. For example, cTnT is elevated in chronic renal failure (CRF) patients in the absence of acute MI (1). The clinical importance of determining whether elevated cTnT represents true positivity is emphasized by the fact that many CRF patients eventually die of cardiac disease.

Matrix assisted laser desorption/ionization (MALDI) time of flight (TOF) mass spectrometry has been used to successfully characterize enzymatic digests of proteins (2). MALDI has also been used to identify proteins immunoaffinity purified from complex biological matrices, a procedure that has been termed mass spectrometric immunoassay (3).

Purpose: The purpose of this study was to evaluate immunoaffinity purification and MALDI as an initial step in determining the exact substance causing elevated cTnT in CRF patients.

Methods: MALDI analysis was performed on a Perceptive Biosystems Voyager Elite time of flight instrument in the linear mode. A saturated solution of 3,5-dimethoxy-4-hydroxy-cinnamic acid in 70:30 water/acetonitrile containing 0.1% trifluoroacetic acid was the standard MALDI matrix utilized in these studies. Troponin standards were washed free of buffering salts by centrifugation in a 20 kD molecular weight cutoff filter before MALDI analysis.

Immunoaffinity purification of cTnT was evaluated by spiking a blank serum matrix at cTnT concentrations ranging from 1.9 to 1900 ng/mL. Specimens were then incubated (1 hour or 24 hours) with biotinylated cTnT antibodies and streptavidin coated agarose beads. Following incubation, samples were centrifuged to isolate the cTnT bound to the antibody/bead complex. Specimens were then washed twice with 1 mL of 0.1% Triton X 100 and then with 1 mL of water. Tryptic digestions were performed directly on the cTnT bound to the agarose beads. The digestion was terminated by adding 1 μ L of the beads to a MALDI sample well followed by 1 μ L of the sinapinic acid matrix.

Results: Figure 1 shows the MALDI spectra of undigested human cTnT which had been washed free of buffering salts with repeated aqueous washes in a molecular weight cutoff filter. Two clearly distinct isoforms are apparent at 33.6 and 34.4 kD along with double charged species at 16.8 and 17.2 kD. The amount of cTnT required for a good signal was 0.15 μ g applied to the MALDI plate, much higher than that obtainable from clinical specimens (0.1 to 15 ng/mL).

To improve sensitivity, tryptic digestion was performed on human cTnT. In order to ensure specificity, tryptic digests of two closely related proteins, bovine cTnT and human skeletal TnT were also analyzed by MALDI. Tryptic digestions were evaluated at various times to determine the optimum for digestion. As expected, longer incubation times resulted in a shift to lower mass ions, a 1 hour incubation provided optimum sensitivity. Figure 2 shows the MALDI spectra obtained when 1.5 ng (44 fmols) of the digested cTnT was applied to the MALDI plate.

Immunoaffinity purification and MALDI analysis of serum samples showed that cTnT could be isolated from this matrix at 1900 ng/mL, demonstrating that immunoaffinity purification could be combined with tryptic digestion. However, as concentrations of cTnT were diluted into the physiologic range, interferences masked the cTnT signal. Future experiments are to design methods for analyzing physiologic concentrations of cTnT following immunoaffinity purification and enzymatic digestion.

Analysis of a New Transthyretin Variant Associated with Type I Familial Amyloidotic Polyneuropathy

Toshie Takahashi, Takeshi Kasama*, Satoshi Baba**, Takao Shimizu

Department of Biochemistry, Faculty of Medicine, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, JAPAN

*Lab. Biomed. Analysis, Tokyo Med. & Den. Univ., Yushima, Bunkyo-ku, Tokyo, JAPAN

**Sec. Dep. Pathology, Hamamatsu Univ. Sch. Med., Hamamatsu, Shizuoka, JAPAN

Introduction

Familial amyloidotic polyneuropathy (FAP) is an autosomal dominant inherited type of lethal amyloidosis characterized by progressive sensory, autonomic and motor polyneuropathy. The FAP is usually caused by systemic deposition of amyloid fibrils consisting of a variant transthyretin (TTR) with one amino acid substitution and, to date, about 30 variants of TTR have been described in FAP. In the present study, we applied Frit-FAB LC/MS for the peptide mapping and amino acid sequencing of an amyloid fibril protein isolated from the heart of a Japanese patient of type I (lower limb type) FAP. We identified co-deposition of the variant TTR and normal TTR.

Methods

Amyloid protein of 14kDa, isolated from crude amyloid fibril extracts using RP-HPLC, was digested with trypsin under ordinary condition. Frit-FAB LC/MS of the tryptic digest was carried out using a 0.32 mm I.D. x 150 mm ODS-microcolumn (Nomura Chemical) and a HX-110 mass spectrometer (JEOL). The flow rate of micro-HPLC was 2-3 μ l/min adjusted by pre-column splitting with conventional HPLC pump. The eluted peptides were introduced into the MS through a Frit-FAB interface. HPLC solvent gradient was made by mixing of solvent A (0.1% TFA/0.5% Glycerol/H₂O) and solvent B (0.1% TFA/0.5% Glycerol/CH₃CN). The gradient was controlled by the concentration of solvent B from 5% to 60% through 40min. LC chromatogram was recorded with 214nm UV.

Results and Discussions

Frit-FAB LC/MS revealed that the isolated amyloid protein of this patient is a TTR (or its minor derivative). Protonated molecules corresponding to all but amino acids of the expected tryptic peptide were detected on the LC/MS. We found an extra-peak of probable variant tryptic fragment of T4 (T4', m/z1380). The T4' fragment was 14amu larger than normal T4 fragment

(GSPAINVAVHVFR). It is noteworthy that amyloid fibrils are generally considered to be consisted with only variant TTR even in the heterozygous FAP patients. Interestingly, however, normal TTR was found in no small amount with variant TTR in the present case. This finding may provide some understanding of the molecular basis of amyloidogenesis in FAP. Nowadays, most of protein sequences are deduced from cDNA sequences. It will clearly of interest and important to be able to identify the heterogeneous and/or modified protein in the biomedical materials. In this respect, LC/MS will be the most advantageous technique, particularly when sample amount is limited.

Detection of specific disorders in neonates using tandem mass spectrometry

Michael Morris, Donald H Chace and Steven L Hillman

Micromass UK Limited, Tudor Road, Altrincham, Cheshire WA14 5RZ, UK.
Pediatric Mass Spectrometry Unit, Duke University Medical Center, RTP, NC, USA.

Introduction

In recent years, a considerable interest has grown in the use of tandem mass spectrometry in the analysis of neonatal blood spots for inherited metabolic disorders, specifically for the detection of abnormal levels of acylcarnitines and amino acids [1]. In a typical analysis, two mass spectrometric functions are acquired as full scan data, and the relative intensities of the analyte peaks are inspected either manually or with the aid of automatic spectral analysis software. This method has proved very useful and is in constant use in some half dozen laboratories around the world. However, this method of data collection is less efficient than only monitoring specific fragmentation pathways in the mass spectrometer.

The purpose of this study was to compare the results from both MRM and full scan acquisitions in order to determine the feasibility of using the more rapid technique in a routine fashion. To date, mass spectrometric methods have been validated for the determination of phenylalanine (for PKU) and tyrosine (for tyrosinemia [2], leucine and isoleucine (for MSUD) [3] and methionine (for homocystinuria) [4].

Methodology and Instrumentation

Dried blood spot samples were prepared for analysis according to the butylation method described by Chace *et al* [2].

The tandem mass spectrometry experiments were performed on a Quattro II instrument coupled to a Gilson sampling unit and an Isco syringe pump. MRM experiments were performed by making 5 μ L loop injections into a 50% aqueous acetonitrile mobile phase flowing at 20 μ L/min into the electrospray source of the mass spectrometer. Full scan acquisitions were made from using 10 μ L loop injections into 50% aqueous acetonitrile flowing at 10 μ L/min into the mass spectrometer; two mass spectrometric functions were acquired. 1) Parents of m/z 85 from m/z 200 to 550 in 4 seconds - MCA acquisition for 30 seconds, and 2) Neutral loss of 102 Da from m/z 120 to 300 in 2 seconds - MCA acquisition for 20 seconds. In the multiple reaction monitoring experiments, 52 reaction channels were monitored with a dwell time of 50 ms per channel and an inter-channel delay of 20 ms.

Results

A selection of the reconstructed reaction chromatograms for the analysis of amino acids is shown in Figure 1. As can be clearly seen, the peaks attributable to both the analytes and standards detected are approximately 45 seconds wide. Since the cycle time of the MRM functions for all the species of interest is 3.6 seconds, it would be reasonable to suggest that the flow rate of the analyte into the mass spectrometer may be increased with a concurrent reduction in analysis time. The comparison of two consecutive injections from the MRM sequence, the latter of which was a blank and was the 60th injection in a sequence showed that there was approximately 5% sample carryover in the analyses run under these conditions, and this is also reflected in the analysis of the acylcarnitine metabolites. It is believed that by modifying the injector rinse method that this may be reduced to demonstrate negligible carryover.

Figure 1: Reconstructed reaction chromatograms for key amino acid metabolites

Conclusions

We have used multiple reaction monitoring (MRM) in an exploratory study to test the feasibility of monitoring a large number of analytes simultaneously whilst maintaining the integrity of the results that would be expected from the full scan data. We have demonstrated the possibility of monitoring more than 50 separate analytes in electrospray MRM and yielding quantitative data that may be used in the diagnosis of metabolic disease. The principal advantage of using MRM as opposed to full scan data is the smaller inter-sample time that may be used. The timescale of this experiment compares favourably with the previous inter-sample time of approximately 3 minutes when full-scan data were acquired and is extremely important if this methodology is going to be used as part of a full neonatal screening programme. The other advantage of using MRM analysis is that only specific metabolites may be monitored following validation of mass spectrometric methods for specific diseases - a fact which may, or may not, have medico-legal implications.

DIAGNOSIS OF SULFUR AMINO ACIDS METABOLIC ABNORMALITIES BY AUTOMATED ELECTROSPRAY MS/MS

Rashed MS, Ozand PT, Al-Shahwan S, Al-Saban E, Sakati N, Surendra J, Jishi E
King Faisal Specialist Hospital and Research Center, and Riyadh Armed Forces
Hospital, PO Box 3354, Riyadh 11211, Saudi Arabia

Hypermethioninemia is a biochemical abnormality detected by routine neonatal screening and by MS/MS analysis of blood spots. This abnormality could be due to several genetic disorders such as cystathionine-B-synthetase (CBS) deficiency (associated with homocystinuria and hypocystathioninuria), hepatic methionine adenosyltransferase (MAT) deficiency, tyrosinemia type-1, liver dysfunction and other unknown causes. Hypomethioninemia is caused by a genetic disorder in vitamin B12 metabolism, and is associated with methylmalonic aciduria, homocystinuria and cystathioninuria.

Cystinuria is a genetic disorder of amino acid transport and is associated with the formation of cystine stones, cystinuria, ornithinuria, lysinuria and argininuria. Early diagnosis and management of these disorders is important for preventing or slowing the progression of the disease(s).

We developed an automated ESI-MS/MS method for rapid diagnosis of these disorders from urine spots. The urine spots were punched into individual wells of a standard 96-well microplate. The spots were extracted with methanol/0.05N HCl (4:1). The extracts were transferred to a new microplate, evaporated to dryness, and derivatized by butanolic HCl as previously described for blood samples (1). The samples were injected automatically from the microplate. The mobile phase was acetonitrile/water (4:1) delivered at a flow rate of 17 ml/min, and ramped to 1000 ml/min, between injections. The main rationale behind the method is that in positive ion ESI, CID of the n-butyl derivatives of homocystine, cystathionine, cysteine-homocysteine, yield a common abundant product ion at m/z 190 (see fig 1A). Therefore, precursor-ion scanning m/z 190 was used for selective and sensitive detection of these compounds, which provides the basis for diagnosis of homocystinuria and cystathioninuria. The n-butyl derivative of cystine on CID, yield two abundant ions at m/z 130 and m/z 208 (see fig 1B). A precursor-ion scan for m/z 208 is therefore a rapid, sensitive and specific method for diagnosis of cystinuria. In total, five MS/MS scan functions were cycled through sequentially for a 2.0 min analysis time: precursor-ion scans of m/z 190; precursor-ion scans of m/z 208; precursor-ion scans of m/z 85 for free carnitine and acylcarnitines; two constant neutral loss scans of 102 Da and 119 Da, for neutral and basic amino acids, respectively. The technique as applied provided a simple, rapid and reliable method for the diagnosis of homocystinuria, combined methylmalonic aciduria/homocystinuria, cystathioninuria, and cystinuria.

DIAGNOSIS OF METABOLIC DISORDERS USING AUTOMATED ESI-MS/MS AND COMPUTER ASSISTED DATA ANALYSIS

Rashed MS, Bucknall MP, Little D, Minnie J, Al-Amoudi MS, Awad A, and Ozand PT

King Faisal Specialist Hospital and Research Center, PO Box 3354, Riyadh 11211, Saudi Arabia

Organic acidemias and aminoacidopathies are a group of inherited metabolic diseases that show high incidence in Saudi Arabia, and throughout the middle east. Metabolic profiling of acylcarnitines and amino acids from blood spots by automated ESI-MS/MS is a powerful technique for "broad spectrum" selective, and neonatal screening for a large number of these disorders (1,2).

Using a newly developed 96-well microplate batch process, modifications to the procedures of sample log-in, and an in-house developed computer-assisted metabolic profiling algorithm (CAMPa), allowed us to increase our sample throughput to 600 blood spots/day/instrument.

Initially each "Guthrie" card was affixed with a unique bar code number, and hospitals participating in the program each received batches of unique cards. Upon receipt of blood spots from these hospitals, each card was bar code read by a laser scanner into our patient database program. Samples were then prepared in batches using the convenience of standard 96-well microplates. An in-house built computer-controlled automatic puncher was used to punch one 3/16" circle out of each blood spot (~ 7 µl) into individual wells of the microplate. The puncher software program written in Microsoft Visual Basic created a plate map and transposed it onto the sample list of the mass spectrometer.

The samples were extracted using 100 µl methanolic solution of isotope-labeled internal standards for 30 minutes. The extracts were transferred to a 200 µl U-bottomed vinyl 96-well microplates and evaporated to dryness using an electric hot-air blower. 100 µl aliquots of butanolic HCl were added to the residue in each well. The plate was then sealed with tape, and derivatization was completed by heating 65°C for 15 minutes. The excess reagent was removed by heated evaporation at ~ 50°C using hot-air blower. The whole plate was washed with hexane, dried and residues reconstituted using 125 µl of mobile phase (acetonitrile/water 4:1).

A Jasco autosampler injected the samples directly from the microplate, and a Jasco HPLC pump triggered the start of acquisition by the mass spectrometer (A VG Quattro, Altrincham, UK). During acquisition, flow rate was 17 µl/minute and was ramped to 1,000 µl between injections. The data was acquired in the MCA mode of analysis and each sample data was acquired as a separate file. Four scan functions were sequentially monitored in 1.9 minutes: precursor ions of m/z 85 for free carnitine and acylcarnitines (m/z 210-500); neutral loss of 102 Da for neutral amino acids (m/z 125-300); neutral loss of 119 Da for basic amino acids (m/z 150-300); and neutral loss of 56 Da for glycine and alanine (m/z 120-160).

A sample processing computer program (CAMPa) written in Microsoft Visual Basic was developed, which included a macro to automate data processing, and an algorithm which evaluated the data according to a set of rules defined for particular ions, in each of the scan functions. CAMPa was launched from a dedicated application menu, running under Windows 95. Upon execution, CAMPa initialized for the run by opening a Microsoft Access Database that contained 3 parameter tables as follows: 1) Functions of Diagnostic Interest (FDI): These are the scan functions used. "Low Quality" flags may be set in this table for base peak intensity. Unrecognized masses above a certain threshold ratio to base peak may be flagged as "exception masses". 2) Masses of Diagnostic Interest (MDI): These are masses of diagnostic interest in each scan function which were checked for. If any of these "Must Find Masses" was absent the data file was flagged as "abnormal". 3) Ratios of Diagnostic Interest (RDI): These are selected peak height ratios which are either threshold tested, or range checked. Blood levels were calculated for metabolites for which a stable isotope internal standards were available. Acceptable concentrations ranges were set for these analytes. Maximum thresholds were set for peak height ratios of certain metabolites e.g. propionylcarnitine/acetylcarnitine peak height ratio, and citrulline/tyrosine peak height ratio. An "abnormal" flag was set if the data failed any of these parameters. CAMPa drove the instrument software "Masslynx" to analyze the analog data for each MS function by generating automated key strokes to access functions, smooth data, background subtract, and peak height measurement of centered masses. CAMPa then forced Masslynx to place the table of masses and intensities on the windows clipboard, and then retrieved the data for further automatic processing. As such CAMPa automatically flagged "abnormal" profiles or "low quality" profiles, and allowed either printout of all the data in a set, or only abnormal profiles.

CAMPa was tested by analyzing a data set which consisted of 558 data files, of which 117 were from patients with known metabolic diseases, and 441 neonatal screening samples. CAMPa correctly flagged all the known cases (i.e. 100% sensitivity), and gave 11% "falsely flagged" samples (i.e. 88% specificity). The program has been in clinical use in our metabolic unit for several months during which >8,000 samples were processed. CAMPa correctly flagged >100 new cases in the last six months from sick children and neonatal screening samples. Additional work is underway to ensure the specificity and sensitivity of CAMPa in as many diseases as possible and to broaden the spectrum of the technique. In conclusion, the use of the described 96-well microplates batch process together with the automatic puncher, plate mapping program, automated ESI-MS/MS, and of CAMPa, resulted in a method that is efficient, cost-effective, and is ideally suited for neonatal screening for inborn errors of metabolism.

Microdialysis and GC/MS of NAA/NAAG in Focal Epileptogenesis

Shen-Nan Lin, John M. Slopis, James Willmore, Ian J. Butler, Li Li and Richard M. Caprioli
The Analytical Chemistry Center and the Department of Biochemistry and Molecular Biology
and Department of Neurology
The University of Texas Medical School, Houston, Texas

Epilepsy is a significant public health problem with an estimated incidence of 28.9 to 53.1 per 100,000 population, but its pathophysiology is poorly understood. Microdialysis and GC/MS techniques were used in animal models of focal epilepsy to study the roles of N-acetyl aspartyl glutamate (NAAG) and hydrolytic enzymes which cleave NAAG to N-acetylaspartate (NAA) and the excitatory amino acid glutamate (Glu). The following experiments were performed: 1. Comparison of epileptic electroencephalographic (EEG) responses to focal infusion of the epileptogenic agent bicuculline methyl iodide (BMI) with and without addition of stable isotopically labeled NAAG-d₃ or NAA-d₃. 2. Determination of variance of extracellular NAA concentrations. 3. Injection of NAAG-d₃ to produce changes in extracellular NAA and NAA-d₃.

Male Sprague-Dawley rats were given pentobarbital anesthesia for initial surgery and for sedation maintenance. A 3mm microdialysis probe was inserted into the rat brain amygdala and artificial-CSF (art-CSF) was delivered at 1.2 µL/min. Dialysate samples were collected in glass vials and frozen at -5°C if not immediately analyzed. BMI dissolved in art-CSF was injected into the amygdala via a 220 µm OD syringe tubing tightly attached to the microdialysis probe so the injector was 1.5 mm shorter than the dialysis probe. The distance between the membrane and the injector needle surface was approximately 140 µm. BMI alone or in combination with NAA-d₃ or NAAG-d₃ in varied concentrations was delivered at a flow rate of 9 µL/min for 1 min. Animals were maintained anesthetized by constant infusion of pentobarbital (10mg/ml at 12 µL/min) until 30 minutes before BMI injection. Rats were paralyzed by IP curare as pentobarbital infusion was ended. EEG tracings by a four channel Grass EEG system were analyzed for time of onset and frequency of sharp wave and spike patterns (SWS) as well as evolution into secondarily generalized epileptiform spike wave seizures (SZ). Three 5-min or two 10-min microdialysate samples (flow rate 1.2 µL/min) were collected after the drug injections. Repetitive injections were administered either 45 min or 1 hour apart. The NAA levels measured in two control samples collected before each injection were used to determine baseline NAA levels. The NAA levels in samples collected after drug administration were expressed as % baseline.

EEG tracings from 18 of 19 rats showed SWS patterns following injections of BMI. The time of onset varied with dose quantities and dosing frequency. Not every SWS pattern evolved into SZ complexes. The SZ duration varied between rats depending on dose quantities and dosing frequency. The presence of 1 nanomole of NAAG-d₃ in combination with 600 picomoles of BMI shortened SZ duration time (75, 56, and 17 sec; avg±SE=49±29 sec, 1st dose) compared to control rats (113, 56, 38, and 168 sec; avg±SE=93±59 sec). There is no clear statistical difference due to the broad variance of SZ durations. No differences were observed after the 2nd or the 3rd doses which were separated by 60 min intervals (2nd dose 131±49 vs 140±75; 3rd dose 143±11 vs 140±18). Substitution of NAA-d₃ injection for NAAG-d₃ produced no discernable effect on the epileptiform response.

Fig. 1 shows no changes in extracellular NAA concentrations after focal injection of BMI (200, 300 and 600 picomoles). Among the drug combinations administered, only BMI plus NAA-d₃ (Fig. 2) produced significant increases in extracellular NAA levels over those of control rats.

NAA and NAA-d₃ levels in the microdialysate were analyzed following injection of NAAG-d₃ into the amygdala. Fig 3 shows variability between the 6 subjects in the amount of NAA-d₃ produced, presumably from degradation of the infused NAAG-d₃. Extracellular NAA levels correlate with the amount of NAA-d₃ produced but not with the NAAG-d₃ delivered.

These studies suggest significant biologic variability in hydrolytic enzyme activity and therefore a propensity for seizure between rats of similar genetic characteristics. This concept would also explain variance in seizure duration observed within and between groups of rats treated uniformly with BMI. Currently, we are unable to explain the increase in extracellular NAA with focal injection of NAA-d₃. It is possible that NAA-d₃ could act either as a neurotoxic compound or as a depolarization stimulant when present in high extracellular concentrations but not as a direct epileptogenic agent.

Determination of 1-¹³C]leucine enrichment in muscle proteins using Isotope Ratio Mass Spectrometry

P. Balagopal, G.C. Ford and K.S. Nair
Mayo Clinic, Rochester, MN 55905

Introduction: Advances in biomedical mass spectrometry techniques have made it possible to measure mixed muscle protein synthesis rates in humans. However, measurement of individual muscle protein synthesis rates has been very difficult because of the need for large sample amounts.

We report the application of two GC based methods for measuring 1-¹³C]leucine enrichment in muscle biopsy samples that require less sample than older techniques. All analyses were performed on a Finnigan MAT DeltaS Isotope Ratio Mass Spectrometer (IRMS) with on-line combustion system.

Methods: The first method (Ninhydrin/GC/IRMS) utilized the ninhydrin reaction to liberate the carboxy carbon as CO₂. Leucine (20 - 50µg) was isolated from muscle protein hydrolyzates using HPLC. The ninhydrin reaction was performed in an evacuated 1.5ml autosampler vial. The CO₂ was separated by Gas Chromatography using a Chrompack Poraplot 'Q' capillary column held at 50°C, prior to IRMS (Fig 1). In the second method (GC/Combustion/IRMS), a J&W DB-5MS capillary column was used to separate amino acids from muscle hydrolyzates derivatized as their heptafluorobutyl methyl esters (approx. 25ng leucine injected on-column). The amino acids were passed through an on-line combustion system (oxidation and reduction furnaces held at 960°C and 600°C respectively) prior to IRMS (Fig 2). In addition, these two methods were compared to the traditional ninhydrin method (Ninhydrin/Dual inlet/IRMS).

Quadriceps muscle biopsies were obtained during a primed continuous infusion of L-1-¹³C]leucine given intravenously to human subjects. 1-¹³C]leucine enrichment in mixed muscle protein (MMP) and myosin heavy chain (MHC) was measured.

Results and Discussion: All three methods showed excellent correlation ($r^2 > 0.999$). The differences in the measurement of 1-¹³C]leucine enrichment in muscle protein using the three methods were less than 6%. The precision for the GC methods was 0.0002 atom percent for Ninhydrin/GC/IRMS and 0.0003 atom percent for GC/Combustion/IRMS. A comparison of enrichments obtained by the two GC-based methods of the same sample (biopsies performed at six hours apart) showed good correlation ($Y = 1.0757X - 0.0006$; $R^2 = 0.9253$; P-two tail = 0.19137; n=24; N/S). (Fig 3). The combustion technique required 20-50 times less sample for analysis than the ninhydrin based methods. The GC/Combustion/IRMS method described here increases the potential for studying individual proteins in human muscle like myosin, actin, tropomyosin, mitochondrial proteins, etc. from small biopsy samples. One disadvantage of this technique, however, is the dilution of the ¹³C- label by other carbons in the leucine and those from the derivatizing groups upon combustion. This may determine the optimum interval between biopsy sampling. Using this technique, simultaneous measurement of synthesis rates of MHC and MMP was performed in human subjects (Table 1).

Detecting the *in vivo* Conversion of β -Carotene- d_8 to Retinol- d_4 by APCI-MS and GC/ECNCl-MS

Guangwen Tang¹, Bruce A. Andrien², Gregory G. Dolnikowski¹

¹Jean Mayer USDA HNRCA at Tufts University, 711 Washington Street, Boston MA 02111

²Analytica of Branford, Inc., 29 Business Park Drive, Branford, CT 06405

Introduction

The human body converts dietary β -carotene (β -C) to retinol (Vitamin A). It is important to study the conversion of β -C to retinol because in many developing countries β -C is the primary source of retinol in the diet. Because retinol is homeostatically controlled, blood levels do not increase when β -C is injected. Therefore the conversion of β -C to retinol cannot be studied in humans using unlabeled β -C. To solve this problem we used β -C- d_8 which the body converts to retinol- d_4 , and we have developed an atmospheric pressure chemical ionization mass spectrometry method (APCI-MS) for detecting β -C- d_8 in human serum and a electron capture negative chemical ionization mass spectrometry (ECNCl-MS) method for tracking its conversion in the body to retinol- d_4 .

Experimental

Crystalline all-trans β -C- d_8 (11, 11', 19, 19, 19, 19', 19', 19'- 2H_8 - β -C, 82.0% in all-trans form, 8.0% in 13-cis form, 4.2% in 9-cis form and 3.4% in 15-cis form) in a sealed amber ampoule was provided by BASF (Ludwigshafen, Germany). The purity of β -C- d_8 was checked by HPLC and was 97.5% spectroscopically pure, but it contained β -C- d_7 (15.7%), β -C- d_6 (2.9%) and β -C- d_5 (0.3%).

After an overnight fast, a 47 year-old female volunteer weighing 67 Kg, consumed gelatin capsules containing 235 μ mol of β -C- d_8 in 2 g corn oil with a high fat (30g) breakfast. Serum samples were collected at 0, 1, 3, and 6 hours and at 1, 2, 4, 8, 14, and 21 days after the dose.

The lipid fraction of the serum was extracted using $CHCl_3$ and hexane. The β -C and retinol were isolated using HPLCs equipped with a C30 carotenoid column (YMC Inc., Wilmington, NC), and a Nova-pak C18 column (3.9 x 150 mm and 4 μ m particle size, from Waters, Milford, MA). The purified β -C and retinol fractions were evaporated under N_2 and re-dissolved in 50 μ l of 100% ethanol.

Concentrations of β -C and retinol in a 100 μ l aliquot of serum were measured by HPLC equipped with a Pecosphere-3C C18 column (Perkin-Elmer, CT) and a Waters 994 Programmable Photodiode Array Detector with the wavelength set at 450 nm for carotenoids and 340 nm for retinoids.

A flow injection system was used for β -C- d_8 analysis. The mobile phase of absolute ethanol was pumped through a 0.005" ID PEEK tube by a Waters 6000A LC pump at a flow rate of 1 ml/min. A manual injection valve (Rheodyne, 8125) with a 5 μ l loop (Rheodyne, 8020) was installed between the LC pump and the APCI source. A quadrupole mass spectrometer (Hewlett Packard, 5988) was fitted with an electrospray interface (Analytica of Branford, 102506) and an APCI source cover (Analytica of Branford, 103590). The APCI nebulizer was operated with a pressure of 60 psi of nitrogen supplied from boiling off of a liquid nitrogen cylinder. The temperature of APCI heater and the voltage of capillary exit were optimized at 325°C and 140 V to minimize the fragmentation and thermal degradation of the β -C. The counter current drying gas (also N_2) was set to 200°C at a flow rate of 2.2 L/min. This APCI source used a corona discharge from a needle generated by the following potentials: corona needle = +1350 V, endplate = -2250 V, and capillary = -2650 V. These potentials produced the following ion currents: corona needle = 2.5 μ amps, endplate = 2 μ amps, and capillary = 0.4 μ amps. The MS scan range was 535-550 daltons.

One μ l of derivatized retinol was injected by an HP 7673A autosampler into an HP 5890 GC. The GC employed a cool on-column injector. The on-column injector was fitted with a 1m deacti-

vated fused silica retention gap. The retention gap was connected with an zero dead volume connector (HP part No. 5061-5801) with ferrule (HP part No. 5061-5804) to 15m x 0.25 mm id. fused silica capillary column, coated with a DB-1 stationary phase of 0.1 μ m film thickness from J&W Scientific, Rancho Cordova, CA. The temperature of the column oven and the on-column injector was programmed from 50°C to 285°C at 15°C/min. The GC/MS interface temperature was set at 285°C. Helium was used as the carrier gas. The tert-butylmethylsilyl derivative of retinol eluted at ~7 min. The GC eluate was detected by an HP 5988A quadrupole mass spectrometer, using 0.5 torr methane negative ion chemical ionization. The temperature of the ion source was 200°C. The mass spectrometer was scanned repetitively from 260-280 daltons.

Results

Under APCI conditions, β -C is readily ionized to a protonated molecule with a molecular weight of 537 daltons by proton transfer from protonated ethanol. β -C analyzed by APCI-MS exhibits a linear correlation between concentration and signal response over 3 orders of magnitude. The detection limit was 50 pg of β -C.

The heights of the flow injection peaks are highly variable. The typical coefficient of variation (CV) for three replicate flow injection peak heights is 25%. The peak heights depend to some extent on the speed with which the instrument operator opens the sample loop valve. Fortunately the ratio of peak areas are more reproducible. The typical CV is about 10% in the range of >10% enrichment. Below 5% enrichment, the data are highly variable. Since labeled β -C percent enrichments of >10% were easily achieved, the lack of reproducibility at low enrichment is not a limiting factor in this study.

We measured the naturally occurring isotopes of β -C by integrating the reconstructed ion profiles of m/z values of 537 (MH^+ of β -C- d_0), 538 (MH^+ of ^{13}C - β -C- d_0), and 539 (MH^+ of $^{13}C_2$ - β -C- d_0). Since we did not have a isotopically pure β -C- d_8 standard, we measured the total isotopic enrichment of the labeled β -C in human serum by integrating the reconstructed ion profiles at m/z values of 544 (MH^+ of β -C- d_7), 545 (MH^+ of ^{13}C - β -C- d_7 and MH^+ of β -C- d_8), and 546 (MH^+ of ^{13}C - β -C- d_8 and $^{13}C_2$ - β -C- d_7).

The signal response to various concentrations of the retinol derivative showed a linear correlation over 3 orders of magnitude. The detection limit was 6 pg of retinol MTBSTFA derivative (The total enrichment of labeled retinol was determined by integrating the peak area under the reconstructed mass chromatograms of the negative ions at m/z 271 (d_3), 272 ($d_4 + ^{13}C$ - d_3), and 273 (^{13}C - d_4). The natural abundance of retinol was determined by integrating the peak area under the reconstructed mass chromatograms of the negative ions at m/z 268 (d_0), m/z 269 (^{13}C - d_0), and m/z 270 ($^{13}C_2$ - d_0). The analysis indicated that the enrichment of retinol- d_3 was less than 1%. Therefore, the contribution of ^{13}C -retinol- d_3 to m/z 272 (<0.2%) was ignored. Deuterated retinol enrichment in serum after β -C- d_8 supplementation showed an increase starting at 6 hr and reached a peak at 24 hr with 5.8% enrichment and absolute concentration of 92 nM.

We detected the conversion of β -C- d_8 to retinol- d_4 *in vivo*. The serum enrichment of labeled β -C rose to a maximum of 30.9% in 2 days and declined exponentially thereafter but was still at 18.4% at 21 days. The serum enrichment of labeled retinol rose to a maximum of 5.8% in 1 day and declined exponentially thereafter but was still detectable at 0.9% at 21 days. In serum, the minimum detectable enrichment of β -C- d_8 was 5% using APCI-MS and the minimum detectable enrichment of retinol- d_4 was 0.1% using GC/ECNCl-MS.

Drug Screening of Amines in Biological Matrices with On-line CE/ESI/MS/MS

Kevin Wheeler and Iain Mylchreest

Finnigan Corp., subsidiary of ThermoQuest Corp., San Jose, CA

Kim Lilley and Thomas Wheat

Thermo Capillary Electrophoresis, subsidiary of Thermo Instruments Corp., Boston, MA

Capillary electrophoresis combined with tandem mass spectrometry provides a highly selective method for screening target compounds in biological matrices; however, electrophoretic running buffer systems must be chosen to prevent the suppression of the electrospray ionization process. This example demonstrates the use of a volatile buffer system consisting of a mixture of ammonium acetate, between 50 and 75 mM, and methanol. Figure 1 shows the CE/ESI interface.

A nine component standard mixture of amine-based drugs contained five active components of over-the-counter cough medicines (phenentermine, pseudoephedrine, ephedrine, phenylpropanolamine and chlorpheniramine maleate) and four drugs of abuse (amphetamine, methamphetamine, methylenedioxymethamphetamine, and methylenedioxymethamphetamine). These compounds are efficiently separated by capillary electrophoresis and characterized by

full scan mass spectrometry. However, a potential for misidentification of the cough medicine ingredient phenentermine with the illicit drug methamphetamine exists due to their very similar electrophoretic migration and their isobaric molecular weights (MW 149). In biological systems, this problem is further compounded by individual differences and matrix interferences. To alleviate ambiguity, automated MS/MS experiments were performed to distinguish between components. Figure 2 shows the reconstructed mass chromatograms for the CE/ESI/MS separation of the standard mixture of 9 amine-based components.

When these compounds are present in biological matrices, such as urine, high salt concentrations degrade peak shape and shift migration times (although the relative order of migrations remains the same.)

An ICL procedure was repetitively conducted throughout the CE/ESI/MS/MS run to screen for these target compounds. Each MS/MS experiment was performed in 0.5 seconds and required only 4.5 seconds for all nine compounds, sufficient for repeating several experiments across any one peak.

The results of a typical MS/MS screening run are present in Figure 3. The mass chromatogram of a control urine was compared with that obtained following an oral dose of pseudoephedrine. Four hours after the ingestion of one tablet containing the pseudoephedrine, the urine was collected. The sample was diluted 5x with dH₂O and 164 nL of the sample was injected onto the CE capillary without further sample cleanup.

Figure 4 shows the MS/MS mass chromatogram for an amphetamine-spiked urine. The urine sample was spiked at a concentration of 10 µg/mL amphetamine and 379.5 pg were injected onto the CE capillary column. The resulting MS/MS spectrum was then run in a library search against a user-defined library. The results of the library search verified the presence of the amphetamine.

In conclusion, simple volatile buffers systems can provide effective CE separations and good sensitivity in the CE/ESI/MS signal; CE/ESI/MS/MS can provide stable and reproducible results; CE/ESI/MS/MS provides a highly specific method of identifying amine-based compounds in biological matrices; urine samples were analyzed with no sample preparation beyond dilution with water; CE/ESI/MS/MS had sufficient sensitivity for the direct analysis of pseudoephedrine at typical physiological levels in urine.

Quantification of a New Leukotriene Antagonist (CGP 45715A) in Human Plasma Using Electrospray LC/MS/MS

S. Carlsen, M. J. Hayes and L. Khemani, Bioanalytics and Pharmacokinetics, Pharmaceuticals Div., Ciba-Geigy Corp., Summit, NJ 07901

An analytical method has been developed for the determination of CGP 45715A (the sodium salt of (1R,2S)-(3E,5Z)-7-[1-(3-trifluoromethylphenyl)-1-hydroxy-10-(4-acetyl-3-hydroxy-2-propylphenoxy)-3,5-decadien-2-yl-thio]-4-oxo-4H-1-benzopyran-2-carboxylic acid) in human plasma. The method is based on LC/MS/MS and utilizes the 3,5-undecadiene analog as the internal standard.

A Gilson® ASPEC® XL solid phase extraction system equipped with Varian® Bond Elut® C18 solid-phase extraction columns (3 cc/500 mg) were used during sample preparation. The columns were preconditioned with 6 mL each of water and methanol. Human plasma samples (1 mL) were treated with 2 mL of methanol and centrifuged. The supernatants were loaded onto the columns. The columns were rinsed with 3 mL water and 1.5 mL of 2:1 water/methanol. Then, the analytes were eluted with 3 mL of methanol. A Savant® Speed Vac Plus® was utilized to condense the eluates to 0.5 mL. These were transferred to 0.7-mL autosampler vials and further condensed to 50 µL and sealed.

LC separation was accomplished using a Shimadzu® binary gradient system (two Shimadzu® LC-10AD HPLC pumps controlled by a Shimadzu® SCL-10A system controller) equipped with a Zorbax® XDB-C8 2.1 x 150-mm C18 column. Solvent A was 5% methanol and 0.5% triethylamine in water. Solvent B was 5% water and 0.5% triethylamine in methanol. The flow rate was 200 µL/min. A gradient was done from 20% to 90% B in 1.0 minute.

Daughter ion mass spectrometry was carried out under negative ion electrospray conditions on a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer. The following precursor-to-product ion reactions were monitored

with dwell times of 400 msec: m/z 709 to 491 (CGP 45715) and m/z 723 to 505 (internal standard).

The fragmentation represented a loss of the benzopyran ([M-219]) group for both drug and internal standard. The collision energy was set at 25V. Argon was used as the collision gas at a pressure of 1.2 mTorr. The limit of quantification (LOQ) is 100 pg/mL. Specificity was demonstrated by the lack of interfering peaks at the retention time of the drug and internal standard. Recovery and reproducibility assessments indicate good accuracy, precision and linearity over the validated concentration range of 0.1 to 10 ng/mL. For six QC's at each of four concentrations (0.1, 1, 5, 10 ng/mL) the intra-day accuracy ranged from 90.7% to 111.8%, with CV's ranging from 1.7% to 11.1%. The inter-day accuracy ranged from 94.3% to 102.3% with CV's ranging from 6.2% to 11.4%.

Identification of Flavopiridol (NSC 649890) in Clinical Samples Using Liquid Chromatography/Mass Spectrometry

L. R. Phillips*, W. D. Figg**, D. J. Headlee**, K. Hill*, R. M. Lush**,
E. A. Sausville**, A. Senderowitz**, T. L. Wolfe*, and S. F. Stinson*

*Developmental Therapeutics Program, DCTDC, and **Division of Clinical Sciences,
National Cancer Institute, Bethesda, MD

Flavonoids are widely distributed plant pigments which represent an extremely large class of naturally occurring compounds. Many possess potent biological activity, thus ensuring continued research into these structurally interesting compounds. Isolated from *Amora rohituka* in 1979, rohitukine (**I**) is the first reported example of a naturally occurring chromone alkaloid [1]. This unusual compound possesses antiinflammatory and immunomodulatory properties *in vivo* [2]. The flexibility of the total synthesis of **I** [2] has facilitated the preparation of structural analogs for further SAR study [3]. Flavopiridol (NSC 649890 **II**) is a semisynthetic analog of **I** which has been shown to significantly retard progression through the cell cycle *in vitro*, most notably inhibiting transition from G(1) to S and from G(2) to M [4]. Preliminary studies at the National Cancer Institute have shown flavopiridol to possess potent activity against several human tumor cell lines including those derived from lung and breast carcinoma [5]. In phase I clinical trials, **II** was administered to patients by 72 hr continuous IV infusion. Monitoring the plasma concentration of the drug was accomplished

by liquid chromatography (LC) using electrochemical detection. However, specificity of the method was questioned when it was observed that, upon termination of the drug administration in some of the patients, following an initial decline in the apparent plasma concentration of the drug, levels temporarily and unexpectedly increased before continuing to decline. LC using positive ion thermospray (TSP) mass spectrometric (MS) detection was therefore employed to adequately identify the drug throughout the course of drug administration.

Results and Discussion. Employing LC with positive ion TSP-MS detection, the apparent post-administration increase in plasma concentration of the drug was confirmed. Positive ion TSP-MS is seen to yield essentially only M+H ions with no discernible fragmentation (Figure 1) and the specificity of the method using electrochemical detection was verified. The presence of a single chlorine atom on B-ring of the parent drug molecule allows for easy monitoring for the presence of the drug since the ratio of the ions containing Cl-35 and Cl-37 remains fixed and is not subject to variations in experimental conditions as would fragment ions. Coupled with retention time, a two-ion selected ion detection provides sufficient confirmatory evidence for the presence of the drug. Using 100- μ l samples of plasma, drug concentrations were determined to less than 0.15 μ M (about 5 ng on-column). Examination of the plasma samples by LC with TSP-MS detection clearly demonstrated absence of endogenous components which might interfere with determination of the drug (Figure 2). Improvement in sensitivity (currently 50 ng/ml using a 100- μ l plasma sample) by increasing sample size should be attainable without otherwise modifying the method.

Figure 1 Averaged TSP mass spectrum acquired during the elution of a 0.5- μ g flavopiridol standard by continuous scanning over a mass range of 150-500 u with positive-ion detection.

Figure 2 Liquid chromatograms determined with mass selective detection at m/z 402 and 404. Lower trace is chromatogram of drug-free plasma; middle trace is chromatogram of plasma to which flavopiridol was added at a concentration of 0.15 μ M; upper trace is chromatogram of patient plasma sample which was obtained after the infusion of drug had been terminated. Chromatography was performed at ambient temperature on a 4- μ m Nova-Pak C₁₈ column (15 cm x 3.9 mm I.D.) eluted with acetonitrile-0.05 M ammonium formate buffer, pH 3.0 (45:55, v/v) at a flow rate of 0.7 ml/min. Chromatograms have been offset for clarity.

Identification and Quantification of Spinosad Metabolites in the Fischer 344 Rat using LC/MS.

J. R. Gilbert, D. A. Markham, J.Y. Domoradzki, and A. L. Mendrala.
DowElanco, Indianapolis, IN 46268

Atmospheric pressure ionization techniques have greatly extended the capabilities of mass spectrometry, both in the identification of thermally labile analytes and in the trace quantification of these analytes in complex matrices. Spinosad, a fermentation derived insect control agent, is a mixture of two thermally-labile active components (spinosyn A and spinosyn D). The structure of spinosad is shown at the top of figure 1. Both these spinosyns are were found to undergo extensive metabolism in Fischer 344 rat absorption, distribution, metabolism, and excretion (ADME) studies. The majority of the spinosad metabolites were eliminated in the feces and bile within 24 hours. Much of the spinosad metabolism involved the formation of polar conjugates, which were more thermally labile than the parent molecule.

Using more traditional ionization techniques such as particle beam (PB/MS), probe, and chemical ionization, we were only able to identify a small percentage of the spinosad metabolites. Several of the remaining metabolites represented >10% of the dose, requiring their identification under current EPA guidelines. Through the use of both electrospray (ESI) and atmospheric pressure chemical ionization (APCI) we were able to identify all of the major rat metabolites of spinosad. Much of this metabolism involved the formation of glutathione and cysteine conjugates. A list of all the spinosad rat metabolites that were successfully identified in these studies is shown in Table 1.

Table 1. Spinosad metabolites identified using ESI and APCI

Spinosyn A

- *glutathione conjugate of bi-(N & O)-demethylated spinosyn A
- *glutathione conjugate of N-demethylated spinosyn A
- *glutathione conjugate of O-demethylated spinosyn A
- *glutathione conjugate of spinosyn A
- *bi-(N & O)-demethylated spinosyn A
- *macrolide-hydroxylated spinosyn A
- *cysteine conjugate of O-demethylated spinosyn A
- *cysteine conjugate of spinosyn A
- N-demethylated spinosyn A
- O-demethylated spinosyn A
- parent spinosyn A

Spinosyn D

- *glutathione conjugate of N-demethylated spinosyn D
- *glutathione conjugate of O-demethylated spinosyn D
- *glutathione conjugate of spinosyn D
- *cysteine conjugate of spinosyn D
- N-demethylated spinosyn D
- parent spinosyn D

*compounds that could not be identified without the use of ESI and APCI

As part of these spinosad ADME studies, several metabolites were quantified in excreta and selected tissues. The relative percent of dose in these samples ranged from 13.2% down to 0.004% of the administered dose. Several of these metabolites were present below the limit of detection of conventional techniques (HPLC with fraction collection and ^{14}C counting). A quantitative HPLC/APCI/MS method was developed that allowed the quantification of parent and the target metabolites to the sub part per billion level. Using this method we were able to quantify these target metabolites in all the matrices of interest.

The additional information obtained through the use of ESI and APCI has greatly expanded our knowledge regarding the metabolism of spinosad. The proposed metabolic pathway for spinosad in the fischer 344 rat is shown in Figure 1.

Figure 1. The proposed metabolic pathway for spinosad in the fischer 344 rat.

Characterization and Quantitation of GSH-related Metabolites of 4-Ene VPA in Rat Bile Using LC/MS/MS

Wei Tang and Frank Abbott

Division of Pharmaceutical Chemistry, Faculty of Pharmaceutical Sciences,
University of British Columbia, Vancouver, BC, Canada, V6T 1Z3

Hepatotoxicity of the anticonvulsant drug valproic acid (VPA) is most likely associated with the bioactivation of its P450 metabolite, i.e., 4-ene VPA which is known to induce microvesicular steatosis in rat liver (1). Previous metabolic studies have indicated that 4-ene VPA is further subjected to P450 catalyzed epoxidation to 4,5-epoxy VPA and β -oxidation to (E)-2,4-diene VPA, both of which react with GSH and therefore may disturb cellular GSH stasis (2,3). This report presents an on-line LC/MS/MS identification of new GSH related conjugates of the reactive metabolites of 4-ene VPA. Bile samples collected from male Sprague-Dawley rats dosed i.p. with 4-ene VPA or its [$^2\text{H}_7$]-analog (100 mg/kg) were injected onto a HP Hypersil ODS column (100 x 2.1 mm, 5 μm) interfaced to a Fisons VG Quattro LC/MS/MS instrument using ionspray ionization. The core voltage was 29 V with skimmer offset by 5 V, collision energy 50 eV, collision gas, argon at a pressure of 3.0×10^{-4} mbar, and source temperature 80°C. HPLC mobile phase consisted of methanol/water (0.05% TFA) and the flow rate was 50 $\mu\text{L}/\text{min}$. Comparison of HPLC retention times and MS/MS properties of the putative metabolites with that of authentic reference compounds made available by chemical synthesis confirmed the presence of the biliary cysteinylglycine, cysteine and N-acetylcysteine (NAC) conjugates of 4,5-epoxy VPA and (E)-2,4-diene VPA, respectively, in addition to the GSH conjugates (Fig. 1 and 2). The NAC conjugates were also detected in the urine. Because of structural similarity among conjugated metabolites, the selected ion transition for each metabolite was not exclusive. For example, the transition m/z 448 $\rightarrow$ 162 selected for the monitoring of 5-GS-3-ene VPA could also be derived from 5-GS-4-hydroxy VPA lactone (Fig. 1). Thus, HPLC was developed such that no overlapping of peaks occurred among those metabolites which may potentially produce common fragments of interest. Quantitatively, the GSH and cysteinylglycine conjugates made up 45% and 40% of the biliary mercapturic acid pathway metabolites, respectively. Relatively larger amounts of the cysteinylglycine conjugates found in the bile conceptually contradict the assumption that these primary metabolites of the GSH conjugates are formed and degraded in the kidney or small intestine. This observation is novel for 4-ene VPA metabolism in terms of degradation of the GSH conjugates to the corresponding mercapturic acids occurring in the liver (4). Overall, the detected mercapturic acid pathway metabolites accounted for 5% of the dosed 4-ene VPA. In addition, the GSH- and NAC-glucuronide di-conjugates of (E)-2,4-diene VPA were identified as the biliary metabolites with the GSH-glucuronide di-conjugate being 10% of the corresponding mono-GSH conjugate. Di-conjugation occurs most likely via the glucuronidation of (E)-2,4-diene VPA "leaked out" from mitochondria followed by GSH conjugation of the glucuronide ester in the cytosolic compartment. The results provided insight into the GSH dependent metabolism of the hepatotoxicant 4-ene VPA in rat liver.

Comparative LC/MS/MS Studies of the Metabolism of 4-Ene VPA and Its Fluoro-analog in Rat Hepatocytes

Wei Tang¹, Malle Jurima-Romet², and Frank Abbott¹

¹Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC, Canada V6T 1Z3 and ²Health Protection Branch, Health Canada, Ottawa, ON, Canada, K1A 0L2

One hypothesis for the hepatotoxicity of the anticonvulsant drug valproic acid (VPA) is β -oxidation of the P450 metabolite 4-ene VPA to form reactive species (1,2). We report herein the LC/MS/MS investigation of 4-ene VPA metabolism in rat hepatocyte incubations. The α -fluorinated 4-ene VPA analog, α -F-4-ene VPA, was included for comparison. To primary cultures of hepatocytes isolated from male Fisher 344 rats (175-225 g, Charles River, PQ) was added aqueous 4-ene VPA or α -F-4-ene VPA (pH 7.2, final conc.: 10 μ M - 20 mM). In some cases, hepatocyte GSH was depleted by buthionine sulfoximine (BSO) treatment (final conc.: 2 mM) prior to drug challenge. After incubation with drug for 24 h, aqueous VPA-Gln (50 μ L, 5 μ g/mL, internal standard) was added to the hepatocyte cultures. The mixture was acidified to pH 3.0 with hydrochloric acid and subjected to clean-up by solid phase extraction (C₁₈ cartridge). The resulting sample (2 μ L) was injected onto a HP Hypersil ODS column (100 x 2.1 mm, 5 μ m; mobile phase: methanol/water, 0.05% TFA; flow rate: 50 μ L/mL) and analyzed by LC/MS/MS (Fisons VG Quattro tandem mass spectrometer; ionspray; collision gas: argon at a pressure of 3.0×10^{-4} mbar; collision energy: 50 eV; source temperature: 80°C). The metabolites of interest were identified in MRM mode by comparing their LC/MS/MS properties with that of synthetic reference compounds. Quantitation was obtained by comparing the intensities of the MS/MS responses of the metabolites to those obtained from known amounts of injected standard compounds. At a concentration of 10 μ M, metabolism of 4-ene VPA in hepatocyte cultures produced 5-GS-3-ene VPA with no indication of 5-GS-4-hydroxy VPA lactone. When the concentration of 4-ene VPA was increased to 100 μ M, 5-GS-4-hydroxy VPA lactone became a major metabolite (Fig. 1). These results indicate that β -oxidation takes place preferentially when concentrations of 4-ene VPA are low, but the capacity of this pathway is saturated at high levels of the drug and the metabolism shifts to the P450 mediated pathway. BSO treatment had a drastic effect on the degree of GSH conjugation, resulting in 2 - 4-fold decreases in the formation of 5-GS-3-ene VPA. The decrease in formation of 5-GS-3-ene VPA in BSO treated cultures suggests that the addition of GSH to 2,4-diene VPA is limited by the available mitochondrial GSH. Assuming that treatment by BSO had no effect on the β -oxidation of 4-ene VPA, the reactive form(s) of (E)-2,4-diene VPA, which would otherwise be detoxified via GSH conjugation, may attack critical bio-macromolecules to induce liver injury (3). Under similar conditions, neither 5-GS-3-ene VPA nor 5-GS-4-hydroxy-2-fluoro VPA lactone were detected in hepatocyte cultures involving α -F-4-ene VPA, rather, its glutamine conjugate was identified (Fig. 2). Using LDH leakage as an index, the cytotoxicity of 4-ene VPA (1 μ M) was apparent in hepatocytes depleted of GSH by BSO, whereas α -F-4-ene VPA was estimated to be 100-fold less cytotoxic. The data suggest that the β -oxidative pathway plays a major role in 4-ene VPA hepatotoxicity.

Studies on the Glutathione-Dependent Bioactivation in Rats of Sevoflurane Degradate "Compound A"

Lixia Jin, Margaret R. Davis, Evan D. Kharasch, George A. Doss and Thomas A. Baillie
 Department of Medicinal Chemistry, University of Washington, Seattle, WA 98195
 Department of Drug Metabolism, Merck Research Laboratories, West Point, PA 19486

Fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether, commonly referred to as "Compound A", is a breakdown product of the inhalational anesthetic sevoflurane. Compound A is nephrotoxic in rats, but the underlying mechanism remains unclear. The structural similarity of Compound A to several known nephrotoxic haloalkenes suggests that metabolism *via* glutathione (GSH) conjugation and the cysteine conjugate β -lyase pathway may play a role in mediating the renal toxicity of Compound A. The present studies were carried out to investigate this hypothesis.

By means of ionspray LC-MS/MS, a total of four GSH conjugates (A1-A4) were detected in the bile of rats dosed with Compound A. A1 and A2 were identified by MS and NMR spectroscopy as two diastereomers of *S*-[1,1-difluoro-2-fluoromethoxy-2-(trifluoromethyl)ethyl]glutathione, while A3 and A4 were identified as (*E*)- and (*Z*)-*S*-[1-fluoro-2-fluoromethoxy-2-(trifluoromethyl)vinyl]glutathione, respectively. Quantitative analyses indicated that approximately 29% of the administered dose of Compound A was excreted into bile in the form of the above GSH conjugates over a period of 6 hours. Studies conducted *in vitro* demonstrated that the reaction of Compound A with GSH was catalyzed by both rat liver cytosolic and microsomal glutathione *S*-transferases (GST), with the two enzyme systems exhibiting different product selectivities. Formation of these GSH conjugates also occurred nonenzymatically.

The presence of the corresponding Compound A-mercapturic acids was confirmed by MS/MS analyses of urine of rats treated with Compound A. Aminoxyacetic acid, a competitive inhibitor of renal cysteine conjugate β -lyase, was shown to partially protect animals from Compound A-induced diuresis and proteinuria.

These results indicate that spontaneous and enzyme-mediated conjugation with GSH represents a major pathway of metabolism of Compound A in rats. Conjugation of Compound A with GSH *in vivo* appeared to be catalyzed preferentially by microsomal rather than cytosolic GST, based on comparison of biliary, microsomal and cytosolic metabolic profiles. Compound A-GSH conjugates were metabolized further to the corresponding cysteine conjugates and cleavage of these cysteine conjugates by renal cysteine conjugate β -lyase may lead to the formation of reactive acylating agents, which would be expected to bind covalently to cellular macromolecules and cause organ-selective nephrotoxicity.

Antibiotic Resistance: Novel Rearrangement Reaction Characterized by LC-MS and LC-MS-MS*

K.P. Bateman^{1,2}, K. Yang², P. Thibault¹, R.L. White², L.C. Vining² ¹Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, Nova Scotia, Canada, B3H 3Z1; ²Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J3

Antibiotics of the streptogramin B group are macrocyclic peptidolactones in which an N-terminal threonine is N-acylated with 3-hydroxypicolinic acid and esterified via its 3-hydroxyl group with a C-terminal phenylglycine or phenylsarcosine [1]. Type B-I streptogramins have six amino acids; etamycin (Figure 1) with seven amino acids is a type B-II streptogramin. The streptogramins inhibit most major Gram-positive and some Gram-negative bacterial pathogens, and for over 25 years have been used in the treatment of *Staphylococcal* infections in humans [2].

Figure 1. The structure of etamycin.

The development of resistance to virtually all of the older antibiotics by members of the *Streptococci*, *Staphylococci*, *Enterobacteriaceae*, and *Pseudomonas* families has created a need for effective new antibiotics [3]. An understanding of the antibiotic resistance mechanisms in bacteria is critical for a rational approach to the design of such drugs [4].

During the course of experiments aimed at cloning an etamycin resistance gene from an etamycin producer, we detected enzyme-catalyzed inactivation of etamycin in the cloning host, *Streptomyces lividans*. The products of the enzyme-catalyzed reaction were characterized by LC-MS, LC-MS-MS and proton NMR spectroscopy. Reaction of the antibiotic etamycin in 1.0 M NaOH gave a mixture consisting of the product expected from hydrolysis of the lactone bond and a product corresponding to that from the enzyme reaction. Experiments with O-18 water showed incorporation of label into the base hydrolysis product. No incorporation of isotope was observed in the product or substrate when the enzyme-catalyzed reaction was carried out in O-18 water. The LC-MS analyses of etamycin, and its enzyme and base reaction products are shown in Figure 2.

*NRCC# 39710

The characterization of the inactivated product supports lactone ring scission by a rearrangement reaction, in contrast to the hydrolysis route previously reported for streptogramin B antibiotics [5]. The generality of this enzyme inactivation mechanism was demonstrated by the formation of linear dehydrobutyryne peptides from other streptogramin B antibiotics.

Figure 2. LC-MS analysis: TIC's and extracted mass spectra (shown as inserts). (a) Etamycin (15.6 min). (b) Enzyme-catalyzed reaction product (extracted mass spectrum for product at 13.0 min). (c) Base-catalyzed reaction product (extracted mass spectrum for product at 12.1 min).

Free Radicals In Tamoxifen Metabolism: Study By On-Line HPLC-Electrospray MS

Russell M. Jones*, John H. Lamb, Adrian Davies, Ian N.H. White, Chang Kee Lim and Lewis L. Smith.

MRC Toxicology Unit, Hodgkin Building, University of Leicester, P.O. Box 138, Lancaster Road, Leicester LE1 9HN, U.K.

Introduction

Tamoxifen [2-(1-(4-(2-(dimethylaminoethoxy)phenyl)-1,2-diphenyl-1-butene)] is widely used in the treatment of breast cancer and is currently undergoing clinical trials as a possible chemopreventative agent for women with a higher than normal risk of developing the disease. Tamoxifen has been shown to cause hepatocellular tumours in rats following prolonged feeding experiments and there is an apparant causal relationship between DNA adducts and the developement of liver tumours¹. The metabolism of tamoxifen has been studied previously, but detailed analysis of metabolites has only been possible with the development of "on-line" HPLC-MS systems. The exact nature of the reactive metabolite responsible for DNA and protein binding *in vivo* has not been fully identified, although several metabolites have been proposed. Recent studies have reported several possible routes for the formation of DNA adducts from tamoxifen, via alpha-hydroxytamoxifen², 4-hydroxtamoxifen³ and arene oxides of tamoxifen⁴. This work describes the study of tamoxifen and its metabolism using "on-line" HPLC-electrospray ionisation mass spectrometry (HPLC-ESI MS) and evidence for new reactive metabolites derived from a free radical mediated reaction.

Experimental

Microsomal incubation. Rat microsomes were incubated with tamoxifen or 4-hydroxytamoxifen in the presence of NADPH and MgCl₂ at 37°C for 30 min in the dark. Reaction was terminated and extracted with DMSO:methanol (1:4 v/v) and the resulting metabolites analysed by on-line HPLC-ESI MS.

Horseradish peroxidase incubation 4-Hydroxytamoxifen was incubated with Horseradish peroxidase in the presence of hydrogen peroxide at 37°C for 5 min in the dark. Reaction was terminated and extracted with DMSO:methanol (1:4 v/v) and the resulting products analysed by on-line HPLC-ESI MS.

On-line HPLC-ESI MS. A varian Associates liquid chromatograph was connected to a VG Quattro BQ electrospray MS (VG Organic, UK) system operating in positive-ion mode. Separation was performed on a 5 µm 25 cm x 4.6 mm Hypersil BDS column (Hypersil, UK) with 0.5 M ammonium acetate in methanol (25:75 v/v) as mobile phase at a flow rate of 1 ml/min. The effluent from the HPLC column was split 1:6 before entering the electrospray ion source. Source temperature was 150°C and continuum data was aquired over the mass range of m/z 300 to 500, at a scan rate of 2 sec.

Results

"On-line" HPLC-ESI MS analysis of the incubation products of rat liver microsomes with tamoxifen has shown that in addition to N-demethylation, N-oxidation and ring-hydroxylation, two arene oxides

have been detected. These two metabolites have also been detected following activation of tamoxifen by horseradish peroxidase system. Studies on the activation of 4-hydroxytamoxifen by horseradish peroxidase have demonstrated the formation of two compounds with m/z at 773 and 1159, values consistent with dimers and trimers of 4-hydroxytamoxifen. Further analysis of these compounds by on-line HPLC-ESI MS have shown that there are 2 major isomers of the dimer which are more hydrophobic than tamoxifen. Several isomers of the trimeric compound have also been detected, which are more hydrophobic than the dimers. *In vitro* microsomal metabolism of tamoxifen and 4-hydroxytamoxifen has shown the production of similar dimeric compounds, in lower quantities than with horseradish peroxidase. The levels of dimer are higher from 4-hydroxtamoxifen than tamoxifen. Preliminary "on-line" HPLC-ESI tandem MS studies of the ion at m/z 773 have confirmed that the dimeric metabolites are tamoxifen derived.

Conclusions

The metabolism of tamoxifen has been further studied by the application of "on-line" HPLC-ESI MS. The formation of two arene oxides have been detected which have been shown to react with DNA to produce adducts⁴. In addition, it has been demonstrated that both horseradish peroxidase activation of 4-hydroxytamoxifen and *in vitro* microsomal metabolism of tamoxifen and 4-hydroxytamoxifen lead to the formation of dimers of 4-hydroxytamoxifen. The formation of these dimers of 4-hydroxytamoxifen can be explained by a free radical mediated reaction, leading to polymerisation. The fact that *in vitro* microsomal activation leads to a greater amount of dimer formed from 4-hydroxytamoxifen than tamoxifen, suggests that 4-hydroxtamoxifen derived from tamoxifen *in vitro* is first activated by a free radical mediated reaction, resulting in phenoxy- or carbon centred radicals, which can then either react with DNA or with themselves. Recent work has shown that DNA adducts could be formed directly from 4-hydroxytamoxifen by both *in vitro* microsomal and horseradish peroxidase activation³. However the true identity of the active metabolite responsible for DNA damage *in vivo* still requires further work.

Combining the high resolution of HPLC with the sensitivity and specificity of MS has provided a powerful technique for the study of drug metabolism, allowing identification of previously undetected metabolites.

Mass Spectrometric Investigations of Quinone/Amino Acid Interactions

*C.H. Oberth and A.D. Jones, Facility for Advanced Instrumentation,
University of California, Davis, CA 95616

Quinones are important natural products, synthetic food additives, therapeutic drugs, and metabolites that can initiate modifications of amino acid side chains in proteins and cytotoxicity. Mechanisms of quinone toxicity are complex and can involve covalent attachment to nucleophilic groups, quinone-mediated side-chain oxidations, and/or crosslinking through disulfide bridges or through addition of more than one side chain to the quinone. In previous experiments, we demonstrated the effective use of flow injection ESI MS for identification of amino acid/quinone adducts. In some ESI spectra, ions were displayed corresponding to dimers and it was unclear whether these were products of covalent attachment or non-covalent dimers formed during ionization. HPLC/MS using atmospheric pressure chemical ionization (APCI) is an alternative ionization technique that can be compared with ESI, LC separation allows for isolation of covalent dimers from monomers before introduction to the ion source.

The aim of this study is to demonstrate 1,2-naphthoquinone cross-linking by formation of covalent bonds with two nucleophilic amino acid side chains, or alternatively by formation of cysteine disulfides through oxidation by the quinone moiety. In addition, we compare the performance of loop injection ESI MS to HPLC/APCI MS for these analyses.

To perform these experiments, HPLC purified N-acetylcysteine/naphthoquinone mono-adduct was reacted with equimolar amounts of N-acetylcysteine or t-BOC-histidine. Parallel experiments were conducted under ambient or N₂ atmosphere to rule out any oxidation due to exposure to oxygen.

All mass spectra were acquired using a VG Quattro-BQ triple quadrupole mass spectrometer. Electrospray spectra were obtained by loop injection of analyte. The solvent system (1:1 acetonitrile:water v:v) was delivered to the ionization source at a flow rate of 5 μ L/min. Approximately 60 nmol were analyzed so that minor reaction products could be observed. All spectra were run in positive mode using multichannel acquisition. LC/APCI spectra and ion chromatograms were obtained by direct coupling of an HPLC pump fitted with a C-18 reverse phase column. Isocratic mobile phases were employed of composition: 29.75% acetonitrile, 69.75% water, 0.5% acetic acid for positive mode APCI, and 30% acetonitrile, 70% water for negative mode APCI analyses. The flow rate was 0.25 mL per minute. Approximately 120 nmol analyte were injected per experiment. All APCI spectra were acquired in centroid mode.

The structures of the products observed in this study are listed in Figure 1. Nucleophilic side chains on amino acid residues such as cysteine and histidine react with 1,2-naphthoquinone via Michael addition, which yields a hydroquinone product. If oxidants such as O₂ or other quinones are present, these hydroquinones can undergo 2-electron oxidation to yield quinones, which may react further. Oxidation followed by another nucleophilic addition is crucial for quinone/protein cross-links to form. The positive mode electrospray spectrum shows evidence for this in the form of a peak at m/z 575, [M+H]⁺ corresponding to addition of one N-acetylCys and one t-BOC-His to 1,2-naphthoquinone. Confirmation that this is a covalent attachment comes from the positive

APCI ion chromatogram and the negative APCI ion chromatogram (m/z 573, [M-H]⁻). In addition, the cross-linked product ion NAcCys/NQ/NAcCys was observed in the negative APCI ion chromatogram (m/z 481, [M-H]⁻), but was not detected in positive ion modes using either ESI or APCI. An oxidant must be present for formation of disulfide cross-links. Quinones can oxidize pairs of cysteine sulfhydryl groups to form disulfide linkages. Disulfide formation was observed even in experiments conducted in an N₂ atmosphere. Control experiments performed without addition of the N-acetylcysteine/naphthoquinone mono-adduct did not show measurable disulfide formation or presence as a pre-existing impurity in either ambient or N₂ atmospheres. Evidence of disulfide formation is shown in ESI+ spectrum as protonated NAcCystine (m/z 325) and in the negative APCI ion chromatogram (m/z 323, [M-H]⁻). Additional evidence of the formation of reactive oxidants can be seen in the negative APCI ion chromatogram (m/z 270, [M-H]⁻) which represents hydroxylated t-BOC-histidine.

These experiments illustrate how LC/APCI MS complements flow injection ESI/MS. For all compounds used in this study, electrospray ionization was more sensitive than APCI and yielded profound improvements in signal-to-noise. ESI cannot distinguish between covalent Michael adducts and cluster ions however, and prior separation by HPLC becomes necessary. The combination of techniques afforded confirmation of formation of a covalent di-adduct.

APCI/MS AND MS/MS FOR THE STRUCTURAL ANALYSIS OF TOCOPHEROLS AND THEIR OXIDATION PRODUCTS

Thomas D. McClure and Daniel C. Liebler

Southwest Environmental Health Sciences Center, Department of Pharmacology and Toxicology, College of Pharmacy, University of Arizona, Tucson, AZ 85721

Introduction:

Randomized controlled trials have shown that Vitamin E (α -tocopherol, TH) plays a role in preventing atherosclerosis, presumably via inhibition of oxidation of low density lipoproteins(1). The antioxidant effect of TH is believed to result from peroxyl radical trapping. Evidence for the antioxidant effects of TH is obtained by studying reaction products in the form of tocopherolquinone (TQ) and epoxyquinones (TQE1 and TQE2). Figure 1 shows the structure of TH and its oxidation products and oxidative pathways(2). These compounds are thermally labile and are typically analyzed by GC-MS as the trimethylsilyl ethers. We have developed LC-MS and MS/MS methodology to simplify product identification and quantification of TH and its oxidation products.

Figure 1 Oxidation products and pathways of α -Tocopherol

Methods

The TH (R,R,R, α -tocopherol) used was a gift of the Natural Source Vitamin E Association (Excelsior, MN). The oxidation products TQ, TQE1, TQE2, and THQ were synthesized from TH by oxidation with peroxyl radicals [generated by thermolysis of azobis(2,4-dimethylvaleronitrile) in oxygen saturated acetonitrile at 50 deg.] for 120 minutes. The oxidation products were purified by reverse-phase HPLC. All studies were done using a Finnigan TSQ 7000 triple quadrupole mass spectrometer equipped with an APCI source and DEC alpha computer. Source conditions: Solvent flow rate - 0.5 mL/min methanol; vaporizer temperature - 450 deg; heated capillary - 225 deg. Scan Conditions: The MS spectra were acquired by scanning the first quadrupole from m/z 50 to 500 in one second. The co-averaged MS-MS spectra were acquired using a product ion scan mode from m/z 50 to 500 in three seconds and CID with Ar (1.5 mTorr cell pressure).

Results and Discussions

Solvent Effect on APCI Spectra: Methanol appeared to be the softest reagent with the protonated molecule or molecular ion present in the spectra of TH, TQ and TQE1. The most prominent ion in these spectra is the dehydrogenation product (MH-H₂, TH), dehydration species (MH-H₂O, TQ and TQE1), and loss of hydroxyl (MH-OH, THQ). Ammonium hydroxide was added to the methanol in hopes of preventing dehydration but produced little change in the TH and TQ spectrum, but changed the epoxide spectra such that the most prominent molecular weight related ion was the loss of a methoxyl group from the protonated molecule. Using benzene as the ionizing reagent caused significant fragmentation such that the base peak in the spectra of TH and TQ was m/z 165 formed by cleavage of the non-aromatic ring in the chromanol system. The most prominent ion signal in the epoxide (TQE2) system was formed by loss of methoxyl from the protonated molecule.

MS/MS of TH and Its Oxidation Products: The fragmentation patterns observed in the MS/MS products ion spectra of TH and its oxidation products almost exclusively involve cleavage of C-C bonds in the phytyl side chain rather than fragmentation of the ring system. While the precursor ions are themselves fragments of the protonated parent molecule, the fragmentation patterns are much like those observed in the electron capture negative chemical ionization (ECNCI) product ion mass spectra for the same compounds. These simple sequential cleavages of the phytyl side chains are thought to occur by charge-remote fragmentation(3).

MS/MS of the Isomers TQE1 and TQE2: The product ion spectra from the dehydration precursor for TQE1 and TQE2 contain primarily signals from sequential cleavage of the phytyl side-chain. The relative intensities of the signals for these fragments vary significantly. Consequently, we can differentiate these two isomers based on the relative signal intensities of the phytyl side-chain fragment ions. Unique ion signals that appear to be compound specific are present in both spectra. The structure of several of these unique ions result from the side chain and differ between the two isomers by 2 amu, possibly due to unsaturation in either fragment. The structure of some of these unique ions have not yet been determined. This work is underway in our laboratory.

Conclusions

1) Methanol APCI can be used to ionize α -tocopherol and its oxidation products. However, the most prominent ion signals observed in the spectra will result from dehydrogenation (TH), dehydration (TQ, TQE1, and TQE2), and loss of OH (THQ). The addition of ammonium hydroxide to the methanol does not prevent dehydration. Benzene as the ionization reagent causes non-structurally significant fragmentation.

2) The majority of the fragments observed in the MS/MS spectra of prominent ions result from fragmentation of the phytyl side-chain and are indicative of compound identity.

3) The MS/MS spectra of the dehydration fragments for the isomers TQE1 and TQE2 contain characteristic signals that differ by relative intensity and mass, thus permitting compound identification.

⁴Department of Allergy Research, Mayo Clinic, Rochester, MN., 55905

The separation and identification of a wide variety of analytes found in complex biological samples warrants the use of capillary electrophoresis on-line with mass spectrometry (CE-MS) for ultimate resolution and detection. In conjunction with CE-MS, membrane preconcentration can be used on-line prior to analysis to provide cleanup and concentration of the sample. Membrane preconcentration CE-MS (mPC-CE-MS) incorporates the use of a membrane to allow large sample injections and cleanup. An impregnated membrane is inserted into Teflon between two adjoining segments of uncoated silica tubing which is connected at the CE capillary inlet.

A mPC-CE-MS method has been developed to separate and identify biotransformation products formed when 3-phenylamino-1,2-propanediol (PAP) is incubated with rat hepatocytes. Earlier LC-APCI-MS work has shown a biotransformation product, 3-(phenylamino)alanine (PAA), to provide a direct chemical link between Toxic Oil Syndrome (TOS) and Eosinophilia-Myalgia Syndrome (EMS), two widespread and serious illnesses with unknown etiologies. Other biotransformation products, including hydroxylated PAA (HPAA), are also proposed as important intermediates, however, the lack of retention of the hydrophilic products on standard LC reverse phases did not allow identification of these compounds.

A mPC-CE-MS method utilizing a new 3M membrane, poly(styrenedivinylbenzene)-reverse phase sulfonated (SDB-RPS), has allowed the identification of several hydrophilic and hydrophobic products *in vitro*. Optimal mPC-CE-MS method conditions were developed using four synthetic standards including PAP, PAA, HPAA, and hydroxylated PAP (HPAP). The rat hepatocyte PAP incubation mixture and control were then analyzed under the same conditions.

Experimental mPC-CE-MS conditions are as follows:

1. Polybrene coated capillary - 50 μ m x 75 cm
2. Membrane - 3M SDB-RPS
3. Sample load - 3 μ l rat hepatocyte incubation
4. Separation media wash - 7 μ l of 2 mM NH_4OAc in 1% acetic acid
5. Elution buffer - 100 nl of 50 mM NH_4OAc in 75% MeOH:1% AcOH:24% H_2O .
6. Voltage - 10 kV
7. Finnigan-MAT 95Q with ESI ionization
8. Scan range 100 to 300 amu at 3 sec/decade

SDB-RPS membrane is ideal for analyzing both hydrophobic and hydrophilic PAP biotransformation products simultaneously when using mPC-CE-MS. Several products can be identified *in vitro* as demonstrated in Figure 1. Migration times of ions at m/z 181 and 184 correspond to migration times of synthetic standards of PAA and HPAP respectively.

HPAA is hypothesized by the authors to be an active intermediate in the biotransformation of PAP and PAA in the body and may be the responsible etiological agent in TOS and EMS. Migration time of the product at m/z 197 does not correspond to standard HPAA migration time. Synthetic HPAA has been shown to be unstable in solution and with time degradation products form including an ion at m/z 197 with a migration time similar to the m/z 197 ion observed in the incubation mixture.

Work continues to structurally characterize these products to identify the causative agents responsible for TOS and EMS.

Figure 1 mPC-CE-MS of Biotransformation Products of PAP

Contaminants of L-Tryptophan Associated with Onset of EMS Characterised by LC-ESI-MS/MS

Brian L. Williamson¹, Linda M. Benson¹, Andy J. Tomlinson¹, Arthur N. Mayeno², Gerald J. Gleich³ and Stephen Naylor^{1,4}

¹Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN 55905, USA. ²Pharmaceutical Development, Pharmacia and Upjohn Company Inc., Kalamazoo, MI 49001, USA. ³Department of Immunology, Mayo Clinic, Rochester, MN 55905, USA. ⁴Department of Pharmacology and Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN 55905, USA

During the fall of 1989, an epidemic of a new disease occurred in the USA. The illness was characterised by blood eosinophilia (raised number of a type of white blood cell) and myalgia (severe muscle pain), and was termed the eosinophilia-myalgia syndrome (EMS). Epidemiological studies demonstrated an association between EMS and consumption of L-tryptophan (L-Trp) manufactured by one company (Showa Denko) and suggested that a contaminant of L-Trp was responsible for the illness.

Using a HP 1090 chromatograph, with a Phenomenex Primesphere C-18 column (flow rate = 400 μ L/min) coupled via a Finnigan MAT ESI source on-line with a MAT 95Q (EBQQ) mass spectrometer, a HPLC- MSMS study is described in the analysis of this contaminated batch of L-Trp.

The HPLC analysis of case related L-Trp by UV detection is shown in Figure 1. This data indicates many low concentration impurities of this contaminated batch of L-Trp. Previously suggested contaminants, peak PAA, 1, 2, E, 100, 200, 300 and 400 are characterised by LC-MS/MS for the first time. The MS/MS spectra from their pseudo molecular ions are consistent with the previously suggested structures for these compounds.

Four previously uncharacterised impurities, peak C, peak FF, peak OO and the peak eluting at 31.6 minutes have been structurally elucidated. The MS/MS spectra from the pseudo molecular ions of peak FF, peak OO and the peak eluting at 31.6 mins are shown in Figure 2, together with the interpretation of these fragmentation processes. Both peak C and peak FF have been implicated in EMS.

Figure 2 MS/MS data for (A) peak OO, (B) peak FF and (C) the peak eluting at 31.6 mins

Analysis of Heterocyclic Amine Metabolites by μ LC-ESI/MS/MS

Donald M. Eades¹, Michael A. Malfatti², James S. Felton²

²Chemical and Structural Biology Division, Biology and Biotechnology Research Program
Lawrence Livermore National Laboratory, Livermore, CA 94551

INTRODUCTION

Heterocyclic aromatic amines, such as 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP), are formed in meat products during high temperature cooking. These compounds are present at ppb levels, exhibit high mutagenic activity with the Ames assay, and are carcinogenic and mutagenic in animal models. Our interest here was to characterize the urinary metabolic profile of PhIP for various laboratory animals and to develop a highly sensitive μ LC-ESI-MS/MS method for metabolite detection following low dose exposures.

EXPERIMENTAL

All experiments were performed on a Finnigan MAT TSQ 700 mass spectrometer with an ESI source. At a pressure of 1 mTorr Ar, CID spectra were obtained with optimized collision energy. Micro liquid chromatography (μ LC) was performed with a Michrom BioResources UMA at 50 μ L/min. Metabolites were separated on a 1mm X 15 cm Zorbax C18 SB column with a linear gradient of 10% B - 60% B in 20 minutes (A=1% HOAc, B=MeOH). The μ LC-ESI-MS/MS method utilized a C18 trap cartridge, in place of the LC sample loop, for preconcentration and sample cleanup. Retention efficiencies were from 80%-95% and the LOD was 50-150 fmoles on column for the various metabolites. Utilizing the trap cartridge and large injection volumes, metabolite levels in the attomole/ μ L range could be detected. Each metabolite exhibited a linear response when quantitated with d₅-PhIP as the internal standard.

Candidate metabolites were characterized by their MS/MS, their sensitivity to enzymes (i.e. β -glucuronidase, 10,000 units/mL and arylsulfatase, 500 units/mL), and by deuterium labeling (dosing with d₅-PhIP). Chronic dose mouse urine samples were collected at various time points (dose = 400 ppm in food, approximately 45 mg/kg/day) and graciously donated by Dr. James Tucker, LLNL. Low dose mouse urine was collected for 24 hours following a single IP injection of PhIP at various concentrations. Mice also were dosed in a similar fashion with 50 mg/kg of d₅-PhIP (all five deuteriums located on the phenyl ring). Milk from lactating rats originated from collaborations with Dr. Elizabeth G. Snyderwine. Monkey urine was a kind gift from Dr. Elizabeth G. Snyderwine.

RESULTS

Following high dose exposure, rodent urine was analyzed via μ LC-ESI-MS. Ten candidate metabolites were detected and characterized via MS/MS. Candidate metabolites were those giving rise to CID fragment ions which corresponded to the parent compound, PhIP, or OH-PhIP. To verify that the observed metabolite candidates were indeed PhIP related, mice were dosed with 50 mg/kg of d₅-PhIP. Note that all five deuteriums were located on the phenyl ring. This configuration provided the ability to distinguish between a 4'-metabolite (i.e. 4 Da shift) and an N-type metabolite (i.e. a 5 Da shift) of PhIP. All ten candidate metabolites exhibited the mass shifts due to the heavy label. Observed were two OH-glucuronides related to the 4' position, and three OH-glucuronides related to N-type position, two direct glucuronides (N² & N³), two hydroxyl metabolites (i.e. 4' & N²), and the 4'-SO₄ (see Figure).

To further characterize the metabolic profile and for complete identification, the metabolites were tested for their susceptibility to enzymatic reaction. The sample was pooled urine from mouse, rat, and monkey, each exposed to a high dose. An aliquot was kept at 4°C for comparison purposes and another aliquot, which served as the control, was incubated for 4 hrs at 37°C in the presence of buffer but without enzyme or acid. Upon exposure to β -glucuronidase three OH-glucuronide peaks and one direct glucuronide peak exhibited susceptibility and upon exposure to arylsulfatase, the 4'-SO₄ metabolite also was digested. Note that the arylsulfatase contained β -glucuronidase activity. Based on these results, and the data presented with the deuterated PhIP, the identities of each metabolite have been assigned.

Shown in the figure is a comparison of the μ LC-ESI-MS/MS analysis of chronically dosed mouse urine and a control. Note that 100 fold excess of the control mouse urine exhibited no PhIP related metabolites.

The μ LC-ESI-MS/MS method has been employed for metabolite detection following very low dose exposures. To verify that the method could be used for doses approaching human exposure levels, mice were dosed with a one time exposure of 100 ng/kg (dose equivalent to amount of PhIP in a chicken sandwich). Indeed, four metabolites were observed (N²-OH-N² gluc, N²-OH-N³ gluc, 4'-SO₄, 4'-OH, as well as the parent, PhIP). In another study, lactating female rats were exposed to doses down to 50 ng/kg and the mother's milk was analyzed for PhIP metabolites. At high dose (10 mg/kg) two metabolites were observed (4'-SO₄ & 4'-OH) together with the parent, PhIP. At low dose (50 ng/kg), however, only the parent PhIP was observed. This suggested that either the metabolite levels were below detection (100 fmoles on column) or that at these low doses, only PhIP was transferred into the mother's milk.

The authors thank Dr. Hugh Gregg, LLNL, for his assistance with the instrumentation and Dr. Robert Mauthe, LLNL, for his assistance with the biological samples. This work was performed under the auspices of the U.S. DOE by LLNL under contract # W-7405-Eng-48 and supported by the NCI grant CA55861.

APPLICATION OF ESI-LC-MS/MS TO THE ANALYSIS OF HETEROCYCLIC AROMATIC AMINES IN HUMAN URINE

W. G. Stillwell¹, L. R. Kidd¹, M. C. Yu², R. K. Ross², B. E. Henderson²,
J. S. Wishnok¹, P. L. Skipper¹ and S. R. Tannenbaum¹.

Massachusetts Institute of Technology¹, Cambridge, MA 02139; University of Southern California², Los Angeles, CA 90033.

The heterocyclic aromatic amines (HAAs) produced by high temperature cooking of meats represent an important class of mutagenic/carcinogenic compounds. Exposure to the HAAs in humans may be estimated by measuring the excretion of the unchanged amine and/or the conjugated metabolites in urine (1, 2). In determining exposure of humans to these food-borne mutagens, NCI GC-MS analysis of derivatized extracts prepared from urine samples has generally been used for quantification of the excreted HAAs. However, because of the instability of one of the derivatized HAA, this procedure was found to be unsuitable in our laboratory. In present study we have utilized an electrospray ionization LC-MS/MS procedure employing selective reaction monitoring for the analysis of the HAAs found in human urine.

PhIP (2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine), *d*₃-methyl-PhIP, MeIQx (2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline), and *d*₃-methyl-MeIQx were purchased from Toronto Research Chemicals (Ontario, Canada). The *d*₅-phenyl analog of PhIP was also used in some of the analyses. The isotopic purity of the deuterated standards for MeIQx and the two PhIP compounds, by GC-MS and/or LC-MS, was 98.7%, 99.2% and 99.3%, respectively. Human urine samples were spiked with the deuterated internal standards, hydrolyzed with acid, extracted with ethyl acetate, and then purified by immunoaffinity chromatography. The samples were then analyzed by electrospray ionization LC-MS/MS (Finnigan TSQ 7000). The mobile phase, water:methanol(50:50) containing 0.1% formic acid, was delivered at a flow rate of 200 μ l/min to the MS inlet through a Vydac narrow-bore HPLC column. Selective ion-reaction monitoring was utilized to analyze the precursor and product ions of the deuterated standards and the nondeuterated HAA. Product ions were generated using an energy of -30 volts with an argon gas pressure of 3 mTorr in the collision cell. For PhIP the transition of *m/z* 228 and 225→ *m/z* 210 (loss of a methyl group) was monitored, while for MeIQx the analogous transition of *m/z* 217 and 214→ *m/z* 199 was monitored. The amount of the HAA in the sample was determined by integrated area measurements of the respective product ions.

PhIP and MeIQx excretion in human urine was measured in samples collected from individuals in a Los Angeles study relating HAA excretion to ethnicity (3). Studies are underway on determining the HAA excretion in a Shanghai subpopulation in which a comparatively high incidence of colorectal cancer has been reported. PhIP and MeIQx levels have been measured in acid-hydrolyzed samples of urine obtained from individuals ingesting cooked meats. Analysis of the HAAs was carried out after acid hydrolysis of urine samples. This procedure liberates the amine from polar conjugates thus providing an estimate of phase II conjugation reactions in the excretion of these compounds.

The data obtained with the standard compounds using selected ion-reaction monitoring showed detection limits in the low picogram range for both amines. Calibration plots obtained by selective ion-reaction monitoring for the standard HAAs were linear over the low picogram

to nanogram range. For PhIP a signal/noise ratio above 10 was established for 6.5 pg injected.

The results for urinary MeIQx in human samples were in agreement with the results using GC/MS of the derivatized HAA, whereas we were not able to measure PhIP by GC/MS because of the instability of the derivatives. Illustrated in Figures 1 and 2 are the ESI-LC-MS/MS selected reaction-ion chromatograms for PhIP and MeIQx isolated by immunoaffinity chromatography from human urine samples.

In the Los Angeles study (3) the MeIQx values analyzed by GC/MS ranged from undetectable (<1 pg/ml) to 312 pg/ml, while for PhIP the values analyzed by LC/MS ranged from undetectable (<10 pg/ml) to 150 pg/ml. These results demonstrate that ESI-LC with selected ion-reaction monitoring may be applied to the analysis of HAAs in biological samples. The method supplies specificity and sensitivity of detection of these compounds in lieu of more laborious techniques which in the case of PhIP were not satisfactory. The use of immunoaffinity purification yields samples that are clean and require no derivatization for analysis by LC-ESI-MS/MS.

Figure 1

ESI-LC-MS/MS analysis of human urine. The selected reaction-ion chromatograms are of PhIP (upper trace) and the *d*₃-deuterated internal standard (lower trace). The concentration of PhIP in this urine sample was 460 pg/ml

Figure 2

ESI-LC-MS/MS analysis of MeIQx in human urine. The selected reaction-ion chromatograms are of MeIQx (upper trace) and the *d*₃-deuterated internal standard (lower trace). The concentration of MeIQx in this sample was 410 pg/ml

QUANTIFICATION OF HETEROCYCLIC AMINE CARCINOGENS IN COOKED MEATS USING LC-APCI/MS/MS

Daniel R. Doerge¹, C. Lee Holder¹ and Steve W. Preece²

¹National Center for Toxicological Research, Jefferson, AR 72079

²Micromass, Altrincham, WA14 5RZ, U.K.

INTRODUCTION

Heterocyclic aromatic amines (HAAs) are formed in meats under typical cooking conditions. These compounds are the major mutagenic compounds isolated from cooked meats and fish and have been shown to induce colon and mammary tumors in rodent bioassays. Epidemiological studies have

shown an association between cooked meat consumption and an elevated risk of colon, breast and other cancers in humans. The mechanism for formation of HAAs appears to be varied but pyrolysis of amino acids alone and in the presence of creatine/creatinine and sugars appears to be involved. It

has also been shown that the amount of HAAs formed in meats depends on meat type, cooking temperature, and cooking time. Methods used for the analysis of HAAs in typical Western foods have relied on LC-UV procedures; however, quantification using these methods often are limited by the variability of analyte recovery at trace levels, the sensitivity of response and the ability to confirm the presence of HAAs unambiguously. In this study, we report an efficient liquid-liquid extraction procedure to isolate and cleanup HAAs followed by accurate quantification using isotopically labeled HAAs as internal standards for on-line LC-APCI/MS/MS measurements. The methods described provide the sensitivity and specificity to detect with a high degree of confidence HAAs in meats cooked using typical practices.

EXPERIMENTAL

Meat samples were cooked under conditions typically used in an American kitchen. Crumbled hamburger or minced chicken meat (5 g) was spiked with 25 ng each of a mixture of the four labeled HAAs in 0.1 ml methanol (5 ppb). The samples were extracted, cleaned up using liquid-liquid partitioning, evaporated to dryness and the residue dissolved in 0.5 ml of mobile phase for analysis using LC/MS. A VG Quattro II triple quadrupole mass spectrometer (Micromass, Altrincham, England) equipped with an APCI interface with a heated nebulizer probe (500 °C) or electrospray ionization interface was used at an ion source temperature of 150 °C to acquire product ion scans and MRM data. The MRM transitions used for IQ (m/z 199 $\rightarrow$ 184), MeIQx (m/z 214 $\rightarrow$ 199) and PhIP (m/z 225 $\rightarrow$ 199) involved loss of the N-methyl group ($MH^+ - 15$) and the transition monitored for AAC (m/z 184 $\rightarrow$ 140) involved cleavage of the heterocyclic rings. Isotope dilution responses for standards (MRM peak area for native HAA/MRM peak area generated by 5 ppb spike of labeled HAA) were plotted vs. the amount of native HAA to generate calibration plots. These plots were

highly linear ($r^2 \geq 0.99$ for all HAAs from 0-50 ppb) and the slopes were used to calculate the concentration of HAAs in cooked meat samples. Detection limits varied with HAA and sample type but were generally in the range of 0.1-1 ppb.

CONCLUSIONS

1. These results demonstrate that LC-APCI-MRM provides the sensitivity required to measure formation of HAA carcinogens in meat cooked under typical conditions.

2. The use of labeled internal standards for isotope dilution measurements reduces variability due to extraction efficiencies and gives confidence in the accuracy of amounts quantified. The selectivity of LC-MRM also provides a measure of HAA structure confirmation not possible using LC-UV procedures.

3. Cooking time and technique has a major influence on the formation of HAAs in meat. Low level formation of HAAs was seen in medium and well-done hamburgers (≤ 1 ppb). While pan-fried chicken had essentially undetectable HAAs, grilled chicken contained large amounts (up to ca. 400 ppb) of the HAAs determined.

4. The efficient extraction procedure, and the sensitive, selective and accurate quantification procedures described here should be useful in determining exposure of Americans to these potential carcinogens in the diet and aid in developing accurate human cancer risk assessments.

Figure. Effect of Cooking Time/Method on Formation of HAAs in Chicken Breast. Boneless, skinless chicken strips were cooked either by pan frying (medium heat) until just done, or broiled over a medium gas flame for varying amounts of time. The HAA content was determined using isotope dilution LC-MRM following extraction and cleanup as described in the Experimental section.

MULTIRESIDUE CONFIRMATION OF GENTIAN VIOLET AND LEUCOGENTIAN VIOLET IN CATFISH MUSCLE USING LC-APCI/MS

INTRODUCTION

Gentian violet (GV), a mixture of triphenylmethane dyes consisting primarily of hexamethylpararosanine, has been used as an antiseptic agent in human and veterinary medicine. A related triphenylmethane dye, malachite green (MG), has been widely used in the aquaculture industry for control of ectoparasites and fungal infections. Although neither MG or GV are approved for such uses in aquaculture, the effectiveness and low cost make it possible that both are still used surreptitiously. A substantial body of evidence from chronic rodent bioassays implicates GV in the induction of thyroid and liver tumors, and some evidence for the carcinogenicity of MG has been reported. Triphenylmethane dyes are efficiently reduced to the corresponding leuco-form in mammals, by isolated anaerobic intestinal microflora, and leucomalachite green (LMG) is the principal metabolite observed in fish treated with MG. Because of these properties, it is necessary to develop analytical methodology capable of monitoring the presence of both GV and LGV in edible tissues from aquaculture species for unequivocal confirmation of the presence of residues in suspect samples with the specificity required for enforcement action.

In these studies, we used in-source collision-induced dissociation (CID) with a single quadrupole mass spectrometer to produce diagnostic fragment ions with adequate intensity by varying the sampling cone-skimmer voltage. This method of rapidly switching the cone-skimmer voltage to a unique value for each target ion permits optimal detection of molecular and fragment ions without sacrificing sensitivity. This abstract describes the confirmation of GV and LGV residues in edible tissues from catfish dosed with GV under putative aquaculture use conditions.

EXPERIMENTAL

Catfish were exposed to 10 or 100 µg/l (ppb) GV in aquarium water for a period of 1 hr and then transferred to fresh water for a period of 24 hr. Fish samples were prepared as follows: thawed, blended catfish fillets were homogenized and subjected to liquid-liquid partitioning and solid phase extraction prior to confirmation using LC/APCI/MS. The LC separation used a short-chain deactivated analytical column with a mobile phase consisting of 55% acetonitrile and 45% aqueous ammonium acetate (5.8 mM, pH 3.6) at a flow rate of 1.5 ml/min. A VG Platform II single quadrupole mass spectrometer (Micromass, Altrincham, England) equipped with an APCI interface and heated nebulizer probe (500°C) was used with an ion source temperature of 150 °C. Positive ions were acquired in full scan (m/z 100-400 in 1 sec cycle time) or selected ion monitoring mode

(dwell time of 0.3 sec, a span of 0.02 Da and an interchannel delay time of 0.03 sec). The sampling cone-skimmer voltage was varied between 30-100 V to produce in-source collision-induced dissociation (CID) in concert with the acquisition of the respective selected ion.

CONCLUSIONS

1. On-line LC-APCI/MS provides a linear response (0.01-5 ng and 0.1-50 ng ranges studied for GV and LGV standards, respectively), high sensitivity (low pg LOD), and is useful for determining incurred residues of GV and LGV, the principal metabolite, from muscle of catfish treated with GV under putative use conditions (10 or 100 ppb in aquarium water for 1 hr).
2. In-source CID was used to produce multiple fragment ions from GV and LGV and a rapid cone voltage switching method was used to acquire ion responses from MH^+ and diagnostic fragments for use in intensity ratio determinations.
3. Accurate and precise concordance was observed for ion intensity ratio determinations generated from authentic standards and incurred residues of GV and LGV at residue levels in catfish of 0.5/0.8 ppb GV and 44/118 ppb LGV.
4. These data demonstrate that LC-APCI/MS using a rapid cone voltage switching procedure can generate ion intensity ratio data from incurred residue samples with sufficient quality to meet the criteria for regulatory confirmation that have previously been applied to EI/MS and MS/MS data.

Figure. Summed ion chromatograms for GV and LGV from: residues incurred in muscle from catfish treated with 10 ppb GV, comparable amounts of authentic standards and a control catfish extract. Note that a common relative intensity was used for each set of three chromatograms. Ion intensity ratios were determined from the area under the respective selected ion chromatogram. Data generated in this manner gave accurate and precise agreement between intensity ratios derived from LGV and GV residues in catfish and authentic standards.

DETERMINATION OF INCURRED CLENBUTEROL RESIDUES IN BOVINE LIVER USING LC-APCI/MS AND MS/MS

M.I. Churchwell¹, C.L. Holder¹, S. Preece², S. Bajic³ and D.R. Doerge¹.

INTRODUCTION

The illegal use of β -agonists as growth stimulants in livestock continues to demand regulatory scrutiny. The high potency of growth promoting effects and rapid metabolism of β -agonists require highly sensitive analytical methods for quantification and confirmation of residues in livestock tissues. While screening of livestock tissue residues can be done using rapid immunochemical tests, quantification and confirmation require the sensitivity and specificity of mass spectrometry. We have previously demonstrated the usefulness of LC-APCI/MS for the analysis of β -agonists in bovine plasma and bovine retina at trace levels. In this study, we simultaneously quantify and confirm the presence of incurred clenbuterol residues in extracts from bovine liver using ¹³C-labeled clenbuterol as an internal standard and ion intensity ratios obtained from SIM or MRM transition ratios derived from on-line LC-APCI/MS and MS/MS. This comparison was made to test the relative strengths of LC/MS and LC/MS/MS for providing proof of chemical structure with sufficient specificity for regulatory enforcement action as previously done with EI-MS data.

EXPERIMENTAL

Cattle were treated with clenbuterol by USDA-ARS Food Production Laboratory (College Station, TX). Animals were treated for 5 days (20 μ g/kg/day) and then withdrawn for various times before slaughter. Residues in livers were determined by USDA-FSIS MidWest Lab (St. Louis, MO) prior to shipping samples to NCTR for LC/MS analysis. Livers were selected to provide a range of incurred clenbuterol levels (ca. 5-200 ppb). Control livers were obtained from FDA Center for Veterinary Medicine (Beltsville, MD) from cattle never treated with clenbuterol. Liver samples (ca. 1 g) were spiked with ¹³C₆-clenbuterol (100 ng of 99% purity material, synthesized at NCTR), homogenized in 4 ml of 5 mM ammonium acetate (pH 7.5), centrifuged and a 2 ml portion removed for SPE cleanup on a C18 SepPak. Recovery from the incurred samples was determined to be 53 $\pm$ 6% based on the response for ¹³C-clenbuterol. The LC separation used a Metachem C4/E analytical column (250 x 4.6 mm, 5 micron particle size) with a mobile phase consisting of 20% acetonitrile and 80% aqueous ammonium acetate (25 mM, pH 7.2) at a flow rate of 1.2 ml/min. A VG Platform II single quadrupole mass spectrometer (Micromass Inc.) equipped with an APCI interface and heated nebulizer probe (500 °C) was used at an ion source temperature 150 °C to acquire MS data. The sampling cone-skimmer voltage was varied between 15-55 V to produce in-source collision-induced dissociation (CID) in concert with the acquisition of the respective selected ion (m/z 277, 259, 203, 132). A VG Quattro II triple quadrupole mass spectrometer similarly equipped was used to collect MRM transition responses (m/z 277 $\rightarrow$ 203, 168, 132).

CONCLUSIONS

1 On-line LC-APCI/MS using the rapid cone voltage switching method described produces SIM data that can provide simultaneous quantification by isotope dilution and confirmation by accurate and precise agreement between intensity ratios for four unique ions generated from incurred residues

and authentic standards.

2. On-line LC-MRM can also produce transition intensity data suitable for simultaneous isotope dilution quantification and confirmation using concordance between ratios for three LC-MRM transitions for clenbuterol derived from incurred residues and authentic standards.

3. LC-SIM is applicable to quantification and confirmation of clenbuterol residues incurred in bovine liver at an estimated quantitation/confirmation limit of 15 ppb using the described extraction methods; moreover, the enhanced sensitivity of LC-MRM makes it possible to quantify and confirm incurred residues at ca. 5 ppb. The clenbuterol values determined using both techniques were comparable to each other and with those derived from GC/MS analysis at the FSIS Midwest Lab.

4. Both LC-APCI-SIM and LC-APCI-MRM data showed a high degree of concordance between ratios produced by incurred residues or authentic standards. This suggests that both techniques can provide confirmatory data of sufficient quality to be used for regulatory enforcement action as EI-MS data have historically been used. It will be important to validate these methods in several laboratories.

upFigure. Comparison of LC-SIM and LC-MRM Signals for an Incurred Clenbuterol Sample. The SIM and MRM responses are shown for analysis of a common incurred liver extract (Cow 15, clenbuterol = ca. 40 ppb). The baseline subtracted, but unsmoothed, summed ion/transition responses for native clenbuterol are shown along with a blow-up of the noise levels in each sample (9-11 min). The S/N ratio was at least 2.5-fold greater for the LC-MRM response.

Characterization of Fumonisin Mycotoxins by LC/ESI/MS/MSⁿ Using a Quadrupole Ion Trap

Jonathan L. Josephs

Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Introduction: The Fungus *Fusarium moniliforme* infests corn and has been shown to cause animal diseases including leukoencephalomalacia (LEM) in horses and has been implicated in human esophageal cancer. A family of mycotoxins known as the fumonisins have been isolated and characterized from cultures of *F. moniliforme*. Toxicological studies have focused on fumonisin B₁ (FB₁) as it is the major fumonisin produced by *F. moniliforme*. FB₁ has been shown to reproduce LEM in horses and be responsible for the hepatotoxic and carcinogenic effects observed in rats fed a diet containing culture material of *F. moniliforme*.

Reliable studies require that the materials used for dosing be completely characterized prior to administration. Reported here is the use of liquid chromatography-electrospray/mass spectrometry (LC-ESI/MS) to detect and characterize fumonisins in mixtures. The use of a quadrupole ion trap allowed structural analysis and elucidation of the fragmentation pathways of FB, and FB₁ tetramethyl ester by multi-stage tandem mass spectrometry (MSⁿ). LC-ESI/MS/MS spectra of minor peaks in a mixture were obtained 'on the fly' by the use of data dependent scan functions, where detection of a peak by a full scan MS scan triggers the instrument to acquire a product ion spectrum of the detected precursor ion.

Method: *Sample Preparation:* Fumonisin B₁ (5 mg, 98%) (Sigma Chemical Co., St. Louis, MO) was dissolved in 50:50 acetonitrile/water to make a stock solution of 20 µg/µl. 10 µl of the 20 µg/µl solution of fumonisin B₁ was dissolved in dry methanol (100 µl), 3 drops of acetyl chloride were added and the mixture held at room temperature for 1 hour. The solvent was evaporated and the residue taken up in 50:50 acetonitrile/water containing 0.1% formic acid (100 µl) to give a solution of mixed fumonisin methyl esters at the 2 µg/µl (total) concentration.

HPLC Conditions: LC separations were performed on a 4.6x150 mm YMC J'Shere ODSL80 column with a gradient of 75% A for 5min, to 60% A over 30 min, hold 60% A for 2 min, to 40% A over 3 min, where A is 0.2% formic acid and B is acetonitrile containing 0.2% formic acid. Flow rate was 1ml/min.

Ion Trap Mass Spectrometer Conditions: Mass spectrometry data was recorded with a Finnigan MAT LCQ™ equipped with the Finnigan Electrospray Source. For infusion studies the source conditions were: Capillary temp 225°C, needle voltage +4.0KV, sheath gas pressure 40 psi, auxiliary gas flow 1 unit. For 1ml/min LC flow the conditions were: Capillary temp 275°C, needle voltage +4.0KV, sheath gas 80 psi, auxiliary gas flow 1 unit.

Conclusions: MSⁿ analysis of the fragmentation pathways of the parent fumonisin FB, aids in the structural elucidation of related impurities. High column loadings on a 4.6mm ID column allows detection of low level impurities. Data dependent LC/MS and LC/MS/MS 'on the fly' enables the collection of both full scan MS and full scan MS/MS spectra of a complex unknown sample in a single run.

TANDEM MASS SPECTROMETRY AS A TOOL IN DETERMINING POSSIBLE CAUSES OF DISEASE

Helen H. Schurz, Robert H. Hill, Ruth Etzel, Rossanne Philen, and Larry Needham,
Centers for Disease Control and Prevention, Environmental Health Laboratory
Sciences, Atlanta, GA 30341

Manuel Posada, Direccion General de Ordenacion de la Investigacion y Formacion,
Fondo de Investigacion Sanitaria, Ministerio de Sanidad y Consumo, Madrid, Spain
28029

In our laboratory, we may be called upon to determine the cause of disease by examining human samples (blood, urine, tissue) or substances that may be the source of an exposure to a toxin (food oil, food supplements). In many cases, there are no methods already available, and the methods we may use are developed over the course of an investigation. Though many analytical techniques (GC, LC, UV, IR, NMR, etc) may be employed, we have found that atmospheric pressure ionization (API) techniques coupled with tandem mass spectrometry have provided us with an edge in the analysis of many substances.

The various scanning techniques that are available with tandem mass spectrometry make it an excellent tool in the search for biomarkers of disease or contaminants in various substances that are suspected of causing disease. Probably the most commonly used technique is daughter-ion (product-ion) scanning which provides structural information by selectively fragmenting specific parent ions. Useful in the identification of unknowns, parent-ion scanning may be employed to determine the source of a particular fragment-ion while scanning in MS/MS mode. Using combinations of all of these techniques we have identified many unknown compounds that can be associated with incidences of disease. Two studies in which these MS/MS analyses have been useful are described below.

In 1993 cases of idiopathic pulmonary hemosiderosis (IPH) were observed occurring among infants in Cleveland, OH. A black mold found growing in the homes of the infants was suspected to be the cause of the illness. This mold was suspected to contain a strain of fungus called *Stachybotrys atra*, which under certain conditions can produce a macrocyclic trichothecene (satratoxin) that has been shown to produce a similar disease in farm animals. There is a deficiency of research in this area, therefore little is known about the metabolism of satratoxin in humans. Assuming that satratoxin would hydrolyze or be subject to glucuronide attachment in the human body, we developed a method to analyze infant and parental urines using the base hydrolysis product of satratoxin (verrucarol).

We examined a purchased verrucarol sample by daughter-ion mass spectrometry. We found that very different MS/MS spectra (see figure) were obtained with different orifice potentials (OR). At low OR (45 V), the fragmentation was superficial, with losses of external groups (OH, CH₂OH, etc.) occurring. At median OR (60 V), almost no fragment-ions were detected. When we used high OR (90 V), we found that the fragmentation increased and included breakage of the epoxide bonds. Careful examination of the purchased standard also revealed that no fewer than 12 isomers may exist that respond to the same monitoring conditions in an MRM experiment. This has seriously limited our ability to see low amounts verrucarol in urine. To date, we have not detected verrucarol in

the urine of infants afflicted with IPH.

The toxic oil syndrome (TOS) occurred in 1981 and was associated with the consumption of an aniline-denatured rapeseed oil. The oil was refined to remove the aniline, and in that refining process toxins were produced. Presently, there is no animal model for this disease, making the absolute identification of a toxin impossible. We have been able to identify compounds that were produced in the refining process, however, and these compounds are considered highly case-associated with oils that caused disease.¹ Identification of these compounds was made possible using the MS/MS techniques of parent ion mass spectrometry and daughter ion mass spectrometry. These compounds are being used in animal tests now to determine their possible toxicity and to help identify an animal model.

DETERMINATION OF EDTA IN FORENSIC SAMPLES BY CAPILLARY GC-MS AND GC-MS/MS. Kevin D. Ballard, Ralph S. Orkiszewski, Marc S. Taylor¹, Elizabeth A. Johnson², and Larry Ragle³. Center For Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030; ¹Technical Associates, Altadena, CA 91001; ²Harris County Medical Examiner's Office, Houston, TX 77054; ³Center for Forensic Sciences, Laguna Beach, CA 92652.

During forensic cases, the question occasionally arises as to whether a reference blood sample from a suspected criminal has been deliberately planted on evidence by someone in a position of public trust, in an effort to secure a criminal conviction against the suspect. Reference samples are usually blood samples anticoagulated with a salt form of ethylenediaminetetraacetic acid (EDTA), using a commercial purple (lavender) topped blood collection tube. Thus, one means of testing for the occurrence of evidence planting is the quantitative determination of EDTA in evidentiary bloodstains. Methods to address this issue have been developed in these laboratories. Initial screening for EDTA is accomplished through GC-MS with selected ion monitoring (GC-MS-SIM), with definitive identification and quantification through GC-MS/MS with selected reaction monitoring (GC-MS/MS-SRM). The methods employ the tetramethyl ester derivative of EDTA, with [¹³C₄]EDTA as an internal standard. EDTA is extracted from forensic bloodstains in a manner such that the genetic material is preserved, enabling DNA typing for the same samples. An assay for EDTA in a forensic setting must take into account the many chelated and five free forms in which EDTA can exist in forensic stains. The methods described here accomplish this by taking advantage of the fact that the stability of EDTA chelates is dramatically reduced under strongly acidic conditions. Chelated and non-chelated forms of EDTA are driven to a common final derivative that has chromatographic and mass spectrometric properties suitable for GC-MS and GC-MS/MS analysis.

METHODS: [¹³C₄]EDTA was synthesized using a variation on an established synthesis [1]. Heat denatured, chloroform extracted, filtered aqueous extracts of stains were dried, treated with 3 M HCl/methanol at 90 °C, dried, and redissolved in tetrahydrofuran, and analyzed by GC-MS-SIM and GC-MS/MS-SRM.

RESULTS: The electron impact ionized tetramethyl ester derivative of EDTA exhibits an intense molecular ion signal (*m/z* 348), which formed the basis for the GC-MS-SIM assay, which was used essentially as a screening assay. Under low energy CAD conditions, the derivative exhibits a highly favored fragmentation giving an *m/z* 174 ion which formed the basis for the GC-MS/MS-SRM assay. The overall extraction and derivatization process is highly efficient. Deuterated internal standard ([²H₁₂]EDTA) is not suitable for these assays due to extensive isotope exchange. Both assays exhibited excellent linearity with [¹³C₄]EDTA as an internal standard. Using 400 ng of internal standard, the lower limit for reliable quantification is approximately 1-2 ng of EDTA per sample. The inherent sensitivity of both methods, and particularly the GC-MS/MS method, is such that the assay could easily extend into the picograms per sample range with an appropriate reduction in the amount of internal standard. These methods overcome potential interferences from mixed stains, salts, and heavy metal ions such as iron and copper. These methods have shown that EDTA is selectively excluded from red cells, and no detectable blood levels of EDTA have been found in an ethnically diverse group of normal individuals. These latter findings confirm a previous elegant pharmacokinetic study that employed radiolabeled EDTA [2]. A series of 29 simulated forensic stains, with and without simulated evidence tampering, was analyzed in a blind fashion by both methods (exemplary GC-MS/MS traces are shown in Figure 1). In all cases, both GC-MS and GC-MS/MS assays accurately quantified the EDTA present in the samples, with no false positives and no false negatives. The composite results of these analyses are shown in Figure 2. DNA typing of selected samples demonstrated that the combination of bacterial degradation of an original forensic stain, followed by deliberate spiking of the collected stain with EDTA-anticoagulated blood from another individual, can lead to completely deceptive DNA typing results. The methods described here can provide unequivocal evidence for the presence and quantity of EDTA in forensic stains where evidence tampering involving EDTA-anticoagulated blood has occurred.

Quantification of Drugs of Abuse by SPE and GC/MS using Microliter-Amounts of Serum

Wolfgang Weinmann, Christa Bohn
Institute for Legal Medicine, Albertstr. 9, D 79104 Freiburg

A method for the simultaneous quantification of amphetamine, benzoylecgonine, morphine and codeine has been developed consuming only 0.1 ml of serum-sample. This method is used for the confirmation of positive immuno-assay results. Very often less than 1 ml is available for the analysis, so that a "micro"-method for low serum-volumes is desirable. The quantification is performed by adding deuterated standards to a serum-volume of 0.1 ml followed by solid-phase-extraction (SPE) with mixed-mode extraction-columns, and subsequent acylation or esterification with a mixture of perfluoropropionic anhydride and 2,2,3,3,3-pentafluoropropanol prior to GC/MS-analysis [1,2].

Method Evaluation

This method has been evaluated for 0.1 ml serum-samples spiked with 5, 10, 25 or 50 ng/ml of amphetamine, morphine, codeine and benzoylecgonine, respectively. Drug-free serum samples were used as controls. Pentadeuterated amphetamine and trideuterated morphine, d₃-codeine and d₃-benzoylecgonine were added to every 0.1 ml-aliquot of serum to yield a deuterated-standard concentration of 25 ng/ml serum each.

Phosphate buffer (1.4 ml, 0.1 M, pH 6.0) was added to the serum-sample and applied onto a preconditioned mixed-mode solid-phase extraction column consisting of a RP-C8 and a cation-exchanger-bed (200 mg, 1 ml, Macherey-Nagel "DRUG", Düren/Germany). The column was rinsed with 2 ml each of water, 0.1M acetic acid and methanol. After centrifugation the columns were dried in a SPE-vacuum-manifold for 10 minutes. The elution was performed by adding a mixture of dichloromethane/2-propanol/25% ammonia solution (8:2:0.2; v/v/v). After solvent-evaporation at 60°C under a stream of nitrogen, derivatization was performed for 45 min at 60°C after the addition of 50 µl perfluoropropionic anhydride and 35 µl of 2,2,3,3,3-pentafluoropropanol. After quickly evaporating the reagents under a stream of nitrogen, the residue was reconstituted in 15 µl ethylacetate and 1 µl analysed by splitless-injection on a Fisons-MD800 GC/MS. Chromatographic separation was performed with a 12 m HP-1 capillary-column (0.33 µm film thickness, 0.2 mm i.d.) with a temperature gradient (1 min 80 °C; 20 °C/min to 200 °C; 5 °C/min to 240 °C; 30 °C/min to 300 °C; 6 min 300 °C). The split/splitless injector was held at 250°C, the interface temperature was at 200°C. Selected ion scan width was 0.2 amu, dwell-time 80 millisecc. The masses monitored are shown in table 1.

Compound	m/z non deuterated	m/z deuterated	retention time window
Amphetamine-PFP	(91.06)	-	4.0 - 5.0 min
	118.08	123.08

Tab. 1: m/z-values for GC/SIM

Results of the method-evaluation

- Solid-phase extraction was performed with *mixed-mode SPE*-columns.
- *No further precautions* like silanization of vials were necessary.
- The *serum-volume* used per analysis was 100 µl.
- *Detection Limits*: Morphine and Benzoylecgonine 5 ng/ml, Codeine 3 ng/ml, Amphetamine 7 ng/ml.
- *High extraction efficiencies*: > 86 % (at 25 ng/ml serum-drug-concentration).
- *Standarddeviations* of 10 assays (at 25 ng/ml serum-drug-concentration): Amphetamine 4.2%; Benzoylecgonine 3 %; Morphine 2.8%; Codeine 3%.

FAST ANALYSIS OF ANABOLIC STEROIDS IN URINE SAMPLES BY ELECTROSPRAY IONIZATION TANDEM MASS SPECTROMETRY

Yoon-Seok Chang*, BongChul Chung, JungSuk Jang and JongShin Yoo

*Department of Chemistry, Hanyang University, Ansan, 425-791, Korea.

It has been well known that the long term ingestion of the exogenous anabolic steroids causes harmful effects such as adenocarcinoma and hepatic damage. The metabolism of the compounds in question should be understood to monitor the steroid use. The metabolism of most steroids includes reduction of 3-carbonyl group and 4-5 C=C double bond, oxidation of 17 α -hydroxyl group, hydroxylation in alpha or more sites, conjugation, and so on. The analysis of the anabolic steroids could be performed with HPLC and RIA, but the GC-MS data can give the accurate judgement for the existence of anabolic steroids. The three steps, that is extraction, hydrolysis and derivatization, are essential before injection to GC-MS.

In this laboratory, the presence of anabolic steroids in urine samples were directly confirmed by ESI-MS without using the prerequisite three steps of enzymatic hydrolysis and trimethylchlorosilane derivatization. The crude urine was simply filtered and diluted in water/methanol and injected into electrospray ion source. Further structure determination has been conducted by collisionally induced dissociation in a triple quadrupole tandem mass spectrometry. The presence of anabolic steroids, separated by their different masses in the ESI mass spectrum, were directly confirmed by appearance of their dehydrogenated molecular anion peaks in the negative ion mass spectrum (Figure 1). In comparison to the blank urine sample, new peaks at such as m/z 355, 451, and 541 were identified in the mass spectrum of steroid ingested urine. In all urine samples ingested by each banned steroids, the major and minor metabolites were detected by observing their corresponding masses.

The CID spectrum of m/z 451 shows characteristic peaks at m/z 58, 74, 85, and 113, indicating the presence of sugar group attached (Figure 2). Under the low energy collision conditions in the triple quadrupole tandem mass spectrometer, extensive ring fragmentation could not be observed. Meanwhile, the CID spectrum of sulfated steroid is quite different from that of glucuronide one and shows two major peaks at m/z 80 and 96, which are the losses of SO₃ and SO₄ groups from the steroid ring (Figure 3). The CID spectrum of clostebol, in which a sugar and a chlorine is attached, shows not only the characteristic sugar fragments, but also an intense peak at m/z 35 for the loss of chlorine atom.

In conclusion, the presence of anabolic steroids in human urine samples can be directly and rapidly confirmed by electrospray ionization and tandem mass spectrometry. The ESI-MS method excludes time-consuming sample preparation steps such as extraction, enzymatic hydrolysis and derivatization used for the SIM-GC-MS analysis. The detectability could be enhanced by upto ten times for tested samples when the analysis is performed in the negative ionization mode of ESI-MS.

CONFIRMATORY ANALYSIS FOR SPECTINOMYCIN RESIDUE IN BOVINE KIDNEY AND OTHER TISSUES BY HPLC/MS/MS

Rex E. Hornish and John R. Wiest
Pharmacia & Upjohn, Inc., Animal Health Drug Metabolism, 7926-300-401, Henrietta Street, Kalamazoo, Michigan, 49007 USA

Introduction - An analytical quantitative (determinative) method for the detection of parent spectinomycin in bovine kidney, liver, muscle and fat was recently developed in our laboratory. Validation of the method was focused on parent spectinomycin as the marker residue in kidney, with a projected Maximum Residue Level (MRL) or tolerance (R_m) of 5 $\mu\text{g/g}$. Data were also compiled for bovine liver, muscle and fat. The lowest concentration tested in these tissues was 0.10 $\mu\text{g/g}$.

As part of the regulatory requirements for residue methodology, a confirmatory method of analysis that is specific for the marker residue must also be developed that absolutely confirms the identity of the substance detected in the determinative method. A confirmatory method for parent spectinomycin has been developed in our laboratory based on collision induced dissociation (CID) mass spectrometry, or reaction product ion mass spectrometry (MS/MS). This method utilizes the sample prepared for the determinative method, but employs a different chromatographic scheme that is compatible with the atmospheric pressure ionization (APCI) interface to the mass spectrometer. The criteria for confirmation were those proposed by regulatory guidelines, which have been applied in our laboratory to other drug entities such as pirlimycin.

Methods - The HPLC system consisted of a Perkin Elmer 200 pump, a Zorbax SB C18 column (150x2.1 mm), a mobile phase of 92:8 1% acetic acid:methanol at 0.17 mL/min, and an in-line diverter valve post-column. The mass spectrometer was a Finnigan TSQ 7000 fitted with a Finnigan APCI interface. The instrument was set-up in the Q1-Q3 mode with Q1 set at m/z 333 and Q3 set in the selected reaction monitoring (SRM) mode at m/z 98, 116, 158 and 189. The collision gas was argon at 2.5 mT with a collision offset at -30V. The data system was the Finnigan ICIS II, Version 8.1.1.

Results and Discussion

The qualitative confirmatory analysis for parent spectinomycin residue in tissue samples must meet the following three criteria:

I. Observation of peak area responses above a signal:noise (S/N) of 3:1 for the four CID ions m/z 98, 116, 158 and 189 for the confirmation of spectinomycin. The minimum acceptable S/N ratio for each ion may be obtained from three times (3x) the base-line noise for a control kidney sample analysis, or from a "clean" peak-free area of the sample chromatogram.

II. The appearance of the spectinomycin response in the RIC for the sample should be at the appropriate HPLC retention time (R_t within 0.2 min, or 12 sec) relative to an external spectinomycin standard.

III. The Relative Abundances (RAs) of m/z 98, 116, 158, and 189 for spectinomycin in the kidney sample must not differ by more than $\pm 10\%$ from an external spectinomycin standard analyzed just before or after the sample, or from the average of external spectinomycin standards bracketed around the sample, using standard solutions which have a spectinomycin concentration near that in the sample.

The application of these criteria for the confirmation of spectinomycin residue are illustrated with the analysis of several kidney samples - fortified control/blank samples and several incurred-residue samples from spectinomycin sulfate treated cattle. Table 1 summarizes the results of the analysis of several control/blank kidney samples fortified with spectinomycin at a concentration range of 1.8-7.2 $\mu\text{g/g}$ and incurred-residue samples containing spectinomycin at a concentration range of 0.7-4.0 $\mu\text{g/g}$.

Table 1. Summary of confirmatory analysis of spectinomycin-fortified bovine kidney and incurred-residue bovine kidney

Sample	Conc. $\mu\text{g/g}$	n	# Meeting Criteria			% Relative Abundance Range, for m/z			
			I	II	III	98	116	158	189
Standards	1.8-7.4	7				100	46-50	24-28	47-54
Kidney									
Fortified	1.8-7.2	9	9	9	9	100	42-50	24-34	42-51
Incurred	0.7-4.0	18	18	18	18	100	43-56	24-36	37-52
Standard	0.18	3				100	43-49	40-47	40-51
Kidney									
Incurred	0.04-0.34	12	12	12	11	100	39-52	37-47	43-55

In addition to kidney, bovine liver, muscle and fat samples fortified with spectinomycin at concentrations ranging from 0.1 $\mu\text{g/g}$ to 4.0 $\mu\text{g/g}$ were also confirmed

Conclusion - An analytical method for the confirmation of parent spectinomycin in bovine kidney has been developed and validated. The method is a two-dimensional analysis employing HPLC and APCI CID mass spectrometry (HPLC/MS/MS). Three criteria were met for confirmation: I - signal/noise $> 3:1$ for four reaction product ions, II - an HPLC retention time of spectinomycin in the sample within ± 0.2 min relative to an external spectinomycin standard, and III - a relative abundance of four reaction product ions in the sample within $\pm 10\%$ relative to an external standard. The method was shown to confirm parent spectinomycin residue from an upper concentration of 7.2 $\mu\text{g/g}$ down to a Limit of Confirmation (LOC) of 0.05 $\mu\text{g/g}$. The method was also shown to confirm parent spectinomycin in bovine muscle, liver and fat to a LOC of 0.10 $\mu\text{g/g}$.

DNA-Metal Interactions Studied Using MALDI/TOF Mass Spectrometry

Noah P. Christian and James P. Reilly
Department of Chemistry, Indiana University, Bloomington, IN 47405

The binding of inorganic metal ions to DNA plays a role in a number of natural processes. It may be involved in inducing certain diseases, but it also establishes the mechanism through which antitumor drugs such as cisplatin operate. MALDI experiments on DNA can be affected by reactions of acidic matrices with metal probes, and it is important to understand these effects in order to avoid experimental artifacts. Last year, we demonstrated that iron adducts are observable in MALDI/TOF mass spectra of single stranded deoxyribonucleic acid 27-mers¹. The origin of the iron was the stainless steel probe on which the matrix solution was deposited. When the stainless steel was covered by aluminum foil, iron adducts were not observed in the mass spectrum. Likewise, the addition of iron (II) chloride enhances the DNA-(Fe)₁⁺ ion yield and leads to the production of significant quantities of DNA-(Fe)₂⁺, DNA-(Fe)₃⁺ and DNA-(Fe)₄⁺ ions. The spacing between adduct ion peaks in the mass spectrum was only roughly established in the earlier work. A spacing of 56 Daltons would imply that neutral Fe atoms attach themselves to the DNA, probably bound by rather weak van der Waals forces. Spacing of 54 or 53 Daltons would indicate that Fe (II) and Fe (III) ions bind to the DNA and replace two or three protons in the process in order to maintain an overall net charge of minus one. At the pH of our MALDI sample solution, Fe (III) ions should be reduced to Fe (II) so it would be surprising if they were involved in the adduct formation.

In order to accurately assign the Fe adduct mass spacing, we chose to study a smaller DNA oligomer, a 10-mer, having the sequence GGGGTGGGG. With the same instrument used in our previous work, we recorded the mass spectrum displayed in Figure 1. The spacing between parent and Fe adduct peaks was found to be 158 nanoseconds. Based on time-of-flight calculations, this corresponds to a mass spacing of 53.9 amu. We therefore conclude that Fe (II) ions are binding to the DNA, and in the process they are displacing two protons. At the present time, we cannot say whether the Fe ions are binding at the phosphate groups (perhaps bridging two of them), or displacing an amino hydrogen, or possibly binding between a nucleophilic site on a purine base and a nearby negatively charged phosphate group. Our ability to observe Fe adducts of DNA depends on the MALDI matrix in use. The matrix may be involved in the liquid phase complex formation. Alternatively, some matrices may simply be better than others at preserving these adduct complexes in the gas phase.

Metal ions incorporated in inorganic metal complexes can also bind to DNA. Mass spectra of cisplatin-DNA complexes have previously been reported^{2,3}. We have studied the reaction of prospective antitumor agent Rh₂ (acetate)₂ (acetonitrile)₆ with a 10-mer of single stranded DNA, d(TTTTAATTTT). Figure 2 displays mass spectra recorded before and following 5 hours and 96 hours of reaction. Growth of reaction products (labeled in the figure) is evident. This method enables one not only to observe products but also to measure rate constants for the reactions under study.

MALDI ANALYSIS OF SYNTHETIC OLIGONUCLEOTIDES

Len C Packman¹, David C Dingley² & Paul Humphrey²

¹Protein and Nucleic Acid Chemistry Facility, Department of Biochemistry, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QW, UK

²Kratos Analytical, Barton Dock Road, Manchester, M41 7LD, UK.

While specialised laboratories have achieved mass signals from nucleic acids (RNA) up to >450 bases long, most routine analyses involve DNA or RNA up to 40 bases in length. The samples illustrated here were analysed on a Kratos KOMPACT MALDI III. The reflector mode of instrument operation gives the most accurate results but DNA in particular is prone to metastable fragmentation in the reflector and this limits the length of nucleic acid that can be analysed in this way. As a general guide, linear mode should be used above 30 bases long, which yields accuracies of $\pm 0.1\%$ (external calibration) and $\pm 0.05\%$ (internal calibration). Accuracy in reflector mode is much improved and will give results better than $\pm 0.03\%$.

All MALDI samples have to be prepared correctly to ensure satisfactory results. In particular, the use of cation exchange beads is required to remove Na^+ and K^+ from the oligonucleotide and replace them with NH_4^+ , which dissociates during ionisation. In -ve ion mode, the charge is then carried on the phosphate groups; in +ve ion mode, the charge is carried on a base. Using this method synthetic oligonucleotides can be analysed routinely.

Oligonucleotides should be desalted into water using a disposable Pharmacia NAP-10 gel filtration column. A typical sample concentration is in the range 50-1000 μM . The 3-hydroxytypicolinic acid is dissolved in 50% aqueous acetonitrile at a final concentration of 75 mg/ml. A cation exchange polymer is prepared in the ammonium form and suspended in water. 0.5 μl of each solution is then added to the multi-position sample slide. The slide is left to dry in air and all beads are removed with a blast of N_2 before placing the slide in the Kompact MALDI.

Analysis proceeds very quickly as the sweet spot (optimal analysis area) can be found either manually or using the 'Auto Aim' facility of the Kompact MALDI software¹. Using the sweet-spot finder analysis can be performed automatically in a completely "hands-off" mode. A full slide of 30 oligonucleotides can be analysed in half an hour without operator intervention. Calibration is also automatic and is achieved by the use of standard oligonucleotides.

Figure 1 - MALDI spectrum of 20 mer oligonucleotides acquired a) without and b) with ion exchange resin.

Results

The spectra in figure 1 show the benefit of ion exchange resins in analysing oligonucleotides. The sample was a 20mersyntheticoligonucleotide which was analysed without ion exchange step in the sample preparation procedure (Figure 1a) and after treatment with resin as described above (Figure 1b)².

The improvement in signal to noise is clear but more importantly, without ion exchange the peak is very broad due to multiple sodium adduct formation. Consequently it is difficult to obtain an accurate estimate of the mass of the sample. After ion exchange salt levels are reduced and the peak is much narrower. The mass can then be measured with considerably greater precision.

Conclusions

As these results show, synthetic oligonucleotides can be very quality checked in a very rapid, reliable and sensitive manner using a Kompact MALDI system with an appropriate sample preparation protocol. This methodology allows the QC screening of large numbers of oligonucleotides with a speed, accuracy and reliability not previously thought possible.

FACTORS INFLUENCING THE COMPLEX FORMATION IN MALDI-MS OF OLIGONUCLEOTIDE-PEPTIDE MIXTURES

Xiaodong Tang, Akos Vertes*

Department of Chemistry, The George Washington University, Washington, D. C. 20052

In our studies, we have successfully detected protein/oligonucleotide complexes using positive ion mode matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS).^[1] Here we report the preliminary results exploring the possibilities to reduce the fragmentation of oligonucleotides in MALDI analysis through complex formation between basic peptides and oligonucleotides. The influence of base sequence and pH dependence of complex formation are also discussed.

The experiments were carried out on a linear time-of-flight mass spectrometer in positive ion mode with a nitrogen laser excitation. Arg-Lys was chosen as model peptide in combination with different oligonucleotide samples, including pd(A)₉, pd(C)₁₀, pd(G)₁₀, pd(T)₁₀, pd(T)₁₁, pd(T)₁₂, pd(AGCTCAGCTT), d(TTAGCAGCTT), and d(AGCTTTTAGC). 2,5-dihydroxybenzoic acid (DHB), α -cyano-4-hydroxycinnamic acid (CHCA), and 6-aza-2-thiopyrimidine (ATT) were applied as matrices.

It was found that, by forming Arg-Lys/oligonucleotide complexes, degradation of the oligonucleotides might be substantially suppressed in positive MALDI. For example, d(AGCTCAGCTT) exhibited extensive fragmentation in DHB matrix (see Figure 1b), whereas the fragmentation was suppressed in (1:1)⁺ and (2:1)⁺ complexes (Figure 1a). Our explanation was based on the hypothesis that during positive ion formation base protonation initiated the fragmentation of oligonucleotide.^[2] We proposed that the much higher proton affinity of basic peptides prevented the protonation of oligonucleotide, thus minimized the possibility of base loss.

We have also determined the essential role of thymidylic acid in the complex formation of oligonucleotide.^[1] Further investigations showed that the strength of Arg-Lys/oligonucleotide complexes correlated with the position of thymidylic acid in oligonucleotide sequences. Figure 2 shows the mass spectra of the mixtures of d(AGCTTTTAGC) and d(TTAGCAGCTT) with Arg-Lys measured in ATT matrix. Up to 3 Arg-Lys molecules attached onto one d(AGCTTTTAGC) molecule. The intensity of the (1:1)⁺ complex ion was about one third of that of the oligonucleotide molecular ion. In contrast, we observed 4 Arg-Lys units attached to a d(TTAGCAGCTT) under similar conditions, with much more intense (1:1)⁺ and (2:1)⁺ ion signals. According to our simple model, intermolecular ion pair formation between positive charge on Arg-Lys and negative charge on phosphate group of thymidine 5'-phosphate largely attributed to the complex formation. Our observations confirm that the accessibility of T in the oligonucleotide sequence is another important factor in the complexation.

Since both nucleic acids and peptides are polyprotic systems, we expect pH to play an important role in the protein/oligonucleotide complexation process. The effects of increasing the pH on Arg-Lys/d(TTAGCAGCTT) complexes were studied. In the neat ATT matrix solution (pH=2.0), a broad variety of complex ions was observed (Figure 3a). The most abundant peak corresponded to (1:1)⁺, and the maximum number of Arg-Lys molecules attached to one oligonucleotide molecule was equal to the number of thymine bases in the sequence. When ATT was prepared in 1:1 NH₄HCO₃ buffer solution (pH=6.5), complex ions up to (6:1)⁺ were detected and the most abundant peak belonged to (2:1)⁺ (Figure 3b). The presence of Arg-Lys in the complex in excess of the number of T bases indicated the possibility of complexation between Arg-Lys and A, G, and/or C at close to neutral pH.

Introduction

Several strategies have been developed for the application of MALDI-MS towards a rapid determination of DNA sequences. The mass spectrometric analysis of DNA ladders generated by the Sanger technique is the common approach¹. However, limitation can be attributed to DNA fragmentation with increasing length. The use of modified nucleotides such as 7-deaza-purine bases stabilizing the N-glycosidic bond has proven to be a viable strategy to enhance the accessible mass range^{2,3}. Additionally an optimized DNA-polymerase provides further progress in terms of a more reliable Sanger sequencing reaction⁴. A procedure employing RNA-polymerase, ribonucleotides and respective chain-terminators leads to a transcription of the DNA-template into RNA ladders by the sequencing reaction. This takes advantage of the higher ion stability of RNA obtained in MALDI-MS analysis and the potential of RNA-polymerase for repeated transcription of the DNA template⁵. Direct sequencing at the RNA level is also a possible approach with resemblance to the method of Maxam and Gilbert for DNA. Ribonucleases with known specificity of cleavage sites ($T_1 \rightarrow G$, $PhyM \rightarrow U$ and A , $U_2 \rightarrow A$) have been used to generate a set of fragments to determine the position of respective bases⁶. Since no such base-specific enzyme is available for cytidine, mapping can be obtained after additional limited alkaline hydrolysis^{6,7}. For a sequence readout by MALDI-MS a separation of fragments with only single cleavage is helpful. This can be done by a solid-phase procedure via a biotin-tag at the 5'-terminus and streptavidin-coated magnetic beads⁷.

Experimental

20 pmol of a 5'-biotinylated RNA 40mer (10 pmol/μl) digested with RNase T_1 were incubated with an equal volume of a solution of streptavidin-coated magnetic beads (20 mM TRIS/HCl, 2M NaCl) for 15 min at room temperature. After extraction coupled fragments were eluted from the beads after treatment with a 10 mM EDTA, 95% formamide solution for 5 min at 90°C⁸.

Results and discussion

Specificity of the selected ribonucleases and the additional alkaline hydrolysis provide a set of fragments suitable for determination of the sequence. In MALDI-MS analysis fragments originated from single cleavages (retaining 5'- or 3'-end) as well as internal fragments were detected. Separation of single cleaved fragments starting from the 5'-terminus is performed at solid phase by using streptavidin-coated magnetic beads (Figure 1). Unfortunately elution of fragments requires buffer containing high amount of salt leading to reduced quality of the mass spectra due to extensive adduct formation. Further progress is needed to make this approach routinely applicable for determination of RNA sequences by of MALDI-MS.

Figure 1 (+)-UV-MALDI-MS spectra of a synthetic 5'-biotinylated RNA 40mer degraded with RNase T_1 , matrix: 3-HPA, wavelength: 355 nm (only fragments retaining 5'-biotinylated end labeled)

Peptide nucleic acids (PNAs) are a new class of DNA mimics in which the regular nucleobases of adenine, thymine, cytosine, and guanine are connected via a peptide-like backbone [1] (Figure 1). PNA molecules retain the same Watson-Crick base pairing as regular oligonucleotides with the added benefits of greater specificity and resistance to enzymatic digestion [2,3]. While the use of PNAs has grown rapidly because of their potential applications in biotechnology, little work has been done on developing analytical procedures for characterizing them. We have found matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry to be an effective tool for PNA analysis [4]. PNA molecules survive the MALDI process intact and are easily ionized with almost no multiply-charged species. These features allow mixtures to be easily characterized. Traditional protein matrices (e.g., sinapinic acid, 2,5-dihydroxybenzoic acid, α -cyano-4-hydroxy-cinnamic acid) were found to be superior to DNA matrices (e.g., trihydroxy-acetophenone, 3-hydroxypicolinic acid, picolinic acid). In addition, the new DNA matrix 6-aza-2-thiothymine [5] worked well.

When producing PNA oligomers using solid-phase peptide synthesis, "failure sequences" can result from incomplete coupling reactions, which are acetyl-capped, or by failure to remove the Fmoc blocking group (Figure 2). Thus, prior to HPLC purification, crude PNA products may contain a mixture of fragments. MALDI-TOF/MS permits rapid characterization of these synthesis byproducts (Figure 3), from which sequence information may be derived (Table 1). The sequence data may be confirmed by examining the mass differences between the acetyl-capped PNA molecules (Table 2).

Due to the fact that PNAs are enzymatically-indigestible, sequence information may not be obtained by conventional means. The ability of MALDI-TOF/MS to ascertain PNA purity and sequence information at low picomole levels is a valuable tool for quality control of PNA synthesis reactions. We have observed a wide variation in PNA product yields depending on the sequence and are hopeful that the information from this MALDI-TOF/MS technique may be used to improve the synthesis chemistry.

Rockville, MD 20850

Peptide nucleic acids (PNAs) [1] are DNA mimics. PNAs, which can be designed and synthesized as DNA typing probes, bind stronger and more specifically than DNA probes to their complementary DNA sequence. Since PNAs can be easily analyzed by MALDI-TOF mass spectrometry [2], conceptually, by measuring the mass of PNA(s) after hybridization, a rapid DNA typing technique can be achieved.

In this effort, different length PNA probes (9 to 18 mer) were analyzed by MALDI-TOF/MS and their mass was measured within 0.10% accuracy (Table 1). The sensitivity of MALDI-TOF/MS needs to be high enough to detect quantities typical of PCR production, usually in the femtomole region. In this study MALDI-TOF/MS was able to detect as low as 0.01 picomole (10 femtomole) of PNA probe (Figure 1).

PNA probes were hybridized to complementary DNA. The DNA/PNA duplex was analyzed by positive ion MALDI with accelerating voltage of 25,000v. The matrix was 6-Aza-2-Thiothymine (ATT). The DNA/PNA duplex was not observed by MALDI-TOF/MS, rather, the bound PNA probe was released from the duplex during the MALDI-TOF/MS process and its mass was measured as an intact PNA molecule (Figure 2). The PNA molecular weight then reveals which DNA type is present.

Crude PNA products were analyzed and then purified by HPLC. MALDI-TOF/MS give fast and accurate identification of PNA synthesis products and failure sequences which were subsequently separated by HPLC. In conclusion, MALDI-TOF/MS has been shown to be a fast and effective analytical tool for the identification of PNA probes and may be a useful tool for fast DNA typing.

The techniques of matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) represent important advancements in the area of biological mass spectrometry, allowing analysis of proteins over 250 and 100 kDa, respectively. In recent years, the ESI MS technique has been reported to be a powerful tool to detect protein-ligand, enzyme-inhibitor and protein-protein noncovalent interactions. We have successfully applied ESI MS methods to the detection of noncovalent interaction of ras protein with its ligand GDP and GTP. We also utilized ESI MS methodology to screen potential ras protein inhibitors that bind noncovalently with ras-GDP and produce biological activity against tumor cells. The ESI MS method, however, failed to detect a number of noncovalent complexes with molecular weights above 35 kDa (for example, FPT dimer, IL-10 dimer, etc.).

In this report we describe our findings towards the detection of noncovalent interactions using MALDI MS methodology. Three noncovalent complexes were examined by MALDI MS, one represents protein-ligand interaction (ras-GDP) and the other two systems cover protein-protein interactions (FPT-dimer, IL-10 dimer). The MALDI mass spectrum of ras-GDP (Figure 1a) displayed a strong singly charged ion at m/z 19,300 Da corresponding to the average molecular weight (M.W.) of the ras-GDP complex (theoretical value = 19,295 Da). The stability of the complex is dependent on the pH of the sample and the solvent system employed during the sample preparation (Figure 1b), with the complex being more stable near physiological conditions (Figure 1c). The MALDI MS methodology has been extended to the detection of farnesyl protein transferase (FPT), which is a noncovalent dimer of two subunits, alpha (44,408.7 Da) and beta (48,730 Da), with a combined M.W. of 93,138 Da. The MALDI mass spectrum of FPT exhibited singly charged ion at m/z 93,042 Da representing the noncovalent dimer of alpha and beta subunits (Figure 2a). Furthermore, in order to establish the noncovalent association of alpha and beta subunits of FPT, the protein was subjected to chemical modification with glutaraldehyde to form cross-linked glutaraldehyde-FPT, and the product was analyzed by MALDI MS. The MALDI mass spectrum (Figure 2b) showed an intense ion at m/z 95,360 which corresponded to the singly charged cross-linked dimer of alpha and beta FPT subunits. The MALDI spectrum also contained signals at m/z 45,552; 49,881; and 47,787 representing singly charged cross-linked alpha, cross-linked beta, and doubly charged cross-linked FPT, respectively. This MALDI-based methodology was also extended to the characterization of IL-10 dimer, IL-10 is a homo-dimer with a M.W. of 37,556. The MALDI MS data of cross-linked IL-10 provided the most intense signal at m/z 40,675 corresponding to the cross-linked dimer of IL-10. All cross-linked experiments were performed on 2 μ M and 10 μ M concentration of each protein in order to establish the specificity of the noncovalent binding.

Interferon alpha-2 (IFN α -2) a monomeric protein with M.W. 19,266, was subjected to glutaraldehyde cross-linked reaction at both low (2 μ M) and high (10 μ M) protein concentration levels. The products were analyzed by MALDI MS which displayed very intense peak (m/z 20,408) corresponding to glutaraldehyde modified IFN α -2 monomer. A trace level or very weak signal representing glutaraldehyde cross-linked nonspecific dimer (m/z 40,970) was observed in the spectrum. Additional work is in progress to establish the merit of this technique.

Analysis of Molybdopterins by MALDI

Paolo Lecchi¹, Vadim N Gladyshev² and Lewis K Pannell¹

Laboratory of Analytical Chemistry, NIDDK¹, and Laboratory of Biochemistry, NHLBI², NIH

Molybdenum enzymes, are ubiquitous in the biosphere, and play a key role in the biogeochemical cycles of nitrogen, sulfur and carbon. They contain Mo bound to an organic molecule, and can be divided in two categories according to the structure of molybdenum center (i) nitrogenases with an active site that is a "cluster" containing iron, molybdenum and sulfur, and (ii) molybdenum redox enzymes, with an active site that is the molybdenum cofactor, consisting of a Mo atom coordinated to a molybdopterin. However, in most bacterial and archaeobacterial tungstoenzymes, the active site is a molybdopterin bound to a nucleotide moiety. The structural characterization of the molybdoenzyme cofactors has been a difficult task because molybdenum cofactors are extremely unstable. The proposed structure was originally deduced from the established structures of two degradation products obtained from purified molybdoenzymes. In this communication we describe a procedure for the isolation and identification of molybdopterins from bacterial Mo and Se-containing enzymes isolated from two different cultured cell lines: nicotinic acid hydroxylase from *Clostridium barkeri* and formate dehydrogenase from *Escherichia coli*.

After release of the cofactor from the protein with guanidine HCl, it was alkylated with iodoacetamide and reduced with borohydride to give a more stable dicarboxiamido-methyl molybdopterin. In order to isolate the cofactor, advantage was made of the stronger binding of molybdopterin in its reduced state to a reverse phase HPLC matrix which allowed it to be separated away from other co-extractants.

The cofactors were then characterized by MALDI mass spectrometry. In order to develop a MALDI method for the analysis of these low MW compounds, several matrices were tried including α -cyano cinnamic acid, sinapinic acid, 2, 5-dihydroxy benzoic acid and 6-aza-2-thiothymine (ATT). The matrices were tested using folic acid, a pterin-containing cofactor. The best results (considering signal to noise ratio and interference from matrix peaks) were obtained using ATT in ammonium citrate buffer 20 mM pH 8/CH₃CN, 50/50 (4). The low background at low m/z allowed for the determination of these small compounds. Mass spectra were acquired on a KRATOS MALDI III mass spectrometer operated in negative ion linear mode. The mass spectrometer was internally calibrated with a 9-mer oligonucleotide.

The MALDI spectra of the two cofactors extracted from the two enzymes showed a MW that matched closely the proposed structures, as shown on the following page.

CONCLUSION: MALDI-TOF was used for the determination of the MW and hence proof of the structure of the isolated molybdopterin cofactor. This was done by the development of a new procedure for purification of molybdopterin. Mass spectrometry and UV spectroscopy were then used to identify the type of molybdopterin present in nicotinic acid hydroxylase and in formate dehydrogenase.

Acknowledgements. We thank Dr Thressa C Stadtman for her support and helpful discussions. We appreciate the use of the KRATOS MALDI III instrument from the lab of Dr Henry Fales (LBC, NHLBI).

Detection of Pathogenic and non-Pathogenic Bacteria by MALDI-MS Analysis of Protein Extracts and Whole Cell Suspensions

Philip L. Ross and Thaiya Krishnamurthy
U. S. Army ERDEC, Biopolymer Facility
Aberdeen Proving Ground, MD, 21010-5423

A definite need exists for instrumental methods which can rapidly detect and identify a broad range of microorganisms for hazard assessment in field situations. These methods must differentiate between related organisms and furthermore must permit unambiguous identification of particular species and even strains. In an ongoing effort to develop such methodology, we have recently demonstrated the capability of microorganism detection using protein biomarkers.¹ Crude protein extracts from several classes of pathogenic and non-pathogenic bacteria were directly analyzed by MALDI-MS, yielding genus, species and even strain specific biomarkers. We have also adopted a method whereby aqueous suspensions of intact, unprocessed cells are directly analyzed by MALDI-MS following treatment with matrix (α -cyano-4-hydroxy cinnamic acid). The whole cell approach can be carried out in under 15 minutes since cell lysis and protein extraction steps have been eliminated. Some of the important markers identified from analysis of the protein extracts are observed along with additional series of ions in the whole cell experiments.

To examine the feasibility of identifying species specific markers from MALDI-MS analysis of whole cell suspensions, we examined several species of *Bacillus* and *Brucella*. In Figure 1,

Figure 1 Whole cell MALDI-MS spectra for *Bacillus* species. Species specific marker ions are indicated with *.

unique ions are identified which permit differentiation between closely related *Bacillus* species. The results in Figure 1 are particularly encouraging since *B. anthracis*, *B. thuringiensis* and *B. cereus* have been difficult to distinguish even by DNA hybridization.² There are many common ions between these three species, whereas the spectrum for *B. subtilis* has only one ion in common with the other *Bacilli*. These observations are consistent with the established similarity between *anthracis*, *thuringiensis* and *cereus*. Common and unique markers for *Brucella* species

(*melitensis*, *suis* and *abortus*) have been identified in a similar fashion. MALDI-MS analysis of suspensions of bacterial pathogens such as *Bacillus anthracis*, *Brucella melitensis*, *Yersinia pestis*, and *Francisella tularensis* yields profiles that can be easily distinguished at a glance.

With insufficient nutrition, bacteria readily form spores, which comprise a large portion of airborne bacteria. For applicability as a rugged method for analysis in the field, this approach will have to provide consistent information in the presence of high numbers of sporulated bacteria. To this end, we have examined several strains of vegetative and sporulated samples of *B. anthracis*, as shown in Figure 2. Although the spectra are visibly different, a number of common marker ions

Figure 2 Whole cell MALDI-MS analysis of vegetative and sporulated *Bacillus anthracis* samples.

for *Bacillus* are present which permit identification of the organism. Experiments with several strains of *B. anthracis* has indicated that individual strains can be distinguished based on whole cell MALDI-MS data. In particular, we observe clear differences in spectra obtained for virulent and non-virulent strains of *B. anthracis*. Differentiation of such closely related organisms represents the ultimate challenge for successful microorganism detection and subsequent risk assessment in the field.

Experiments are currently underway to examine a larger group of

organisms incorporating many strains to construct a database with both MALDI and ESI-MS data. In addition to examination of various strains, future experiments will also address the effects of sample contamination through analysis of simulated and real environmental samples

Quantitative Measurement of some DMAP-TH Amino Acid Derivatives With MALDI TOF Mass Spectrometry

J. Zhou, T. D. Lee

Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010

J. M. Bailey

Hewlett Packard Co., Palo Alto, CA 94304

Introduction

Mass Spectrometry has been used to detect and identify the amino acid derivatives for potential coupling to automated protein sequencers. In order to successfully couple to protein sequencer, mass spectrometers must provide a quantitative measurement of the amount of amino acid derivatives released in each sequencing cycle.

Method and Results

Experiments were conducted in a Kratos Compact MALDI III reflectron time-of-flight mass spectrometer. The stainless steel sample slide contains 20 rectangular sample stage wells (2 mm x 1.5 mm). Spectra collected were an average of 100 laser shots over the length of the sample well and at the same laser irradiance. The α -cyano-4-hydroxycinnamic acid (CHCA) matrix was prepared as a saturated solution in 0.1 % TFA and acetonitrile (1:1, v/v). Amino acid derivatives, DMAP-TH (dimethylaminopropylthiohydation) Phenylalanine, Leucine, Valine, Tyrosine, Glycine and Aspartic acid, were dissolved in water and acetonitrile (1:1, v/v) at different concentrations. 1 - 2 μ L matrix solution was loaded onto each sample well to make a matrix pad. A 0.5 μ L aliquot of the sample solution was loaded onto each well in the same slide, and dried in air. Sample wells were first soaked with glycerol for several minutes and rinsed with MeOH before making matrix pad. This step was found to reduce the sodium contamination in spectra, increasing signal intensity of the derivatives. When certain amount of TMAP-TH (dimethylaminopropylthiohydation) Phenylalanine-Cl was used as an internal standard, 0.5 μ L of the appropriate solution was loaded onto the CHCA matrix pad, followed by 0.5 μ L of the sample solution. The two solutions were mixed on the stage and dried.

Figure 1 shows the relative intensity of DMAP-TH Leucine to matrix signal, 1a), and internal standard TMAP-TH Phe 1b), as a function of sample concentration. The linear correlation of signal to the sample amount only extends up to 0.4 pmol without internal standard, but up to 1.2 pmol with the internal standard. The internal standard was found to have some suppression on the signal of those derivatives. Detection limits for the DMAP-TH derivatives were found to be very dependent on nature of the amino acid residue. Table I lists results of the absolute signal intensity of those derivatives in the spectra taken sample amounts near their detection limit. In order to compare their relative sensitivity, the absolute signal intensity is normalized to the corresponding sample amount, and plotted in Figure 2. These results compliment our previous work on these same derivatives using electrospray MS (Basic et al. JASMS 6, 211, 1995)

CONCLUSION

MALDI time-of-flight mass spectrometry can be used to quantitatively measure some DMAP-TH amino acid derivatives. Linear correlation of their signal intensity to sample amount can be obtained in the range of 100-1200 fmol with internal standard. Without the internal standard, the absolute signal intensity is greater but more difficult to quantitate. Detection limits are strongly dependent on the nature of the amino acid residue. Glycerol treated stainless steel sample stage tends to decrease sodium contamination, increasing the signal intensity for the derivatives.

Structural Analysis of the HIV -1 protein Nef by Mass Spectrometry

**Urooj A. Mirza¹, Chi-Hon Lee², John Kuriyan^{2,3} and Brian T. Chait¹
The Rockefeller University, New York NY 10021*

The nef gene of the human and simian immunodeficiency viruses (HIV-1, HIV-2, SIV) codes for a protein that is critical for the development of AIDS. Viruses defective in the nef gene have been isolated from some humans who are experiencing long term non-progressive HIV-1 infection. It has been shown that Nef enhances virus infectivity and replication in primary cells and down regulation expression of CD4 the major receptor for HIV. Nef contains a highly conserved PxxP motif, which binds to the SH3 domain of Src family kinases. Previous studies have showed that the PxxP motif is essential for optimal spread of HIV-1 virus in primary cell cultures.

Initial attempts to crystallize the full length Nef protein (206 residues, 24K Da.) in the presence or absence of SH3 domain of the Src family Kinase Hck were unsuccessful probably because of the influence of the loose or floppy structural components of full length Nef. To probe structural features of Nef in solution and to define a minimal stable construct of the protein with reduced flexible components, we utilized a simple approach which employs a combination of enzymatic proteolysis and mass spectrometry (1). We used this methodology to obtain a minimal stable domain of the Nef protein in the presence as well as in the absence of the SH3 domain of Hck protein.

We used three different proteases trypsin, endo-GluC (V8) and subtilisin and followed the time course partial proteolysis of Nef in the presence and absence of SH3 domain. Both MALDI-MS and ESI-LC/MS were used to characterized the proteolysis fragments of Nef (Fig.1, it summarizes the ESI-LC/MS and MALDI-MS results obtained from a 2hr V8 digest of Nef (in the absence of SH3 domain)). The N-terminal region of the protein was observed to be very floppy. This finding was supported by the results obtained with trypsin and subtilisin. The region between residues 72-161 was highly stable against proteolysis, a result ultimately confirmed the crystal structure (2). The C-terminal region of the protein appears to be partly protected with only minor cleavages observed. The region between residues 153-183 was found to be susceptible to proteolysis as indicated in (Fig 1), later supported by the X-ray crystallography results which failed to obtain any structure of this region. The results obtained with MALD-MS are comparable with ESI-LC/MS (Fig 1). These techniques are very useful in identifying the proteolytic products of Nef protein.

Twentyfour hours of trypsin digestion of Nef in the presence and absence of the SH3 domain gave interesting results. Apart from the extensive digestion of N-terminal region we observed four fragments 46-77, 46-88, 112-140 and 112-150 (Fig. 2a) which were absent after incubation in the presence of SH3 domain (Fig 2b) . Similar results were obtained from the LC-MS experiments. These mass spectrometry results suggest that these regions are protected in the presence of the SH3 domain. Fragment 46-88 is protected because it has a PxxP motif (75-84) that binds specifically to SH3 domain and protection of region between 112-150 residues may be due to stabilization of the tertiary structure of Nef in the presence of SH3 domain. These mass spectrometry results are in good agreement with the crystal structure of Nef-SH3 complex, which shows directly the binding regions of these two proteins (2).

Careful analysis of these results allowed us to define a small stable fragment of Nef (62-212) . This construct retained the high affinity with the SH3 domain and readily yielded large crystals that were used to obtain at 2.5 Å resolution crystal structure (2).

Sequencing Of The Response Regulator Protein SpoOF by MALDI-PSD

William J. Jones, Gary W. Caldwell and John A. Masucci
The R. W. Johnson Pharmaceutical Research Institute
Welsh and McKean Roads, Spring House, PA. 19477

SpoOF is the response regulator protein for the two-component switch phospho-relay system that controls bacterial sporulation. SpoOF shares similar function and sequence identity with nearly 100 response regular proteins which are found only in prokaryotes and lower eukaryotes. The present study was undertaken to demonstrate the use of matrix-assisted laser desorption mass spectrometry in linear and post source decay mode (MALDI-PSD) as a high throughput sequencing method.

Mass spectra were obtained on a VG Tofspec E time-of-flight mass spectrometer at a source voltage of 22.5 KV. The laser used is a 337nm pulsed UV laser pulse at 5/sec. The matrix used was α -cyano⁴cinnamic acid prepared as a 10mg/ml solution in 50:50 water : acetonitrile with 0.1% trifluoroacetic acid. 1 μ l of matrix solution was pipetted onto the target, the solvent was allowed to evaporate, then 1 μ l of sample was pipetted onto the same spot and the solvent allowed to evaporate.

SpoOF, when needed in larger quantities for study, is produced with an N-terminal chain which contains 10 histidine residues. We have used this variant of SpoOF as well as naturally occurring SpoOF for mass spectral studies in protein sequencing.

The molecular mass of natural SpoOF was verified by MALDI-TOF and was in good agreement with the calculated mass. A trypsin digest of SpoOF was analyzed in linear mode showing the presence of 13 predicted fragments. In reflectron mode, ions were measured for 5 fragments of which only 1 fragment had a large enough S/N to obtain an adequate PSD spectrum. This PSD spectrum did not contain enough peaks to completely identify the fragment.

The linear mode mass spectrum of histidine "tagged" SpoOF showed the presence of two components. A sample of the histidine "tagged" SpoOF was digested with Xa enzyme which cleaves specifically after the amino acid sequence HIEGR. Mass spectral analysis of the digest shows a single peak in the singly charged molecular ion region and single peaks for the doubly and triply charged ions. Two additional low mass peaks were detected at m/z 2444 and m/z 2265. This digest was separated using a 10K molecular weight cutoff filter to separate the SpoOF from the fragments. The reflectron mode mass spectra, which have higher accuracy than linear mode mass spectra, of the fragment enriched sample showed two peaks at m/z2450 and m/z 2272. The peak at m/z2272 corresponds to a peptide of GHHHHHHHHHHSSGHIEGR. The PSD spectra of this ion shows the presence of nearly every predicted fragmentation including a large number of internal fragment ions as indicated by peaks corresponding to 1 to 8 histidine residues. The PSD spectrum of the ion at m/z2450 did not have enough S/N to identify it but a proposed sequence could be MGHHHHHHHHHHSGHIEGR which has a calculated MW of 2450. Further work must be done to improve PSD S/N in order to prove or disprove this sequence.

Histidine "tagged" SpoOF - mass determination - linear mode

Histidine "tagged" SpoOF - Xa digest - overnight

Post Source Decay - fragment 2272

PROTEINASE SPECIFICITIES STUDY BY MALDI-TOF MASS SPECTROMETRY.

INTRODUCTION

Proteinases have evolved specificities that make them precise and efficient actors in a number of physiological functions. The study of these functions needs a precise knowledge of the specificities of these enzymes, especially when they are involved in biological processes of pharmacological interest.

We describe here the use of MALDI-TOF MS for the rapid identification of the peptides generated kinetically from a known substrate during enzymatic digestion. This methodology allows the fast determination of the most susceptible bonds of the substrate and hence the specificities of the enzyme.

RESULTS

1) The methodology.

The classical approach to investigate the substrate specificity for a proteinase consists in a time-dependent generation of cleavage peptides from a known substrate followed by an rp-HPLC separation for each time point considered. The isolated peptides are then usually submitted to Edman degradation and the cleavage sites determined from the sequences. This method is time consuming, poorly sensitive and it does not allow the study of many incubation times.

Our methodology consists in directly analysing, by MALDI-TOF MS, diluted aliquots from the crude digestion mixture without separation. The analysis of these aliquots is therefore extremely rapid and easy which allows as many incubation times to be analysed as necessary for obtaining the sharpest image of the cleavage events. More, as MALDI-TOF MS is sensitive and tolerant to salts, only picomolar amounts of enzyme and substrate are needed and several different conditions can be tested simultaneously.

To validate the method, the kinetic of insulin B-chain digestion of two enzymes of known specificities, cathepsin G and neutrophil elastase, has been investigated¹. By displaying the spectra kinetically (fig. 1), it has been possible to classify the peptides' susceptible bonds into several categories according to their relative sensitivities to proteolysis and to compare easily the enzymes specificities for a given substrate. Our results are in very good agreement with those of the literature and show a few more cleavages (fig. 2)

2) Applications: determination of cleavage sites on membrane receptors.

Study of the thrombin receptor².

Upon thrombin digestion, the TRAP region of the thrombin receptor induces conformational changes responsible for the platelet activation (fig. 3). As this mechanism is inactivated by pretreatment with neutrophil proteinases, their specificities have been tested on synthetic overlapping peptides corresponding to the putative region of cleavage. The three enzymes tested (Cat. G, NE and PR3) are both able to cleave the thrombin receptor before the TRAP region therefore preventing the conformational change responsible for the activation (fig. 3)

Study of the $\alpha_{IIb}\beta_3$ integrin.

It has been previously demonstrated that while NE by itself does not activate platelets, it strongly enhances, in presence of exogenous fibrinogen, the weak aggregation induced by threshold concentration of Cat. G (thCat. G)³. In order to delineate the molecular mechanism involved in this potentiation process, several data focused our work on the $\alpha_{IIb}\beta_3$ C-terminus of the platelet fibrinogen receptor $\alpha_{IIb}\beta_3$ integrin⁴ (fig. 4). The NE cleavage site was searched on a synthetic peptide corresponding to the $\alpha_{IIb}\beta_3$ 827-841 sequence and has been precisely located between Val 837 and Asp 838. The mechanism of activation is illustrated on figure 4.

CONCLUSION

Our methodology allows the fast and highly sensitive determination of enzymatic specificities on natural substrates. The reproducible enzymes footprints obtained for a given substrate can easily be compared. By working on synthetic overlapping peptides corresponding to putative region of cleavage, the method allows also the fast determination of the enzymes' preferred cleavage sites on membrane receptors.

Grain Research Laboratory, 1404-303 Main St., Winnipeg, Manitoba, Canada,
R3C 3G8

Recently, MALDI has been applied to the mass analysis of high molecular weight glutenin subunits and the detection of large proteins from highly complex mixtures found in the wheat gliadins [1,2]. We have used linear mode MALDI TOF-MS to investigate the properties of the wheat protein fractions most responsible for processing quality. Mass spectra of the monomeric gliadins showed a complex pattern, consistent with the large number of individual components observed with reversed phase high pressure liquid chromatography (RP-HPLC) and electrophoretic analysis. Differences in mass spectra profiles were evident among 11 varieties from four Canadian wheat classes (Figures 1-4). These differences were sufficiently distinct to permit not only classification of these varieties but also correct identification of an unknown. Higher resolution may be required to resolve individual components to enable effective variety identification within each class.

The polymeric glutenin proteins of Katepwa, a hexaploid red spring wheat, were reduced and separated into high molecular weight (HMW) and low molecular weight (LMW) fractions. For the HMW fraction, five major peaks with molecular weights ranging from 68.3 to 89.3 kDaltons were resolved (Figure 5). The number of peaks was consistent with profiles obtained from RP-HPLC and SDS polyacrylamide gel electrophoresis (SDS-PAGE). Individual subunits collected by RP-HPLC each gave single mass spec peaks corresponding to each of the five peaks in the HMW fraction (Figure 6). The LMW mass spec profile was more complex than the HMW profile. Major peaks were obtained at 32.6, 37.9, 39.8 and 42.4 kDaltons. Peak shapes suggested the presence of multiple components in each peak, indicating a need for higher resolution.

Results of this study indicate that MALDI of gliadins may prove useful for wheat class and possibly wheat variety identification. This technique can also be used for identification and accurate determination of molecular weights of wheat glutenin subunits.

Rapid Identification of Intact Whole Bacteria Based on Spectral Patterns Using MALDI/TOF MS

Ricky D. Holland, Jon G. Wilkes, Fatemeh Rafii, John B. Sutherland, Cecil C. Persons, Kent J. Voorhees*, and Jackson O. Lay, Jr., National Center for Toxicological Research, Jefferson, AR, and *Colorado School of Mines, Golden, CO

INTRODUCTION

Use of MS for the characterization of bacteria was investigated in 1975 by Anhalt and Fenselau [1]. Recently, pattern recognition and sample pyrolysis have been the basis for the identification of intact bacteria, for example the work of Deluca *et al.* [2]. Cain, *et al.*, reported the use of MALDI/TOF MS to differentiate bacteria based on a different approach, the analysis of proteins in solutions obtained after cell disruption [3]. Herein, we report a method for the rapid identification of bacteria based on ions formed by MALDI directly from intact cells.

METHODS

Bacteria: Five species (different genus) were grown for 24 hours on Trypton Soy agar plates. These samples were used to obtain "reference" spectra. The same bacteria (different cultures) were blind-coded and reanalyzed as unknowns along with four other bacteria (controls). For species-specific identification three *Pseudomonas* bacteria were cultured, grown and analyzed under identical conditions. **Sample Preparation and Analyses:** A saturated matrix solution was prepared by dissolving α -cyano-4-hydroxycinnamic acid in a 2:1 (H_2O :ACN), 0.1 % TFA. Bacteria were removed from the agar plate using a disposable pipette, suspended in matrix solution (1 μ l) and placed on sample pins. Care was taken to minimize removal of agar. Spectra were obtained with a Vestec Lasertec (Houston, TX) MALDI TOF MS (positive ions, 26 kV acceleration voltage) with a Nd-YAG laser at 355 nm.

RESULTS

Reference Spectra: After it was determined that each bacteria gave a unique spectrum all were recultured, blind-coded, and reanalyzed along with four other bacteria (blind-coded controls). A representative spectrum from each of the nine bacteria was compared to the "reference" spectra. Five of the unknowns were judged to match reference spectra, whereas the other four were not. After the samples were decoded, spectra from the five bacteria matching a reference spectrum were found to be recultured samples from the identified bacteria. Figure 1 shows a typical spectrum from one of the unknowns and the corresponding reference spectrum. In this case and with the other bacteria, at least two ions were observed in both the reference and unknown spectra that were not seen with other bacteria. For example, with *Enterobacter cloacae* (fig. 1) unique signals were observed near m/z 7700 and 9600. With *Proteus mirabilis* signals were observed near 6200, 6400, 12700, and 16300 u (weak). While *Shigella flexneri* and *Escherichia coli* also showed a signal near m/z 6300, *Proteus mirabilis* gave signals near both 6200 and 6400 u and also had other characteristic signals. In summary, diagnostic ions were observed from all five bacteria.

Species-specific Identification: Minor variations between reference and unknown spectra were noted. Also some non bacteria-specific ions were observed. Therefore, for the experiments aimed at species-specific identification, co-analysis of samples was employed. A more complete statistical treatment (or artificial intelligence) may also allow species-specific identification based on comparisons with reference spectra, but this has not yet been demonstrated. Figure 2 shows the spectra obtained from three *Pseudomonas* bacteria under identical conditions. As noted in the legend, although some ions were observed with more than one bacteria (in one case all three), enough unique ions were observed to allow all three species to be unambiguously identified. Also, an ion near 8700 u, observed in all three *Pseudomonas* spectra but not with other bacteria, may be *Pseudomonas* specific.

CONCLUSIONS

The findings that some signals were encountered in more than one bacteria and that signals were not always observed from the same bacteria in replicate experiments were not unexpected. Current sample collection procedures retrieve both living and dead organisms and potentially include contamination from the culture medium as well. Moreover, whole bacteria were analyzed, without any purification or pretreatment. Nevertheless, five bacteria were easily identified from a larger group (including controls) based on a comparison of their MALDI/TOF mass spectra with reference spectra. This result suggests that such comparisons should be useful for the rapid determination of genus. When analyses were conducted under near-identical conditions, it was also possible to obtain unique spectra for three different species of bacteria *Pseudomonas*.

Peptide Profiling with MALDI-TOF MS of Isolated Neurons from Marine Invertebrates

Rebecca W. Garden, Leonid L. Moroz, Tatiana P. Moroz, and
Jonathan V. Sweedler

Department of Chemistry, University of Illinois, Urbana, Illinois, 61801

In order to understand neuronal function, knowledge of the signaling molecules present in individual neurons is important. Peptide transmitters and hormones are a complex group of signal mediators that are difficult to identify and assay within single cells. One goal of our research is to develop methodology necessary to study bioactive peptides within individual invertebrate neurons and to determine their physiological activity. A critical step toward this goal is the ability to rapidly profile the peptide content of cellular samples. Such analysis is achieved in our laboratory by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). The application of MALDI-TOF MS to the identification of peptides contained in complex environments is widespread. One of the most complex samples examined by MALDI is biological cells and tissues. Van der Greef and coworkers have developed an elegant method of isolating individual peptidergic (neuropeptide-containing) neurons from the pond snail *Lymnaea stagnalis*, placing the cells on a MALDI target, and acquiring mass spectra of the peptides present in individual cells.^{1,2}

Peptidergic cells from marine mollusks including the herbivore *Aplysia californica* and the predator *Pleurobranchaea californica* provide an excellent opportunity to study many fundamental aspects of neuronal function and cellular communication. However, the direct mass spectrometric analysis is complicated by the physiological salt concentrations encountered with marine species. Although the matrix, 2,5-dihydroxybenzoic acid (2,5-DHB), is known for tolerating salts and impurities, the 500 mM sodium chloride associated with these cells results in excessive sodium adduct formation, poor spectral resolution, and problems with reproducibility. Because sample preparation plays such a critical role in the ability to routinely obtain MALDI mass spectra, many approaches to eliminate inorganic salts from samples have been developed, ranging from thin-film loading techniques³ to micropreparation using a packed capillary.⁴ However, such methods are not applicable to intact cells. We report a unique rinsing procedure that permits individual neurons from marine invertebrates to be placed directly on the MALDI target and assayed for their bioactive peptides.

The procedure previously used with freshwater invertebrates is modified in order to accommodate the ten-fold increase in salt content associated with cells from marine species. Spectral degradation is greatly reduced by employing a simple "matrix rinsing" step either directly on the MALDI target or during the microdissection. The matrix 2,5-DHB not only serves to facilitate ionization, but is also used to remove salts, denature endogenous proteolytic enzymes, and to aid in dissections by stabilizing cell

membranes. Our technique yields mass spectra which indicate the presence of many known, as well as unknown peptides and precursors. The effectiveness of our strategy was confirmed by applying it to neurons isolated from *Lymnaea*. Resulting MALDI mass spectra are similar to those previously reported.² A representative spectrum acquired from a single light yellow cell neuron is shown in the following figure.

Several groups of identified neurons from the central nervous system of *Pleurobranchaea* have been assayed. Consistent, cell-specific mass spectra are obtained which suggest that up to 10-12 individual peptides can be co-localized in individual neurons. The figure below shows a typical mass spectrum of a single efferent copy cell. We expect MALDI-TOF MS to have a large impact on fundamental studies of peptidergic communication.

A Thin-film MALDI Matrix Loading Technique for Water Insoluble Compounds. Richard Milberg and Rebecca W. Garden, University of Illinois, School of Chemical Sciences, 600 S. Mathews, Urbana, IL 61801

INTRODUCTION

MALDI is usually performed either by mixing sample and matrix solutions on the target or combining these together beforehand and applying the mixture to the target. Most matrix solutions are usually prepared in water/acetonitrile which precludes the analysis of samples soluble only in chloroform, methylene chloride, or toluene. Results have previously been reported for the analysis of water insoluble compounds by metal ion attachment^{1,2} or the use of organic-soluble matrices, co-mixed or sprayed on the target, as well as the use of an IR laser.^{3,4,5,6}

A method of analysis has been developed here for water insoluble compounds based on the previously reported thin-film rapid evaporation technique⁷. Matrices such as α -cyano-4-hydroxycinnamic acid (ACHC), [2-(4-hydroxyphenylazo)-benzoic acid] (HABA), *trans*-3-indoleacrylic acid (IAA), and *all-trans*-retinoic acid (TRA) have been employed with a 337 nm N₂ laser. Compounds such as metalloporphyrins, organic dendrimers, surfactants, and polymers, some with molecular weights in excess of 40,000 Da, have been routinely analyzed by this method. The technique requires 10-100 picomoles of material and samples can be loaded from most volatile organic solvents. The organic solvent often re-dissolves the matrix and sample together but this does not affect the performance. The loading technique also provides sub-picomolar sensitivity for peptides and proteins as previously reported.⁷ This provides a means for the mass calibration of the instrument. The method also permits the washing of the target to remove excess salts and buffers.

EXPERIMENTAL

Mass spectra were acquired on a Micromass (Manchester, UK) ToFSpec MALDI mass spectrometer operated in the linear mode employing the 337 nm nitrogen laser. Multiple laser shot data were acquired in the MCA mode and processed using a Micromass SIOS/OPUS data system. ACHC (5 mg plus 2% H₂O), HABA (5 mg) and IAA (4 mg) were dissolved in 1 mL of acetone. These concentrations were found to be optimal for use with the ToFSpec targets, whose spots are 2.5 mm in diameter. 0.034-M TRA was prepared in methylene chloride as previously reported⁸ and exposed to the fluorescent lights in the laboratory at room temperature for at least 72 hours.

2.0 μ L of the matrix solution was loaded on each target spot and allowed to air dry. The samples were dissolved in a suitable solvent, usually methylene chloride, chloroform, or THF at a concentration of 100 picomoles/ μ L. 1.0 μ L of sample solution was added to each target spot and allowed to air dry. Proteins such as bovine insulin, employed for calibration, were prepared in 0.1% TFA at a concentration of 1 picomole/ μ L and 0.5 μ L of the solution was deposited in the center of the matrix and allowed to air dry. Peptide and protein samples were washed after drying by depositing 2.5 μ L of 0.1% TFA on each target spot and then blowing off the drops with dry nitrogen after a few seconds.

RESULTS AND DISCUSSION

The selection of a matrix for unknowns is often empirical; samples are frequently run on more than one matrix. ACHC and IAA are better suited for lower molecular weight compounds than HABA due to the reduced intensity of background matrix peaks. IAA often produces (M+Na)⁺ or (M+K)⁺ species for dendrimers⁹ and porphyrins, which can be confusing when analyzing unknown compounds. TRA appears to be useful for organic dendrimer compounds with molecular weights above 20,000 Da which do not produce satisfactory spectra employing HABA or IAA. HABA generally provides better mass resolution than IAA or TRA for dendrimers.

The concentration of matrix employed is dependant on the target spot size. An excess of matrix is detrimental to the performance of the technique. The concentration of matrix employed and the amount deposited have to be determined experimentally for a particular target spot size.

One problem with thin-film matrix loading is the relatively few laser shots one can obtain from a point on the target spot before exhausting the sample there. The laser beam must be moved frequently to maintain a constant signal. It was observed employing ACHC as a matrix on a MALDI mass spectrometer with a color video imaging system that the yellow matrix/sample coating was ablated away after a number of laser shots at a given position.

CONCLUSIONS

A simple, rapid method for the analysis of a wide variety of water insoluble compounds by MALDI has been developed. The technique does not require that the sample and matrix solutions be miscible. The technique provides excellent mass measurement accuracy and permits the instrument to be calibrated with peptides and proteins of known mass. The technique is routinely used in this laboratory.

ACKNOWLEDGEMENT

The Micromass ToFSpec mass spectrometer was purchased in part with a grant from the Division of Research Resources, National Institutes of Health (RR07141). I would like to thank Professors J. S. Moore, K. S. Suslick, and S. C. Zimmerman in the Chemistry Department here for the dendrimer and porphyrin samples.

SEARCHING FOR THE BIOCHEMICAL MARKERS FOR ALZHEIMER'S DISEASE USING IMMUNOPRECIPITATION/MASS SPECTROMETRY

Rong Wang

Laboratory for Mass Spectrometry, The Rockefeller University, New York, NY 10021

Alzheimer's disease (AD) is a neurological progressive degenerative disease that attacks the brain and results in impaired memory loss, thinking and behavior. AD is the most common form of dementia and is the fourth leading cause of death among adults, after heart disease, cancer and stroke. AD was first discovered by Dr. Alois Alzheimer in 1906. Although subsequent researchers have developed a deeper understanding of the changes in the brain and the corresponding clinical symptoms of AD, the causes of AD are still not known. In addition, there is no single clinical test to identify AD nor any cure for this debilitating disease.

One of the characteristic neuropathological features of AD is the presence of amyloid deposits, as senile plaques, in hippocampus and neocortex. In many cases, amyloid depositions are also found in the walls of cerebral and meningeal blood vessels. Such deposits in the AD brain are mainly composed of amyloid β -proteins (A β s) containing between 39 and 43 amino acid residues. However, the relationship between these A β protein deposits and AD remains unclear. Unfortunately, past investigations have not adequately elucidated the metabolism of A β . Without an understanding of its metabolism, we believe it will be difficult to understand the role of A β s in AD.

To investigate the metabolism of A β , we have developed a highly specific method to sensitively (0.1 nM) measure A β and its related species using immunoprecipitation and mass spectrometry (IP/MS). In this method, A β s were specifically isolated by monoclonal anti-A β antibodies. The identities of these isolated A β s were determined by their molecular masses using mass spectrometry. The concentration of A β s were determined by their relative abundance in the mass spectrometric measurement. We have successfully detected A β and its related species from cell culture media conditioned with both human and mouse cells transfected with human amyloid precursor protein (APP) cDNA, from cell homogenizing extract, and from each individual cerebrospinal fluid (100 μ L).

Cultured mammalian cells constitutively produce and secrete A β . The profile of total soluble A β expressed by cultured cells was characterized using mouse neuroblastoma (N2a) cells which were stably transfected with human APP695 cDNAs encoding either wild type (N2a/APP) or Swedish FAD mutant APP (N2a/APP^{swe}). These mouse neuroblastoma cells were incubated in serum-reduced media (0.2% fetal bovine serum) for 24 hr. The sA β peptides secreted into the cultured media (0.5 mL) were analyzed by immunoprecipitation with anti-A β mAbs and MALDI-TOF-MS. The mass spectrum resulting from IP/MS analysis of N2a/APP^{swe} cells using mAb 4G8 is shown in

Figure 1. The identities of peaks were assigned according to mass and are identified in the figure according to A β amino acid sequence numbers. In addition to the species containing amino acid sequence 1-40 (A β ₁₋₄₀) and 1-42 (A β ₁₋₄₂) of A β (the major component found in senile plaque of AD), we have observed several short forms of A β -related peptides. Surprisingly, together with another mAb, 6E10 (Fig. 2), we identified a total of 44 different secreted A β -related peptides. A similar A β profile was observed for cells expressing wild-type human APP695 (N2a/APP).

Figure 1. MALDI-TOF-MS spectrum of human soluble A β and its variants detected from cell culture medium conditioned with N2a/APP^{swe} cells following IP/MS using mAb 4G8.

Figure 2. MALDI-TOF-MS spectrum of human soluble A β and its variants detected from cell culture medium conditioned with N2a/APP^{swe} cells following IP/MS using mAb 6E10.

The sensitivity and dynamic range of IP/MS for measuring A β peptides were tested with 4 synthetic A β peptides. A β ₁₂₋₂₈ which appears not to be produced naturally was used as internal standard. The relative peak heights for every A β peptide to A β ₁₂₋₂₈ were measured for quantitation study. The results from this study demonstrated that IP/MS has Broad Concentration Ranges for A β Peptide measurement. The correlation coefficients between the relative peak height and peptide concentrations are greater than 0.999 for all of peptides tested in the concentration range of 0.01 nM to 100 nM. detection. The overall measurement variation was 21.8%, averaged across all of the data in this study.

MASS ANALYSIS OF GROWTH FACTORS ASSOCIATED WITH PROLIFERATIVE DIABETIC AND VITREO RETINOPATHY BY MALDI - MS

I. K. Perera¹, P. Bagga², D. Verma² and P. E. Dyer¹

¹ Department of Applied Physics, University of Hull, Hull, England.

² Department of Ophthalmology, Hull Royal Infirmary, Hull, England.

Proliferative diabetic retinopathy (PDR)[1] and proliferative vitreous retinopathy (PVR)[2] are two chronic eye disorders that can eventually lead to severe impairment of vision. They both involve the proliferation and migration of cells to form fibrocellular membranes on and around the retina. Of these, PDR affects about 5% of the diabetic population and is characterised by the presence of preretinal neovascular membranes that can later extend into the vitreous cavity. The progressive contraction of these fibrovascular membranes can cause vitreous hemorrhage or retinal traction detachment. PVR, on the other hand, is a process of fibrocellular cascade where both glial and retinal pigment epithelial cells participate to form somewhat similar contractile membranes and thereby initiate a chain of events that can cause dehiscences in the internal limiting lamina and/or complex retinal detachments. In these proliferative phenomena, various peptide growth factors including the two insulin like growth factors (IGF I and IGF II) and growth factor binding angiogenic proteins (GFBAP) are now being recognized to play an important role [3].

The technique of MALDI [4], that has proven to be useful for studying a variety of biomolecules, ranging from simple peptides, proteins, complex fibrous and glycoproteins, carbohydrates to large DNA molecules, offers a unique approach for the detection of these growth factors associated with proliferative retinopathies and for determining their respective molecular masses with high precision and accuracy. The purpose of this presentation is therefore, to detail such an investigation which, to the best of our knowledge, is reported for the first time.

The experimental set up used comprised a research-tec time-of-flight mass spectrometer (Vestec, Houston, TX) equipped with a simple N₂ laser for sample irradiation [5,6]. The 3 ns pulses from the N₂ laser at 337 nm were focussed on to the sample (spot size 200x300 μm²); the maximum fluence on the target being ~50 mJ cm⁻². The samples were maintained at ~25 kV, and upon laser irradiation the ions produced were accelerated in two stages, then drift through the 1.2 m long flight path and were detected in the linear mode by a micro channel plate followed by a 20 stage dynode electron multiplier. The ion signals from the detectors were amplified and then digitized at 500 MHz by a Tektronix (Beaverton, OR, USA) TDS 520 oscilloscope. The spectra were eventually transferred to a 486 based PC for data processing and storage.

Pure vitreous samples from several patients undergoing pars plana vitrectomy (PPV) for various conditions including PDR and PVR were collected using a three way tap and a syringe attached to the suction tubing of the vitreous cutter [3]. They were diluted with the respective matrix solvent at a ratio of ~1:5 and then analysed by MALDI without any purification, using ferulic acid, sinapinic acid or coumarin 120 [5] as matrices. Bovine insulin (M = 5733.5) was used as a standard for external as well as internal calibrations of the resulting mass spectra, internal calibrations being performed employing analyte samples prepared using a mixture of the diluted vitreous and insulin (0.1 g/l) solutions at a ratio of about 10:1.

Figure 1a shows a typical mass spectrum obtained from a PVR vitreous sample in a sinapinic acid matrix. In this externally calibrated mass spectrum (fig. 1a), three molecular ion signals of masses ~6986.8 Da, 7595 Da and 7984.8 Da, and their respective dimers at ~13,929 Da, 15,191 Da and 15,934 Da are observed. Of these, the signals at 7595 Da and 7984.8 Da, probably represent molecular ions of IGF II (M ~ 7471) and IGF I (M ~ 7649) respectively, although small differences (+124 Da and +335.8 Da) were observed between the masses detected by MALDI and those estimated previously using conventional methods [7]. It has also been suggested that some growth factors usually exists in their dimeric forms [3] in the vitreous and it may be the reason for observing relatively higher ion yields from the respective dimers. Additional ion signals probably

Fig.1 Mass spectra of (a) pure PVR, (b) pure PDR, and (c) insulin mixed with PDR vitreous sample in a sinapinic acid matrix

indicating the presence of other growth factors and/or GF-BAP, were observed from PDR vitreous samples, and a typical mass spectrum obtained from one such sample with sinapinic acid as the matrix is shown in fig. 1b. In this spectrum, in addition to the ion signals (IGF₁⁺, 2IGF₁⁺) observed in fig. 1a, monomeric ions of masses 10,171 Da and 11,766 Da, and their respective dimers at 20,369 Da and 23,521 Da, are clearly observed. More accurate mass analysis of the ion signals formed, was performed using insulin as an 'internal calibrant'. This is illustrated in fig. 1c which shows a mass spectrum obtained from a PDR vitreous sample mixed with insulin in a sinapinic acid matrix. It was calibrated internally using the known masses of the monomeric (M⁺) and dimeric (2M⁺) ion signals of insulin. The resulting measurements have indicated that the masses of the detected IGF I and IGF II molecular ions are in the region of 7567.6 Da and 7939.8 Da, while those of the corresponding dimers are ~15114 Da and 15,854 Da respectively. It is also important to note that some growth factors were observed in the desorption of non retinopathic vitreous samples but, the corresponding ion signals obtained were very weak indicating probably that their concentrations in the relevant samples were relatively low. Additionally, albumin (M ~ 66,000) was detected in all vitreous samples (~20) investigated, while human hemoglobin was found to be present in some of the samples.

In conclusion, several peptide growth factors and some GF-BAP, including IGF I and IGF II, have been detected in vitreous samples extracted from patients with proliferative retinopathies, the results demonstrating that the technique of MALDI is a simple and a convenient approach for their mass analysis.

Fragmentation Mechanisms of N-Terminal Charge-Localized Peptide Derivatives

Pao-Chi Liao, John Allison, Zhi-Heng Huang, Douglas A. Gage, Kenneth Roth, and J. Throck Watson

Department of Biochemistry and Chemistry, Michigan State University, East Lansing, MI 48824

Post-source decay (PSD) in matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry is useful for obtaining sequence information of peptides using subpicomolar amounts of samples [1]. However, the complexity of peptide ion fragmentation often makes solving the sequence of an unknown peptide difficult and time-consuming. Localization of a fixed charge to the N-terminus of a peptide promotes only the formation of N-terminal fragment ions, greatly simplifying data interpretation [2]. We report here the use of amino-terminal tris(trimethoxyphenyl)phosphonium (TMPP) derivatives of peptides in MALDI-PSD mass spectrometry. The basic feature of the MALDI-PSD spectra and possible fragmentation mechanisms are discussed.

S-Pentafluorophenyl [tris (2,4,6-trimethoxyphenyl)phosphonium]acetate bromide was synthesized in our laboratory and used to react with the N-terminus of a peptide, by a coupling reaction, for localizing a charged [tris(2,4,6-trimethoxyphenyl)-phosphonium]acetyl (TMPP-Ac-) group at the N-terminus of the peptide. All MALDI-PSD data were obtained on a Voyager Elite (PerSeptive Biosystems, Inc., Framingham, MA) linear/reflector time-of-flight mass spectrometer equipped with a nitrogen laser (337 nm, 3-ns pulse). The acceleration voltage used was 25 kV. The matrix was α -cyano-4-hydroxycinnamic acid.

The product ion spectra of TMPP-peptide derivatives generated by MALDI-PSD-TOF-MS experiments were generally dominated by "a-type" ions. Several possible mechanisms which may account for forming "a-type" fragment ions were considered. Based on the observed m/z value of "a-type" ions, we believe that the "a-type" ion is formed by bond breaking through a charge-remote 1,2-elimination or 1,6-rearrangement, accompanied by a hydrogen shift. Exceptions occurred when aspartic acid residues were involved, where "b-type", "c-type" and "d-type" ions were observed. The nomenclature used here for the product ions of TMPP-peptides is similar to the notation proposed for fragment ions from protonated peptides [3], although the product ions of TMPP-peptides are products of charge-remote fragmentation. Figure 1 shows a MALDI-PSD product ion spectrum of the derivatized peptide, TMPP-Ac-WAGGDASGE-OH. The complete series of "a-type" ions were observed, except at the aspartic acid residue. We have examined several peptides that contain aspartic acid residues. All of the aspartic acid residues exhibit intense peaks representing "b-type", "c-type" and "d-type" ions. In Figure 1, "a+2" and "b+18" ions were also observed.

Why do the aspartic acid residues promote such "unusual" fragmentation? A possible explanation is proposed. Figure 2 shows the possible fragmentation mechanism which leads to the observed "c-type" ions. The aspartic acid side chain may undergo some unique rearrangement reactions which lead to the fragment ions.

ULTRAVIOLET MALDI-TOF MS AND PSD STRUCTURAL DETERMINATIONS OF SPORE CORTEX MUROPEPTIDES

J. Helin^{*,†}, C. E. Costello^{*}, D. Popham^{*} and P. Setlow^{*}

^{*}Boston Univ. School of Medicine, Boston, MA and [†]Univ. of Connecticut Health Center, Farmington, CT. [†]present address, Institute of Biotechnology, Univ. of Helsinki, Finland

Bacterial endospores are formed to permit survival of the bacterium in a hostile environment over long periods of time. The outer shell of the endospore is composed largely of peptidoglycan - a glycopeptide that contains repeating disaccharide units of *N*-acetylglucosamine and *N*-acetyl muramic acid linked to L-alanyl-D-glutamyl-*meso*-diaminopimelic acid-D-alanine or a fraction thereof (Fig. 1). Glycan chains are composed of alternating *N*-acetyl-glucosamine (NAG) and *N*-acetyl-muramic acid (NAM) residues. NAM can carry side chains of either L-Ala or the tetrapeptide L-Ala-γ-D-Glu-Diaminopimelic acid-D-Ala. Approximately 50% of the muramic acid residues have no side chain and have been converted to muramic acid lactam (MAL).

The glycan chains can be cross-linked *via* the tetrapeptide side chains; a peptide bond is formed between the ε-amino group of diaminopimelic acid of one peptide and the carboxy-terminal D-Ala of another peptide. The carbohydrate portion may vary in its modifications and the saccharide chain length between peptide substitutions. These patterns vary among the different types and strains of bacteria. We are presently studying spore cortex peptidoglycans released from strains of *B. subtilis*, a wild strain and a second strain that shows a significant increase in cross-linking. For structural analysis, the cell wall peptidoglycan matrix is digested with muramidase and reduced with sodium borohydride, and the products are separated by HPLC.

Bacterial strains and sporulation conditions. Muropeptide extraction and purification. *B. subtilis* strains are derivatives of strain 168. Spores were washed with water and were lyophilized. Purified spores (3-5 mg dry wt) were rehydrated in 1 ml H₂O (16 h, 40°C). Rehydrated spores were centrifuged, treated with decoating solution and washed. Lytic enzymes deactivated by TCA treatment. The inactivated spores were washed [1 M Tris-UCI (pH 8.0) and 5X in H₂O]. Most protein was removed by tryptic digestion (16 h, 37°C). SDS was added to 1% and the spores were heated (15 min, 100°C). Extracted spores were washed *ca.* 15X in H₂O to remove SDS. Peptidoglycan was then digested [Mutanolysin (Sigma) (16h, 37°C)]. After centrifugation and the supernatant lyophilized. Muropeptides were reduced [100 μL 0.25 M Na₂B₄O₇ (pH 9.0)],

Fig. 1. Structure of the peptidoglycan in spores of *B. subtilis* (Warth and Strominger, 1972).

HPLC: Waters system Hypersil-ODS 3 μm, 250 x 4.6 mm, with Javelin guard column (both from Keystone Scientific), maintained at 51-52 °C. Two gradients were used: (1) buffer A, 20 mM NaPO₄ (pH 4.31) and buffer B, 50 mM NaPO₄ (pH 4.95) in 30% methanol and (2) buffer A, 0.1% TFA (pH 1.5) and buffer B, 0.1% TFA in 20% CH₃CN (pH 1.5).

MALDI-TOF: Finnigan MAT (Thermo BioAnalysis) Vision 2000 reflectron TOF MS. Laser Science, Inc nitrogen laser (337 nm, 3 nsec pulse width) Manual shot control with video observation of sample. Linear mode accelerating voltage: +/- 30 kV; reflectron mode: +/- 5 kV; post-source decay mode. 5 or 10 kV. Samples and 2,5-dihydroxybenzoic acid matrix dissolved in water or water/acetonitrile. Samples: 1-5 pmol for MALDI, 10 pmol for PSD.

Results: Carbohydrate reduction to improve chromatography resulted in muramic acid lactam reduction as well; conditions were selected that allowed complete reduction of terminal muramic acid with 20-30% reduction of muramic acid lactam. Observed molecular weights spanned the range from 800-3000 Da. Fig. 2 shows the molecular ion region of the spectrum of a tetrasaccharide-tetrapeptide (TS-TP). In general, the samples showed better sensitivity in the negative-ion mode. This is understandable, because of the number of free carboxylic groups. Conversion of the acidic residues to methyl esters improved positive-ion sensitivity and diminished the attachment of cations. Mass spectrometric determinations of the molecular weights of the HPLC fractions differentiated among possible multimeric structures that could be accommodated by the amino acid analysis data and suggested carbohydrate and peptide compositions. Both the native material and the methyl esterified material yielded strong PSD spectra that were rich in fragmentation. Both glycosidic and peptide bonds underwent cleavage.

Fig. 2. Negative-ion MALDI-TOF MS of a TS=TP glycopeptide.

Summary: We have developed a rapid and reproducible HPLC method for the quantitative analysis of the complete spore peptidoglycan structure. Amino acid and carbohydrate analyses are useful to characterize the chromatographic fractions, but these methods can only provide ratios of components, and cannot detect structural modifications. MALDI-TOF MS is shown to be a sensitive method for accurate molecular weight measurement, and MALDI-PSD-TOF MS to allow assignment of carbohydrate and peptide sequences. The specific contributions of a large number of gene products to the synthesis and modification of spore peptidoglycan structure can be rapidly determined. As mutations affecting these biosynthetic pathways are identified, it will become more clear which aspects of the spore peptidoglycan structure contribute to spore resistance and germination properties.

Acknowledgements. J. Helin received a fellowship from the National Academy of Finland. The authors are grateful to K. Tang for assisting in some of the MALDI-TOF experiments and G. Korza for performing the amino acid and sugar analyses, and to Boston University School of Medicine, Thermo BioAnalysis and NIH (Grant No. 19698, to P. Setlow) for support of the research.

Rapid and Sensitive Analysis of Enzyme Inhibition by a MALDI Mass Tracer Method

David C. Schriemer, Kelly O'Callaghan, Mark Anders, John Vederas and Liang Li
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada
T6G 2G2

The determination and elucidation of enzyme activity requires extensive experimentation. Ideally, one would like to know what inhibits an enzyme (chemical information), where it is inhibited (epitope mapping) and how it is inhibited (mechanistic information). The steps necessary to elicit this information are many and laborious, and are often plagued by the availability of only a trace quantity of starting material. In the case of irreversible inhibition of enzymes, where a covalent bond is created between enzyme and inhibitor, a mass tracer method can be applied. Incorporation of a biotin tag on the irreversible inhibitor provides the means for fast interrogation of the inhibited enzyme, using avidin immobilized on a chromatographic support as the method for removal of the biotinylated species. The resulting immobilized complex can then be incorporated into the MALDI experiment [1].

This procedure is demonstrated with the analysis of a peptidylglycine α -amidating monooxygenase (PAM). This class of enzymes controls the biosynthesis of C-terminal peptide amides [2,3]. Modified phenylbutenoic acids [3] are inhibitors for the hydroxylating segment of the bifunctional PAM. The phenylbutenoic acids were chosen for tagging with biotin due to the flexible reactivity afforded by the substituent on the aromatic ring. Two were prepared:

For one inhibition, PAM was combined with the cofactors (copper sulfate, DMPD and bovine catalase) and inhibitor A. Tryptic digestion followed the inhibition, whereupon the mass tracer technique was applied. Two principal peptides were isolated (Figure 1A), demonstrating a characteristic mass shift after an on-probe reduction of the disulfide bond (Figure 1B). However, investigation of a blank proved that these peptides arose from a non-specific interaction between the inhibitor and catalase.

Figure 1

For the second inhibition, PAM was combined with inhibitor B plus all the cofactors except catalase. Enzyme inhibition still occurred in this case. The disulfide bridges in the enzyme were then reduced and capped, followed by a tryptic digestion. In this case, application of the mass tracer technique isolated a biotinylated peptide of 3004.5 amu (Figure 2A). Verification of the biotinylated nature of this peptide was achieved as follows: the avidin active sites were sealed with biotin prior to application of the inhibited PAM digest. This resulted in suppression of the 3004.5 amu peak (Figure 2B). Although it was not completely suppressed, application of the same procedure to known biotinylated peptides also does not result in complete suppression.

Figure 2

The above MALDI analyses were conducted on 5.9 pmol of starting enzyme. Work is in progress to determine the exact sequence of this isolated peptide.

Indirect Determination of Multimeric Protein Symmetry Determined By MALDI MS

Terry B. Farmer and Richard M. Caprioli

Department of Biochemistry and Molecular Biology and Analytical Chemistry Center,
University of Texas-Houston Medical School, Houston, Tx 77225

Introduction

All protein subunits are asymmetrical due to the asymmetry of the L-amino acids of which they are composed. The possible classes of symmetry allowed are point rotations: cyclic symmetry (linear or square planar forms), dihedral symmetry (square planar or tetrahedral forms), and cubic symmetry (tetrahedral, octahedral, or icosahedral forms). The most accurate determination of symmetry is obtained by x-ray crystallography or electron microscopy. Large crystals for x-ray crystallography are often difficult to grow and electron microscopy may not adequately detect the number of subunits and their contacts. Mathematical models have previously been developed to correctly determine the spatial relationship of the chains to assign symmetry to some protein multimers using chemical crosslinking with SDS-PAGE analysis (1,2). These models were used to examine the indirect determination of symmetry utilizing MALDI MS analysis of multimeric proteins crosslinked with glutaraldehyde.

Experimental

Protein Crosslinking

Rabbit muscle lactate dehydrogenase (LDH), rabbit muscle pyruvate kinase (PK), yeast alcohol dehydrogenase (yADH), hen avidin, bovine hemoglobin, and hen egg white lysozyme (obtained from Sigma Chemical Co.) and the gamma subunit of *E. coli* DNA Pol III holoenzyme (obtained from Dr. C. McHenry, University of Colorado) at a protein concentration of 10 μ M were crosslinked with 0.5% glutaraldehyde (v/v). Aliquots were removed from the solutions at 1, 2, 3, 4, 5, 10, 20, 30, 40, 50, and 60 minute intervals and added to the MALDI MS matrix solution on the target to quench the crosslinking reaction. The time points were taken to ensure maximum crosslinking had occurred.

Matrix-Assisted Laser Desorption Ionization Mass Spectrometry

Spectra were obtained on a PerSeptive Voyager Elite TOF instrument using a N₂ laser with an accelerating voltage of 25 kV, 90% grid voltage, and 0.3 guide wire voltage. A saturated solution of sinapinic acid (Aldrich Chemical Co.) in 70% acetonitrile/30% 0.1% TFA in water was used as the matrix solution. For each time point 100 laser shots were used to obtain a spectrum. The relative % peak area of each peak of the crosslinked multimer was obtained using an integration algorithm in GRAMS 386.

Results and Discussion

The distribution of species obtained by glutaraldehyde crosslinking with subsequent MALDI MS analysis was examined by graphing the log relative % peak areas for the observed species vs. the oligomeric species (i.e. monomer, dimer, etc.). The results for monomeric proteins after crosslinking for 60 minutes approximates a straight line ($r^2 > 0.92$). However, graphing the log relative % peak areas vs. the oligomeric forms for tetramers after 60 minutes of crosslinking indicates a predominance of dimeric and tetrameric species except for avidin which has a large amount of monomer and trimer present in the crosslinked spectrum. The distribution of the species seen for the crosslinked tetramers can be used to eliminate symmetry possibilities.

Mathematical models can be utilized to obtain a more precise picture of the symmetry using glutaraldehyde crosslinking and MALDI MS. Several assumptions were made for symmetry determinations using crosslinking reagents:

1. Possible structures are assumed to be "closed" structures, all binding sites can be saturated.
2. If conformation changes occur in the subunit upon association, they are the same for each subunit.

3. No preference for a particular type of binding domain occurs except as dictated by physical constraints due to the spatial arrangement of the subunits.

4. Association or dissociation of the tetramers during the crosslinking reaction is neglected.

Hucho, et al., developed a model for determining symmetry based on the assumption that different intersubunit binding domains (P, Q, and R) are expected to have different probabilities for crosslinking using a bifunctional reagent. Crosslinking is thought to occur across these domains with different probabilities depending on the geometric relations between the subunits and the reactivity of the functional groups of the protein toward the crosslinking reagent ($P=Q=R$, I6 tetrahedron, $P=Q$, $R=0$, square or planar C4, and $P \neq Q \neq R$, D2 symmetry).

Hajdu, et al., developed a model for homotetramers that had three two-fold axes (p,q, and r) along each of which two crosslinks could occur. The domain of binding is characterized by a tendency for crosslinking with a bifunctional reagent in terms of the rate constant of crosslink formation (k_p , k_q , and k_r). Construction of a third degree polynomial with subsequent simplification (assuming $r=0$) allowed the determination of symmetry from the amount of protein present in an SDS-PAGE band. The ratio of the rate constants allows the determination of symmetry for homotetramers ($k_p/k_q=1$, heterologous C4 symmetry; $k_p/k_q \neq 1$, isologous D2 symmetry).

Comparison of the experimental results with theoretical calculations is shown in Table 1. LDH, PK, yADH, hemoglobin, lysozyme, and the gamma subunit were examined. LDH, PK, yADH, and the gamma subunit appear to have D2 symmetry. No match was found for the Hucho probability results for lysozyme and avidin, and only imaginary roots could be calculated for the Hajdu constant. Lysozyme is a monomeric protein and should not fit the models. Avidin is a homotetramer, but symmetry determined by x-ray crystallography was two pseudo 22 molecular symmetry demonstrating the ability of the models for detecting symmetries other than D2 for tetramers. Hemoglobin has C2 symmetry due to the α and β subunits, but these two models cannot distinguish heterotetramers and homotetramers. However, MALDI MS of the native protein can easily distinguish the presence of nonidentical subunits by their mass and determine which subunit types associate indicating D2 symmetry is not present. Although absolute determinations of symmetry can only be obtained by x-ray crystallography, MALDI MS in conjunction with chemical crosslinking can give insight into the symmetry of the assembled multimeric protein.

Table 1. Summary of determinations of symmetry by MALDI MS and comparison with experimental symmetry.

Protein	Experimental Results				Hucho Probability Results				Hajdu Results		MALDI Symmetry	Experimental Symmetry
	Monomer	Relative % Dimer	Peak Area Trimer	Tetramer	Monomer	Dimer	Trimer	Tetramer	k_p/k_q			
Lysozyme	48	22	17	13	-	-	-	-	N.R.*	-	-	-
Avidin	38	12	16	34	-	-	-	-	N.R.*	-	-	Pseudo C2

Phosphorylation of Transcriptional Coactivator PC4

Yingming Zhao, Jun Qin, Urooj A Mirza, Brian T. Chait
The Rockefeller University, 1230 York Avenue, New York, NY 10021

Human positive cofactor 4 (PC4) mediates activator-dependent transcription by RNA polymerase II through interactions with transcriptional activators and the basal transcription machinery. The function of PC4 was found to be modulated by phosphorylation. Studies on protein interaction and *in vitro* transcriptional assays demonstrated that only the non-phosphorylated form of PC4 was functional active.

To elucidate the molecular mechanism of the functional switch of PC4, we used a mass spectrometric approach to identify the number of potential phosphorylation sites of the protein. Our strategy included: (1): obtaining MALDI-TOF mass spectra of the intact phosphorylated and unphosphorylated PC4. The mass difference between two forms of PC4 gave the average number of phosphate groups attached to the protein. (2): peptide mapping through enzymatic and chemical degradation in combination with MALDI-TOF and MALDI-ITMS analysis of degradation products to identify potential phosphorylation sites. (3): confirmation and counting of the phosphorylation site(s) by MALDI-ITMS/MS of phosphorylated peptide ions—using losses of 98 Da as the signature (Qin and Chait).

Our results indicated that phosphorylated PC4 contains seven phosphorylated serine residues located in the residue 9-20. All these seven sites can be phosphorylated by CK II. This result is in good agreement with subsequent mutational and *in vitro* phosphorylation experiments.

Mass Spectrometry of Proteins Directly from SDS Gels

*Steven L. Cohen, Brian T. Chait. *The Rockefeller University, New York, NY 10021*

SDS-PAGE is the biologist's tool of choice for protein analysis. Mass accuracies of SDS-PAGE, however, are low—usually no better than 5% and at times as poor as 50% or more. An ideal situation would make use of the protein separation power of SDS-PAGE coupled with the mass accuracy of mass spectrometry. However, analyzing whole proteins directly from SDS-PAGE gels has proven a challenging task since the presence of SDS detergent or Coomassie dye (the most commonly used visualization stain) severely degrades the MALDI-MS response of proteins.

To this end, we have developed a new method to extract whole proteins from gels in a form that is suitable for direct MALDI-MS analysis. The method relies on using copper staining of gels (a commercially available reversible negative stain) in lieu of Coomassie. The protein bands are cut out of the gel, and destained. Destaining of the gel is a simple procedure that entails the complete removal of both the SDS detergent and the copper stain [1]. The destained gel slice is then crushed into a small Eppendorf tube and MALDI matrix solution (30–40 μ l of 1:3:2 (volume ratio) formic acid:water:isopropanol saturated with α -cyano-4-hydroxy-cinnamic acid [2]) is added. The tube is closed and vortexed or shaken for several hours at room temperature. During this time finely divided matrix crystals form in the solution. The matrix crystals 'capture' protein as the protein is extracted from the gel. The crystals are subsequently retrieved for direct MALDI-MS analysis.

We have performed the matrix solution gel extraction method (MSGEM) on a variety of proteins. The method has picomole gel-loading sensitivity. Fig. 1 shows the MALDI mass spectrum of 3 pmol of a recombinant mouse form of the obesity protein, leptin (147 residues; calc. mass 16,134 Da). The spectrum is externally calibrated. Fig. 2 shows that inclusion of equine myoglobin as an internal calibrant protein results in improved mass accuracies for the leptin protein. MSGEM can also be used to analyze in-gel protein digests. Fig. 3 shows MSGEM applied to a gel (originally loaded with 9 pmol of recombinant leptin and destained) that has undergone in-gel trypsin digestion. The MSGEM method favors the inclusion of high mass over the low mass components, a recently discovered hallmark [2] of slow matrix crystallization [3].

We have applied MSGEM to the analysis of the endogenous form of human leptin. The protein was immunoaffinity purified from blood serum. SDS-PAGE of the affinity isolated sample revealed one dominant band that comigrated with recombinant human leptin. Although the two proteins showed similar apparent masses, the poor mass accuracies associated with SDS-PAGE could 'mask' posttranslational modifications of the endogenous protein. Application of MSGEM to the SDS-PAGE band gave the MALDI-MS spectrum shown in Fig. 4. More accurate mass measurements, obtained with internal calibration (as in Fig. 2), gave a mass of the endogenous human leptin protein to be $16,026 \pm 9$ Da. This value agrees exactly, within experimental error, with the value calculated from the human leptin gene minus a putative N-terminal signal sequence (16,024 Da) [4]. In-gel trypsin and CNBr digestions of the endogenous leptin sample confirmed the posttranslational removal of the signal sequence and also indicated the presence of a predicted C-terminal intramolecular disulfide linkage. No other posttranslational modifications were found on the endogenous leptin.

ACCELERATION VOLTAGES NEEDED FOR OBSERVATION OF MALDI IONS FROM SURFACES OF INTEREST TO BIOCHEMISTS

Martha M. Vestling, Murray V. Johnston, and Barbara S. Larsen*

Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716, *Central Research & Development, The DuPont Company, P. O. Box 80228, Wilmington, DE 19880-0228

Mass spectrometry can now analyze the quantities of peptides and proteins found in gel electrophoresis bands (1-3). If these quantities are placed on poly(vinylidene difluoride) or other flat surfaces, molecular weights can be determined by MALDI-TOF-MS (4, 5). To obtain good spectra, several parameters including laser power, acceleration voltage, detector settings, matrix, and matrix solvent need to be carefully chosen.

In this study, mass spectra from a Thermo BioAnalysis (Finnigan MAT) Vision 2000 MALDI-TOF-MS of renin substrate tetradecapeptide (porcine) and cytochrome C (equine) on three different types of surfaces were compared. The three surfaces investigated were the standard stainless steel target, Saran Wrap™ (a non-porous, non-conducting copolymer of vinyl chloride and vinylidene chloride), and Immobilon-PSQ™ (a porous, poly(vinylidene difluoride)). The two polymers were placed on top of the stainless steel target and held in place by tape on the edges.

Samples were deposited on stainless steel and Saran Wrap™ in the following way: 1 μ L of 20 μ M analyte in water followed immediately by 1 μ L of matrix (10g/L) and allowed to air dry. For Immobilon-PSQ™, 1 μ L of methanol preceded the 1 μ L of analyte. α -Cyano-4-hydroxycinnamic acid was dissolved in 70:30 acetonitrile:water; 2,5-dihydroxybenzoic acid in water.

Good reflectron mode peptide spectra were generated from all three surfaces at a low accelerating voltage (5000 V) while only stainless steel and Saran Wrap™ produced good reflectron mode spectra of cytochrome c. The matrix used was 2,5-dihydroxybenzoic acid. It should be noted that the sample areas on stainless steel and Saran Wrap™ were comparable while the sample area on PVDF was larger, giving a lower effective concentration per laser shot. Raising the laser power just increased the amount and kinds of low mass ions seen (Figure 1). PVDF is degraded in the presence of matrix and the 337 nm laser.

The Vision 2000 has dual stage acceleration. In the linear mode, as the acceleration voltage was decreased, the intensity of the renin substrate tetradecapeptide signal decreased for all three surfaces. However, it decreased the most with Immobilon-PSQ™ while the Saran Wrap™ spectra were almost identical to those obtained from stainless steel in intensity. See Figure 2. In order to see proteins such as cytochrome C, high acceleration voltages (15000-30000 V) are needed for all three surfaces to compensate for the lack of voltage on the conversion dynode in the linear mode of the Vision 2000.

Conclusion: High acceleration voltages yield the best linear mode spectra. And analyte/matrix on the top of surfaces (not spread out and embedded in the surfaces)

is important for generating strong analyte signal in both linear and reflectron modes.

Analysis of Crude Spider Venom Extracts using MALDI-sector Tandem Mass Spectrometry

Y.Itagaki, T.Fujita, H.Naoki and T.Nakajima
Suntory Institute for Bioorganic Research
Mishima-gun Osaka, Japan 618

Introduction:

Spider venom contains various glutaminergic blockers such as acylpolyamines besides proteins and peptides. We have elucidated the structures of some of these constituents using continuous flow (CF) FRIT FAB LC/MS and CF FRIT FAB MS/MS methods. However, time-consuming high resolution capillary column separations were required for the identification of these spider toxins.

MALDI is considered a useful method for the analysis of complex mixtures because of less desorption competition between hydrophilic and hydrophobic compounds. The presence of acylpolyamines in spider venom glands had been confirmed by LC/MS, and was also detected without prior separation by MALDI-sector MS (1). For the detailed structure elucidation of these compounds, various MS/MS methods were applied. Low-energy collision and high energy collision MS/MS from $(M+H)^+$ did not produce intense product ions but charge-remote fragmentations from $(M+Alkali)^+$ showed abundant structure-related product ions.

Since the MALDI is a pulse-ionization method, a Time-of-Flight mass spectrometer is used for most MALDI applications. But crude venom extracts contain structurally related compounds differing in their masses only by 1 to 2 Da. In such cases, the MALDI-TOF CID method is not applicable for structure determinations because of poor precursor ion selectivity. MALDI-sector tandem Mass Spectrometry (2) has high precursor ion selection at MS-1 which is required for mixture analysis. The applicability of MALDI-sector MS/MS system for structure analysis was confirmed. In addition, FAB-CID spectra were measured to compare their quality with the MALDI-CID spectra.

Experimental:

MALDI-sector MS/MS experiments were performed on a JEOL HX110A/110A tandem mass spectrometer equipped with a 337nm nitrogen laser MALDI unit at MS-1 and a focal plane array detector at MS-2. CID spectra were generated using helium as the collision gas in the collision cell. The acceleration voltage was 10kV and the cell was floated at 8kV. The MS-1 resolution was set around 1,000.

All samples were dissolved in a saturated aqueous solution of 2,5-dihydroxybenzoic acid (DHB). The solution was applied to the gold plated tip of a FAB probe and allowed to dry in air or under vacuum. Precursor ions were monitored and the peak height was maximized on the array detector prior to the introduction of collision gas and then peak height was adjusted at 30% for product ion detection

after introducing the collision gas.

Results and Discussion:

Product ion spectra obtained by high energy collisions showed identical results and proved that different ionization methods (FAB or MALDI) did not change the fragmentation channels. The structure of the acylpolyamine TNRA643X from spider venom was confirmed as having a new glycine-type structure rather than a β -alanine-type by high energy charge remote fragmentations (Figs.-1a,b and -2a,b). The MALDI method has proven to be useful for direct mixture analysis of such acylpolyamines, when compared with FAB direct mixture analysis because of low chemical background noise. The ionization method is static for MALDI, whether time course of analysis is crucial with continuous flow FAB.

In this regard, sample loss is not a concern in MALDI-tandem MS/MS operation. Sector tandem MS has high MS-1 precursor selectivity and acylpolyamines differing by 1-2 Da still could be separated at the MS-1 and their spectrum analyzed independently by CID. Direct structure analysis of acylpolyamines contained in spider venom glands were achieved using FAB and MALDI high energy collision charge remote fragmentations.

Qualification and Validation of a MALDI-TOF Mass Spectrometer for cGMP Compliance

Joëlle Wellemans, John Spaltro, Ram Seetharam, John McEntire and Greg Adams

Bioanalytical Division, Microbiological Associates, Inc.
9900 Blackwell Road, Rockville, Maryland, 22850, USA

INTRODUCTION

The FDA established the Good Laboratory Practice (GLP) and current Good Manufacturing Practices (cGMP) regulations for laboratories and manufacturers, respectively, to ensure the validity and reliability of product studies.

As a biopharmaceutical product moves from development to clinical trials and to registration, the product is required to meet an array of predefined criteria on the pathway to becoming a well characterized biopharmaceutical.

After early development of a product, analytical characterization will require compliance with GLP/cGMP regulations. A laboratory is required to comply with cGMP regulations with respect to instrumentation and methodology when testing manufactured biopharmaceutical products.

cGMP compliance requires *Installation, Operation and Performance Qualification (IOPQ)* documentation for the instrumentation in an analytical laboratory. This documentation is verification that 1) all key aspects of hardware installation adhere to approved design intentions (Installation); 2) the equipment performs as intended throughout representative operating ranges (operation) and 3) the process system performs as intended throughout all anticipated operating ranges (performance).

GLP regulations require a formal Standard Operating Procedure (SOP) for all analytical assays. The method described in the SOP must then be validated to ensure that the method's performance claims are properly evaluated. Parameters such as Accuracy, Precision, Reproducibility, Specificity, LOD/LOQ, and Robustness need to be considered during the method validation.

Here, we present the procedures undertaken for cGMP compliance of a Hewlett-Packard G2025A MALDI-TOF Mass Spectrometer and the method validation of the SOP.

METHOD

The *IOPQ* assures that the instruments are installed and operational according to the manufacturer's specifications. The *Performance Qualification (PQ)* is documented verification that the instrument meets the manufacturer's operation criteria. The acceptance criteria were defined by the manufacturer and the laboratory. The accuracy and resolution of a standard mixture were investigated under various running conditions, such as internal and external standard, positive and negative ion modes, and automated and manual modes.

The *Method Validation* demonstrates that the performance characteristics of a method (Accuracy, Precision, Reproducibility, Specificity, LOD/LOQ, and Robustness) meet the requirements for the intended analytical applications. Statistical studies need to be determined for different mass ranges that are defined by the *Calibration Standards* prepared by the manufacturer. They are divided into three categories (Low MW, Peptide and Protein ranges). An independent *Reference Standard*, (Bradykinin, Insulin and BSA), one for each mass range, will also be tested.

RESULTS

Performance Qualification Acceptance Criteria

Mass Accuracy: (Based on %Error of Obs. MW of Human r Insulin) Mass Resolution:

Shot Mode:	Automated	Manual	Automated	Manual	Human r Insulin
Internal Std	≤ 0.01%	≤ 0.01%	≤ 0.01%	≤ 0.01%	Positive Ion >600
External Std	≤ 0.1%	≤ 0.1%	≤ 0.1%	≤ 0.1%	Negative Ion >600

Performance Qualification Results

Shot Mode:	Automated	Manual	Automated	Manual	Human r Insulin
Internal Std	0.008%	0.009%	0.022%	0.049%	Positive Ion 1306.0
External Std	0.090%	0.048%	-0.089%	0.234%	Negative Ion 1548.8

Method Validation Acceptance Criteria

Parameters	Statistical Calculations	Criteria
Accuracy	%Error of Average	≤ 0.5 % of theoretical value
Precision	%RSD	≤ 0.5%
Reproducibility	%Error, %RSD	≤ 0.5%
LOD/LOQ	%Error of Avg, Resolution	≤ 0.5 % of theoretical value

Specificity dependent on the excipients added during analysis
Robustness dependent of the variation of analytical parameters

Method Validation Results

	Low MW		Peptide		Protein		Reference Std	
	Pos Ion	Neg Ion	Pos Ion	Neg Ion	Pos Ion	Neg Ion	Pos Ion	Neg Ion
Accuracy	0.017	Not Obs	0.030	0.323	0.147	0.175	0.094	0.261
Precision	0.055	Not Obs	0.074	0.420	0.256	0.252	0.180	0.200

Reproducibility: Two operators analyzing peptide and protein MW ranges in positive ion mode.

Operator 1: Peptide MW Range: 0.07%RSD, Protein MW Range: 0.40%RSD

Operator 2: Peptide MW Range: 0.29%RSD, Protein MW Range: 0.50%RSD

Specificity: Method is tolerant to most excipients except SDS and Tween, Na⁺ and K⁺ result in adducts. Molecular ions were observed in the presence of 6M Guanidine HCl and glycerol.

LOD/LOQ: Accuracy decreased with concentration for proteins; Resolution decreased as concentration increased.

CONCLUSION

The IPQ of the MALDI-TOF Mass Spectrometer demonstrated that the instrument was installed correctly and that the instrument performance met both the manufacturer's and the laboratories initial acceptance criteria. The method validation of the SOP for MALDI-TOF molecular weight determination demonstrated that the accuracy and precision for the three molecular weight ranges were within the acceptance criteria of 0.5%Error and 0.5%RSD, respectively. The method is reproducible and the %Error, SD and %RSD are within 0.5% for inter-day and inter-operator.

Influence of Skimmer Potential on m/z distributions in ESI Spectra: Implications for Polymers

Susan M. Hunt^a, Margaret M. Sheil^a, Peter J. Derrick^b and Mike E. Belov^b

a. Department of Chemistry, University of Wollongong, NSW 2522 AUSTRALIA

b. Department of Chemistry, University of Warwick, Coventry CV4 7AL, UK

Electrospray ionization (ESI) is increasingly being applied to the characterisation of synthetic polymers.¹ Molecular weight determinations based on ESI spectra, however, rely on the observed spectrum being truly representative of all the components of the oligomeric mixture. It is known that the distribution of multiply-charged ions for a single species such as a protein is dependent on a number of factors including the potentials applied to the skimmers² that are commonly employed in ESI sources to maintain the pressure differential between the source and the analyser. The distribution of singly- versus multiply-charged ions from synthetic polymers has also been found to vary with skimmer potential which introduces uncertainty into average molecular mass determinations for polymers from ESI spectra.³

We have examined the influence of skimmer potential for both peptides and synthetic polymers of varying mass and charge. The majority of experiments were performed on a VG Quattro triple quadrupole instrument with a dual skimmer source design. In the case of singly-charged ions of different mass (fig. 1), the optimum skimmer potential increases steadily as the mass of the ion is raised. For example, the singly-charged m/z 482 ion from polyethylene glycol (PEG) has an optimum potential of 85 V, whereas m/z 1010 optimises at 110 V. The range over which the higher m/z ion is observed is also broader. For ions of the same mass and different charge, e.g. the peptide kemptamide shown in fig. 2, the differences are even more marked and there appears to be a linear relationship between the optimum potential and m/z . The optimum potentials for the 3+ (m/z 258), 2+ (m/z 386) and 1+ (m/z 772) ions are 25, 45 and 90 V successively. The very narrow range of skimmer potentials over which the $[M+3H]^{3+}$ ion is observed was also typical of all the higher charge state ions. The variation in relative intensities with skimmer potential for selected ions from PEG in which both the mass and the m/z of the ions was also examined. These data indicate that the optimum skimmer potential does not depend solely on m/z since the optimum for the triply-charged m/z 484 ion from PEG is 60 V compared with 80 V for a singly-charged PEG ion of similar mass (m/z 482 in fig. 1). Thus there appears to be both mass- and charged-based effects contributing to the variation in ESI spectra with skimmer potential.

Fig. 1 Individual singly-charged oligomers from PEG vs skimmer potential

Fig. 2 $[M+H]^+$, $[M+2H]^{2+}$, $[M+3H]^{3+}$ ions of kemptamide ($M = 771$) vs skimmer potential

In order to examine these phenomena in more detail we have attempted to model ion transport in the region between the sampling cone and the ESI source skimmer. The passage of ions from atmospheric pressure into the low pressure region after the first skimmer is accompanied by the formation of a supersonic jet as the gas expands. If the pressure in this region is not sufficiently low then the expansion is accompanied by the formation of a shock wave due to collisions with the surrounding gas molecules. Known as the mach disk this causes considerable scattering of the expanding beam. Calculation of the position and thickness of the mach disk reveals that the motion of the ions between the sampling cone and the skimmer occurs in two independent regions. The ions move almost half way to the skimmer in a supersonic jet, and thereafter they drift under the influence of the electric field with a velocity determined by their mobilities. Thus two mass dependent processes can be identified in the expansion region, firstly ions will be expanded into different solid angles with heavier ions having narrower angular distributions. Therefore ions of different mass start drifting according to their mobilities from disks of different diameters and will be focussed through the skimmer at different voltages. Secondly, ions of higher mass will have a higher collision cross section and thus will start decelerating to subsonic velocities at lower distances from the sampling cone and since the extracted ion current depends strongly on drifting distance this becomes the dominant factor in focussing ions of different masses. Calculations based in these two mass-dependent effects correlated well with experimental results. For example, given that an ion of mass 1010 focussed at 110 V, it was calculated that ion of mass 484 would focus at 88 V which compares well with the experimental value of 85 V. In the case of ions of the same mass but different charge, these ions focus according to their m/z values.

The influence of skimmer potential on average molecular mass (M_n) determinations of synthetic polymers is shown in fig. 3 which illustrates the variation in calculated M_n for three polyethylene glycol (PEG) standards. In this case the polydispersity is low and the variations in calculated M_n are approximately $\pm 5\%$. For the more polydisperse polyesters, however, the variations in M_n with skimmer potential are more significant ($\pm 15\%$). An example of a typical variation of M_n for polyesters is shown in fig. 4. This figure also includes M_n versus skimmer potential determined on two alternate ESI instruments, i.e. a VG Quattro II and an Autospec magnetic sector instrument which both also have a hexapole between the two skimmers. That there are only small differences in the M_n distributions determined from the data from the quadrupoles and the magnetic sector instruments suggest that any influence of mass discrimination of the quadrupole analysers is minimal. Overall these results suggest that ESI can be applied to the determination of molecular masses of synthetic polymers with narrow oligomeric distributions, however, for polydisperse synthetic polymers the dependence on skimmer potential needs to be taken into account.

Optimization of different emitter designs for electrospray ionization applications

David C. Gale, Mike Khosla, Iain Mylchreest, Jonathan L. Josephs, Mark Sanders, and
Matt J. Sweeney
Finnigan MAT, San Jose CA 95134

Electrospray ionization (ESI) has become a powerful technique for the analysis of small molecules, peptides, nucleic acids, and proteins. The first step in analyzing these and other molecules, is to deliver them in a liquid stream to an electrospray ionization emitter. A high potential is then applied to the liquid stream in order to generate an electrospray. The electrosprayed ions are then sampled and desolvated by an atmospheric pressure ionization (API) source and then mass analyzed. The device that generates the electrosprayed ions is typically referred to as the emitter (or probe). A single conventional emitter design may work well for many applications and over a broad range of flow rates, but many times there exist applications where an optimized design is needed or required. This may be due to sensitivity requirements, analyte carry-over problems and/or sample size limitations.

Several modifications of a standard Finnigan ESI probe were performed. A metal needle microsyringe was constructed from a piece of 32 gauge stainless steel hypodermic tubing (Hamilton), two Kel-F ferrules, a custom PEEK double ended column coupler, and a PEEK union. The fused silica of the conventional source was removed and the hypodermic tubing inserted in its place. This emitter was utilized in the analysis of oligonucleotide and drug/oligonucleotide duplex noncovalent complexes. Low flow rate ESI/mass spectra were acquired on a Finnigan TSQ 7000 triple quadrupole and a Finnigan LCQ ion trap mass spectrometer with this probe (Shown in Figure 1). The standard Finnigan ESI emitter can also be modified for low flow rate experiments by replacing the conventional 26 gauge needle with a 30 gauge needle. A piece of 40 μm ID 105 μm OD fused silica capillary tubing is used in place of the standard fused silica (190 μm OD). Sub microliter per minute flow rates can be electrosprayed with good stability from these metal needle emitters (%RSD <3). Modification of the standard Finnigan probe to accept capillary PEEK tubing is also possible. For analytes or separations that suffer from analyte tailing due to adsorption onto fused silica, this may be a possible solution. This design is shown in Figure 2.

Figure 1

Figure 2

Electrospray Ionization Emitter Modified to Accept Capillary PEEK Tubing

The PEEK capillary tubing is threaded through the larger diameter stainless steel spray needle (22 gauge)

Flowing Afterspray. Combining Electrospray Ionization with the Flowing Afterglow Technique

Robert R. Squires, Lee S. Sunderlin, Leonard J. Chyall, Brian T. Hill, Jun Hu, John C. Poutsma, Randal A. Seburg, Dana Byrd, Norman Sproch, Department of Chemistry, Purdue University, West Lafayette, IN 47907.

Electrospray ionization (ESI) provides a versatile source of massive and/or multiply-charged ions for chemical and physical studies. Many different types of instruments have been used to investigate the gas-phase reactions of ions produced by ESI, including high pressure mass spectrometers, ion cyclotron resonance spectrometers, ion traps and tandem quadrupoles. In this presentation, we describe the coupling of electrospray ionization with the flowing afterglow - triple quadrupole technique ("Flowing Afterspray").

This new instrumental combination offers several unique capabilities for investigating the chemistry of electrosprayed ions. These include the means for examination of temporally- and spatially-resolved ion-molecule and ion-ion reactions under thermal conditions, for determination of threshold energies for collision-induced dissociation and other activated reactions of multiply-charged ions, and for characterization of the sequential association kinetics of high molecular weight organic and inorganic ions.

Ions are sprayed from a 12-gauge syringe needle into the room-temperature helium flow reactor of the flowing afterglow instrument through an electrically heated, stainless steel capillary drying tube (0.04 in. id.) which is heated to about 150°C. The needle voltage is typically about 4000 V for positive ions and about 3000 V for negative ions. The capillary tube introduces an air leak into the flow tube sufficient to raise the pressure approximately 120 mTorr. The total pressure in the flow tube is kept between 450 and 600 mTorr. The capillary tube can be placed near the downstream end of the flow tube to maximum ion signal, or near the upstream end of the tube to allow for ion-molecule reactions.

The ESI source can be used to introduce singly or multiply charged ions of either polarity into the flow tube. For example, ESI of an aqueous methanol solution of $\text{Bu}_4\text{N}^+\text{Br}^-$ produces an abundant signal with $m/z = 242$ in positive ion mode corresponding to Bu_4N^+ . The PF_6^- anion and a Na^+ -bound dimer, $(\text{PF}_6^-)_2\text{Na}^+$, can be observed from ESI of K^+PF_6^- in methanol-water. ESI of acidified solutions of Baldwin's peptide ($\text{AcNH-AAKAAAKAAAKAA-CONH}_2$) shows abundant signals in the positive ion mass spectrum corresponding to the doubly- and triply-protonated polypeptide.

Flowing afterspray can also be used to study ion-molecule reactions of multiply charged ions under thermal conditions. ESI of a 1×10^{-5} M solution of the disodium salt of 2-hydroxynaphthalene-3,6-sulfonic acid produces an abundant signal with m/z 151 corresponding to the $[\text{M}-2\text{Na}]^{2-}$ dianion. Addition of acetic acid ($\Delta H_{\text{acid}} = 348.6$ kcal/mol) downstream in the flow tube produces only acetic acid clusters. Addition of trifluoroacetic acid ($\Delta H_{\text{acid}} = 323.9$ kcal/mol) yields the proton transfer products, CF_3CO_2^- ($m/z = 113$) and $[\text{M}-2\text{Na}+\text{H}]^-$ ($m/z = 303$), as well as the corresponding cluster ions (eq 1). The estimated acidity of a naphthalenesulfonic acid is about 313

kcal/mol. An estimated Coulombic repulsion energy in the dianion of 42 kcal/mol suggests a thermodynamic basicity of about 355 kcal/mol. Therefore, proton abstraction from both acids should be exothermic. The occurrence of protonation by only the stronger acid, $\text{CF}_3\text{CO}_2\text{H}$, confirms the presence of a reverse activation barrier.

The flowing afterglow - triple quadrupole instrument has been used to measure threshold energies for collision-induced dissociation reactions, allowing the determination of bond energies and other thermochemical quantities. The new ESI source makes it possible to carry out energy-resolved CID measurements with multiply-charged and high-mass ions. Abundant signals of $\text{Ru}(\text{bipy})_3^{2+}$ (bipy = 2,2'-bipyridine) can be generated by ESI of a 1×10^{-5} M solution of the PF_6^- salt in pure acetonitrile. Collisional activation of $\text{Ru}(\text{bipy})_3^{2+}$ in the 75 - 100 eV laboratory energy range with xenon target gas produces several ionic products. These include $\text{Ru}(\text{bipy})^+$, bipy^+ , and sequential ligand dissociation products. Monitoring the intensity of the major product ion, $\text{Ru}(\text{bipy})_2^{2+}$ ($m/z = 207$), versus the collision energy in the center-of-mass frame gives an appearance curve from which a threshold energy can be derived (eq 2).

The apparent dissociation threshold for loss of a bipyridine ligand is about 3.2 eV. For a molecule with this many degrees of freedom (177 vibrational modes) and, presumably, strong metal-ligand binding, it is essential that the analysis properly accounts for the effects of reactant ion internal energy and the likely possibility of a kinetic shift in the reaction onset due to slow dissociation on the instrumental time scale (ca. 30 μs). A preliminary analysis¹ predicts an average kinetic shift in the dissociation onset in excess of 2 eV, suggesting a $(\text{bpy})_2\text{Ru}^{2+}$ -bipy bond energy of about 1.2 eV.

Future plans include exploring the viability of tandem electrospray sources for investigating thermal energy ion-ion reactions, and direct analysis of reactive organometallic intermediates in catalytically active homogeneous solutions using flowing afterspray.

Fundamental Studies Toward the Analysis of Polymerized Monolayers by ES/MS

Tracy Donovan McCarley, C.J. DuBois, and Robin Lindsey McCarley

Department of Chemistry, Louisiana State University

Baton Rouge, LA 70803

A systematic approach has been used to explore the potential of analyzing polymerized self-assembled monolayers (SAMs) by electrospray ionization mass spectrometry in order to determine their degree of polymerization. The polymerized monolayers are generated by first forming the self-assembled monolayers on a gold substrate using *n*-alkanethiols (1). If *n*-alkanethiols with appropriate tail groups are selected, the tail groups may then be polymerized (2-5). These polymerized monolayers can be removed from the gold substrates on which they are generated by either reductive or oxidative desorption, producing either anions or neutrals in solution, respectively (6-7). The anions are candidates for conventional electrospray ionization, and neutrals which are electroactive are suited for ionization by using the electrospray source as a controlled-current electrolytic flow cell (8-10). Electrospray mass spectrometry of model metallocenes and *n*-alkanethiols has been studied in order to determine the best experimental parameters and constraints for future analysis of polymerized monolayers.

Part of the metallocenes and thiols were purchased, and the rest were synthesized. Purity of the synthesized samples was tested using a Hewlett Packard 5791A GC/MS. All mass spectra were acquired using a Finnigan MAT-900 forward geometry double focusing mass spectrometer equipped with an Analytica electrospray ionization source (model 101491-1).

Electrospray mass spectrometry of alkanethiols has been mentioned only briefly in the literature (11). Therefore, it was necessary to study several simple *n*-alkanethiols before attempting to desorb a polymerized monolayer with multiple alkanethiol groups and analyze it by electrospray mass spectrometry. Thiol groups typically have pK_as of about 9.7 (slightly lower than the pK_a of a phenol), so a strong base is necessary to promote deprotonation of thiols to thiolates. Thus, the thiols were dissolved in anhydrous NaOMe/MeOH and analyzed by negative electrospray mass spectrometry in this study. Thiolate (M - H)⁻ ions are observed as the base peak for dodecanethiol, ferrocenylhexadecanethiol, and 11-undecanethiol. For dodecanethiol, low intensity ions at m/z 233 and m/z 249 are attributed to a sulfinate ion, RSO₂⁻, and a sulfonate ion, RSO₃⁻, which are solution photooxidation products of the thiolate group (12). A spectrum acquired only an hour after addition of the sodium methoxide to the thiol indicates that the solution photooxidation progressed even further, so sodium methoxide was added immediately prior to analysis of thiols in all further analyses.

Because of our interest in analyzing polymers with multiple thiol groups, it is particularly important to know the extent of ionization when more than one thiol group is present in a molecule. It is expected that methoxide ions would deprotonate both thiols of an alkanedithiol. In the electrospray mass spectrum of a solution of approximately one equivalent of the nonanedithiol and one equivalent of sodium methoxide, an (M - H)⁻ peak is predominant, and a doubly charged ion corresponding to (M - 2H)⁻ at m/z 95 is absent. A tiny peak due to (M - 2H + Na)⁻ is observed at m/z 213. This indicates that a small amount of dithiolate has been formed, but has formed a sodium adduct, presumably to shield the two negative charges from each other. Even when over thirteen equivalents of methoxide are added to the dithiol, the (M - H)⁻ ion is the base peak, the doubly charged ion is not observed, but the relative intensity of the (M - 2H + Na)⁻ ion increases. It is interesting that the thiolate groups are observed at all in such a large excess of sodium ions.

A number of the polymerized monolayers formed from self-assembled monolayers are electrochemically active, so they are potential candidates for this type of ionization in the positive ion mode as well as conventional electrospray ionization in the negative mode. Electrospray mass spectra of a number of ferrocenes representative of the tail groups on *n*-alkanethiols were acquired in order to confirm that the electroactive polymers are within the potential range available using the electrospray source for electrochemical oxidation. Ions generated by oxidations requiring as much as 1 V were observed, but that appears to be the limit. The one-electron oxidation of diferrocenylethane was observed, but the two-electron oxidation was not. However, it is observed by adding the volatile oxidant NOBF₄. As the amount of oxidant is increased, there is an increased abundance of the doubly charged ion relative to the

singly charged ion. Most of the polymers of interest to us are within the oxidation potential boundaries of the electrospray source, as demonstrated by our data for model metallocenes. Figure 9, which is the mass spectrum of poly(vinylferrocene), shows that the electrospray source operated as an electrolytic flow cell is sufficient to ionize a polymer with electroactive groups.

Preliminary studies indicate that analysis of polymerized *n*-alkanethiols will be possible by both conventional electrospray in the negative mode in the sodium methoxide solutions necessary to reductively desorb the polymers (6), as well as by electrochemical ionization using the electrospray source as an electrolytic flow-cell.

We thank Professor P. Limbach for helpful discussions. Some of the molecules used in this study were synthesized by J. Long, Dr. J. S. Peanasky, Professor L. S. Curtin, and Professor M. L. McLaughlin. We are grateful to the Louisiana Educational Quality Support Fund and the National Science Foundation for support of this work.

ELECTROSPRAY AS AN ELECTROLYSIS CELL: ELECTROCHEMICAL IONIZATION OF NEUTRALS FOR DETECTION BY ES-MS

Gary J. Van Berkel and Feimeng Zhou

Chemical and Analytical Sciences Division, Oak Ridge National Laboratory,
Oak Ridge, Tennessee 37831-6365

The electrolytic nature of an ES ion source is a fundamental part of its operation as a generator of charged droplets, and ultimately the gas-phase ions sampled and analyzed by the mass spectrometer in ES-MS.¹ Specifically, an ES ion source, as a consequence of maintaining charge-balance, is operationally equivalent to a controlled-current electrolytic (CCE) flow cell.² Recognizing this fact positions one to use ES-MS as a means to perform on-line controlled-current electrochemistry-mass spectrometry without the complication of additional discrete electrochemical cells. In this presentation, we show that this inherent electrochemistry/mass spectrometry combination may be used for the benefit of ionization/detection of specific analytes by ES-MS^{3,4} and, from an electrochemical perspective, as a means to study redox reactions of nonvolatile species with a mass spectrometer (see also refs 5-7).

In order to effectively make use of the ES ion source for electrochemical ionization or for the study of redox reaction products, it is necessary to first understand the nature of controlled-current electrolysis and to be aware of the important variable parameters in such an electrolytic system. The actual charge balancing redox reactions that occur at the metal/solution interface in the ES capillary, and the extent to which those reactions take place, are a function of (i) the relative concentrations and redox potentials of the various species in the solution, including the metal capillary, (ii) the availability of a species for reaction at the metal/solution interface, which is related to capillary dimensions, solution flow rate, and species concentration, and (iii) the magnitude of the ES current, i_{ES} , which is related to the nature of the solvents, solution conductivity, and the electric field at the capillary tip. Important variables to consider in relation to the operation of a CCE cell is the working electrode (ES metal contact to solution) material, geometry, cost/availability/robustness, and potential window. Gold or platinum would appear to be best for positive ion mode operation and stainless steel more suitable for negative ion mode. Other important variables are the solvent and electrolytes (additives), which should be electrochemically "inert"/clean, conductive, chemically inert, sprayable, and cause minimal gas-phase signal suppression. Combinations of water, acetonitrile, methylene chloride, tetrahydrofuran, or methanol might be used as solvents. Suitable electrolytes include KCl, HNO₃, KNO₃, Li⁺/Na⁺/K⁺-PF₆⁻, -BF₄⁻, ClO₄⁻, or -triflate. The tetraalkylammonium salts may be suitable for negative ion mode, but not positive ion mode because of signal suppression.

Electrochemical Ionization. The key to utilizing the electrolytic process inherent to ES for efficient electrochemical analyte ionization (i.e., complete analyte electrolysis) and sensitive gas-phase detection requires that (i) the magnitude of i_{ES} be sufficient to oxidize/reduce the molar equivalent of the analyte exiting the capillary, plus the molar equivalent of all the species present in the system more easily oxidized/reduced than the analyte, including the metal ES capillary, (ii) the flow rate of solution through the capillary must be sufficiently slow to allow adequate time for the analyte to be transported to the metal/solution interface where the redox reaction takes place, and (iii) the steps taken to ensure the first two requirements must not inhibit the formation of gas-phase ions from the ions generated electrochemically in solution. Among these requirements, which can be understood in terms of Faraday's law and the Hendricks equation,^{1,3} are the addition of an

appropriate electrolyte (minimizes signal suppression, increases i_{ES}) to the electrosprayed solutions (e.g., lithium triflate) and operating at the highest ES voltage feasible (increases i_{ES}), the use of relatively slow flow rates (e.g., a few microliters/min) (maximizes electrolysis/diffusion time), and the use of a difficult to oxidize spray capillary (maximizes faradaic that might be supplied by analyte electrolysis in positive ion mode). A search of the literature reveals that compounds from over 10 different classes have been reported to be electrochemically ionized in the ES capillary during ES-MS. These include metalloporphyrins and chlorins, polycyclic aromatic hydrocarbons, aromatic amines, heteroaromatic, carotenoids, and metallocenes, in positive ion mode, and fullerenes, halogens, and quinones in negative ion mode. Many of these compound types would not otherwise be amenable to ES-MS analysis. Thus, making use of electrochemical analyte ionization increases the universality of ES as an ionization method.

Study of Redox Reaction Products. Electrochemical ionization by ES might be viewed as a means to monitor the products of controlled-current electrolysis on-line with mass spectrometry. Carrying out electrolysis in this fashion requires a very small amount of sample and provides the molecular weight, and potentially the structure, for the ionic products of the reactions. A specific example of using ES-MS for the study of the products of nucleophilic chemical followup reactions is illustrated by the data in Figure 1. The spectra shown were obtained by spraying a solution containing perylene and the nucleophile pyridine at about 0.1% by volume. The major ions observed are the electrolytically generated radical cation of perylene (m/z 252) and the pyridinium ion (m/z 330) formed from reaction of the radical cation with pyridine as shown in the reaction scheme. The kinetics of the reaction might be followed by adjusting the flow rate through the capillary which affects the amount of time available for the reaction to occur.

Quantitative Analysis using MALDI/TOFMS with Electrospray Sample Preparation

Russell R. Hensel^{1,2}, Robert Carlton², Cary Kennedy¹, Kevin Owens¹, Rick Hock²

¹ Department of Chemistry, Drexel University, Philadelphia, PA 19104

² Rhone-Poulenc Rorer DMPK, Collegeville, PA 19426

³ Department of Chemistry & Biochemistry, Philadelphia College of Pharmacy & Science, Philadelphia, PA 19104

We have demonstrated that electrospray (ES) sample deposition can greatly improve the quantitative results obtained from the MALDI/TOFMS experiment (1). Fluorescence microscopy, spatially mapped TOFMS signal intensities and scanning electron microscopy (SEM) indicate that ES yields a significantly more homogeneous distribution of analyte on the probe surface. Analyte segregation effects, which occur during crystal formation in the usual sample drying process, are also decreased.

The Electrospray Process: There are four major processes in ES sample deposition: the production of charged droplets from a mixture of matrix and analyte in solution; the build-up of charge at the droplet/air interface; formation of a small filament of droplets (Taylor cone) as the high charge density overcomes the surface tension of the solution; the shrinkage of the droplets through solvent evaporation and Coulombic expansions (2). The electric field potential (E) at the end of the capillary tip is determined by the following relationship

$$E = 2V/r \ln(4d/r)$$

where, (V) is the applied potential, (r) is the radius of the capillary probe tip, and (d) is the distance between capillary and the MS probe tip. The applied potential at which the electrospray process begins (V_{on}) is determined as:

$$V_{on} = 2 \times 10^5 (\gamma r)^{1/2} \ln(4d/r)$$

where, (γ) is the surface tension of the solution phase.(2)

ES Process and Effects on Reproducibility: The applied potential (V) and distance (d) from capillary to spraying surface affect the quality of sample deposition and hence the reproducibility of the response factor (analyte/internal standard MS peak intensities) in the quantitative MALDI/TOFMS experiment. An identical solution of peptides was electrosprayed onto a twenty sample Kratos sample slide. The distance (d) was systematically changed while the electric field potential (E) was held constant. However, in several cases, the applied potential required to initiate ES resulted in higher than desired (E). The following table summarizes the effects of changing applied potential (V) and distance (d) on reproducibility.

Distance (d) (cm)	Electric Field Potential (E) $\times 10^6$ (V/m)	Sample positions covered in a single application	Range of CV (%)	Qual. Estimate of Overall Variability
1.50	6.6	4	5.0 - 50	++
1.75	7.4	4	3.0 - 50	++
2.00	7.2	6	5.0 - 25	+
2.25	7.9	9	5.0 - 50	++
2.50	7.8	7	2.0 - 20	low variability
2.75	8.5	9	2.0 - 50	++

ES Process and Effects on Crystal Morphology: The applied potential (V), distance (d) and electric field potential (E) have an effect on the size of the droplet formed in the ES process. (3) Droplet size affects the reproducibility of the quantitative MALDI/TOFMS experiment. Smaller ES droplets have less solvent at the time of impact on the MS probe tip and therefore dry extremely quickly. Larger droplets have more solvent incorporated at the time of impact and therefore prolong the drying process which causes areas of analyte heterogeneity. Samples were electrosprayed to investigate the changes in crystal morphology as applied potential (V) changed. Scanning electron micrographs were obtained for each ES condition. The SEM results indicate that altering the applied potential alters the size of the matrix crystal formed. We believe that larger crystals form from larger, wet ES droplets.

Choice of Internal Standard: An internal standard (IS) closely related in molecular weight and amino acid sequence

as the analyte should work well. Arginine vasopressin (AVP) was used as IS for four sets of peptides: RPR 1 and 2, structural analogs of a small molecular weight peptide, Substance P 1-11 (SP 1-11) and Substance P 7-11 (SP 7-11); desamino-8-D-arginine vasopressin (DDAVP) and AVP; chicken calcitonin (chCT) and salmon calcitonin (sCT). The coefficient of variation was measured for a number of samples covered with one ES sample application. The results showed that the reproducibility of sCT was enhanced when chCT was used as the IS. However, AVP was as good an IS for the other peptides as each respective structural analog.

Peptide	RPR 1	RPR 2	SP 7-11	DDAVP	SP 1-11	chCT	sCT
Mean Response Factor	1.593	0.9643	0.1989	1.505	0.4606	0.8145	1.188
SD	0.119	0.053	0.055	0.067	0.017	0.450	0.602
CV%	7.5	5.5	28	4.5	3.7	55	51

Peptide	RPR 1 / RPR 2	SP 7-11 / SP 1-11	sCT / chCT
Mean Response Factor	1.654	0.4340	1.494
SD	0.126	0.128	0.085
CV%	7.6	30	5.7

Limit of Quantitation: Chicken calcitonin was selected as internal standard for the quantitative determination of sCT using ES sample deposition and MALDI/TOFMS. Several MALDI matrix compounds were tested, including 2,5-dihydroxybenzoic acid, alpha-cyano-4-hydroxycinnamic acid, indolacrylic acid, and sinapinic acid. Electrospray sample deposition of sinapinic acid at a concentration of 0.1 M in ethanol yielded the highest MALDI/TOFMS signal intensity for sCT and chCT. The ES conditions were optimized at an applied potential of approximately 6 kV and a distance of 2.5 cm. Calibration standards were prepared as neat solutions of analyte and internal standard in matrix. The method of self dilution was applied to create each reference standard curve.(4)

Linear Range ($\times 10^{-12}$ moles/ μ L)	Slope	Intercept	Correlation Coefficient
1.6 to 20	0.0539	0.1380	0.9719
0.9 to 8.8	0.2060	0.0966	0.9696
0.4 to 5.0	0.4103	0.2686	0.8943

A maximum of 2 μ L of sample is electrosprayed over the Kratos MS probe tip. The spray template allows between 3 and 4 sample positions to be covered with one ES deposition. Time of flight mass spectra are acquired as the laser is swept across a single sample position. The laser samples less than 1 % of the total area of a single sample position. Considering the laser area sampled, the limit of detection is on the order of 10^{-14} moles or better.

Conclusion: Electrospray sample deposition for MALDI/TOFMS has resulted in an objective means of quantitation for the peptides tested in our laboratory. Electrospray sample deposition results in a homogeneous application of analyte in matrix. Electrospray conditions of applied potential (V), and distance (d) must be optimized for each type of sample if reproducible quantitative results are to be obtained. Sample composition such as matrix, analyte, internal standard, and solution composition must all be considered when optimizing the ES process.

PHYSICAL PROCESSES OF ELECTROSPRAY IONIZATION

Ross C. Willoughby and Edward W. Sheehan
Chem-Space Associates, 575 Epsilon Dr., Pittsburgh, PA 15238 USA

It is felt that there is a lack of a comprehensive model to describe the physical behavior of electrospray. The current presentation shows our continuing effort to develop a simple model to explain electrospray behavior. Our approach is to develop a one-dimensional model that accounts for conservation of energy, mass, and charge. This work specifically introduces several new terms into the equation.

We cannot model electrospray without consideration of the cone-jet phenomena. Cone-jets have been consistently observed on the electrospray needle, on exploding electrospray droplets, and on electrospray particle residues. Therefore, modeling the cone-jet process is a primary objective of our work.

Initial Model

$$E_T' = \mathcal{E}' + K' + S'$$

Current Model

$$E_T' = \mathcal{E}' + K' + S' + \dot{V}' + \dot{Q}'$$

Total Energy Flow
Electrostatic term
Kinetic term
Surface term
Viscous term
Thermal term

The total energy flowing through the electrospray cone-jet is held constant, however, the relative amount of any type of energy flowing through the system will vary as the x-axis changes

1. Electrostatic energy flow- Virtually all the energy available for aerosol generation in electrospray is provided by virtue of current flowing above some threshold needle potential. The potential energy resulting from the high electrical potential is released as the liquid accelerates down the cone. There is an associated drop in electrical potential as this energy is released.

2. Kinetic energy flow- The average velocity increases as liquid flows from the needle to the jet. The jet forms when the mechanical stress equals the surface tension.

3. Surface energy flow- The surface area per unit mass increases as the liquid flows from the needle to the jet

4. Viscous energy flow- Viscous energy is required to maintain the velocity differences between the various parcels of liquid. The result of this model is relatively constant energy requirements until close to the jet. We could argue bulk property of viscosity is not appropriate when the system has significant mass at or near the surface. In addition, the majority of the motion of this system is at the surface; therefore, the greatest velocity differences are at the surface, not in the bulk.

5. Thermal energy flow- Two effects relating to temperature and heat transfer are considered here; namely, evaporation from the cone surface, and Joule heating in the bulk solution. We conclude that evaporation can be a significant effect on electrospray cone-jets when needle diameters are large, the liquid flow rate is small, and the solvent is highly volatile. Joule heating effects are difficult to model with this system because the random motion associated with Joule heating is competing with the directed motion of charged species across potential gradients.

Conclusions-

1. We can make qualitative predictions using a one-dimensional model of this system. For example- in Figure 1 we show that the cone-jet system can operate independent of pressure as long as electrical discharge does not disrupt the cone-jet.
2. We can make some quantitative predictions of electrospray behavior as seen with jet radius calculations.

Figure 1. Electrospray cone-jets emerging from the same needle, the same solvent, the same flow rate; but different pressures. Energy balance modeling gave us the insight to perform this experiment.

LOCATION OF CHARGE SITES IN DOUBLY PROTONATED ANGIOTENSIN II IONS FORMED BY ESI

M. Cameron Sullards and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to elucidate the location of charge sites in $(M + 2H)^{2+}$ ions of angiotensin II. Furthermore, the method developed for KERD elucidation in MS-MS experiments of both protonated¹ and metallated² species was tested to determine if it could be extended to MS-MS-MS experiments. MS², MS³, and MS⁴ experiments were performed using ESI and a JEOL JMS-SX102/SX102A/E five-sector, tandem mass spectrometer.

The MS³ MIKES spectrum of the y_7^{2+} ions from the $(M + 2H)^{2+}$ ions of ang II and the MS² MIKES spectrum $(M + 2H)^{2+}$ ions of ang III reveal highly abundant singly charged product ions (Figure 1a,b). The singly charged product ions are formed via charge separation reactions. The charge separation reactions have large kinetic energy releases that result in wide, dish-shaped peaks. It should be noted that the b_6^+ ions arising from the y_7^{2+} ions of the $(M + 2H)^{2+}$ ions of ang II are isomeric to the b_5^+ ions arising from the $(M + 2H)^{2+}$ ions of ang III.

Narrow signal-averaged MIKES scans show that both the b_5^+ and b_6^+ ions exhibit a large kinetic energy release. Kinetic energy release distributions (KERDs) yield virtually identical most probable KERs (T_{mp}). The T_{mp} indicate that the b_5^+ ions from MS² of the $(M + 2H)^{2+}$ ions of ang III and the b_6^+ ions from MS³ of the y_7^{2+} ions from the $(M + 2H)^{2+}$ ions of ang II arise from precursors of the same structure and charge-separation reaction.

MS³ and MS⁴ MIKES spectra of the doubly charged first-generation product ions that arise from cleavage of the His-Pro amide bond of ang II dissociate further to yield both singly and doubly charged second-generation product ions (Figure 2a, b). A charge separation reaction to yield b_5^+ ions occurs via cleavage of the Ile-His amide bond. A complimentary y-type ion of $m/z = 138$ is not observed (Figure 2a). A singly charged ion of $m/z 110$, however, is observed ("His" in Figure 2a).

Metastable ion dissociations of multiply charged ions undergoing charge-separation reactions can be used to determine location of charge.^{1,2} Doubly charged first- and second-generation product ions that dissociate metastably via charge separation reactions can be used to further determine location of charge.

Consequently, two major isomers exist for the $(M + 2H)^{2+}$ ions of angiotensin II that decompose metastably. Ions that decompose via cleavage of the His-Pro amide bond to yield singly charged product ions contain a proton on the Arg side chain and a proton on the Pro-Phe amide carbonyl oxygen. Ions that decompose via cleavage of the His-Pro amide bond to yield doubly charged product ions contain a proton on the Arg side chain and a proton on the His side chain. Results from MS³ and MS⁴ experiments suggest that doubly charged product ions formed from cleavage of the His-Pro amide bond do so via a rearrangement mechanism not a direct cleavage. Furthermore, MS³ KERDs are observed to be in close agreement with MS² KERDs results.

SOLVENT AND COUNTERION EFFECTS ON OBSERVED CHARGE STATES OF DIQUATERNARY AMMONIUM SALTS IN ELECTROSPRAY IONIZATION MASS SPECTROMETRY

Guangdi Wang, Department of Chemistry, Xavier University of Louisiana, New Orleans, LA 70125
Richard B. Cole*, Department of Chemistry, University of New Orleans, New Orleans, LA 70148

Previous studies in our laboratory have examined the effect of non-aqueous solvent as a different aspect of the contributions of solution chemistry to negative ion ES mass spectra. Solvent polarity has been found to exert a pronounced effect on the charge state distributions which were observed to consistently shift toward lower values in homologous series of solvents whose dielectric properties were progressively weakening [1].

The current study extends our investigation to the positive ion ESMS mode using diquaternary ammonium salts. An advantage of using diquaternary ammonium salts over, for example, tertiary amines for studies into solvent effects on charge state distributions is that the positive charges on the ammonium cations are "permanent". Thus, complications presented by solvent-induced solution phase shifts in the equilibrium of protonation/deprotonation, or charge (e.g. proton) transfer reactions in the gas phase are excluded. Moreover, loss of a neutral ion pair subsequent to anion attachment to the charge site is not possible in the gas phase, or elsewhere. In addition, a related phenomenon, the degree of ion pairing in solution which depends upon both the solvent dielectric and the nature of the counterion, was also examined by exchanging the anions which participate in the ion pair.

Two diquaternary ammonium chloride salts were used to examine the roles of solvent and counterion in determining the degree of ion pairing in solution, and the resultant charge state distributions in electrospray ionization mass spectrometry (ESMS). Three series of solvents, i.e., alcohol, polar aprotic, and chlorinated solvents have been employed to test the influence of solvent polarity and other parameters on the desorption behavior of diquaternary ammonium ions observed in ESMS. It was found that solvents of higher polarity yield gas phase ions of higher charge states, in accordance with their reduced tendency toward ion pairing in solution. Other solvent properties, including volatility, which are known to influence ES mass spectra in a variety of ways, exhibited no obvious trend in shifting charge states of diquaternary ammonium ions. Counterion effects were investigated via the following approaches: 1) increasing the diquaternary ammonium salt concentration, 2) increasing the concentration of an external electrolyte containing the common counterion Cl^- ; 3) replacing Cl^- with trifluoroacetate (TFAC^-), and 4) increasing the concentration of an external electrolyte containing TFAC^- . Results show that the charge states of diquaternary ammonium ions in ESMS shifted toward lower values when the total analyte concentration (chloride salt form) was raised. In contrast, when the analyte concentration was held constant while CsCl was added, the charge states in ESMS were not affected. These results conform to our previous observations and the rationales therein [2,3]. For another anion characterized by a higher tendency of charge neutralization toward cations [4], (TFAC^-), the charge states of diquaternary ammonium ions were lowered whenever TFAC^- was present in solution, regardless of the form in which it was introduced. It is concluded that the stronger affinity of TFAC^- toward the cation is chiefly responsible for a greater degree of ion pairing in solution, and hence the observed shifts in charge states of diquaternary ammonium ions toward lower values in ES mass spectra.

Multiply-Charged Ions Produced by Sonic Spray Ionization

A. Hirabayashi, Y. Hirabayashi, M. Sakairi and H. Koizumi

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo 185, Japan

Introduction

Recently, we have developed Sonic Spray ionization technique as a novel interface in CE/MS and LC/MS.¹ In this technique, a solution is sprayed from a fused-silica capillary with gas flow coaxial to the capillary. Although the sprayed gas is electrically neutral, ions and charged droplets are produced at atmospheric pressure. The ion intensity depends on the gas velocity and it has a maximum at the sonic velocity. The origin of the charged species can be ascribed to non-uniformity in positive and negative ion concentrations in the solution surface.² Since the non-uniformity in the ion concentrations are determined by the surface potential, they may be regulated by applying an electric field to the solution. In this study, we report the generation of charged sprayed gas by applying an electric field to the solution and investigate the formation of multiply-charged ions.

Sonic Spray Ion Source

A cross sectional view of the sonic spray ion source is shown in Fig. 1. A solution is pumped by a syringe pump through a stainless steel joint, which is held at ground potential, to a fused-silica capillary. The capillary tip is inserted through a Duralumin orifice in the Duralumin source housing. A voltage is applied to the housing which is electrically isolated from the solution by the fused-silica capillary. The housing is pressurized with nitrogen causing gas flow through the orifice. A spray is thus generated in which ions and charged droplets are produced.

Results and Discussion

In Fig. 2 the current for all the charged species produced is shown as a function of the voltage V applied to the source housing. From the figure, we conclude the following: 1) the ion current is zero at $V = 0$, 2) for $|V| \leq 1.2$ kV the ion current decreases with increasing voltage, 3) for $|V| \geq 1.2$ kV the ion current is almost independent of the voltage.

Fig. 3 shows a typical example of the mass spectrum obtained from the 1 μ M solution of cytochrome-C (MW: 12300), where a voltage of -1 kV is applied to the housing. It is found that the voltage dependence of the intensity for the multiply-protonated molecule (or the ion formation efficiency) is almost the same as the one of the ion current shown in Fig. 2. Although singly and doubly protonated molecules of peptides are detected at $V = 0$ V,¹ it is

difficult to detect the multiply-protonated molecules. Since the size of the charged droplet initially produced is expected to be independent of the voltage, we conclude that the charge density of the produced droplet is increased by applying voltage.

EVIDENCE FOR SENSITIVITY ENHANCEMENT OF ESI-MS BY OPERATING IN THE CORONA-ASSISTED CONE-JET MODE

Keqi Tang and Richard D. Smith

M/S P8-19, Environmental Molecular Science Laboratory, Pacific Northwest National Laboratory, Richland, WA 99352

When a cone-jet mode electrospray of an aqueous solution was operated in a carbon dioxide environment, two well distinguished stability domains were found in the plane defined by the voltage applied to spray needle vs. the liquid flow rate (1). The first of these domains corresponded to the "classic" cone-jet mode. However, the second domain that applied at relatively low voltage, cone-jet electrospray was found to be stabilized by a corona discharge. This mode of spray operation has been recently labeled as corona-assisted cone-jet mode. Electrosprays operating in this special mode have the important consequence of reducing the minimum liquid flow rate by more than an order of magnitude compared to the classic cone-jet mode electrospray. Monodisperse sprays at flow rates on the order of 100 nL/min can be easily established using the same size of capillary as used for conventional micro-electrosprays. Of particular significance is that the spray in the corona-assisted mode carries a much larger electric current than that of the classic cone-jet mode spray and the difference in the total current between these two modes increases as the liquid flow rate decreases. This feature of the corona assisted spray mode suggests the potential for a significant sensitivity enhancement in electrospray ionization mass spectrometry and is explored specifically in this work.

The experimental investigation was performed using a Sciex TAGA 6000E mass spectrometer. The electrospray ionization source consisted of a stainless steel capillary (I.D.=177 μ m, O.D.=355 μ m) charged to a high electric potential relative to the sampling aperture of the mass spectrometer, typically positioned between 5 to 10 millimeters away from the tip of the metal capillary. A CO₂ sheath flow, coaxial with the capillary, was applied to isolate the capillary tip from the air environment in an effort to suppress the onset of corona discharge (2). Six different solutes, namely Phe-Met-Arg-Phe amide, bradykinin, angiotensin I, ubiquitin, insulin B-chain and cytochrome c, were used (thus molecular weight varied by over an order of magnitude from 900 u to 12000 u). Deionized water, having electrical conductivity of $3.538 \times 10^{-6} \Omega^{-1} \cdot \text{cm}^{-1}$, was used as the solvent. To compare the sensitivity for different electrospray modes, all experiments were performed using the same low resolution mass spectrometer scanning conditions.

Figures 1 and 2 show the mass spectra of bradykinin solution with electrosprays introduced at liquid flow rate of 1 μ L/min and 5 μ L/min, respectively. The count rates observed increase by more than an order of magnitude upon switching electrosprays from classic cone-jet mode to corona-assisted cone-jet mode. Table 1 further listed the ion counts for the most abundant m/z peak in the mass spectra of all studied compounds. The electrosprays were operated at fixed liquid flow rate of 3 μ L/min. The results showed a similar order of magnitude enhancement of measured ion abundance by the corona-assisted cone-jet mode electrospray compared to the classic cone-jet mode spray.

All the experimental data indicate that the significant sensitivity enhancement by the corona-assisted cone-jet mode electrospray is both independent liquid flow rate or droplet diameter and sample volatility. It was also observed that the signal sensitivity was enhanced uniformly by the corona mode electrosprays for all major peaks. It is thus unlikely that this sensitivity enhancement is due to ion-molecule collisions in the gas phase, after complete droplet desolvation, as in the case of atmospheric pressure chemical ionization (APCI). If the physical mechanism behind this sensitivity enhancement is similar to the one behind APCI, one should expect that the effectiveness of the sensitivity enhancement will be highly selective to the sample molecular weight, liquid flow rate and the m/z of the peak. One explanation for this

uniform sensitivity enhancement is that the corona discharge increases the charge on the droplets by a field charging process. We are currently investigating this and other possible explanations for these observations

Fig. 1 Mass spectra of bradykinin for a) classic cone-jet mode electrospray; b) corona-assisted cone-jet mode electrospray. The listed numbers in the spectra correspond to the ion counts for the most abundant species. Liquid flow rate: 1 μ L/min

Electrospray Ion Resolution in a Time-of-Flight Mass Spectrometer

Matt A. Lasater and David A. Laude

University of Texas at Austin, Department of Chemistry and Biochemistry, Austin, TX 78712

The exploration of resolved ions is important to understand the behavior of ions in the intermediate state between bare gas phase ions and the bulk phase solutions. In this work, the characterization of a vertical Time-of-Flight mass spectrometer was undertaken to help more fully understand this intermediately solvated area. The experiment consisted of two parts. The first part was an orthogonal intersection of a skimmed supersonic beam of neutral clusters with a thermionically emitted alkali metal ion beam, followed by pulse sequence to extract the resultant solvated ion into the vertical TOF mass spectrometer. The off axis detector opening was rotated through a 90° arc to probe the directional dependence of the velocity of the solvated clusters. The second part of the experiment involved the substitution of an electrospray ion source in place of the thermionic emitter.

An overview of the instrument is shown in figure 1. A pulsed expansion valve was used to create a supersonic expansion of saturated ethanol vapor in argon. The resulting collection of internally cool clusters was skimmed with a 500 μm skimmer cone and then allowed to react with thermally desorbed sodium and potassium ions. The heat of solvation from the reaction was dissipated by evaporation of the alcoholic clusters. The resulting internally warm clusters were orthogonally accelerated

Figure 2

by using a pair of extraction pulses from a fast, high voltage pulsers (See figure 2). The ions were then allowed to drift with their residual sideways velocity until the ions impinged on a TOF ion multiplier that had an 8 mm opening that was centered 16 mm off axis. The extraction pulse was typically 100 μs in duration to allow all the ions to enter the flight tube

Figure 1

The electrospray source was a concentric tube design that used a counter current gas flow for desolvation at a flow rate of 0-2 l/min and a variable temperature from ambient to $>130^\circ\text{C}$. The electrospray ions then passed through a 300 μm conductance limit with 0-100 V applied to it for focussing into an region of 1-2 Torr. The ions were then collimated with a 250 μm orifice skimmer cone. The ions were then focussed by electrostatic lenses into the acceleration region of the spectrometer. The relatively small volume of the ion stream that is sampled on each pulse yields a current of only 100 pA of alkali metal ions at the detector entrance. As seen in figure 3, the resolution of the thermionic emitter is quite good. The 100 shot average shows a resolution ($t/\delta t$) of 660. Because of the energetics of the solvation event and location of the collision area between the neutral beam and the ions, the signal of the resolved ions is significantly lower, about 5-10 pA at the detector. However, this is still enough current to see the resultant solvated ions as is seen in figure 4, a one shot spectrum of a single and double cluster of ethanol with potassium. With electrospray ions, the signal level is still lower. In a typical experiment, the signal at the conductance limit plate is around 0.1-1 μA , and the current on the skimmer cone is 100-1000 pA. Unfortunately, the small orifice size of the skimmer cone restricts the ion current post-skimmer to a 1-10 pA, and the level that reaches the acceleration region is at most 1 pA. This low level of primary signal precludes the study of resolution by crossed neutral ion beams, but the resolution may be possible by introducing a seed gas in the counter current gas stream and allowing the seed gas to freeze out on the electrospray ions during the supersonic expansion. Another problem in general is the noise level introduced by the voltage pulsers. The rapid high voltage spikes tend to introduce RF ringing in the system. This ringing occurs at 21 μs intervals, and can easily swamp out signals that occur near that time. In conclusion, the resolution and detection of electrospray ions is feasible, but challenges await. The low signals generated in electrospray can be increased by enlarging the skimmer cone orifice at the expense of significantly increased pressures and pumping requirements, but the increase in signal would allow the exploration of internally warm electrospray ion-neutral clusters. Future work includes increasing the S/N and resolution by adding a reflectron stage and to improve the signal in the electrospray by increasing the orifice diameter of the skimmer cone and shortening the distance between the skimmer cone and the middle of the acceleration region. Also, by increasing the maximum pulser voltage, the maximum flight tube voltage can be raised to improve detection efficiency for higher masses by decreasing the flight time and allowing the more massive ions with slower drift velocities to impinge upon the detector entrance.

ELECTROSPRAY MASS SPECTROMETRY OF SILVER-CONTAINING ADDUCTS OF PEPTIDES AND PROTEINS

Hongbo Li, K.W. Michael Siu, Roger Guevremont, Institute for National Measurement Standards, National Research Council of Canada, M-12, Montreal Road, Ottawa, Ontario, Canada K1A 0R6.

Gas-phase silver (I) ion complexes of proteins and peptides containing one to several silver ions can readily be produced in electrospray mass spectrometry from peptide/protein solutions containing silver (I) nitrate. Fig. 1 shows an electrospray mass spectrum of a solution of 50 μ M insulin, 1 mM silver (I) nitrate, and 50 mM acetic acid in 50/50 water/methanol; up to five silver ions can be seen bound to one unit of insulin. Shorter sulphur-containing peptides, such as methionine enkephalin and Substance P, also exhibited significant silver ion binding. In comparison with their sulphur-containing analogues, leucine enkephalin and [Nle¹¹]-Substance P appeared to bind silver ions to a much lower extent under identical experimental conditions. This difference between sulphur and non-sulphur containing peptides was also evident in the cases of di- and tripeptides although the magnitude was smaller.

Collision-induced dissociation (CID) of the $[M + Ag]^+$ ion from twenty S-containing and non S-containing di- and tripeptides produced both N-terminal and C-terminal fragment ions, including $[a_n + Ag - H]^+$, $[b_n + Ag - H]^+$, $[c_n + Ag + 2H]^+$ and $[y_n + Ag + H]^+$ (Fig. 2 and 3, notations of Roepstorff/Biemann for neutral peptide). This means that the $[M + Ag]^+$ precursor ion was either a composite of structures in which Ag^+ was bound separately to the N, O and S atoms of the peptide, or a structure or structures in which Ag^+ was coordinated (chelated) to the N, O and S sites. Recent results on alkali {1} and alkaline earth {2} metal-binding lend weight to the chelation scenario. Semi-empirical quantum mechanical calculations (a variant of ZINDO/1) on the optimized structures of $[M + Ag]^+$ for glycylmethionine and methionylglycine also revealed ligation to the N, O and S sites.

Gas-phase peptide ions did not appear to bind gas-phase Ag^+ ions to any significant extent in both the one-atmosphere zone and the lens region of the electrospray source. No peptide- Ag adduct ions were evident when a peptide solution and a silver nitrate solution were electrosprayed separately into two chambers whose exits terminated in a common transfer tube positioned directly in front of the orifice of the mass spectrometer. Significant Ag^+ ligation on peptides appears only possible in the solution phase.

Study of Metal-Ligand Interactions with Electrospray FTICR Mass Spectrometry

John R. Eyler, David Richardson, Richard Burton, Yarjing Yang, and Clifford H. Watson
Department of Chemistry, P.O. Box 117200, University of Florida, Gainesville, FL 32611-7200

Introduction

We have been combining electrospray ionization with Fourier transform ion cyclotron resonance (FTICR) mass spectrometry to form various metal ions bound to ligands in the gas phase. The advantages of the FTICR technique allow us to study both the reactivity and spectroscopy of these species. This poster reported our studies aimed at obtaining reliable quantitative values for the bond dissociation energies of alkali ion-crown ether complexes and at examining the solvation of organometallic complexes.

Studies of host-guest complexes in the gas phase have permitted better understanding of the fundamental details of molecular recognition in the absence of solvent. Mass spectrometry can give information about ion structures based on the fragmentation patterns observed. Collisionally activated dissociation (CAD) processes can provide quantitative bond dissociation energy (BDE) estimates if the interaction energy is precisely controlled during collisions. Investigations using CAD to study crown ether complexes with alkali metal cations have been previously reported, but quantitative information about the BDE's of crown ether complexes has only been reported by our group. In an earlier study, we reported approximate binding energies of metal/crown ethers formed using the laser desorption technique. In the work reported on this poster, we carefully measured quantitative BDE's using on-resonance CAD of crown ethers with either hydronium or metal ions attached, formed using an external electrospray ionization (ESI) source.

We have studied a variety of organometallic ions in our laboratories for the past 10 years. All have been singly charged. The use of electrospray ionization now permits us to generate multiply-charged ions, which are closely related to species observed in solution. In addition, careful manipulation of experimental conditions allows ions with 1-4 solvent molecules attached to them to be produced and studied in the FTICR mass spectrometer.

Results

Results obtained to date for alkali ion-crown ether binding energies are in general agreement with earlier published experimental and theoretical studies. However, they disagree with certain qualitative, comparative binding studies. We are currently working to obtain improved vibrational frequencies for these complexes and their transition states in order to improve the predictions of the RRKM calculations utilized in the "CRUNCH" data analysis program (provided by Peter Armentrout's group at the University of Utah).

A spectrum showing solvent-attached organometallic ions is given in the Figure on the next page. Work to date has shown that a variety of solvated ions can be produced by careful manipulation of the electrospray conditions. We are continuing our studies of their structures, formation mechanisms, and photochemistry.

OXIDATION OF GAS-PHASE PEPTIDE-COPPER TERNARY COMPLEXES WITH ALKALI METAL CATIONS

Tomáš Vaisar, Christine L. Gatlin, and František Tureček
Molecumetics, Inc., Bellevue, WA 98005, and Department of Chemistry,
University of Washington, Seattle, WA 98195-1700

Dissociations of gas-phase peptide-metal complexes are sensitive to the peptide structure, metal ion, and its binding site (1). Ternary peptide complexes with Cu(II) and diimine ligands 2,2'-bipyridyl and 1,10-phenanthroline undergo dissociations that involve peptide radical intermediates and are reminiscent of radiolytic processes in solution (2). Collisional activation of ternary peptide-copper complexes induces intramolecular electron transfer that results in sequential metal reduction Cu(II) → Cu(I) → Cu(0), accompanied by oxidation of the peptide residue to a radical or cation, depending on the binding amino acid.

We find that peptide-Cu ternary complexes are readily converted to alkali salts in solution, and the corresponding [Cu(peptide - 2H + X)bpy]** odd-electron ions are obtained in the gas phase by electrospray ionization of aqueous-methanol solutions. Upon collisional activation at low ion kinetic energies, $E_{lab} = 10$ -30 eV, the ternary complexes smoothly decarboxylate to give intermediates denoted as P(X)** for X = Li, Na, K, Rb, and Cs. Subsequent collision-induced fragmentations of P(X)** depend on the nature of the alkali metal ion (X) and the peptide C-terminal amino acid (3).

P(Na)** ions derived from Ala-Leu, Leu-Ala, and Phe-Leu eliminate neutral sodium atoms as the most abundant process in the CID spectra. Eliminations of neutral K and Rb from gas-phase Phe-Leu complexes also occurred together with the formations of K⁺ and Rb⁺, while cesium appeared exclusively as Cs⁺. We interpret these effects by competition for electron between the alkali metal cation and the peptide-Cu-bpy complex that depends on the relevant neutral ionization energies. The complexes are irreversibly oxidized by Na⁺, but oxidize Cs to Cs⁺. The ionization energy of the Phe-Leu complex is bracketed at 4.2 eV, which is the lowest value ever found experimentally for an organic or organometallic species.

The position of Phe in the peptide residue has a strong effect on the fragmentations. Complexes with N-terminal Phe undergo losses of metal atoms, as for Ala-Leu and Leu-Ala. In contrast, the complex of Leu-Phe eliminates predominantly bpy for all alkali metal ions. This effect is interpreted by intramolecular displacement of bpy by the phenyl group which is sterically possible only for Phe at

the C-terminus (Scheme).

The gas-phase dissociations show a few other trends depending on the alkali metal ion. Lithium is exceptional in promoting loss of Cu(0) and formation of [bpy + Li]⁺, while loss of Li(0) is not observed at all. Loss of Cu(0) is typical for complexes in which Cu⁺ is dicoordinated to electron-rich ligands, such as dehydrohistamine or α-histaminyl radical. This fact and the high affinity of Li⁺ to nitrogen ligands suggest that bpy is coordinated to Li⁺ in the gas-phase P(Li)** ions. All the peptide complexes are oxidized with Cu(bpy)⁺, which is lost as a neutral fragment. Loss of bpy from P(X)** increases in the series Na, K, Rb, Cs. This likely reflects an increasing polarization of the X⁽⁺⁾-O⁽⁻⁾ bond, which elevates the electron density in the peptide R-CH⁺-N=C(O) moiety, making it an even stronger electron donor ligand for Cu(I).

While the observed dissociations of peptide-Cu complex alkali salts do distinguish peptide isomers, they occur outside the amino acid residues and thus their utility for structure elucidation is limited. It is possible, however, that sodium salt formation can promote complexation to Cu of larger peptides and thus provide a means for sensitive detection by electrospray ionization mass spectrometry (4).

Ion Pairing Effects of TFA in ESI/MS

Barbara P. Wolf and David H. Russell
Laboratory for Biological Mass Spectrometry
Department of Chemistry, Texas A&M University, College Station, TX 77843

Ion pairing effects of trifluoroacetic acid (TFA) are well known, having been used extensively for reversed-phase HPLC separations to increase the retention times of basic compounds. When TFA is used in conjunction with positive ion ESI/MS, analyte signals are significantly suppressed as compared to signals obtained using a weak acid such as acetic acid.^{1,2} Signal suppression has also been reported for analyte solutions containing significant levels of strong electrolytes.³ Kuhlmann and coworkers proposed that ion pairing, not solution conductivity, was responsible for the suppression effects of TFA.¹ If ion pairing is in fact responsible for the observed signal suppression, then an accompanying decrease in charge state distribution may be expected for multiply charged analytes. Mirza and Chait have reported this shift for peptides and proteins when TFA is used.² Conversely, Wang and Cole reported an absence of any shift in charge state distributions for proteins when strong electrolytes were present in the ESI spray solution.³ In this study we examine the effects of differing amounts of TFA and acetic acid on analyte charge states, signal strengths, and water cluster intensities.

A Vestec 201A ESI quadrupole mass spectrometer was used for these studies. The ESI source was heated to 285°C and the probe temperature was held at 55°C. The ESI needle potential was 2.0 kV and the solution flow rate was 1.6 µL per minute. Positive ESI/MS was performed on the peptide bradykinin (MW=1060.2) and on two proteins: myoglobin (apo form MW=16950.6) and cytochrome-c (MW=12360.5). A series of spectra was acquired for each using a varying amount of TFA or acetic acid (HOAc) in 1:1 (v/v) H₂O:MeOH. Figure 1 compares the water and methanol cluster spectra obtained using 0.1% TFA (a) and 1% HOAc (b). Water cluster intensities are greatly enhanced by the presence of TFA. Figure 2 compares the ion intensities recorded for cytochrome-c over a wide range of pH of TFA and HOAc. The TFA suppression is observed over the entire pH range. Figure 3 shows the charge state distribution for cytochrome-c over a wide pH range. A measure of the charge state distribution is provided by determining the ratio of two charge states. The charge state distribution shifts to higher charge states as the pH is lowered. No significant difference in the charge states was observed between solutions containing HOAc and TFA. Similar results were obtained for myoglobin and bradykinin (not shown). These results would seem to contradict those of Mirza and Chait² who did observe a shift in the charge state distribution when strong acids were used; however, we believe that differences in their instrumental conditions account for this. Mirza and Chait noted a broadening of the multiply charged analyte peaks in their spectra when the strong acids were used. Our spectra show no such broadening. Our interpretation is that ion pairing is indeed responsible for the suppression effect, because ion paired analyte ions within electrospray droplets would appear neutral and thus would not be ejected from the droplet according to the ion evaporation model. Partially ion paired analyte ions would be ejected, but if instrumental conditions are such that the anions can be removed through energetic collisions, then no shift in charge state would be detected. In the Mirza and Chait experiments, the collisions did not remove all of the anions involved in the ion pairing and peak broadening resulted from a distribution of anion attachments and protonations that would result in the same charge state. Our theory is supported by the results of Wang and Cole who detected no shift in charge state distributions.³

DESIGN AND PERFORMANCE OF A MICROELECTROSPRAY ION SOURCE

Craig Whitehouse, J. Fred Banks and Glenn Whitehouse
Analytica of Branford, Inc. 29 Business Park Drive., Branford, CT 06505

Electrospray (ES) has rapidly grown to become a widely popular ionization technique for mass spectrometry samples when preceded by on-line liquid separation schemes. As the majority of applications and hardware have been developed for conventional high flow rate (1 ml/min) use, low flow rate systems have been frequently ignored.

The widespread use of high liquid flow rates and current interest in low flow rates with ES is ironic in that ES was initially developed for use at lower flow rates, i.e. about 1 μ l/min. Since ES seems to behave as a concentration sensitivity detector, at least in the 100 nL/min flow rate regime and higher, it seems reasonable to pursue the design and construction of systems which can operate well in the low flow rate area in order to optimize mass sensitivity or total amount of sample required for analysis. As the ion signal observed with ES is generally the same for sample flow rates between 100 nL/min and 1 ml/min, orders of magnitude of increase in mass sensitivity can be realized by simply operating at low flow rates.

To capitalize on the benefits from low flow rate electrospray, an ES source has been designed and optimized for this purpose. Figure 1 below shows the TIC from the direct infusion of a peptide mixture obtained with this system as the flow rate was decreased from 1000 to 50 nL/min. As can be seen, the TIC is relatively constant over this flow rate range. Figure 2 shows that the mass spectra obtained at the two extremes in these data, 1000 and 50 nL/min, respectively, are essentially identical.

This system was also tested for use with loop injections (1 μ l) using the same peptide mixture. Figure 3 below shows the TIC obtained from injections at flow rates ranging from 200 to 50 nL/min. Figure 4 shows the mass spectra obtained from each of these peaks. Note that at 50 nL/min, the signal strength in TIC and mass spectra are nearly the same as at 200 nL/min.

(Figure 3)

(Figure 4)

Optimization of APCI LC/MS Conditions for the Analysis of Polycyclic Aromatic Hydrocarbons

R.W. Smith, C.H. Marvin and B.E. McCarry.

Department of Chemistry, McMaster University, Hamilton, ON, L8S 4M1, CANADA.

Polycyclic aromatic hydrocarbons (PAH) with molecular weights greater than 250 are prevalent in a variety of matrices including carbon blacks, tars, asphalts, coal tar-contaminated sediments and urban air particulates. Some of these compounds are potent carcinogens, but their presence in complex environmental mixtures has been largely ignored owing to the limitations of conventional methods of analysis. Analytical methods such as GC/MS have proven ineffective for the analysis of PAH with $mw > 300$ due primarily to their low volatility.

Atmospheric pressure ionization techniques such as atmospheric pressure chemical ionization (APCI) has made LC/MS analysis of high molecular weight PAH possible (1). However, gradient elution programmes, which typically employ acetonitrile (MeCN) and dichloromethane (DCM) for separation of PAH with $mw > 300$, may not yield a reagent plasma conducive to maximum analyte ion intensity. Post-column addition of water to an MeCN/DCM mobile phase has been reported (2) to enhance proton transfer, resulting in an improvement in the detection limits for PAH. Consequently, the effect of mobile phase composition and instrumental parameters on APCI signal intensity, and the nature of the ionic species observed were studied to optimise conditions for the detection of PAH ranging in mass from 250 to 500.

APCI was performed with water, MeCN and DCM mobile phases (1 ml/min). PAH were introduced either by flow injection at a concentration of 14 - 18 μ molar or using a Vydac reverse phase C_{18} column employing a HP 1090 liquid chromatograph interfaced to a Fisons Platform quadrupole mass spectrometer. APCI source temperature, 120°C, probe temperature, 500°C and a cone voltage of 35V were employed in all experiments (unless otherwise stated). All chemical ionization (CI) experiments were performed with a VG ZAB-E mass spectrometer. PAH employed in this study were used as supplied by the manufacturer or Dr. J. C. Fetzer (Chevron Co.).

In the flow injection study, instrumental conditions such as source temperature, probe temperature, corona discharge voltage and focusing voltages were optimised for the detection of dibenzo[a,l]pyrene (mw 302) in 100% MeCN at a concentration of 15.2 μ molar. As can be seen in Figure 1, the optimum analyte response was achieved at a probe temperature of 500°C ($[M+H]^+$ intensity arbitrarily set to 1000). This resulted in a full scan detection limit of 5 ng and a SIR detection limit of 200 pg (5:1 S:N). The addition of water (5% aqueous MeCN) resulted in a ten-fold decrease in signal intensity (Figure 2). In addition, as the aqueous content was increased to 10% the M^+ ion was observed. The intensity of the M^+ species could be reduced and the $[M+H]^+$ ion increased when the probe temperature was increased to 600°C. The decrease in analyte response and formation of the M^+ species was also observed for benzo[a]pyrene (mw 252) and benzo[g,h,i]perylene (mw 276). Benzo[c]chrysene (mw 278) exhibited the M^+ species with all mobile phases employed. For high molecular weight PAH such as diindeno[1,2,3-cd]perylene (DIIP, mw 400), the protonated ion dominates in MeCN/DCM mobile phases containing $>50\%$ MeCN however in aqueous mobile phases the response decreased dramatically. In mobile phases containing $>75\%$ DCM the M^+ ion was prominent ($\sim 1:1 M^+ : [M+H]^+$ at a probe temp of 600°C) whereas in 100% DCM, only the M^+ ion was observed.

LC/MS analysis of a mixture of the 302, 278 and 252 PAH yielded similar responses and mass spectra observed in the flow injection study. In order to elute DIIP from the LC column it was necessary to use 100% DCM and the mass spectrum showed a $\sim 1:1$ ratio of the M^+ and $[M+H]^+$ ions with a full scan detection limit of 15 ng (5:1 S:N). The discrepancy between the intensities of the ions observed from DIIP in flow injection and in LC/MS can be explained in terms of residual MeCN being eluted from the column when 100% DCM is delivered under "fast" gradient conditions. However other PAH standards in the range 326 to >500 all showed intense protonated ions as these species elute in mobile phases containing appreciable MeCN concentrations.

CI experiments employing H_2O and MeCN yielded both the $[M+H]^+$ ion and a less intense M^+ ion (15 -

40% of the $[M+H]^+$ intensity) whereas DCM showed only the M^+ ion. Observation of the M^+ species has been documented previously for PAH with CH_4 and H_2 reagent gas (3). The APCI and CI mass spectra were similar however, the intensity of the M^+ ions was greater in APCI. For example, benzo[c]chrysene always exhibited the M^+ ion in APCI whereas in CI it yielded primarily the $[M+H]^+$ ion with H_2O and MeCN. Poor analyte response was always observed in APCI when the M^+ ion dominated. This may reflect the non-resonant nature of the charge exchange process, that is, H_2O , MeCN and DCM have IE's > 11 eV while IE's of PAH are < 8 eV.

The nature of the ionic species observed ($[M+H]^+$ and/or M^+) and the analyte response depends primarily on: (a) the composition of the mobile phase and (b) APCI probe temperature. Other experimental parameters, such as source temperature, corona discharge and focusing voltages exhibited little effect on the analyte response and ionic species observed. High MeCN concentrations favour the formation of $[M+H]^+$ ions and maximises analyte response (for most PAH studied). Addition of water or DCM causes a decrease in response and a shift towards the formation of M^+ . Changing the APCI probe temperature from the "optimum" causes a reduction in response however, for aqueous mobile phases, elevated temperatures increase the analyte response and promotes the formation of $[M+H]^+$.

These results would indicate a potential problem for PAH analysis when dealing with complex mixtures and mobile phases. The observed sensitivity may vary greatly and the complication as to which ionic product is observed may lead to misinterpretation unless care is taken to characterize the behaviour of representative PAH under typical analysis conditions. Future experiments will include: (i) why is the M^+ ion more intense in APCI than in CI when H_2O is used?, (ii) whether the "optimum" APCI probe temperature is compound and mobile phase specific, (iii) does post-column addition of H_2O cause the same decrease in response and formation of M^+ when the instrument has been optimised as described in this study? and (iv) is the discrepancy between these results (when aqueous mobile phases are employed) and post-column addition of H_2O (which is reported to enhance proton transfer and increase sensitivity) instrument specific?

Design and Application of a New Micro-Electrospray Device for Magnetic Sector Instruments.

H. Muenster, R. Pesch and P. Dobberstein;
Finnigan MAT GmbH, Barkhausen Str. 2, D-28197 Bremen, Germany

Since electrospray had become the most utilized ionization technique the demand for a low flow rate ESI (i.e. nanoliter) was very high. Various groups (1-3) already have reported about their micro or nanoliter ESI, but these devices need special handling or treatment like drawn fused silica capillaries.

We have built a micro-ESI for high resolution sector instruments, capable for flow rates ranging from low nanoliter to one microliter.

We are using a standard fused silica capillary with a special x,y,z-adjuster to optimize the position of the spray capillary. The standard Finnigan MAT API interface is used in combination with the micro ESI sprayer.

Operating the micro ESI with low nanoliter flow allows a complete set of experiments to be performed from less than 5 µl of total sample volume of bombesin.

We measured:

- low resolution ESI spectrum
- accurate mass measurement by high resolution electric scan
- accurate mass measurement by high resolution peak matching
- low resolution ESI skimmer CID spectrum
- low resolution ESI B/E linked scan CID spectrum.

The sample consumption for all experiments was less than 50 fmol except for the linked scan. Good structural information is gained from the skimmer CID spectrum of bombesin (Fig. 1). Almost the complete sequence can be determined with the B- and A-series ions.

Fig. 1: Micro-ESI skimmer CID spectrum of bombesin

High sensitivity was also demonstrated with a measurement of the protein myoglobin in low and high resolution mode.

The high resolution (RP > 18000, 10% valley) spectrum (Fig. 2) shows good accordance with the theoretical isotope pattern and was generated from only 200 fmol of myoglobin.

Fig. 2: High resolution micro-ESI spectrum of $[M+17H]^{17+}$ of myoglobin

Library Affinity Selection-Mass Spectrometry: Characterization of SH2-Ligand Interactions.
 *Michele A. Kelly, Hongbin Liang, Iou-Iou Sytwu and Lawrence P. Wennogle. Ciba Pharmaceuticals Division, 556 Morris Avenue, Summit, NJ 07901.

Synthetic combinatorial libraries are a valuable source of diverse structures useful for large-scale biochemical screening. The use of this technology has great potential for rapidly identifying enzyme inhibitors and elucidating protein-protein interactions. Various techniques for the evaluation of combinatorial libraries have been developed; however, many systems deal with resin-bound substrates that may hinder substrate binding. Likewise, chemical tagging of libraries may be burdensome. Due to the variety of structures that can be produced and the complexity and size of the library to be screened, the isolation and chemical identification of the active species are a challenge.

We have developed a practical technique for screening such libraries by integrating library affinity selection with electrospray ionization mass spectrometric detection. Using a soluble peptide library containing 361 compounds, we applied this procedure to the isolation and characterization of library components with affinity for the SH2-domain of PI3-Kinase. The method has broad applicability to combinatorial library screening; moreover, electrospray tandem mass spectrometry (ES-MS/MS) yields sequence-specific identification of individual components without the need for chemical tags.

Experimental: Four standard peptides: 1) GY(Nle)P(Nle)S-amide; 2) G(pY)(Nle)P(Nle)S-amide; 3) G(F₂Pmp)(Nle)P(Nle)S-amide; 4) GNGDS(pY)MPMPKS-amide, were synthesized by the Fmoc solid phase method (where Nle = norleucine; pY = phosphotyrosine; and F₂Pmp = (phosphonodifluoromethyl) phenylalanine). The combinatorial library was purchased from Multiple Peptide Systems (San Diego, CA) and was defined as: G(F₂Pmp)X₁PX₂S-amide, where X = 19 of the 20 standard L-amino acids (minus cysteine). Therefore, this library consisted of 361 (19²) compounds.

Purified human PI3-Kinase SH2-domain was produced as a fusion protein with glutathione-S-transferase (GST). The SH2 fusion protein was immobilized to Glutathione-Agarose and used to screen all compounds. Three gradient elution methods (phenylphosphate, chaotrope agent (KSCN) and acid elution) were evaluated for separating the four standard compounds on the SH2 affinity column. The acid elution, using a batch procedure and a peptide trap (Michrom BioResources, Inc.; Auburn, CA) to concentrate components, was utilized for subsequent coupling of this assay with mass spectrometry. Mass spectral analyses were performed using a PE Sciex API III instrument in the positive ionization mode.

SH2-Ligand Interactions: SH2-domains bind phosphotyrosine-containing sequences, where adjacent residues contribute to binding energy and specificity (Songyang *et al.*, 1993). Binding assays of the four standard compounds revealed IC₅₀ values reflective of the selectivity of this affinity system. Additionally, all three gradient procedures (see above) released the standard compounds from the SH2 affinity system and afforded unique separation profiles. The order of elution differed among the various methods, most likely reflecting the differing mechanisms by which the elution agents were disrupting the binding interactions. For example, displacer elution reflects relative affinities at the phosphate binding pocket; chaotrope elution is based upon disruption of hydrophobic interactions; and acid elution is related to the titration of acidic amino acids in the SH2-domain as well as the titration of phosphonate and phosphate groups.

Library Affinity Selection-Mass Spectrometry: ES-MS analysis of the intact library revealed the complexity of the 361 components of the library and the distribution of the peptides properly reflected the expected statistical distribution of molecular weight combinations of amino acids. Affinity selection of the library was performed using a batch procedure consisting of five sequential elution steps: unbound; 1M salt/pH 7.5 wash; pH 4.5 wash; pH 3.5 elution; and TFA elution. As seen in Figure 1, a small subset of

library components were detected in the pH 3.5 elution. The molecular ions found in the pH 3.5 elution, as compared to the theoretical predicted masses, implicated the presence of methionine in the strongly bound peptides, although in some cases, there was potentially more than one X₁/X₃ combination possible for a given molecular ion. Thus, the identity and order of residues in positions X₁ and X₃ was probed by ES-MS/MS.

Structural Characterization by ES-MS/MS: The strength of ES-MS/MS detection when used in conjunction with library affinity selection lies in its ability to facilitate the identification of individual molecules within a mixture. ES-MS/MS was performed for the most abundant peptide in the above pH 3.5 elution at m/z 798.5, a molecular weight that matches theoretical X₁/X₃ of MM, FD and VY. This mass spectrum revealed that, of the three possibilities, only the MM combination was present in the pH 3.5 elution. ES-MS/MS analyses of three other molecular ions in the pH 3.5 elution also confirmed the presence of methionine in position X₃ (i.e., X₁/X₃ combinations of I/LM, EM and FM).

We have demonstrated that affinity screening combinatorial libraries in conjunction with ES-MS and ES-MS/MS detection is a feasible approach, yielding an abundance of information concerning peptide disposition and sequence information in a rapid time-frame. This methodology is ideal for the analysis of soluble, unbound library components, which can be of unlimited design with respect to small-molecule libraries. Significant aspects of the current method include: the simplicity of the experimental design using a peptide trap; the ability to analyze the integrity of an intact combinatorial library; the practicality of a well-planned library related to the affinity system; the applicability of the method to unnatural amino acids; the selectivity of the method with the possibility for ranking; and the key advantage of ES-MS/MS for structural identification.

Optimization of pp60^{c-src} Substrates by Decoding Peptide Libraries Using LC/MS

R. K. Blackburn*, D. B. Kassel*, G. Tian[†], and W. B. Knight[‡]

Departments of Structural Chemistry* and Enzymology[†], Glaxo Wellcome, Inc.
Five Moore Drive, Research Triangle Park, NC 27709

The tyrosine kinase pp60^{c-src} (Src) plays an important role in cell signal transduction through phosphorylation of peptide and protein substrates. Src has been implicated in several disease states including colon and breast carcinomas and neuroblastoma. Exploration of the substrate specificity of Src and several other kinases was recently reported by Songyang et al. (1). These workers used degenerate peptide libraries and N-terminal sequencing to obtain the preferred consensus sequence for each kinase. In order to obtain more detailed SAR information, we have conducted a series of substrate optimization experiments for src using focused peptide libraries and LC/MS or LC/LC/MS for decoding.

The following libraries were synthesized in order to probe amino acid preferences N-terminal to the site of Tyr phosphorylation: Ac-YQQIX-NH₂, Ac-YQXTY-NH₂, and Ac-YXQIY-NH₂, where X ≠ Glu, Asp, Arg, Lys, or Cys. Charged residues were not included in our libraries in order to provide the option of using anion exchange chromatography to separate phosphorylated from nonphosphorylated substrates. Each monosubstituted library was individually incubated with src, and aliquots were removed and analyzed by reversed phase perfusion LC/ESI-MS using a rapid (<15min) gradient. Based on the 80 Da mass increase upon phosphorylation, phosphorylated substrates were readily detected, and their relative abundances estimated using peak areas from extracted ion chromatograms. The preferences for N-terminal residues determined using the three monosubstituted libraries are as follows: P1=Ile; P2=Gln/Asn; P3=Leu/Ile.

Based on data from the N-terminal optimization, a new library (Ac-LQIYXXI-NH₂) was synthesized for optimization of C-terminal residues. This library contained two amino acid substitutions rather than one, increasing the potential number of components after incubation with src from 30 (for monosubstituted libraries) to 450. In order to decrease the complexity due to components of the same molecular weight, LC/LC/MS was used for decoding. After incubation of the library with src, the reaction mixture was passed over an anion exchange column at pH 8.0, which preferentially bound phosphorylated peptides and allowed nonphosphorylated substrates to pass through. Next, phosphopeptides were eluted from the anion exchange column and trapped onto a reversed phase perfusion column for subsequent LC/MS analysis. Figure 1 shows the composite MS spectrum obtained for the Ac-LQIYXXI-NH₂ incubation with src. The four best substrates identified (Ac-LQIYGAI-NH₂, Ac-LQIYAGI-NH₂, Ac-LQIYGGI-NH₂, Ac-LQIYGI-NH₂) were synthesized and tested against src, and kinetic data for these discretely are summarized in Table 1.

In summary, four peptides were identified from our libraries which were good substrates for pp60^{c-src}. The best substrate identified in our studies, Ac-LQIYGAI-NH₂, was a 10-fold better substrate than RRLIEDAEYAARRG, a substrate based on the src autophosphorylation domain. However, it was a poorer substrate than others which have been reported (1,2). LC/MS was found to be suitable for decoding libraries of ≤ 30 components, and introducing an anion exchange LC step prior to LC/MS to separate phosphorylated from nonphosphorylated substrates allowed for decoding a mixture of ≤ 450 components. We feel this approach which combines LC/MS or LC/LC/MS with the use of focused peptide libraries would be useful for substrate optimization for other kinases.

Characterization of Peptide Combinatorial Libraries by Direct Infusion and HPLC ESI-FT/MS

Brian E. Winger, John A. Castoro and Joseph Campana, Finnigan FT/MS, 6416 Schroeder Rd., Madison, WI 53711-2424.

Mixtures that exist in solution are very often amenable to analysis by using ESI-MS and ESI-MSⁿ. The accurate mass, high resolution and MSⁿ capabilities of Fourier transform mass spectrometry (FT/MS) in combination with ESI, yields a powerful tool for accurately characterizing complex mixtures. Direct infusion ESI-MS may have limited success in analyzing complex mixtures due to factors such as suppression of low level analytes and of components with low basicity, i.e. limited ability to accept a proton, as well as a low tolerance to high salt concentrations. These limitations can often be overcome by using LC-MS. Direct infusion ESI-FT/MS, MS/MS, and LC-FT/MS were used to identify and characterize components of the peptide library cyclo[-X₁-X₂-Hyp-X₃-Leu-] (where X₁ was either D-Trp or D-Gln, X₂ was either D-Asp or D-Ala, Hyp is hydroxyproline, and X₃ was either D-Val or D-Thr) as well as by-products of the synthesis.

By using a dual-cell FT/MS system equipped with MALDI on the source side and an ESI source on the analyzer side, an accurate mass measurement method was developed in which the analyte and mass reference compound were introduced into the mass spectrometer independently. Figure 1 illustrates the use of Multiple Ionization Techniques Simultaneously, or MITS, for accurately determining the mass of the library components. In this example, ions for the mass reference poly(methylmethacrylate) PMMA 640 were generated via MALDI while ions for the library components were generated via direct infusion ESI. With a detect time of 2.2 seconds (512K data points collected), a resolving power of greater than 90,000 was obtained for all species. The RMS mass error for the 8 library components was 1.2 ppm.

Figure 2 is the LC-FT/MS total ion chromatogram of the peptide library. In addition to the expected library components, several peptides containing t-butyl protecting groups were identified by LC-FT/MS that were not detected by direct infusion. By using di(2-ethylhexyl)phthalate as the 'lock-mass', the RMS mass error for the 8 expected peptides and the 4 t-butylated peptides was 4.2 ppm. The lock-mass method is based on correcting the electric field term of the calibration equation with a known *m/z*. This mass error could be improved by either using a mass reference with multiple ions, e.g. a polymer, or by using a lock-mass that is higher in mass than the analyte.

Finally, MS/MS was performed on several of the library components to confirm their identity. Due to the nature of a cyclic peptide, a variety of different peptide-backbone fragments are possible. As an example, there are 16 possible backbone fragments for a cyclic pentamer. For the peptide -Trp-Ala-Hyp-Val-Leu-, 13 fragments were detected. The RMS mass error for these 13 fragments was 3.4 ppm

Immunoaffinity Extraction and LC/MS for Screening Small Molecule Combinatorial Libraries

Ray Wieboldt, Jerry Zweigenbaum, and Jack Henion

Cornell University, Analytical Toxicology, 927 Warren Dr., Ithaca NY 14850

This approach to screening chemical libraries combines immunoaffinity extraction with analytical information provided by mass spectrometry. Binding of a drug molecule to a biological target is required for activity and therefore the use of receptor mimetic molecules for the recognition step provides a reasonable means to identify library components which are the best candidates for further biological testing. Capture of individual components from a target mixture by antibodies raised against clinically useful drugs provides a basis for molecular recognition. The libraries used here consist of mixtures of compounds related to benzodiazepines and were provided by Hoffmann La-Roche, Nutley NJ. In principle, any antibody or biomolecule receptor with affinity for library components can be used to provide definition of a pharmacophore represented by captured library components.

Immunoaffinity extraction:

Our procedure employs diafiltration to accomplish the binding, washing and elution steps of the immunoaffinity extraction. Aliquots of an antibody and the compound library are combined in a Microcon centrifugal filter (Amicon) chosen with a nominal molecular weight cutoff of 50,000 daltons in order to retain the antibody. The molar ratio of antibody to target molecules is adjusted to provide an excess of the antibody; typically, 0.1 to 1 nmol of the antibody is used in a total volume of 100 μ L. Centrifugation steps remove unbound components and the elution stringency is adjusted by choice of wash solutions. Different concentrations of saline, acetic acid and chaotropic agents such as thiocyanate were tested. Captured library components which remain bound to the antibody during the washes are separated from the antibody by a final centrifugation with 1.5 M acetic acid. The extracted components are reconstituted in a minimum volume of buffer for examination by LC/MS. The diafiltration membrane provides rapid separation (less than 5 minutes for each centrifugation step) and different combinations of antibody and wash conditions may be tested in parallel.

LC/MS of extracted components:

LC/MS of extracted library mixtures was performed on a PE/Sciex API 300 with the IonSpray interface. A fast gradient was used to provide chromatographic separation on a reversed-phase microbore HPLC column. PE/Sciex data processing software was used to uncover overlapping chromatographic peaks and to derive the masses of library components.

An example of an extraction of a 20 component benzodiazepine library with an antibody to oxazepam is shown in the figure below. The upper panel presents an LC/MS chromatogram of components trapped by the antibody. High stringency binding conditions using washes with thiocyanate and dilute acetic acid were used to retain only the most strongly bound components. The middle panel shows a chromatogram of the original multicomponent library mixture as the summed ion current over a range of 200 to 400 amu. Peaks are labelled with the mass of the most abundant ion associated with each signal. The unknown peak is associated with an ion at $m/z = 242$ as shown in the lower panel (oxazepam $m/z = 287$).

Mass spectrometry can provide further information about captured unknown components from the library. Contour plots can be used to deconvolute overlapping peaks and cluster analysis can be used to isolate components with selected spectral properties. Further identification can be achieved with fragmentation data. When screening data are generated from a series of library mixtures by extraction with multiple antibodies, relative intensities of the captured peaks provide a means of scoring the selection results. Comparison of scores of relative affinity of the components found in a library provides a measure of both the diversity of the library as well as the dissimilarity of the individual components.

SCREENING COMBINATORIAL LIBRARIES USING PULSED ULTRAFILTRATION/ELECTROSPRAY MASS SPECTROMETRY

Richard B. van Breemen, Chao-Ran Huang, Dejan Nikolic,
Charles Woodbury, Yong-Zhong Zhao and Duane Venton
University of Illinois at Chicago, College of Pharmacy
Dept. of Medicinal Chemistry and Pharmacognosy
833 S. Wood Street, Chicago, IL 60612-7231

In the classical approach to drug discovery and development, single compounds are synthesized and tested for a given biological activity. Because both syntheses and bioassays are labor intensive, this approach is inefficient and expensive. Significant enhancement in efficiency may be gained by simultaneously producing many compounds, called combinatorial libraries, and testing them as a group. Numerous methods have been developed for the synthesis of molecularly diverse chemical libraries (Moos, 1993). However, a difficult challenge has been the screening of these libraries to detect molecules with a desired biological activity or binding profile that is specific for a given target receptor.

The majority of available screening methods require that ligands or receptor be covalently bound to a stationary support (Lam, 1991). However, such attachments chemically alter the compounds and can result in false positive and/or negative results. In response to the need for screening molecular diversity using *solution phase* ligands and receptors, we have devised apparatus called **pulsed ultrafiltration (PUF)/electrospray mass spectrometry** in which the receptor molecules are trapped in solution in an ultrafiltration chamber, and the solution phase ligand mixture is pumped through the chamber. This identical PUF/electrospray mass spectrometry apparatus may also be used to measure binding constants for ligands interacting at specific sites on a receptor (see related abstract in this session).

Experimental Section

Pulsed Ultrafiltration. The PUF chamber was built in-house and was equipped with a 10,000 MW cutoff ultrafiltration membrane (Amicon). The binding buffer consisted of 50 mM, pH 7.5, potassium phosphate. Adenosine deaminase (Sigma Chem. Co.) was used as a model macromolecular receptor. A library of possible ligands for adenosine deaminase was prepared by dissolving adenosine and 19 of its analogs in binding buffer (Sigma Chem. Co.). All components of the library were equimolar except for the high affinity inhibitor of adenosine, erythro-9-(2-hydroxy-3-nonyl)adenine (EHNA), which was included at a 10-fold lower concentration. In a typical experiment, the PUF chamber was loaded with 6.3 μ M adenosine deaminase that had been incubated with 4.4×10^{-5} M of the library mixture (4.4×10^{-6} M EHNA) for 10 min. The PUF chamber was rinsed with water at 100 μ L/min for 6 min to wash away phosphate buffer and unbound ligands. Then the bound ligand(s) was released from the PUF chamber and eluted into the mass spectrometer using a mobile phase consisting of water/methanol (50:50; v/v). Control analyses were carried out without the receptor protein, adenosine deaminase.

Mass Spectrometry. Electrospray mass spectra were obtained using a Hewlett Packard 5989B MS Engine equipped with a HP1090L HPLC system. The range m/z 100-500 was scanned in approximately 2 s. During selected ion monitoring (SIM), the dwell time was 5 s/ion. Postcolumn addition of 1% acetic acid was used to enhance formation of protonated ligand molecules.

Results

The basic principles of combinatorial library screening using pulsed ultrafiltration-electrospray mass spectrometry are shown in Figure 1. After a library mixture has been injected into a PUF bonding chamber, the ligand-receptor complexes are retained while the non-binding and low affinity ligands are washed out. Elution of the high affinity ligands is accomplished by perturbing the ligand-receptor complex through the addition of organic solvent to the mobile phase, raising the temperature, changing the pH, or eluting with a high concentration of competing ligand. In this example using the adenosine analog library, the PUF chamber containing adenosine deaminase was eluted with methanol, and the only compound detected by using electrospray mass spectrometry was the high affinity (K_d approx. 1×10^{-5}) inhibitor EHNA (see electrospray mass spectrum in Figure 2). Note that the concentration of EHNA was ten-fold lower than any other compound in the library mixture. In this manner, PUF/electrospray mass spectrometry was demonstrated to be an elegantly simple and powerful new method to screen combinatorial libraries as part of new drug discovery.

QUANTIFICATION OF LIGAND/RECEPTOR INTERACTIONS USING ELECTROSPRAY LC/MS

Richard B. van Breemen, Chao-Ran Huang, Dejan Nikolic,
Charles Woodbury, Yong-Zhong Zhao and Duane Venton
University of Illinois at Chicago, College of Pharmacy
Dept. of Medicinal Chemistry and Pharmacognosy
833 S. Wood Street, Chicago, IL 60612-7231

During drug discovery and development, and as part of biochemical and pharmacological studies of receptors and enzymes, quantitative measurements of receptor-ligand and enzyme-substrate interactions are essential. For example, the design and testing of specific enzyme or receptor agonists and antagonists requires measurement of binding constants, K_a or K_i . Existing methods such as equilibrium dialysis are time-consuming and lack precision. Therefore, a faster, more precise and accurate method is needed. In this investigation, we focused on the development of a flow-through binding system called, "pulsed ultrafiltration (PUF)," interfaced it to an electrospray mass spectrometer, and then used this unique apparatus to measure the interaction of ligands and receptors in solution.

Experimental Section

The pulsed ultrafiltration/electrospray mass spectrometry system is summarized in the block diagram shown in Figure 1. In this system, the PUF chamber contains an ultrafiltration membrane to trap the macromolecular receptor in solution and at the same time allow the solution-phase ligands to flow through after interacting with the receptor. The detector is either a UV/vis absorbance detector (when single ligands are studied that have strong chromophores) or an electrospray mass spectrometer (essential when competitive binding assays are carried out, or when the ligands lack a suitable chromophore).

Pulsed Ultrafiltration. A pulsed ultrafiltration (PUF) chamber was built in-house and equipped with a 10,000 MW cutoff ultrafiltration membrane (Amicon). The binding buffer consisted of 33 mM, pH 7.0, potassium phosphate for analyses using UV/vis absorbance detection, or 50 mM ammonium acetate for electrospray mass spectrometric detection. The flow rate through the binding chamber was 100 μ L/min. The PUF chamber was loaded with approximately 20 μ M receptor protein (i.e., human serum albumin), and typically 10 μ L of 5 mM ligand (i.e., phenylbutazone and/or warfarin) was injected per analysis to give approximately 60 μ M ligand in the binding chamber. Control analyses were carried out that were otherwise identical except that the PUF chamber contained no receptor protein.

Mass Spectrometry. Electrospray mass spectra were obtained using a Hewlett Packard 5989B MS Engine equipped with a HP1090L HPLC system. The range of m/z 100-600 was scanned in approximately 2 s. During selected ion monitoring, the dwell time was 5 s per ion. In source collision induced dissociation (CID) was carried out by applying 300 V between the end of the capillary and the first skimmer.

Figure 1

Figure 2

SCATCHARD-TYPE PLOT WARFARIN/HSA

Figure 3

Results. The ligand elution curve (Fig. 2) measured in the PUF chamber effluent contains all the information necessary to produce a Scatchard Plot and calculate the binding constants describing the ligand-receptor binding interactions. If there is no binding, then the elution curve shows exponential decay, and a natural log plot of the ligand concentration is linear. By measuring the elution curve using electrospray mass spectrometry during a control experiment in which no receptor is present in the PUF chamber, we verified that the mass spectrometer provided a linear detector response during PUF/MS.

Because of ligand-receptor binding, the curve shape changes. We have developed a pair of differential equations describing changes in the elution profile related to ligand/receptor bonding, and the simultaneous solution to these equations provides quantitative descriptions of the binding interactions. A Scatchard-type plot of the binding of warfarin and human serum albumin obtained using PUF is shown in Fig. 3. In this plot, two separate binding sites and constants are identified.

Automated LC-MS for the Characterisation of Combinatorial Libraries

J Batt, P A Bott, M A McDowall, S W Preece and J A Rontree

Micromass UK Ltd, 3 Tudor Road, Altrincham, Cheshire, WA14 5RZ

Introduction. The traditional approach to drug discovery has used rational drug design where lead compounds, often based on a structure derived from natural products, are optimised by a series of manual synthetic and screening steps. By its nature, this approach is time consuming and costly, leading the pharmaceutical industry to investigate more cost effective methods of drug discovery. Combinatorial chemistry involves the preparation and screening of large numbers of diverse compounds by the systematic coupling of an assortment of small reactive molecules or 'building-blocks'. By increasing the number and diversity of compounds available for drug discovery the number of leads generated should also be increased, and with advances in automation it is possible to synthesise compounds and pass them through biological screening in a very short period of time. Initially it was hoped that biological screening could be carried out with mixtures of large numbers of compounds. However, screening complex mixtures can often give misleading results due to a combination of several weak activities. By reducing the number of components in a mixture to ten or less, confidence in screening results is greatly improved. To this end, synthesis is often carried out using the multiple parallel synthesis approach. This is usually performed by carrying out a number of sequential parallel micro-reactions on 96 well microtitre plates, resulting in a product or small mixture of products in each well of the microtitre plate. For this approach to be successful, it is necessary to confirm the success of the synthetic chemistry to ensure that the library has the expected degree of diversity prior to screening. Due to the large number of samples involved, a highly automated approach is needed to allow rapid analysis and to prevent the analysis becoming the rate-limiting step in the process. Advances in automation of mass spectrometry and liquid delivery/autosampler systems now allow atmospheric pressure ionisation to be used for this purpose.

Methods. A HP1050 solvent delivery system (Hewlett Packard, Palo Alto, CA, USA), under control from the MS data system, was used to pump methanol at 0.5 mL/min through the autosampler to the mass spectrometer. A Gilson 215 sample handling system (Gilson Inc, Middleton, WI, USA) also under control from the MS data system (figure 3), was used to inject the selected samples into the mobile phase. The samples were presented on 96 well microtitre plates and a random selection of wells were selected for analysis. A Platform single quadrupole mass spectrometer (Micromass UK Ltd, Tudor Road, Altrincham, UK) equipped with an atmospheric pressure chemical ionisation (APCI) source was used for detection. Alternate positive and negative ion scans were acquired over a mass range of 100-1000 amu for the 1.0 minute duration of each analysis. The system was fully automated using the MassLynx NT mass spectrometer data system (Micromass UK) running within the Windows NT operating system. OpenLynx-Diversity, a module working within MassLynx NT, allowed the set-up for analysis, data processing and reduction of the produced data sets according to a number of selected criteria. Prior to analysis, the system required the following information: (i) the location of the microtitre plate wells selected for analysis and (ii) the masses or molecular formulae of the expected components in each well. This information could be entered manually or could be imported from a LIMS or from a spreadsheet programme. For these analyses, single components were expected in each well. As the samples were injected directly, the sample eluted into the source at the same time for each analysis, allowing the data to be automatically collected from a pre-set time window. For each sample, the system took a combined, background subtracted spectrum from the sample peak and applied a pre-set data threshold. The mass peaks remaining after thresholding were then searched for the expected target masses. The masses expected were the $[M+H]^+$ in positive ion mode and the $[M-H]^-$ in negative ion mode. As the samples in the wells may have also contained excess reaction

materials, the system allowed possible adduct ions (e.g. Na^+ and NH_4^+) to be searched for the same compound. The thresholded spectra for the entire sample set were then stored in a results file along with success criteria. The reduced data set could then be viewed rapidly from a results browser in the OpenLynx-Diversity software. If the expected mass was found at above a target threshold then the sample was flagged as found and a representation of the well on a microtitre plate in the browser was coded green. If the expected mass was not present then the sample was flagged as not found and the well was coded red.

Discussion. The OpenLynx-Diversity system has proved successful for the analysis of combinatorial libraries and meets the criteria laid down prior to its development. The highest priority for the system was that it should be a rapid and highly automated. The number of compounds produced by a combinatorial approach to synthesis is such that it is impossible to analyse each sample manually, and then check the data for the presence of the expected mass, without the analysis step becoming prohibitively time-consuming. The current set-up allows 1.0 minute cycle times for sample analysis. As the data for a sample is being acquired, the Gilson sample handler performs a wash cycle ready for the introduction of the next sample to prevent carry-over and false results. Speed of analysis is not the only important criterion. The reduction of the data to a form which can be quickly assimilated is also a fundamental requirement of the system. The first piece of information that the chemist requires after analysis is whether the expected mass is present in the sampled wells. The reduced report allows the level of success to be judged quickly by red/green colour coding of a microtitre plate schematic. If a number of wells do not contain the expected mass or, if a successful result requires further scrutiny, then the spectra generated from a well can be viewed by selecting the well with the mouse. Once the data has been reviewed it is necessary to archive the relevant information. To this end, the results are also produced in a tabular format which allows the data to be exported to a spreadsheet or to a LIMS where the results can be added to the information produced from the automated synthesis and screening of the library. Generally only a subset of the 96 wells will be tested. The reasoning behind this is due to the philosophy of the combinatorial approach, which is completely different to that of traditional drug discovery methods. In rational drug design the aim at any point is to synthesise and screen a single compound. To this end, it is necessary to ensure that the intended product is made by a rigorous programme of testing. In the combinatorial approach it is intended that a large number of diverse compounds are passed through the screening process to increase the probability of a positive result being found. Therefore, it is not necessary to check that each intended product of the automated synthesis has been successfully produced, it is only necessary to ensure that sufficient diversity has been achieved prior to screening. This allows for some of the tested wells to show a negative result without the overall synthesis being considered to have failed. Also, as each microtitre plate is likely to contain compounds produced by similar chemistry, it is only necessary to analyse the contents of a small number of the wells to check if the intended chemistry is working.

Conclusions. Combinatorial chemistry as an approach to drug discovery is rapidly becoming more widely used as pharmaceutical companies look for ways to produce lead compounds more rapidly and in a more cost-effective manner. The number of compounds produced means that a rapid, highly automated analytical method is required to prevent the analysis becoming the rate-limiting step in the process of automated synthesis-analysis-screening. This large number of compounds could also produce an unmanageable amount of analytical data. It is therefore necessary to reduce the data sets to give only the information necessary to confirm diversity. The method developed here (OpenLynx-Diversity) has proved successful for the rapid and accurate analysis of combinatorial libraries. Since this paper was submitted, further work has enabled the use of the system for the automated analysis of mixtures using simple liquid chromatography conditions with automatic peak detection. This work will be discussed in future papers.

Automated Mass Spectral Data Analysis for Combinatorial Chemistry

David S. Wagner, Wanda Bodnar, and H.Mario Geysen
GlaxoWellcome Research Institute, 5 Moore Dr., RTP, NC 27709

The history of drug discovery suggests that no single class of compound will provide all the drugs of the future, thus, a large number of different chemical libraries must be generated. Although most known chemistry is optimized for the solution phase, experts believe that solid phase chemistry is essential for multistep synthesis of libraries. In order for solid-phase chemistry to have a maximum impact, a large range of bond-forming reactions must be evaluated and optimized (reaction screening). As library synthesis moves away from amide coupling to other reactions less well-tailored to solid phase synthesis, the validation of all chemical steps to ensure good yields will be vital.

An important element of the combinatorial discovery process is the ability to extract the information made available by library screening (SAR). In order to manage this, each library must be characterized. The common analytical tools of the synthetic organic chemist, such as NMR and IR are not amenable to pools or large libraries. A major dilemma of synthesis of combinatorial libraries is the difficulty in confirming the degree to which the expected chemistry has proceeded on the entire population of substrate molecules (pooled or discretes).

The time and effort to analyze mass spectral data from a given library or reaction screen would be enormous. In order to make efficient use of the collected data, the interpretation must be automated as well. We have written a computer program to automatically ascertain the yield, purity, and side products from a given reaction or combinatorial synthesis using mass spectral data. The data analysis can be tailored for any set of monomers and reactions. The operator can provide unlimited number of transformations or side reactions into the program, which then will determine their presence and relative abundance of each transformation. The program utilizes the isotopes pattern to determine the presence of any given transformation. A chemically pure organic compound will give a mixture of mass spectral peaks because the elements that compose it are not isotopically pure.

The computer algorithm uses raw data from the mass spectrometer. It finds all peaks in the file (the manufacturers program was not adequate for precise mass measurements). It determines the experimental isotope ratio, calculates the theoretical isotope ratio from a molecular formula, and then uses a Chi Squared test to determine the fit of the data (presence of any transformation). The program will then estimate the relative yield of each transformation found using ion intensities. Quantitating in this manner will be accurate if the relative basicity of the parent molecules do not change from the chemistry (in most cases).

Our computer program successfully interprets mass spectra for pools and or discretes. The output gives predictions for relative yields, purity, and side products. The algorithm reduces the time for data interpretation from days (manually) to hours. The program will be invaluable for characterizing library syntheses, reaction screening, and chemical optimization.

THE POTENTIALS OF FTMS IN ADDRESSING STRUCTURAL DIVERSITY OF COMBINATORIAL LIBRARIES

Paul Speir^{*}, Charles W. Ross III[†], Harri Ramjiit[†], Gary Kruppa^{*}, and Frank Laukien^{*}
^{*}Bruker Analytical Systems Inc., Billerica, MA, and [†]Merck & Co. Merck Research Labs., West Point, PA

Combinatorial synthesis applied to disciplines such as medicinal chemistry and biochemistry can be regarded as a laboratory emulation of naturally occurring processes, distorted by structural diversity. The potentials of such combinatorial processes, whether liquid phase or solid phase, perpetuates those challenges in analytical techniques whereby molecular weights, elemental composition, structure and product yields are deemed necessary.

The isolation and characterization of components in a given library often require extensive sample preparation, isolation, and purification by TLC, HPLC, and HPLC/MS. However, such extensive duty cycles are not only prohibitive, but economically unsound. Accordingly, we have embarked on FTMS, incorporating ESI and MALDI, in order to expedite such demands. The basis of our strategy is to enable simultaneous analysis of multicomponent libraries without the use of traditional separation and clean up procedures. Taking advantage of the resolving power capabilities of FTMS (> 100 k), we are able to separate, identify, and target specific compounds with a high degree of confidence. The criterion for compound identification relies upon the following: (i) molecular weight, (ii) elemental composition, (iii) stable isotope distributions, (iv) characteristics of product ions (MS/MS...).

In the top trace of Figure 1, a broad band ESI-FTMS spectrum is shown of a 60 component library in which 54 components were identified. Based on the ability to accurately assign molecular weights (< 2 ppm error) to each of the components, elemental compositions may be searched to aid in the characterization of the compound of interest. The middle trace of Figure 1 shows that for lower resolving powers, matches to the isotopic profile (m/z 574 component) of the suggested elemental composition can be misleading (poor fit to the $^{13}\text{C}_2$). However, by increasing the resolving power of the mass spectrometer for the same component ($> 45,000$), peak splitting is observed for the $^{13}\text{C}_2$ region due to overlapping peaks, thereby enabling the component of interest to be 'separated' in the mass spectrometer.

Figure 1. (top trace) Broad band ESI-FTMS spectrum of a 60 component library (middle trace) Overlay of theoretical isotopic profile over experimental profile (bottom trace) Same overlay as in middle trace at higher resolving power. Mixture Analysis Using LC/APCI/MS
 Ronald G. Smith, Scott Woodard, and Kindrick Leschinsky
 Monsanto Company, 800 N. Lindbergh Blvd., St. Louis MO 63167

API techniques have proven useful for the analysis of combinatorial libraries. In the analysis of complex mixtures the goal are to 1) verify the presence of target compounds (includes distinguishing between isobaric components when present), 2) characterize side-products, and 3) quantify all products. This is an in-depth analysis of a mixture of biphenyl diamides prepared as outlined in Scheme 1. A set of 5 isoamylamines and 5 glycinamides were reacted with the biphenyl diester to obtain a target

Scheme 1

mixture of 10 symmetrical (AA-JJ) and 45 unsymmetrical (AB-IJ) components. Analysis was performed by chromatography on a 4.6x250 mm ODS column. The eluent was passed through a UV detector at 254 nm before going to a mass spectrometer with an APCI source. All 55 target compounds were picked out of the chromatogram (Figure 1) with relative ease by locating each (M+H)⁺.

Figure 1

The isoamylamides and glycinamides of each series (in which one amide group is fixed) gives distinct chromatographic elution order patterns. These patterns were useful in making structural assignments where isobaric components appeared. These patterns were also very helpful in recognizing side-product series. Another useful tool in identifying side-product series is the patterns exhibited by the (M+H)⁺ ions in the cumulative mass spectrum, obtained by summing the spectra over the entire chromatographic region. Subtraction of the ions attributed to the 55 target compounds from the cumulative mass spectrum gives a residual spectrum from which more series can be found.

Product analysis strongly suggests a couple side reactions. One involves the aldol condensation of two aldehydes prior to reacting with the primary amines. This results in unreacted isoamylamine and glycinamide which go on to form secondary biphenyl diamides. Another side reaction involves the transamidation of glycinamide which results in formation of a dipeptide-like component and morpholine. These are outlined in Scheme 2.

Aldol Condensation

Scheme 2

In all, 162 compounds were identified in this mixture. An additional 19 compounds were characterized but remain unidentified. The target compounds composed 79% of the total ion current and were typically 0.5-2.5% for each. (Assuming 100% reaction and no side products, the theoretical yields are 1% for the symmetrical and 2% for the unsymmetrical products.) Many of the minor side products constituted only 0.02-0.05% of the total ion current.

With the large number of components in this mixture a high degree of isobaric multiplicity exists: 30 cases of two isobaric components, 16 cases of three isobaric components, 5 cases of four isobaric components and one case each for six and seven isobaric components. Most of this multiplicity would be lost without chromatography.

This analysis was simplified with minimal number of additional ions from fragmentations or solvent adducts. The loss of morpholine (87) from some of the glycinamides was the only significant fragment observed. Spreading the components out by LC significantly enhanced the information available. Series pattern recognition was a valuable tool for locating and assigning structures of many components. Recognition of product series beyond the 55 target compounds is helpful in identifying unwanted side reactions. Most of these could be minimized by altering appropriate reaction conditions.

COMBINATORIAL LIBRARY AUTOMATION FOR RAPID APCI ANALYSIS

Richard G. McKay, Barbara S. Larsen, Robert S. Livingston*, and James G. Doughty*, The DuPont Company, Central Research and Development, Agricultural Products*, P. O. Box 80228, Wilmington, DE 19880-0228

Combinatorial libraries are proving to be an excellent way to generate large numbers of novel new compounds for the crop protection industry. One key advantage of the library approach is the rapid assembly of diverse compounds by using automation for the synthesis on solid support. Large increases in productivity can be realized using these methods for synthesizing new compounds. Due to the numbers of compounds generated, rapid analytical support is necessary to develop optimal synthetic processes and monitor the purity of products produced. We report here our approach for rapid analysis of these samples by APCI and Electrospray.

Sample information is supplied by the chemist in an Excel spreadsheet which is merged into the instrument sequence list. Data is acquired using either a Fisons Trio 2000 or a Quattro II. The sample introduction on the instruments is slightly different. 1) The Trio 2000 has a Hewlett Packard 1090 HPLC with a 100 vial autosampler (Figure 1) and 2) the Quattro II has a HP 1050 HPLC and a Gilson 215 microliter plate XY coordinate autosampler (Figure 2). The Quattro system has the ability to sample directly from many vial configurations or as many as four 96 well microtiter plates at one time while analyzing each sample in both the positive and negative APCI mode. The Trio-2000 system can be configured to run up to 100 samples in either APCI or Electrospray, by using an LC Packings Accurate post column splitter. Using these direct injection techniques allows a throughput of 50 samples per hour in APCI mode. After the data is acquired, a post analysis macro averages the data across the sample peak and subtracts the background scans (Figure 3). The resulting spectrum is either printed out or saved in an Excel file as a list of mass and intensity data with a picture of the spectrum imbedded inside (Figure 4). The Excel file can be sent to a server for storage and to be archived. With appropriate software the chemist can view the data at any time from the server using a desktop PC.

AUTOMATED HIGH THROUGHPUT LC/MS FOR THE RAPID PROFILING OF PHARMACEUTICAL COMPOUNDS

M.E. Hail, B.M. Warrack*, A.S. Arroyo, G.C. DiDonato and M.S. Lee
Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ 08543-4000

In recent years, significant change has occurred in the way pharmaceutical companies are synthesizing and identifying new lead drug candidate compounds. This change has been brought on by the use of automated synthesis and/or combinatorial synthesis methods. These methods allow for the simultaneous, milligram-scale production of hundreds of new compounds. Within Bristol-Myers Squibb Discovery Chemistry, these new methods are projected to increase the number of final compounds synthesized from the current ~10,000 per year to over 100,000 per year by 1997. If these targets are to be achieved, analytical methods which allow for rapid and efficient characterization of these new compounds and their impurities are essential.

In this presentation, streamlined methods employing automated liquid chromatography/mass spectrometry (LC/MS) to support combinatorial drug discovery are described. Implementation of the automated high throughput LC/MS profiling method included the utilization of a rapid, universal HPLC method in conjunction with automated data interpretation and reporting algorithms. In addition, a new electronic sample submission protocol was developed which eliminated the redundant entry of sample information required for sample tracking and documentation. The high throughput method can be summarized as follows:

- Chemists submit automated synthesis products pre-diluted in autosampler vials and placed in an autosampler tray.
- Information about each reaction mixture is compiled by Discovery chemists into a Microsoft Excel spreadsheet.
- This file is placed on a file server where it is retrieved electronically and is automatically processed into a method list which sets up the LC/MS instrument for data acquisition.
- A rapid gradient HPLC method is utilized which can analyze each reaction mixture in a total time of ~18 minutes.
- Post-acquisition software automatically processes the data for each sample. A two page report is automatically printed for each analysis, showing mass spectra for the five largest peaks in the HPLC/UV chromatogram and highlighting the location of the expected product (if present).
- A single result file is automatically created. This master electronic result file is transferred to the chemistry file server after completion of the LC/MS analyses.
- The results are retrieved by the chemists.

The automated method results in a dramatic savings (18-fold) of analyst time through the elimination of manual data entry and interpretation and the minimization of sample handling procedures, freeing analyst time for other projects and providing faster turnaround for the samples analyzed. In addition, previous manual LC/MS profiling methods allowed analysis of a maximum of approximately 5 samples per 8-hour day. Using the new automated method, 51 samples can be processed during a single overnight run (from 4 PM - 9 AM). Automated LC/MS profiling with universal HPLC

methods are presently being used to analyze between 200 and 450 samples monthly. Implementation of universal HPLC methods (including solvents, gradient conditions, and column) by the discovery chemist and the analyst allows the LC/MS retention times to be correlated with preparative HPLC methods used for product scale-up and isolation. It is anticipated that this method could be used as a template for the development of automated LC/MS profiling methods for many other discovery and development programs as well.

Analytical Protocol for the Rapid Characterization and Elucidation of Combinatorial Libraries using LC/MS and LC/MS/MS Techniques

Robyn A. Rourick¹, Jeffrey L. Whitney¹, Steven E. Klohr¹, Kevin J. Volk¹,
Edward H. Kerns¹ and Mike S. Lee², Bristol-Myers Squibb Company,

Recent initiatives in Drug Discovery have been aimed at increasing the productivity of Preclinical Lead Candidate discovery in order to accelerate the introduction of novel drug therapies. Combinatorial chemistry methodologies aim to increase the production of new drug candidates in the pharmaceutical industry up to ten fold^{1,2}. Clearly, research and development groups can not simply increase resources by ten fold to examine the potential of these new drug candidates using traditional protocols. Libraries of compounds in solution or on solid support present numerous challenges when traditional proof of structure approaches are applied. These resulting libraries contain hundreds or even thousands of structurally similar compounds in sub-milligram amounts. At certain stages during the development of a synthetic strategy, it may be important to analyze a number of components of the library to verify that the synthesis is producing the desired compounds. In addition, a reasonable strategy may be needed to determine the structure of compounds within a library which have been found to be active in biological assays. We have developed analytical strategies utilizing electrospray ionization and tandem mass spectrometry for the rapid profiling of synthetic, natural, and metabolic products^{3,4}. Combinatorial libraries can be coupled to these trace mixture profiling methodologies to provide a rapid on-line approach for characterization of matrix components, and the elucidation of specific products⁵.

The initial portion of the LC/MS profiling protocol incorporates LC/UV separation under a standard set of conditions providing insight into the number, relative amount, and retention time of the library components of interest. The second portion of the protocol is the measurement of the molecular weight of each component using the full scan mass spectra of each HPLC peak, a specific characteristic of each component and provides insight into its structure. The final portion of the profiling protocol is the substructural analysis of individual components using the product ion (MS/MS) mode. This entails comparison of substructures identified of an unknown component to a substructural "template" of a known compound in the same class to determine similar and distinct substructural regions. MS/MS precursor screens can be performed in effort to identify structurally similar components.

These profiling methodologies were used to rapidly profile individual members of a 625 peptide library. A standard set of HPLC conditions provided reproducible retention times for the library components. A representative LC/UV chromatogram of the peptide library is shown in Figure 1. The molecular weights of selected library members were obtained on-line from the full-scan ionspray mass spectra at their respective retention times, as illustrated in Figure 2. The extracted ion chromatogram at m/z 465 in Figure 2 suggests two isobaric components differing by retention time. Substructural analysis was performed on each component using the product ion MS/MS mode. The differences

observed in the product ion spectra provide an additional dimension of information by which one can propose a unique structure to each of the compounds. The multidimensional data which is obtained through application of this standard profiling protocol can be assembled into a structure database and be used to correlate structure with activity, bioavailability, lipophilicity, or solubility. This database can then serve to facilitate the selection of a drug candidate for development.

Structure elucidation of pharmaceutical degradants and metabolites is traditionally accomplished using methods involving extensive isolation and spectrometric analysis of individual degradants from the bulk drug substance and low level metabolites in biological fluids. We have utilized a predictive stability profiling strategy aimed at the identification of degradants and metabolites in advance of their appearance during the drug development process. Predictive degradation and metabolism information permits comparison of the stability (chemical and biological) profiles of competing drug candidates early in the discovery/development process, indicates chemically labile substructures of the compound, and allows the early establishment of a profile database facilitating later stages of the development process. Our predictive models involve a new stability profiling strategy which involves the degradation/metabolism of a combinatorial mixture of compounds. This parallel approach dramatically increases the capacity and throughput of the predictive stability profiling process, permitting this information to be used early during the drug candidate selection process. We employ a strategy using standard LC/MS profiling and LC/MS/MS substructural analysis conditions to rapidly propose the structures of the degradants and metabolites. The chemical relationship and structure of each product is determined by the retention of specific parent drug substructures, known chemistry, and associated MS/MS characteristics. These strategies were applied to a library mixture containing from 4 to 15 components, respectively. Small libraries of compounds are incubated under various conditions (heat, light, acid, and base) to provide chemical indicating stability information. Biological stability information is rapidly obtained by incubating the libraries with plasma and microsomal preparations such as rat and human S-9 to monitor the production of phase I metabolites. Additional information added to the databases consists of profile data from penultimate materials and final bulk drug product. Individual structural libraries for each compound include information on molecular structures, chromatographic behavior, molecular weight, UV spectrum, and substructure-specific MS/MS product ions of the individual components. Once developed, these libraries can then be used as a springboard for the structure dereplication and elucidation of degradation products, impurities, and process related by-products encountered in samples throughout the drug discovery-development-manufacturing continuum.

Automated Multi-Dimensional HPLC/UV/MS for Qualitative Method Development

Lily Y T. Li and James N. Kyranos

ArQuile Inc 200 Boston Ave, Suite 3600, Medford, MA 02155

Introduction

Organic compounds which are synthesized in the laboratory are traditionally analyzed by HPLC/UV for purity and mass spectrometry to confirm synthesis and/or identify side products. Typically, chemists work on a small number of compounds at any given time and the development of the analytical methods are not a major issue. However, with the development of combinatorial techniques, the synthesis of a large number (500-1000/day) of organic compounds is becoming relatively common. In order to effectively characterize a large number of combinatorial library compounds, the analytical methods must be developed rather quickly. The analytical methods must be applicable to the entire library, and not optimized for any particular component. This need, requires a number of different columns and mobile phase conditions, as well as mass spectrometric conditions, be explored using several representative compounds from the library in order to find the best overall conditions. Using the manual approach of investigating several gradients with one column and then adjusting the gradient and the column accordingly, would take a relatively long time. An alternative approach is to automate the column and gradient switching using commercially available valves and connect the HPLC/UV to the mass spectrometer. This procedure can be performed in an unattended fashion, which would give a large amount of information in a relatively short period of time. Once the data is acquired, the column and gradient conditions that yield the best separation for all the representative library compounds are picked to characterize the entire library. The utility of this multi-dimensional HPLC/UV/MS approach is presented using ornithine arylidene diamide obtained from a synthesized amino acid arylidene diamide (AA-ADA) combinatorial library.

Experimental

Six different HPLC columns (Keystone Betasil C18, Betasil basic, Hypersil C18, Asahipak ODP, SMT OD, and YMC ODS) were simultaneously connected via a 14 port switching valve through a UV detector and to the mass spectrometer. Three different HPLC gradient conditions (gradients A, B, and C) were programmed to run through each column. The mass spectrometer was operated in the APCI positive mode to obtain full-scan HPLC/UV/MS data.

Results

Three different gradients through six different columns using an automated switching valve have been evaluated. The Keystone Betasil C18 column and gradient A gave the best performance (Figure 1). The HPLC separation and identification for synthesized ornithine arylidene diamide is confirmed by on-line mass spectrometry (Figure 2)

Conclusion

The automated multi-dimensional HPLC/UV/MS procedure can evaluate six different columns with a variety of different gradients in an unattended mode. This analytical approach allows the rapid development of appropriate separations amenable to the entire combinatorial library. Moreover, the use of mass spectrometry during this developmental phase provides assurance that the separation method is being optimized for the components of interest rather than the possible side products.

Mass Spectrometry Approaches to Hard Tag Decoding of Combinatorial Libraries

Nikhil Shah, William L. Fitch, Derek Maclean, Zhi-Jie Ni
Affymax Research Institute, 3410 Central Expressway, Santa Clara, CA 95051

Introduction

Encoded combinatorial organic synthesis has emerged as a powerful tool for pharmaceutical lead discovery and compound optimization from chemical libraries. The Affymax encoding methodology uses chemically robust secondary amines, incorporated into a coding oligomer through simple chemistry.

In the decoding process, acidic hydrolysis of the tagging polymer regenerates the secondary amines, which after dansylation are resolved and detected at sub-picomole levels by reversed phase HPLC with fluorescence detection. The HPLC method is slow and subject to interference especially when residual ligand can hydrolyze to amine products. We present high throughput mass spectrometry approaches to solving this analytical problem.

Conclusion

The current Affymax HPLC decoding method does not adequately meet the needs of high throughput and specificity. It is, however, very sensitive at low femtomole levels of compound. A GC/MS method has been developed which shows an intermediate specificity, a turnaround of 15 minutes and a sensitivity limit of 50 femtomoles injected. Direct infusion ESIMS without derivatization could be turned around in 10 minutes per sample with a detection limit of 1 picomole. An LC/time programmed SIM/ESIMS method has sufficient specificity advantage relative to Fluorescence detection that run time could be reduced to 30 minutes. But baseline noise limits this method to a minimum of 1 picomole injected. An FIA/ESIMS/MS method has been tested which has 1 minute turnaround and a single compound demonstrated sensitivity of 250 femtomoles. None of our MS methods has yet been able to beat the sensitivity of the HPLC fluorescence method. We continue efforts to improve the Affymax "Hard Tag" method for the discovery of biologically active compounds from complex chemical libraries.

Affymax produces solid phase split-pool libraries using a photo-cleavable linker¹ and encoding with dialkylamine tags². The finished product, with unique compounds each on **single beads**, is released into various assay formats by photolysis. Active compounds are then identified by decoding the tags after acid hydrolysis. Quality assurance of this process involves extensive rehearsal of the chemistry, in-process checking of intermediates and statistical evaluation of the finished product. For this evaluation multiple single beads are cleaved and analyzed.

This process is illustrated with a triazine library. Single beads are photo-released into methanol and the molecular weight of the ligand determined by flow injection analysis electrospray ionization mass spectrometry (FIA/ESIMS). The corresponding tags are released and read by HPLC. The molecular weight should correspond to that of the compound designated by the specific set of tags. Failed couplings or incompletely removed protecting groups are often seen in the FIA/ESIMS pattern. MALDI/TOFMS has also been evaluated for semi-automatically photocleaving and ionizing bead bound triazines in a single process, but is not as amenable to a high throughput setting. We now routinely use FIA(or APCI)/ESIMS for quality control of combinatorial libraries.

Single Bead FIA/ESIMS of a Triazine

Single Bead MALDI/TOFMS of a Triazine

FIA/ESIMS is the method of choice for high throughput structure confirmation in the medicinal organic chemistry laboratory, either in a service or an open access context. In contrast low level analysis and especially quantitative analysis is normally done by LC/MS. LC/MS is much slower and difficult to institute in an open access instrument. We report efforts to utilize FIA/ESIMS for single bead external standard quantitative analysis as a high throughput, open access, mass spectrometric method useful for relatively clean materials, such as single bead photolyzate. We report a method for a single triazine, calibrated from 0.1-2 picomoles/mL for measuring single bead loadings and for developing tiered release methods.

The early success with the rapid deconvolution of assay data obtained from testing pools of related compounds instead of discretely, suggests a statistical approach to understanding the requirements for pharmacokinetic parameters (bioavailability, metabolic stability, toxicology, etc.). Evaluation of diverse chemical libraries for these properties should provide a rational basis for discrimination between candidate libraries in the short term. Analysis of the extensive pharmacokinetic data relating to compound structure can be expected to impact lead optimization in the long term.

We are identifying rate limiting processes that can be addressed (ex. ADME/TOX) and investing in innovative strategies for expediting these processes early in drug discovery. Interpretation of the biological and chemical information will require ground breaking approaches and rely on diverse analytical paradigms which incorporate mass spectral technology. The strength of the technique is the ability to analyze mixtures of compounds. Thus library pools can be analyzed in very short time periods by mass spectrometry, as compared to other analytical techniques.

We have successfully employed mass spectrometric methods in the evaluation of pharmacokinetic properties of chemical libraries. Bioavailability of compounds within pools was determined by examining the percentage of each compound transported through a Caco-2 cell monolayer. This system provides an in vitro model for intestinal absorption of candidate drug compounds. Library pools were loaded on the apical side of a transwell containing the Caco-2 cells and transport buffer. Components which permeate the cell layer end up on the basolateral side in the well. If a particular class of compounds are not bioavailable, then that library pool does not contain good lead compounds for drug development. Shown below are spectra obtained from a library pool in which the majority of the components are bioavailable to some degree, with the exception of a compound at 502 amu.

Metabolic stability of library components was addressed by two independent methods. In the first, pools of compounds were incubated with rat liver microsomes and the necessary cofactors. This system provides an in vitro model for degradation by P450 enzymes. Two time points were surveyed, $t=0$ and $t=30$ min. Proteins and cellular material were precipitated out, and the supernatant desalted prior to analysis by ESI MS. An internal standard was included to assess the extent of degradation (data not shown).

In the other method, compounds were passed through a capillary column containing immobilized enzyme (in this case, pepsin). The column had been equilibrated with digestion buffer prior to loading the sample. This technique has wide applications provided the enzyme of interest can be immobilized without loss of activity. The resulting mixture was desalted in-line with the ESI source of the mass spectrometer. Shown below are spectra from a library pool which is not altered upon exposure to immobilized pepsin. This data suggests that this class of compounds should be examined further in stability and bioavailability tests.

In the two methods we are tracking the disappearance of a mass spectral signal for the compounds of interest. Our results indicate that we can differentiate between components which undergo complete, partial or no degradation.

As pharmaceutical companies begin to rely more heavily on combinatorial libraries for their lead compounds, analytical methods must be incorporated at an earlier stage of the process. Mass spectrometry will play a key role in the early evaluation of candidate libraries, and thus make a significant contribution to drug discovery.

Direct Characterization of Solid Phase Resin-Bound Molecules by Mass Spectrometry

Michael C. Fitzgerald, Ken Harris, Charles G. Shevlin, and Gary Siuzdak*
Department of Chemistry, The Scripps Research Institute, La Jolla, CA, 92037

In this work we demonstrate that analytes, covalently linked to a polymeric support through a photolabile linker, can be directly analyzed by matrix-assisted laser desorption/ionization (MALDI). Mass spectral analysis has been performed in a single step requiring no pretreatment of the sample to induce cleavage from the support. Our results show that the UV laser light in the MALDI experiment can be used to simultaneously promote an analyte's photolytic cleavage and ionization for subsequent mass spectral analysis. Thus, MALDI facilitates the dissociation and identification without chemical pretreatment (Scheme 1).

Scheme 1. Schematic representation of the products generated upon MALDI photolysis/ionization of a peptide covalently attached to a solid phase resin through a photolabile α -methylphenacyl-ester linker.

The results in Figure 1 show that MALDI analysis of the resin-bound peptide yielded a characteristic $[M+H]^+$ signal at m/z 1247 which is consistent with the expected mass of the free peptide (MW = 1245.5 Da). Using the visualization system on the Voyager Elite instrument, we were also able to irradiate very specific regions of the sample. Here, peptide signal was only observed when individual matrix/bead deposits were irradiated on the sample plate. No peptide signal was observed upon irradiation of matrix crystals not associated with resin beads, suggesting that there was little or no free peptide in the sample prior to MALDI analysis.

Figure 1. Positive ion MALDI mass spectrum of the peptide KPAFLKPQFLG (MW 1245.5 Da) covalently attached to a resin through a photolabile linker. α -cyano-4-hydroxycinnamic acid was used as the matrix.

Also as expected, in the absence of matrix, no signal was produced from the resin-bound peptide. In addition, our ability to recover the peptide from resin samples following analysis indicates that the sample was not completely photolyzed in the MALDI experiment.

The rapid, one-step MALDI procedure for the direct analysis of resin-bound molecules described above is ideally suited for studying chemical reactions on the solid phase. As a demonstration of the technique's utility, we followed the time course of the coupling reaction of a Boc-Arg(Tos) residue (preactivated as the hydroxybenzotriazole ester) to the protected 11 amino acid peptide described above. Our results show that the reaction proceeded quickly and coupling appeared nearly complete in just six minutes.

Figure 2. MALDI mass spectra showing the time course of reaction for the coupling of Boc-Arg(Tos) (MW = 428.5 Da) to the protected resin-bound peptide of sequence KPAFLKPQFLG. MALDI analysis was performed directly on peptide-resin samples after deprotection of the lysine side chain amino groups. Resin samples were taken after the reaction was allowed to proceed for (A) 0, (B) 1, and (C) 6 minutes.

The direct analysis of resin-bound molecules by MALDI has several important advantages over other procedures which require an additional cleavage step prior to mass spectral characterization. Most importantly, the procedure can be used to monitor chemical reactions on the solid phase in real time, in much the same way that thin-layer chromatography is used to monitor reactions in solution. The capacity to perform MALDI directly on the solid phase also provides for more efficient sample management since the resin-bound sample can be easily recovered for subsequent manipulations. In conclusion, resin-bound analytes that are amenable to MALDI ionization should prove suitable for routine analysis and the use of ionization tags may also facilitate the analysis of compounds that are not easily ionized.

The efficient generation of information from data is an important step in the application of analytical methods in the drug discovery setting. With the advent of automated instrumentation, data production and complexity are increasing at a tremendous rate. This trend has shifted the bottleneck from instrument analysis to information production. Typically, information extracted from instrumental analysis datasets is represented in two dimensional form, such as a spectrum. This extraction requires *a priori* knowledge of the desired information in the data (i.e., the molecular weight or spectrum at a given retention time). However, data from a complex dataset, such as an LC/MS profile (1,2), includes many dimensions of insight. Some trends may not be *a priori* anticipated in datasets of this complexity. Also, other trends may not be recognized by this "directed extraction" and may only be realized when more than two dimensions of data are interrelated for examination. The application of scientific visualization software, such as IDL (Interactive Data Language), permits the analysis and visualization of complex relationships within datasets in multiple dimensions. Preliminary work has illustrated the utility of this technique for visualizing substructural trends in a LC/MS profiled combinatorial library (3).

One advantage of scientific visualization is that the eye can recognize trends in a dataset when presented as a three dimensional (3-D) surface that may be difficult to extract using traditional processing techniques. For example, the 3-D surface rendering of a full scan LC/MS dataset obtained on a 625 combinatorial peptide library mixture (Figure 1) indicates hundreds of early eluting molecular ion peaks in the 300 - 600 Dalton range and several late eluting low level impurities. A 3-D extracted ion surface of m/z 496 (figure 2) indicates three major regions where components with MW 496 have eluted. Substructural information can also be obtained by visually representing molecular connectivities and substructures contained in a dataset. For example, the software neutral loss 3-D surface generated from an APICID/LC/MS dataset obtained on the same peptide library mixture (figure 3) indicates several components containing a neutral loss of 264 (V-F-COOH). One of the peak series corresponds to a component with MW 495, also observed in the extracted ion surface. This molecular ion and substructure relationship is consistent with an expected library member having a NH₂-T-L-V-F-COOH sequence. In this way specific substructural relationships can be visually represented as a function of the entire dataset. The 3-D visualization of full scan, extracted ion and neutral loss datasets provides specific molecular and substructural information quickly and visually, at a level of representation not possibly by using 2-D spectra alone.

Searching for a method to increase efficiency in developing new potential drug candidates, the field of combinatorial chemistry has rapidly developed into one of the most promising synthesis methods. In an effort to analyze the complex mixtures that have been synthesized many traditional tools like NMR, elemental analysis or low resolution mass spectrometry are not applicable without time consuming separation steps. On the other hand, using Fourier Transform Ion Cyclotron Resonance Mass Spectrometry, with its high resolution capability, potentially all components of a mixture can be identified at the same time by determining their exact molecular mass. In contrast to using a triple quadrupole instrument^{1,2}, nominally isobaric components can be resolved so that no fragmentation or separation of the sample mixture is needed.

Direct infusion ESI-FTICR MS analysis of the library samples was performed on a Bruker BioAPEX 47-e Fourier Transform Ion Cyclotron Resonance Mass Spectrometer (Bruker Analytical Systems, Inc. of Billerica, MA) equipped with an Analytica Electrospray Ionization Source (Analytica of Branford, CT) with an rf only hexapole ion guide. Samples were dissolved in MeOH/H₂O (1mg/ml) and acetic acid(3%)/ammonium hydroxide(1%) was added for positive/negative ionization of the samples. The four library samples were synthesized using a core molecule and several amino acid building blocks to generate libraries of 36, 55, 78 and 120 compounds.

Results:

36 Component Library

- 29 components (81%) could be identified by using both positive or negative ESI mode
- errors are 5 ppm or less
- 6 out of the 7 missing components contain Tryptophan^{Me} building blocks.

55 Component library

- 30 components (55%) could be identified in the negative ion mode with an error of 10 ppm or less

78 Component library

- 54 components (70%) from 77 expected peaks (due to isomers) could be identified by using both positive or negative ESI mode
- errors are 10 ppm or less
- using an error cutoff of 12 ppm or less, 58 components (75%) could be identified

- 8 out of the missing 19 peaks contain Glutamic Acid building blocks and 4 contain Threonine^{Me} building blocks

120 Component library

- 70 components (68%) from 103 expected peaks (due to isomers) could be identified by using both positive or negative ESI mode with errors of 10 ppm or less
- 73 components (71%) from 103 expected peaks (due to isomers) could be identified by using both positive or negative ESI mode with errors of 12 ppm or less
- 12 out of the missing 30 peaks contain Glutamic Acid building blocks and 6 contain Threonine^{Me} building blocks

OBSERVATION OF A HIGHER ORDER STRUCTURE FOR *CLOSTRIDIUM PERFRINGENS* ALPHA-TOXIN IN THE GAS PHASE

Dominique Despeyroux, Bryan Linguard, Rick Titball and Peter Watts
Chemical and Biological Defence, Protection and Life Science Division, PortonDown,
Salisbury SP4 0JQ, U.K.

Clostridium perfringens is a spore-forming gram-positive bacterium which is frequently associated with gas gangrene in humans. Type A organism produces at least 8 toxins. The major one of these is alpha-toxin, which is a phospholipase C single polypeptide zinc-metalloenzyme of RMM 42,500 Da. The elucidation of the mechanisms of action of alpha-toxin and structure-function studies may facilitate the design of potential vaccines or inhibitors. A model has therefore been produced for the amino-terminal domain of alpha-toxin from the X-ray derived coordinate data of an homologous phospholipase C of known structure (*Bacillus Cereus*).

The model structure is an all helix protein containing eight helices (A, B, C, D, E, F, G and H). The study of the structure, motions and deformations of the helices show the helix assembly to be a tightly packed and rigid construct. The A and B helices form an antiparallel pair packed tightly against the other helices. The forces involved appear to be largely hydrophobic interactions. Once the zinc ions are removed, however, the long flexible loop between the B and C helix is no longer fixed by the zinc binding residues.

In conjunction with this study, electrospray mass spectrometry of *C. Perfringens* alpha-toxin was also undertaken. At a cone voltage of 60 V the molecular weight obtained after deconvolution for alpha-toxin, denoted A at 42,523.2 Da, matches the expected value of 42,524.0 Da (without Zn atoms) deduced from the known amino acid sequence (Figure 1a and 1b). A second component labelled B at 32,080.2 Da, however, appears in the mass spectrum 10,443 Da lower than the intact protein peak. No component of 32 kDa has been reported by SDS-PAGE gel which suggests that a very specific dissociation has occurred during the electrospray process. Varying the cone voltage shows that this is indeed the case (Figure 2)

Under the same operating conditions at a cone voltage of 35 V no dissociation occurs. At 50 V the second component at 32,082 Da starts to appear and at 65 V the dissociation reaches a maximum. At higher values both components tend to diminish in a greater background noise and mass accuracy is considerably reduced. Both components A and B show a similar charge state for their multiply-charged ions (Figure 1a). This may explain why the 10,443 Da fragment lost is not identified in the raw data spectrum as it may be carrying too few charges for its multiply-charged ions to be detected in the mass range scanned. It may also be due to the fact that further fragmentation occurs during the dissociation process, producing a series of ions at low mass.

A 10,443 Da polypeptide fragment can be associated with a fragmentation of the N-terminal part of the alpha-toxin molecule (Helices A and B) up to the proline in position 91 and dynamic simulation of the model of the amino terminal domain of the alpha-toxin was therefore performed to attempt to understand this unusual cleavage.

We suggest that if the A and B helix region of the structure were to move and eventually separate from the helix assembly then considerable energy might be imparted near the proline prior to the C helix (Proline 91). The kinetic energy of the backbone atoms of proline 91 is shown to have a slightly higher mean value than the other prolines in the molecule which would then agree with a specific cleavage at this point. The kinetic energy of backbone atoms of each of the prolines and the respective previous residue was also investigated by calculating the mean, standard deviation, maximum and minimum kinetic energy values. The backbone at Ile90-Pro91 was found to display the highest mean kinetic energy and the highest minimum energy values. Whilst it may be difficult to draw a definitive conclusion, these data match the observations made during ESI/MS. A specific cleavage at Pro91 corresponding to a 10,443 Da loss of the first two helices A and B

occurs only when high cone voltage values are used during the electrospray process which in turn suggests that alpha-toxin has kept to some extent a very folded and compact structure in the gas phase.

Methods: Electrospray mass spectrometry was performed on a Quattro II tandem quadrupole mass spectrometer (VG Organic). All modelling was carried out using SYBYL (Tripos Ltd) running on an Evans & Sutherland ESV30 or a Silicon Graphics Indigo 2 Extreme Workstation.

Noncovalent Quaternary Protein Analysis by Matrix Assisted Laser Desorption/Ionization Mass Spectrometry

Lucinda R. H. Cohen^{*}, Kerstin Strupat and Franz Hillenkamp

Institute for Medical Physics and Biophysics University of Münster 48149 Münster, FR Germany

^{*}Current Address: Parke Davis Pharmaceutical Research 170 Tabor Rd. Morris Plains, NJ 07950 USA

Many enzymes and high molecular weight proteins exist as quaternary ensembles of lower molecular weight subunits. Matrix Assisted Laser Desorption/Ionization (MALDI) mass spectrometry has emerged as an extremely useful technique for the analysis of proteins, but, unfortunately, analysis of noncovalent complexes using typical matrices such as sinapinic acid or dihydroxybenzoic acid (DHB) yield spectra of the protein subunits rather than the intact complex. The intact quaternary structure of the noncovalent complexes for streptavidin (52 kDa), yeast alcohol dehydrogenase (150 kDa), and beef liver catalase (240 kDa) have been observed using the matrix 2,6-dihydroxyacetophenone in an organic solvent. Intact streptavidin tetramers could also be observed with ferulic acid and other hydroxyacetophenone derivatives, with a variety of organic solvents. The most startling aspect of this analysis is that intact noncovalent complexes can only be observed for the first shot at a given position: successive laser shots at the same position yield primarily monomer peaks.

Representative spectra are shown in Figures 1 and 2 for yeast alcohol dehydrogenase and beef liver catalase, respectively. The intact noncovalently associated tetramer of the alcohol dehydrogenase sample was observed in Figure 1a, as well as the dimer (or doubly charged tetramer). Successive laser shots at the same spot show the monomer and dimer (Figure 1b) with the dimer exhibiting greater intensity than that observed for streptavidin, which most probably reflects the amount of solution state association for alcohol dehydrogenase. Higher molecular weight aggregates such as the dimer of the tetramer ($2T^+$) and the tetramer plus one or two subunits ($T+SU^+$), ($T+2SU^+$) are also present, as well as multiply charged tetramer and monomer ions. Similar results were observed for beef liver catalase in Figure 2a. The catalase tetramer ion (T^+) is a relatively wide peak (ca. 15 kDa) possibly due to the successive losses of the 4 heme groups which are noncovalently bound to the protein, as well as matrix and cation adduction.

Comparative analysis of covalently crosslinked complexes has shown similar behavior, with intact complexes only for the first shot at a given position. This behavior may be due to physical segregation or precipitation of the quaternary complex at the crystal surface, and is independent of the macroscopic matrix crystal structure or the type of substrate (hydrophobic vs. hydrophilic). Previous work in our laboratory has also shown that the origin of the noncovalent complex only for first shot spectra cannot be explained by photodissociation of complexes deeper within the sample. Observation of intact complexes is not affected by addition of modest amounts ($\leq 100\text{mM}$) of salts, buffers, or detergents, and appears to be independent of the pH stability range of the protein samples. Although both ferulic acid and the dihydroxyacetophenones have acidic pK_s (4-6), intact complexes can still be observed despite the stability range of catalase (pH 7.0) and alcohol dehydrogenase (8.4-9.5).

An *in vitro* refolding process is a key step in the production cycle of recombinant proteins, and therefore, merits special investigation. In order to better understand *in vitro* renaturation and oxidation of cysteine-containing proteins, refolding intermediates are trapped by chemical modification and subjected to structural analyses. We have developed a novel method for trapping protein-folding intermediates by selective modification of bis-cysteine sulfhydryls with phenylarsonous acid derivatives (PAA). PAA-derivatives form cyclic dithioesters in the

presence of two suitably spaced sulfhydryl groups of a peptide or protein. This method allows trapping and characterization of protein folding intermediates which have not yet formed covalent disulfide bonds. We have synthesized PAA-derivatives with improved solubility and compatibility with protein refolding conditions. The PAA derivatives 4-aminophenylarsonous acid (A-PAA), Melarsen oxide (MEL), and pyridinarsonous acid (PYR) were characterized by IR, NMR, FAB-MS, ESI-MS, and MALDI-TOF-MS. Modification conditions such as solubility of reagent, chemical selectivity of the organoarsenicals, and quantity of modifications were determined using model peptides. The combination of tris-(2-carboxyethyl)-phosphine (TCEP) for cysteine reduction and Melarsen oxide (MEL) for selective modification proved to be superior in terms of specificity and product stability over other reducing and derivatizing reagents. This fast trapping reaction was found to be applicable in a broad pH-range. Side reactions and artifacts were observed in model

studies only when preparing peptides under basic conditions but could be eliminated by employing slightly acidic work up conditions. MALDI-TOF-MS was used to follow the time course of *in vitro* refolding of recombinant human macrophage-colony stimulating factor (rhM-CSF).

Macrophage Colony Stimulating Factor (M-CSF) is a cytokine of increasing interest within the pharmaceutical and medical communities, especially because of its activity as an anti-infective in immune compromised patients. It is a hematopoietic growth factor that stimulates the survival, proliferation, differentiation and function of mononuclear phagocytes. The recombinant human M-CSF (rhM-CSF) we studied here closely resembles the species of secreted native M-CSF recovered from human urine except that it is not glycosylated. rhM-CSF contains 9 disulfide bonds, three of them participating in intermolecular bridges resulting in a 49 kD homodimer. rhM-CSF is produced in *E. coli* as insoluble and inactive inclusion bodies. Isolated inclusion bodies are reduced, denatured and diluted under appropriate conditions to initiate folding into an active molecule. The refolding reaction was initiated by dilution of denatured and reduced monomer in a buffer of high reducing potential. The highly reducing potential was selected to slow down possible monomer oxidation. Aliquots were taken at various time points and derivatized with MEL and rhM-CSF derivatives were purified by micro-filtration. Molecular weight determinations using MALDI-TOF-MS showed a decrease of protein sulfhydryl esters in subsequent time points of refolding.

These results are compared to trapping reactions with iodoacetamide, where covalent dimerization of rhM-CSF preceded formation of intramolecular disulfide bonds. The mass spectrometrical investigation of certain stages in the refolding of rhM-CSF was possible because several endopeptidases including lys-C, thermolysin, and proteinase K provided peptides cleaved at specific sites for convenient peptide mapping by fast atom bombardment mass spectrometry (FAB-MS). The dimer content of iodoacetamide-alkylated half cystines of trapped refolding intermediates was estimated by SE-HPLC. Intermediates trapped at each of several time points were partially purified using RP-HPLC and were analyzed using FAB-MS in a reducing matrix. The first underalkylation observed occurred at Cys157 and Cys159 and corresponded to the first sample (17 h time point) containing disulfide linked dimer. In samples containing only monomer, no disulfide bond formation could be detected therefore, disulfide shuffling at the monomer stage can be ruled out under the refolding conditions tested. Using the M-NSF-60 analysis no biological activity was found for the monomer M-CSF samples.

The data from this investigation support the following refolding pathway for rhM-CSF *in vitro*. In early refolding events, monomers (M) form intermediates that have no disulfide bonds under the redox conditions employed here. Initial oxidation leads to the formation of the inactive dimer intermediate with Cys157 and Cys159 forming the first intermolecular disulfide bonds. Subsequent folding leads to the formation of further intermediates that form more and more disulfide bonds until the native homodimer is developed.

Protein conformations and folding intermediates in solution studied by H/D exchange/ESI-MS

Claudia S. Maier¹, Mark Englen², Ok-Hee Kim¹, Michael I Schimerlik², Max L. Deinzer¹
Department of Agricultural Chemistry; Department of Biochemistry and Biophysics, Oregon State University, Corvallis, OR

Structural information of equilibrium folding intermediates is essential for understanding the mechanism of folding and the principles of structural stabilization. Compact nonnative equilibrium states like the compact acid-denatured state (A-state) of cytochrome c (cyt c), possess a native-like content of secondary structure but a highly fluctuating tertiary structure (so-called molten globule states). The relevance of structural description of these nonnative equilibrium intermediates is stressed by the observation of kinetic folding intermediates with properties closely resembling those of molten globule states [1,2].

We used H/D exchange-in experiments and the protein fragmentation approach [3] in combination with LC-ESI-MS/MS to study the A-state of cyt c in comparison to the native conformation and the denatured state. The partially unfolded state of cyt c in 4M guanidinium-HCl as well as the A-state show higher deuterium incorporation in comparison to the native state indicating the more open structure under mild denaturation conditions. The denatured state of proteins in general represents an ensemble of conformations that are highly open and solvent-exposed. In 18mM DCl cyt c possesses at least two clearly distinguishable conformations whereby the more open state incorporates about 12-15 deuterons more. A study of the deuterium incorporation of peptic fragments derived from the A-state generated under H/D quenching conditions (0 °C, 50mM phosphate, pH 2.5) revealed a substantially different exchange-in behavior of the A-state in comparison to the native and acid-denatured state: (1) all peptides show higher deuterium incorporation due to a general destabilization of tertiary structure, (2) peptide P 22-23 shows the highest deuterium up-take of all peptic peptides, (3) analysis of P 37-64 in comparison to P 47-64 revealed a major loss of structural stability in partial sequence 37-46, (4) peptides which cover the 60s-helix and the C-helix show only slightly higher deuterium content. These results demonstrate that the A-state of cyt c represents a partially folded conformation in which the 60s-helix and the C-helix are highly stabilized structural domains. The N-terminal partial sequence 1-21 is destabilized in comparison to the native conformation, however, due to the length of this peptide and the lack of overlapping peptides a more precise mapping of the exchange behavior focusing exclusively on the N-terminal helix is until now not possible. The extraordinarily high deuterium uptake indicates that the partial sequence 22-46, covering the so-called Ω -loop of cyt c, is highly disordered in the A-state. These results are in agreement with results obtained by H/D-exchange/NMR [4] and FT-Raman spectroscopy [5]. The results are discussed with regard to surface accessibility coefficients (14.5 nm probe) and the B-factor plot of native cyt c, in which regions with high temperature factors (B) indicate fluctuating partial sequences in the crystal structure.

Disulfide intermediates are very useful probes to study late protein folding intermediates. However, the successful formation of disulfide bridges increases the globule stability and very often causes resistance against proteolytic degradation. Furthermore, disulfide-linked peptides generated by the protein fragmentation approach reduce the precise location of exchange events and make MSMS experiments extremely difficult. Therefore, we are evaluating protocols which may allow a compatibility of H/D labeling experiments with chemical thiol-modification reactions, e.g. performic acid oxidation and partial reduction with TCEP under H/D-quenching conditions. BPTI which is virtually indigestible, and recombinant human macrophage colony stimulating factor β (rhM-CSF, 49 kD, 436 aa) which has a unique disulfide pattern [6], were chosen as model systems. BPTI (6514 Da, 58 aa) was used as a model protein to study reduction and oxidation reactions under acidic conditions. Reduction was attempted with a variety of reagents including tris(2-carboxyethyl)phosphine hydrochloride (TCEP), Zn/HCl and NaBH₃CN/AcOH at pH 1-4 and 0 °C, however, all attempts were unsuccessful. Oxidation of the three cysteines and a methionine residue (M52) was achieved with performic acid. Performic acid reagent was produced by mixing 30% H₂O₂ with formic acid in a ratio of 1:9. The performic acid oxidation was performed under minimum H/D exchange conditions (pH 2.3, -20 °C, 2h). The resulting oxidized BPTI contained six cysteic acids and one methionine sulfone. Peptic digestion of the fully oxidized BPTI was performed with immobilized pepsin under minimum H/D exchange conditions (pH 2, 0 °C, 5 min) giving four major peptides R1-Y21, F22-F33,

F22-F45 and F22-A58, and seven minor peptides R1118, R1-F22, Y23-F33, Y23-F45, V34-F45, V34-A58 and K46-A58. Performic acid oxidation (in 10% formic acid, pH 2.7, 0 °C) of rhM-CSF was monitored by analysis of aliquots of the solution taken at different points. Oxidation of the dimer increased continuously with time. Oxidized monomer first became apparent after 2 h. Some oxidized dimer persisted throughout the experiment, indicating that at least one intermolecular disulfide bond remained. Peptic digests of native rhM-CSF were prepared in 0.01N HCl or in the presence of 3.2M urea, in 2% HCOOH (adjusted with NH₄OH to pH 2.7) and in 50mM sodium phosphate (pH 2.8). Exchange-in experiments were performed by transferring rhM-CSF in citrate buffer (pH 6.5) into either 18mM DCl or into sodium d3-acetate (10mM, pH 5.5-5.8) utilizing Amicon microultrafiltration tubes (MWCO 10 000, dilution factor was approx. 100). Exchange-in experiments were carried out at room temperature over 48 h. Exchange-out was initialized by transfer into sodium acetate (10 mM, pH 5.8). Aliquots were taken over a period of 3 h, exchange-out was quenched by diluting into 10% 2-propanol/2% acetic acid and immediately frozen in liquid nitrogen. Residual buffer salts were removed by repeating concentration and dilution into 10% 2-propanol/2% acetic acid. ESI-MS analyses showed that approximately 42% of amide deuterium (ND) were still remaining after a exchange-out period of 2 min. When exchange-in was attempted in DCl at pH 2, only a slightly higher number of remaining ND was measured. Additional 17 % of amide deuterium changed-out over a period of 3h from rhM-CSF deuterated under conditions which preserve the native structure (fig. 1).

Structural Elucidation of Gaseous Cytochrome c Ions by Hydrogen/Deuterium Exchange

Ziqiang Guan, Troy D. Wood, Ulrich Haupts, Neil L. Kelleher, David J. Aaserud
and Fred W. McLafferty
Baker Chemistry Laboratory, Cornell University, Ithaca, NY 14853-1301

Cytochrome c gaseous ions, 12.4 kDa, can be formed in 6+ to 17+ charge states by electrospray ionization. Reaction with 10^{-7} torr D_2O for 30 min gives H/D exchange (~98% complete) of 64 to 136 of the 198 exchangeable (high kinetic energy) hydrogen atoms, presumably a measure of those exposed in different gaseous 3-dimensional structures. Like protein conformations in solution, these gaseous conformers can be made more open ("denatured") by heating (IR laser) and folded by removing protons ("charge stripping") with an amine. Similarities in the H/D exchange values for different charge states indicated the existence of at least 6 stable conformers.¹

MS/MS of the Deuterated Species The combined approach of H/D exchange with tandem mass spectrometry (MS/MS) is able to distinguish subtle differences in gaseous conformations. 30 min H/D exchanges are followed by sustained off resonance irradiation (SORI) dissociation, and subunit exchanges are readily obtained from the mass increases of fragment ions. Figure 1 shows the variable levels of H/D exchange within each charge state, indicating different degrees of regional accessibility to D_2O in the gas phase. The relative percentage of exchange in fragments containing the C-terminal tends to be greater than in the protein as a whole, while the exchange in the N-terminal region tends to be nearly the same as the chain overall.

Site Exposure by Charge Stripping Although the 17+Lo conformer undergoes 18 less H/D exchanges than the 9+, charge stripping of the deuterated 17+Lo to the 9+, followed by H/D exchange yields 6 more H/D exchanges than the 9+ itself; therefore 6 exchange sites on the 17+Lo are folded in the 9+, so that it actually has 24 exchangeable sites not in the 17+Lo. However, the deuterated 16+Hi, 15+, and 13+Hi when charge stripped to the 9+, with further H/D exchange, show the same (139) H/D exchanges, strong evidence that essentially all their exchangeable sites are also exposed in the 9+. Despite the large difference in electrostatic repulsion, charge states from 9+ to 16+ have the same conformation. Although the 8+, 7+ and 6+ conformers have far fewer H/D exchange sites, 3 to 31 of these sites are not in the higher charge states.

Adduct Dissociation During Detection One of the most intriguing features of FTICR/MS is its unique 'non-destructive' detection process. Collisions with background gas are major factors responsible for signal decaying and/or relaxing the ions to the center of the cell. This feature has been utilized to enhance signal/noise ratios by multiply remeasuring the same population of ions. We show here that such collisional process can be 'destructive' to the weakly bound adduct ions (butylamine adduct formed during charge stripping of cytochrome c ions), and lead to surprisingly low resolution measurement (Figure 2, $P = \sim 1 \times 10^{-8}$ torr).

Summary The most stable conformational units of native cytochrome c in solutions, the N- and C-terminal α -helices,^{2,3} are not important in any of the several gaseous conformers examined here. The highly charged state actually have many non-exposed (folded) sites not in the low charge states (e.g. 31 sites in 17+Lo not in 6+), as well as vice-versa (e.g., 88 sites in 6+ not in 17+Lo). The same conformer (II) is stable in 9+ to 17+ charge states, despite the doubling of electrostatic repulsion.

Deuterium exchange studies of the conformation of a peptide fragment comprising the H helix of myoglobin by electrospray mass spectrometry

Tun-Li Shen and Douglas A. Gage
Department of Biochemistry, Michigan State University, East Lansing, MI 48824

Introduction

Recent experimental and theoretical advances have improved our understanding of the protein folding problem. Models have been developed which predict that secondary structures are formed early in folding. One approach to study the early events of protein folding processes is to analyze peptide fragments that comprise particular secondary structural motifs with known three-dimensional structure.

Our understanding of the protein folding come mainly from the study of the folding of small single-domain proteins. Myoglobin consists of eight α helices (A-H) that form a hydrophobic pocket for the heme group. In the structural characterization of the partly folded apomyoglobin intermediate (Hughson, et al., Science, 249, 1544 (1990)), it has been shown by hydrogen/deuterium exchange and NMR studies that protons in the A, G, and H helix regions are protected from exchange. Further studies on the H-helix show evidence of helical conformation (Walther, et al., Biochemistry, 32, 6337 (1993)). Anderegg and coworkers have shown (Anderegg, et al., JASMS, 5, 425 (1994); Wagner, et al., Prot. Sci., 3, 1305 (1994)) that hydrogen/deuterium exchange coupled with tandem mass spectrometry can be used as a tool to elucidate peptide conformation.

Based on this evidence, we are interested in using mass spectrometry to investigate the peptide model of protein folding. Here, we report the study of the conformation of a peptide fragment corresponding to the H-helix of myoglobin that has been shown by NMR experiments to be involved in early folding events, forming a helical structure.

Experimental

The peptide synthesized corresponds to residues 124 to 150 of sperm whale myoglobin - MbH. The sequence is MbH: Ac-GADAQGAMNKALELFRKDIAAKYELLG-NH₂

The peptide was synthesized on an Applied Biosystems Synergy Personal Peptide Synthesizer employing Fmoc chemistry.

All mass spectrometry experiments were performed on a Sciex API 300 mass spectrometer (Sciex, Ontario) in the positive ion mode. The ion spray needle was biased at 5300 V and the orifice plate at 50 V. To start a hydrogen/deuterium exchange experiment, the peptide samples were dried in a speedvac. The deuterated solvents were then added to the peptide sample. The peptide solutions were directly infused into the instrument in the shortest possible time, in our case, 35 to 40 secs. (1) The hydrogen/deuterium exchange with three different solvent systems were monitored continuously by mass scanning the +4 charge state peak for a period of time. (2) continuous MS/MS recording on the precursor ion (+4 charge state) during exchange was also carried out.

Results & discussion

In the Mb-H peptide there are 54 exchangeable protons, including 26 amide backbone protons - NH, 2 Asp COOH, 2 Glu COOH, 1 Gln CONH₂, 4 Lys NH₃⁺, 1 Asn CONH₂, 1 Arg NHC(NH₂)₂, 1 Tyr OH. The exchange rate constants are obtained from the slope of plots of $\ln(N_H)$ vs. exchange time, N_H is the number of proton remaining, see Figure 1. The protons with the fastest rates, those of the side-chain protons, have been exchanged before MS analysis under our experimental conditions; the first part of the curve suggest that they consist more than 20 protons. After the rapid exchange of the side chain protons, two linear regions between 1 and 3.5 min and between 3 and 20 min are identified; their first-order rate constants are 0.0518 min⁻¹ and 0.0269 min⁻¹, and half-life of 12 min and 28 min respectively. The group of slow exchange protons with a half-life of 28 min are likely involved in hydrogen bonding. The number of slowly exchanging protons are consistent with the presence of a partial helical structure as predicted by the NMR experiments. However, from these data, we can not conclude where the hydrogen bonded protons are located. By recording MS/MS spectrum of the

precursor ion continuously, we can follow the mass changes of the product ions at each time point. MS/MS experiment on the +4 charged ion of the Mb-H peptide is shown in Figure 2.

It has been suggested from NMR studies in solution that the central region (residues:133-149) has the highest tendency of forming helical structure. From the hydrogen/deuterium exchange MS/MS experiment, we can observe the mass shifts of the fragment ions of the Mb-H peptide. The number of proton remaining on individual fragment can be estimated by the difference in mass compare to the fully deuterated one, and the mass increment of sequential fragment ions can provide an estimation of amide proton(s) that are involved in hydrogen bonding forming a helical structure. Although we did not have the complete series of ions that would be required for a more definitive analysis, the mass difference in y_9 and y_{12} , decreasing from 3.4 to 1.6, for the first ten minutes, seems to indicate that it is likely Arg 139-Ile 142 (within the region of 133-149) may contain hydrogen bond(s), consistent with the NMR results.

Detecting Conformations and Conformational Changes by Hydrogen Exchange and Mass Spectrometry

Yuzhong Deng, Zhongqi Zhang and David L. Smith

Department of Chemistry, University of Nebraska-Lincoln, NE 68588

Kinetic and thermodynamic information, as well as the possible existence of intermediates in protein unfolding, can be determined from the rates at which amide hydrogens located at peptide linkages undergo isotopic exchange. Processes associated with protein unfolding can be studied when denaturants are used to destabilize folded forms relative to unfolded forms of proteins. We have used the protein fragmentation/mass spectrometry approach (Zhang and Smith, 1993 Protein Sci. 2:522-531) to investigate urea induced unfolding of rabbit muscle aldolase (M_r 157 kDa). Hydrogen exchange (HX) kinetics associated with the momentary unfolding of proteins are illustrated in Fig. 1. When the rate constant for HX from the unfolded protein is much less than the rate constant for refolding ($k_2 \ll k_1$), the HX rate constant, k_{ex} is given by $K_{unf}k_2$, where K_{unf} is the equilibrium constant describing the extent of unfolding. This mechanism for hydrogen exchange follows EX2 kinetics. When the rate constant for hydrogen exchange from the unfolded protein is much greater than the rate constant for refolding ($k_2 \gg k_1$), EX1 kinetics dominate and k_{ex} is given by k_1 .

The number of deuteriums per peptide molecule can be determined directly from the isotope pattern present in the mass spectrum of the peptide. When EX1 kinetics prevail, all of the amide hydrogens within an unfolded segment are replaced with deuterium before the segment refolds. Mass spectra of peptides derived from protein undergoing HX via EX1 kinetics may have two envelopes of isotope peaks. The relative intensity of the low mass envelope, which is a direct measure of the number of protein molecules that have remained folded in the region represented by the peptide, may be used to determine the unfolding rate constant, k_1 .

A continuous-labeling experimental method was used to determine the unfolding rate constant. Mass spectra of peptides representative of the 327-336 and 257-269 segments of aldolase, incubated in 4M urea for different times, are presented in Fig. 2. Results for the 327-336 segment show that this segment unfolds in nearly all of the aldolase molecules during the shortest incubation time, 8 min. In contrast, the 257-269 segment unfolds in only a few aldolase molecules during this time. After 150 min, this segment unfolds in approximately 60% of the aldolase molecules. Unfolding rates of 17 segments of aldolase in 4M urea have been calculated. These results show that different parts of aldolase unfold at very different (50-fold) rates. These results suggest that segments of aldolase located on the subunit binding surface are particularly resistant to unfolding in urea.

A pulsed-labeling experiment was performed to determine the concentrations of folded and unfolded protein from which the equilibrium constant of unfolding can be determined. When protein unfolding follows EX1 kinetics, a brief D_2O pulse labels only the unfolded part of a protein. The relative intensities of the low and high mass envelopes of isotopic peaks, which are a direct measure of the concentrations of folded and unfolded protein, may be used to determine the unfolding equilibrium constants, K_{unf} . Equilibrium constants of 14 segments of aldolase incubated in 2.5, 3 and 3.5 M urea were determined. These results show that the unfolding equilibrium constants for different parts of aldolase differ by less than a factor of 2 which corresponds to a $\Delta\Delta G$ of less than 0.5 kcal/mol.

Detection of Protein Conformations by On-line Rapid Hydrogen Exchange and Protein Fragmentation/MS

Kuruppu Dharmasiri and David L. Smith

Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

Although several methods for determining the primary structures of proteins are presently available, analytical methods for evaluating secondary and tertiary structural features of proteins are inadequate. Of particular interest is identification of specific regions that differ in conformation, thereby altering the function of the protein. For example, the oxidized and reduced forms of cyt c have nearly identical X-ray crystallographic structures, but exhibit different functions. Amide hydrogen exchange is the basis of an alternate method for locating regions that differ in folded structure (i.e., conformers).

The rates at which hydrogens located at peptide linkages in folded proteins undergo isotopic exchange may differ by as much as 10^6 . Principal factors affecting amide hydrogen exchange rates are intramolecular hydrogen bonding and accessibility of peptide linkages to the aqueous solvent. Hence, isotopic exchange rates of peptide amide hydrogens are extremely sensitive to noncovalent structural features of folded proteins in solution. Although NMR has been used extensively for hydrogen exchange studies, mass spectrometry offers significant advantages in several areas, including speed, sensitivity, protein solubility and protein molecular weight (1,2). This study demonstrates how exchange rates of the most rapidly exchanging amide hydrogens can be used to distinguish oxidized, reduced and apo cyt c.

A flow/quench system was developed so that isotopic exchange on the 0.2 s to 5 min time scale could be studied (3). This system that was constructed from low-volume mixing Tees, PEEK tubing, and a Harvard Apparatus syringe pump, was connected directly to the HPLC injector used for HPLC/ESIMS analysis. The time allowed for isotopic exchange was varied by changing the flow rate or volume of tubing.

The results (Fig. 1 and 2) show that isotopic exchange in the segments of apo cyt c is approximately as expected for an unstructured polypeptide, suggesting that there is little if any hydrogen bonding in these segments and these amide hydrogens have essentially complete access to the aqueous solvent. Isotopic exchange rates in all other segments of apo cyt c are consistent with this conclusion. These results also show that isotopic exchange rates of the most rapidly exchanging hydrogens located at peptide amide linkages can be determined in fast-exchange conditions (pH 7) using this flow quench apparatus and the protein fragmentation/ESIMS.

Isotopic exchange rates in the 1-10 segment of oxidized and reduced cyt c are much less than in the same segment of apo cyt c, demonstrating how hydrogen bonding and limited solvent accessibility can dramatically decrease isotopic exchange rates in folded proteins. The results in Fig. 1 also show that the isotopic exchange rates in the 1-10 segments of oxidized and reduced are very similar, suggesting that the non covalent structure in this region of these functionally different forms of cyt c is very similar. Other segments for which isotopic exchange rates are similar in oxidized and reduced cyt c include residues 1-21 and 83-104.

The rates of isotopic exchange in several segments are substantially different in oxidized and reduced cyt c. Results in Fig. 2 show that three amide hydrogens in the 66-82 segment exchange much faster in oxidized cyt c than in reduced cyt c. These results suggest that the oxidized and reduced forms of cyt c are structurally different in this region. Decreased rates of isotopic exchange were also found for reduced cyt c in the region including residues 22-65. The results of this method demonstrate that the flow/quench system can be used with the protein fragmentation/MS method to identify the protein conformations and the regions that undergo conformational changes.

Extended Mass Range Quadrupole Mass Spectrometer

B.A. Collings and D.J. Douglas
Dept. of Chemistry, University of British Columbia
Vancouver, British Columbia
V6T 1Z1, Canada

The study of noncovalent associations in large biological molecules with high mass to charge ratios has demanded the development of extended mass range mass spectrometers.¹ In this work an extended mass range (up to 8585 m/z) quadrupole mass spectrometer, utilizing an electrospray ionization source, has been used to obtain mass spectra of soybean agglutinin (SBA), a glycoprotein with monomer mass ca. 30 000 amu (at pH=3.5 SBA is found in the tetrameric form and is held together by weak inter- and intramolecular noncovalent bonds) and of polypropylene glycol (PPG) with average molecular weights of 2000 and 4000 amu. Initial characterization experiments of the mass spectrometer system were carried out using PPG 2000 and PPG 4000.

Ions formed by pneumatically assisted electrospray were passed through a dry nitrogen "curtain" gas, a 0.25 mm diameter sampling orifice, a skimmer (0.75 mm orifice diameter) to a radio frequency quadrupole and then to the analyzing quadrupole of the mass spectrometer system. The extent of collisionally assisted dissociation (CAD) was controlled by varying the potential difference between the orifice and skimmer. The mass range was extended by lowering the radio frequency of the mass spectrometer from 1.00 MHz (maximum mass of 4000 m/z) to 768 kHz (6750 m/z) and 683 kHz (8585 m/z) while maintaining a constant field radius of 4.16 mm. In the figure below mass spectra are displayed for PPG 4000 at orifice to skimmer potential differences (OS) of 90 and 240 V.

At OS=90 V peaks in the mass spectrum extended to ca. 3500 m/z. At OS=240 V peaks are present in the mass spectrum up to 7000 m/z. Increasing the OS potential difference from 90 to 240 V produces higher energetic collisions with the background gas in the orifice-skimmer region. This leads to charge stripping⁴ of multiply charged ions to form ions which arrive at higher m/z. A closer look at one of the higher m/z peaks shows that the mass spectrometer is capable of attaining unit resolution (see figure above). Additionally, a high resolution scan of the peak at 5025 m/z results in only a moderate decrease in signal intensity by factor of 20 from that of the low resolution scan.

Characterization of the mass spectrometer transmission as a function of frequency is ideally expected to vary as the square of the frequency leading to a decrease in signal intensity with increased mass range. The results, for PPG 2000, show that upon decreasing the frequency from 1.00 MHz to 683 kHz there is a decrease of $\times 3$ for 176 m/z, no change for 1027 m/z and an increase of $\times 2$ for 2471 m/z. A decrease of $\times 2.15$ was expected, however, this comparison is difficult to measure quantitatively. A comparison requires that each mass peak be measured under identical electrospray conditions, peak width and with the identical effects from fringing fields due to the ion optics transporting the ions to the analyzing quadrupole. The results indicate that the sensitivity for this quadrupole mass spectrometer system is however not significantly affected upon reduction of the frequency.

The figure below shows a preliminary mass spectrum of the tetrameric form of SBA (0.32 mg/ml, 90% water, 10% MeOH, 0.02% formic acid) over the range 4000-8500 m/z. The charge state of the ion species are indicated in the figure and give a mass of ca. 117 kDa for the neutral parent species. The tetrameric form of SBA is held together through noncovalent bonding and readily survives the electrospray ionization process. The heterogeneity of the charged species (native SBA is known to have at least six tetrameric forms, each with slightly different masses) and the high mass demonstrate the need for an extended high mass range mass spectrometer with high resolution capabilities.

Determination of Protein Reactive Sites by Multiple SORI Experiments in Electrospray/FT-ICR

J. M. Robinson, R. C. Arkin, C. L. Hendrickson*, V. L. Campbell, and D. A. Laude
Dept. of Chemistry and Biochemistry, University of Texas at Austin
Austin, TX 78712

*National High Magnetic Field Laboratory, Tallahassee, FL

The functions and activities of proteins are highly dependent on their conformations. For this reason, much research focuses on determining the structural features of biomolecules. Analyzing the relative reactivities of protein residues through mass spectrometry should provide rapid information relating to protein conformations.

Proteins can be effectively labeled through the application of traditional solution-phase reactions which modify proteins with site specific adducts. By using solvent conditions which preserve the native conformation of a protein during the reactions, the location of the adducts will reflect the intact, solution phase, native conformation of the protein. The adduct should bind more strongly to targeted residues on the surface of the molecule as opposed to the residues that are shielded in the center of the molecule. If the adduct bonds are stable in mild electrospray ionization (ESI) solvents, then ESI/MS analysis should reflect the binding that occurred in solution. [1]

In order to develop this technique, acetone was combined with bovine ubiquitin to form Schiff-bases at the free amine sites of the protein. Experiments were run on an electrospray FT-ICR mass spectrometer. Once the modified proteins were ionized, the adducted protein at the plus ten charge state was isolated using stored waveform inverse Fourier transform (SWIFT), and then dissociated with sustained off-resonance irradiation (SORI) to generate products which contained the adducts. The y_{58} fragment was then selected for further dissociation.

All experiments performed on the adducted ubiquitin, were first performed on the native form for comparison. Figure 1a shows the ms^3 SORI fragments of the non-adducted y_{58} , and figure 1b shows the fragments of the adducted y_{58} . Because the y_{58} only had one acetone adduct, it is obvious that there were many different forms of this fragment present. This is illustrated by the fact that complimentary fragments both show adduction. The multiple forms of adducted fragments are probably due to the fact that the solution conditions were not mild enough to preserve the native conformation, and any excess acetone was then able to react with the denatured protein. One way to overcome this problem would be to remove the excess acetone after the adduction reactions take place. Another solution may be to employ nanospray injection, which is capable of spraying with much milder solvent conditions than typical electrospray.

It is clear from the results that this is a viable technique for tracking the adduction of a protein. As long as the systems to be investigated do not involve any reactions or solvents that would denature the protein of interest, the resulting data should reflect solution phase conformation. This technique should also be well suited for systems exhibiting much higher binding specificity, such as species that bind only in the active site of a protein. Once this procedure is an established method, it will be possible to examine many other systems with various adducts.

Competition between Protein Unfolding and Amide Hydrogen Exchange Determined by High Resolution ESI Mass Spectrometry

Eric Lund and David L. Smith
Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

Understanding the processes through which proteins unfold under unnatural conditions may help us to understand processes through which proteins fold under natural conditions. Specific questions to be answered include. (1) At what concentration of denaturant does a protein unfold? (2) How much time is required for a protein to unfold? (3) Does a protein unfold in one or many steps? When used with amide hydrogen exchange, mass spectrometry will likely become an important tool for studies designed to answer these questions.

The rates at which hydrogens located on peptide amide linkages undergo isotopic exchange are profoundly dependent on the structure of a protein. As a result, hydrogen exchange rates in folded proteins are typically several orders of magnitude slower than in unfolded proteins. Furthermore, the distribution of isotopic hydrogen among the molecules in a sample can be determined by mass spectrometry and used as a direct evidence for sub-populations that differ in structure. To investigate rapid structural changes, a high speed flow/quench system has been used to expose ribonuclease A and apomyoglobin to denaturants for short times during which hydrogen exchange was used to label various structural forms of these proteins.

RNase A: Folded RNase A in which all exchangeable hydrogens had been replaced with deuterium was mixed with 5.5 M GdHCl in H₂O (1:5 mix ratio) in a rapid mixing flow-quench apparatus. Following a time (5 ms to 1000 s) during which the deuterated RNase A was destabilized with denaturant and exposed to H₂O, the pH was decreased to 2.2 to quench isotopic exchange. The samples were immediately frozen at -80°C for storage until analysis by HPLC ESIMS. Capillary Perfusion HPLC was performed using protic solvents to desalt the samples and to remove rapidly exchanging deuterium, leaving deuterium only at peptide amide linkages. Perfusion packing material was used to minimize analysis time. ESI mass spectrometric analysis was performed with a Micromass Autospec high resolution mass spectrometer operated in the voltage scan mode at a resolving power of 3,000 at the point detector. The reproducibility of mass measurement in this mode was 10-12 ppm.

The ESI mass spectra of the +10 charge state of RNase A are presented in Fig. 1 for *Fully Labeled* protein, and after various destabilization/hydrogen exchange times. The deuterium level in RNase A, determined from the centroids of these peaks, is plotted in Fig. 2 as a function of the destabilization/hydrogen exchange time. For reaction times less than 1 s, one envelope of isotope peaks was found (Fig. 1, 10 ms). The rate of deuterium loss from the backbone of folded RNase A is illustrated in Fig. 2 for $t < 1$ s. In the 5-10 s time interval, RNase A in 5.5 M GdHCl undergoes cooperative unfolding. Molecules that unfold lose all of their deuterium very rapidly (< 10 ms). The intensities of the bimodal isotope envelopes found at 5 and 10 s (Fig. 2, Boxed) are a direct measure of the number of RNase A molecules that have unfolded. For $t > 10$ s, isotopic equilibration is achieved among RNase A molecules.

Apomyoglobin: A similar procedure was used to study urea-induced unfolding of deuterated apomyoglobin over the time range from 40 ms to 60 s. However, the ESIMS analyses differed in that multi-channel array detection was used to increase sensitivity so three charge states (+19-21) could be monitored with good S/N.

At least four populations of apomyoglobin, each distinguished by a specific level of deuterium are attributed to multiple structural forms of apomyoglobin, each undergoing isotopic exchange with the aqueous solvent at a characteristic rate. Since the solution was 20% D₂O, apomyoglobin populations with 20 deuteriums have evidently equilibrated with the solvent. It is important to note that isotopic equilibration will be complete in unstructured apomyoglobin in less than 10 ms under these experimental conditions. Finding 50-80 deuteriums in two populations, the most highly folded forms, clearly demonstrates that these forms retain considerable secondary and tertiary structure. After approximately 300 ms, the deuterium content of these forms abruptly decreases to 20, indicating rapid isotopic equilibration with the solution. This rapid isotopic equilibration is attributed to cooperative unfolding of apomyoglobin after incubation in 5.5 M urea for 300 ms. Whether these structural forms were present prior to mixing of apomyoglobin with urea, or whether they formed as unfolding intermediates before the first time point of this experiment (40 ms) cannot be determined from these results.

Loss of Deuterium as RNase Unfolds

Probing Protein/protein Interactions with Mass Spectrometry and Isotopic Labeling: Analysis of the p21/Cdk2 Complex¹

Richard W. Kriwacki, Jiangyue Wu†, Gary Siuzdak†*, and Peter E. Wright*

Departments of Molecular Biology and Chemistry†, The Scripps Research Institute, La Jolla, CA 92037

Identification of the amino acids at the protein/protein interface is an important step in understanding protein/protein recognition. Various approaches such as random mutagenesis and chemical cross-linking have been used to study these interfaces. Earlier, a simple and rapid biochemical method, MALDI mass spectrometry combined with proteolysis, had been developed to study the solution structure of DNA-binding proteins². More recently, we have extended it to the more difficult problem of protein/protein complexes and further improved it by using isotopic labeling. The key to this method is the notion of the protection against proteolysis in which the protected regions refer to the protein/protein interaction²⁻⁴. Identification of the exact sites of the proteolytic cleavage can provide information on these interactions.

Here we report the application of MALDI-MS proteolysis to the analysis of the p21-B/Cdk2 complex. In this investigation, MALDI/MS analysis was performed on trypsin digestion of the kinase inhibitory domain of the cell cycle regulatory protein, p21 Waf1/Cip1/Sdi1 (p21-B), in both the free solution state and in the 1:1 complex of p21-B and cyclin-dependent kinase 2 (Cdk2). MALDI mass spectra of trypsin digests of p21-B in the presence of Cdk2 show that several p21-B fragments produced in the absence of Cdk2 disappear in the presence of Cdk2 (Figure 1).

Figure 1. MALDI mass spectra of tryptic digestion of a) free p21-B and b) p21-B/Cdk2 complex. Some major tryptic fragments of p21-B in (a) are not observed or have reduced intensities in (b) and other major fragments of p21-B appear in (b). Label "a" indicates the tryptic fragments of Cdk2.

The mass spectra for the 1:1 p21-B/Cdk2 complex is complicated by the appearance of peaks due to tryptic cleavage of both p21-B and Cdk2. This complication was eliminated by

performing a duplicate set of experiments using ¹⁵N-p21-B within the p21-B/Cdk2 complex. All fragments from ¹⁵N-p21-B are shifted to higher mass by an increment of ΔM Da with a corresponding number of nitrogen in the protein fragment, while those from Cdk2 are not shifted (Figure 2). Comparing two spectra of unlabeled and labeled p21-B/Cdk2 complexes allows both unambiguous differentiation of p21-B and Cdk2 fragments and identification of protected amino acids for p21-B within the complex. Specifically, amino acids 46, 48, and 67 are protected from trypsin in the Cdk2 complex (Figure 3). The results clearly reveal a segment of 22 to 36 amino acids of p21-B that is protected from trypsin cleavage, suggesting this constitutes the Cdk2 binding site on p21-B.

Figure 2. MALDI mass spectra of tryptic digestion of a) unlabeled and b) labeled p21-B/Cdk2 complexes.

Figure 3. Protected regions of p21-B within the p21-B/Cdk2 complex. a) Cdk2 absent; b) Cdk2 present.

In conclusion, the combined use of isotopic labeling, proteolysis, and MALDI/MS offers a general approach for the study of the solution structure of protein/protein complexes and may allow rapid access to highly accurate maps of protein/protein interfaces.

Salt, Detergent and Ligand Induced Protein Conformational Changes Probed by H/D Exchange Using ESI-MS and LC-ESI-MS

Xue-jun Tang*, Fang Wang, and John S. Blanchard

Department of Biochemistry, Albert Einstein College of Medicine, Bronx, New York 10461, USA

The development of electrospray ionization mass spectrometry (ESI-MS) has made it possible not only to measure accurate molecular weights of proteins but also to study protein conformations in solution. In particular, hydrogen/deuterium exchange in combination with ESI-MS has been used to detect global conformational changes of proteins in solution [1,2]. Detailed deuterium incorporation in proteins can also be studied with the protein fragmentation method [1]. In this approach, the deuterated protein is first fragmented into peptides at the slowest exchange conditions (pH ~3, 0 °C) with an acid protease, such as pepsin, the deuterium incorporation in each peptide can then be obtained by LC-MS analysis of the peptide mixture. With this method, an intermediate spatial resolution can be achieved with no limitation on the size of proteins.

We have demonstrated that global conformational changes of proteins, including apo-myoglobin (apo-Mb) and cytochrome c, induced by salts or detergents at acidic pH, can be detected by H/D exchange monitored by ESI-MS [2]. In this investigation, we have applied the protein fragmentation method and LC-MS analysis in order to obtain the deuterium incorporation in various segments of apo-Mb deuterated at pH 2 in the presence of different concentrations of salt or detergent. As an example, Figure 1 shows the extent of the deuterium incorporation in peptic fragments of apo-Mb deuterated at different concentrations of $\text{CCl}_3\text{COONH}_4$ at pH 2. As it can be seen from Figure 1 that, for the $\text{CCl}_3\text{COONH}_4$ salt induced acidic molten globular state of apo-Mb at pH 2, regions represented by peptic peptides 14-29, 30-40, 33-55, 107-134 and 138-153 has considerable less amount of deuteriums than the rest of the protein, which suggests that these regions have the most folded structures in the molten globule. Apart from peptide 70-76, Deuterium distribution pattern in the acidic molten globule of apo-Mb induced by SDS detergent is very similar to that induced by $\text{CCl}_3\text{COONH}_4$ salt, which suggests the two acidic molten globules have similar folding structure.

The techniques described above have also been applied to the studies of solution conformations of dihydronicotinamide reductase (DHPR), a large tetrameric protein (MW~115 032 Da). DHPR is a two-domain enzyme found in bacteria and higher plants involved in the biosynthesis of diaminopimelic acid and lysine. Figure 2a shows the global H/D exchange rates of DHPR, DHPR in the presence of a cofactor (β -nicotinamide adenine dinucleotide) and both of the cofactor and the inhibitor (2,6-pyridinedicarboxylic acid). The results indicated that deuterium incorporation in DHPR was reduced ~10 and ~15%, respectively, upon cofactor and inhibitor binding, suggesting that significant conformational changes occurred.

LC-MS analyses of deuteriums at peptide amide positions in peptic fragments of DHPR (incubated in D_2O for 10 minutes) have indicated that regions represented by peptic peptides 77-91, 232-246 have considerable less deuteriums after cofactor binding (Figure 2b & c). This result is consistent with X-ray crystallographic results [3] which indicate that residues 81, 84 and 240 are involved in the cofactor binding. Our results also show that peptic peptides 126-129 and 153-172 have less deuterium incorporation after inhibitor binding, this may provide information of the enzyme-inhibitor interaction sites.

Higher-Order Structure of Gas-Phase Peptides from Gas-Phase H/D Exchange Experiments

Zhongqi Zhang, Weiqun Li*, Shenheng Guan*, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab, Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

* Member of the Department of Chemistry, Florida State University

Protein folding is a challenging problem in modern molecular biology. To understand protein folding, one must understand each individual force involved in the folding process. Hydrophobic interactions constitute one of the most important forces that control the protein folding process. Higher-order structures of proteins and peptides in the gas phase, where hydrophobic interactions are presumably absent, should reveal how the hydrophobic interactions contribute to the folding of a protein. The exchange of deuterium for hydrogen (H/D exchange) in proteins and peptides can serve to identify and characterize surface-accessible amino acid residues, both in solution and (for ionized proteins and peptides) in gas phase. The accessible surface area of a protein depends on protein conformation; therefore, the rate and extent of deuterium incorporation offer a powerful mass spectrometric probe of protein high-order structure in solution and gas phase. [1]

Here, we form quasimolecular ions of peptides by MALDI, and confine them in a Penning trap for varying periods of time to exchange their hydrogens with D₂O (4 × 10⁻⁶ torr). Peptides may be trapped for up to 3 hours (e.g., more than 1,000,000 ion-neutral collisions) by use of repeated axialization. [2] The H/D exchange extent and rate may be calculated from the time-dependent increase in peptide ion mass. All experiments were performed at 3.0 T on a Finnigan FTMS-2000 FT-ICR MS equipped with MALDI.

Gas-phase H/D exchange experiments were performed for four different peptides. Fig. 1 shows the MALDI FT-ICR mass spectrum of the LHRH quasi-molecular ion following exposure to gas-phase D₂O for 3.1 h. The average deuterium content can be calculated from the increase of average molecular weight following H/D exchange. Fig. 2 shows the H/D exchange time courses and rate constant distribution of four peptides. Note that different peptides have grossly different exchange rate constants, suggesting that they may have different gas-phase conformation and/or exchange by different mechanisms. For angiotensin II and [M¹¹-OH]-substance P, all of the peptide hydrogens exchange at a common rate, suggesting that some fast-exchanging hydrogens exchange first, followed by intramolecular H/D exchange for the slow exchanging hydrogens.

Interestingly, [M¹¹-OH]-substance P shows an initially bimodal isotopic pattern (Fig. 3), suggesting coexistence of two conformers. Work supported by NSF (CHE-94-13008), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

ESI MS is rapidly establishing itself as a routine technique for the observation of non-covalent protein-small molecule and natural protein-protein complexes. In a continuation of our investigations of enzyme-substrate and enzyme inhibitor interactions by ESI mass spectrometry we have examined a series of non-covalent complexes formed between Bovine Trypsin and Bovine Pancreatic Trypsin Inhibitor BPTI, R_{cam}BPTI [S-S 14-38 reduced and carboxymethylated] and Soybean Trypsin Inhibitor. The BPTI lys¹⁵val mutant, which lacks the critical lysine for binding in the active site of trypsin and does not bind in solution, was used as a control.

ESI mass spectral analysis, at low cone voltage [+40v], from 2.5mM NH₄OAc, pH 6.5, at solution of trypsin [5-10pmol/μl] showed a very simple 'native state' spectrum with three charge states 10⁺, 9⁺ and 8⁺, for the 'trypsin-Ca⁺⁺' complex. Analysis of the incubation products formed between trypsin and the two BPTI inhibitors showed similar very simple low charge state spectra with complete conversion of the 'trypsin-Ca⁺⁺' species to a 1:1 'trypsin-Ca⁺⁺-inhibitor' complex at 1:1 molar ratios, with 12⁺, 11⁺ 10⁺ charge states. In marked contrast the BPTI lys¹⁵val mutant showed

neither complex formation nor any change in the 'trypsin-Ca⁺⁺' complex charge state distribution. ESI mass spectral analysis of the trypsin-soybean incubation products again showed the formation of a 1:1 'trypsin-Ca⁺⁺-soybean inhibitor' complex with a simple low charge state distribution 14⁺, 13⁺ and 12⁺. Gas phase dissociation *via* increased cone voltage [+80v] showed very little dissociation of the 'trypsin-Ca⁺⁺-soybean inhibitor' complex, but considerable dissociation of the two 'trypsin-Ca⁺⁺-BPTI' complexes. The charge state distribution of the resulting 'trypsin-Ca⁺⁺' complex, predominantly 7⁺, suggests that two to three of the protonatable residues in the 'native state trypsin-Ca⁺⁺' complex are protected in the inhibitor complex and that they are not protonated on gas phase dissociation of the BPTI complexes. The X-ray crystal structure of the trypsin-BPTI complex shows that three lysine residues, lys¹⁷⁶, lys²⁰⁶ and lys²⁰⁸ are in close contact in the complex, but are on the surface in native state trypsin. It is tempting to suggest that it is these three residues which are not protonated on gas phase dissociation of the 'trypsin-Ca⁺⁺-BPTI' complexes and account for the observed difference in the charge state distribution.

Mass Spectrometric Analysis of Noncovalent Protein-Protein Interactions Using ESI-sector MS. J.Wang, M.Busman, D.R.Knapp, Department of Pharmacology, Medical University of South Carolina, Charleston, SC 29425

Introduction. Recently, electrospray ionization(ESI) - mass spectrometry(MS) studies of tetrameric protein complexes have been reported.[1] For the most part such studies have been conducted on quadrupole analyzers. Here we describe ESI-MS experiments utilizing high m/z range, sector-type instrumentation for the observation of such noncovalently bound tetrameric complexes.

Experimental. **MS.** All ESI-MS experiments were carried out on the JEOL HX110/HX110 tandem mass spectrometer (JEOL USA, Peabody, MA) in our laboratory. During acquisition of the spectra the mass spectrometer was operated at an acceleration voltage of 5 kV. Mass spectra were acquired in positive ion mode with a resolution of 1000, 10% valley definition. Typically, 25 scans were averaged to improve the signal to noise ratio. **ESI.** An ESI source manufactured by Analytica of Branford (Branford, CT) and JEOL USA has been recently interfaced to the instrument. The electrospray source is similar to the one described by Cody et al.(2), with the exception of the addition of a ring-electrode immediately at the exit end of the glass inlet capillary. The analyte solution was infused into the ESI source with a syringe pump (Model 22, Harvard Instruments, South Natick, MA) at a flow rate of 0.5-3.0 $\mu\text{L}/\text{min}$. The electrospray needle was held at about 4.3 kV relative to the potential on the front of the inlet capillary, which was normally set at ground. A counter-current flow of N_2 at a flow rate of 100 mL/min was used. Ordinarily, no nebulization gas was used. **Materials.** Proteins were dissolved in an aqueous 10 mM ammonium acetate solution (pH 6.8). Concanavalin A (ConA) and soybean agglutinin (SBA) were purchased from Sigma Chemical Co. (St. Louis, MO) and the human hemoglobin (Hb) was extracted from a fresh sample of human blood.

Results. Molecular weights of the oligomers. Figures 1a-c show ESI mass spectra for three proteins: ConA, SBA and Hb. Each protein was dissolved in aqueous 10 mM ammonium acetate (pH 6.8) at a concentration of about 10 μM . The high quality of these spectra, with a >10:1 signal to noise ratio and baseline separation between adjacent charge states, allows molecular weights to be readily calculated from each spectrum. Molecular weights for the proteins were calculated according to m/z values for the multiply charged ions. The m/z value for each peak was obtained from the leading edge of each peak. Residual solvent and other impurities in the samples, not removed from analyte ions during sampling into the mass spectrometer, broaden the peaks. Molecular weights calculated from the centroid peak m/z values have a large uncertainty.

The heterogeneity of the SBA sample results in the broad peaks observed in the SBA spectra. The observed molecular weight is higher than that calculated from the sequence. It could be speculated that the preservation of the native conformations in the gas phase result in the retention of residual solvent and/or other adducts.

Interestingly, it was observed that oligomer ions, different from those corroborated by other physical methods, were found in the mass spectra for each of these proteins, upon spraying from neutral pH aqueous solution. In the spectra for ConA there are groups of peaks corresponding to dimers, tetramers and hexamers. In the case of Hb and SBA, dimer, tetramer and octamer peaks were observed. In the SBA spectra, only the tetramer peaks were well defined. The hexamer species for ConA and the octamer species for Hb have not been previously reported. No trimers or pentamers were observed in these experiments. In particular, these complexes could be observed at high m/z .

Envelopes representing higher order multimers occur at progressively higher m/z values. The observation of only limited numbers of physiologically "non-relevant" types of complexes (i.e. oligomers not observed in biological systems) leads one to question the degree to which specific and non-specific interactions contribute to the appearance of the larger complexes. It could be suggested that the hexameric and octameric species reflect non-specific dimerizations of multimeric species already existing in the bulk analyte solution. Recently, non-specific noncovalent associations have been implicated in observations of such complexes in studies reported by Standing et al.[3]

Conclusions. ESI-MS spectra for Hb, ConA and SBA, containing peaks reflecting tetrameric species, are presented. In addition, observations of higher order complexes (dimers, trimers, etc.) of the tetrameric proteins are noted. The application of high mass range scans (up to 20,000 m/z) to mass determinations of the higher order complexes is described.

Hydrogen/deuterium exchange (H/D) as well as charge state distribution (CSD) monitored by electrospray ionization mass spectrometry (ESIMS) have been demonstrated to be a powerful and effective new tool for probing conformational properties of proteins in solution. In this work, the influence of single amino acid replacements on the global conformation of cytochrome c₅₅₃, from the sulfate-reducing bacteria *Desulfovibrio vulgaris* Hildenborough (DvH), was studied by monitoring CSD and isotopic exchanges using ESIMS. Site-directed mutagenesis experiments were designed to probe the role of tyrosine 64 in the three-dimensional structure of this cytochrome. This amino acid, which is not conserved in sequences of homologous cytochromes c, was expected to play an important role in the structure/function relationship. Mutants (Tyr64Phe, Tyr64Leu, Tyr64Val, Tyr64Ser, Tyr64Ala) were overexpressed in *Desulfovibrio desulfuricans* G200.

Based on their respective CSD and isotopic exchanges, we have studied the relative stability of mutants of tyrosine 64 under specific conditions of pH and determined the following decreasing order of stability: wild-type > Tyr64Phe = Tyr64Leu > Tyr64Val > Tyr64Ala.

At 0.5% of acetic acid, the CSD of Y64A and Y64V were found to be significantly different from the wild-type or even from the Y64F or the Y64L mutants with the appearance of two distributions with a new CSD centered around the +10 charge peak (Figure 1). This bimodal repartition might be due to the presence of two conformations in solution [1].

We performed further studies to confirm these results using an experimental approach described recently [2]. The deuterated sites of the backbone amide proton were located using peptic cleavages combined with MS. After incubation of the wild-type and mutant proteins in deuterated water, we quenched the exchanges at low pH and low temperature. The proteins were rapidly digested at high enzyme-to-substrate ratio using immobilized pepsin. The resulting peptides were characterized by HPLC coupled with ESIMS and by MALDIMS and Edman degradation. We have identified specific regions for which the H-bonding or solvent accessibility properties were perturbed by the mutations. For each peptide, deuterium incorporation was calculated as a mass increase compared to the theoretical value (Table 1).

Our results presented here showed that the replacement of Tyr64 in the DvH cytochrome c₅₅₃ by Phe, Leu, Val or Ala has a destabilizing effect, increasing with decreasing the side chain volume. The small difference in the behaviour of the wild-type protein and the Y64F and Y64L mutants indicates that the contribution of Tyr64 to the stability of the protein is predominated by hydrophobic interactions rather than by the

hydrogen bond with the Lys8 amide proton. We have shown that regions involved in structural perturbation can be assigned with our fast enzymatic digestion method.

DETHIOBIOTIN SYNTHETASE AND OTHER NON-COVALENT COMPLEXES

Martha M. Vestling, Barbara S. Larsen*, and Murray V. Johnston

*Central Research & Development, The DuPont Company, P. O. Box 80228, Wilmington, DE 19880-0228, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

Non-covalent ligand/receptor, substrate/enzyme, inhibitor/enzyme, and antigen/antibody complexes have important roles in biological systems. The first report using electrospray mass spectrometry to detect non-covalent complexes was published in 1991 (1), and in 1995 a list of non-covalent complexes examined by mass spectrometry was compiled (2). Often the ions for complexes are found along with the ions for the individual components in the same spectrum. We report the observation of dimer ions in the presence of monomer ions for dethiobiotin synthetase and the progress of our search to find for "milder" electrospray conditions to increase the abundance of the dimer ions. Smith *et al.* have found conditions to observe the non-covalent tetramer of chaperone SecB with and without the presence of monomer ions using a heated metal capillary and an extended range quadrupole mass spectrometer (3). Our challenge was and is to find optimal conditions for non-covalent complexes that work on an Analytica of Branford electrospray source with an unheated glass capillary.

Myoglobin in 10 mM ammonium acetate, pH 8 was sprayed with a variety of sheath liquids. Ions for myoglobin with its heme are observed when the sheath liquid is 75:24.5:0.5 (v:v:v) acetonitrile:water:ammonia hydroxide while myoglobin without its heme are found when 75:24.5:0.5 (v:v:v) acetonitrile:water:acetic acid is the sheath. Figure 1.

Dethiobiotin synthetase catalyzes the formation of the ureido ring of dethiobiotin from 7,8-diaminononanoic acid and carbon dioxide in *E. coli* (4, 5). The active form of the enzyme consists of two identical subunits, non-covalently bound. The molecular weight for the subunit (monomer) calculated from the sequence is 24,008 Da. Our electrospray results to date for the dimer are shown in Figure 2.

Correlations Between Protein X-ray Structures and Electrospray Mass Spectra

Klaus Eckart, Janko Verhey, and Joachim Spiess, Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann Rein Str. 3, D-37075 Goettingen, Germany, e-mail: eckart@mail.mpiem.gwdg.de

INTRODUCTION

Investigation of proteins with electrospray ionization (ESI) mass spectrometry (MS) at neutral pH allows the transfer of tightly folded protonated proteins in the gas phase. It was recently reported that conformational changes induced by binding of ligands to an active enzyme such as hexokinase resulted in a decrease of the number of protons deposited by electrospray on this protein (1). This effect was attributed to a reduction of the protein surface size as a result of the ligand induced change in the enzyme conformation. Possibly, this reduction of the proton load may also be controlled by a decrease of the number of basic amino acid side chains accessible at the protein surface. Furthermore, it would be interesting to investigate the relationship between the ligand-induced change of the protein surface area size and the changed proton load of the protein as observed with ESI MS.

METHODS

Calculations on yeast hexokinase and its complex with glucose were based on the coordinates obtained by x-ray crystallography available in the PDB database. Calculations of the Connolly surface (2) were performed on a Silicon Graphics Indigo 2 XZ with the operating system Irix 5.3 and the program package Insight II V.95.0. The following parameters were used: probe radius 0.01 Å; resolution 30 points/Å².

Mass spectral investigations were carried out on a Micromass AutoSpec-T tandem mass spectrometer. Hexokinase (10 µM) in 10 mM ammonium acetate buffer at pH 10 containing different concentrations of various hexoses was delivered with a flow rate of 10 µl/min. The remaining instrument parameters for those investigations were reported recently (3).

RESULTS

Fig. 1: Space filling model of native hexokinase and of its conformation after glucose binding

The conformations of native yeast hexokinase B without ligand (Fig. 1, left) and of yeast hexokinase A linked to glucose (Fig. 1, right) are represented by the space filling models. The space filling models of the different conformations of native yeast hexokinase showed clearly the deep binding cleft which is closed by a 12° movement of the upper towards the lower lobe upon binding of glucose (4) or mannose. The Connolly surface areas of the free hexokinase and of the hexokinase glucose complex were calculated to be $A=40840 \text{ Å}^2$ and $A=38230 \text{ Å}^2$, respectively. By glucose binding the Connolly surface area was reduced by 2610 Å^2 , which corresponds to a reduction of 6.4 % of the original Connolly surface area.

The addition of 0.6 mM mannose (Fig. 2) or 2.5 mM glucose resulted in a reduction of the proton load of 2 % and 0.8 %, respectively, as was determined by the charge differences of

$\Delta z=0.3$ for and $\Delta z=0.12$ for mannose and glucose, respectively. Control experiments were performed with the hexose galactose (Fig. 2), and the pentoses arabinose and xylose.

Fig. 2: The effect of mannose (left) and galactose (right) to hexokinase

DISCUSSION

The greater reduction of the Connolly surface area in comparison with the proton load is interpreted as a partial fragmentation of the extremely labile complexes of yeast hexokinase with mannose ($K_M=5 \times 10^{-5} \text{ M}$) or glucose ($K_M=10^{-4} \text{ M}$).

This approach was also considered for investigations of the avidin-biotin complex. Unfortunately, avidin and streptavidin crystallized as dimeric and not as tetrameric complexes and therefore no x-ray crystallography data for the tetrameric avidin or streptavidin complexes is available. The reduction by 0.5 % of the Connolly surface area of the dimeric deglycosylated avidin complex by binding of biotin points into the same direction in agreement with the corresponding 1.2 % shift in charge state of tetrameric streptavidin, as calculated on the basis of recently published data (3). A quantitative comparison of these data was not possible because of the differences in the systems.

CONCLUSION

The calculated Connolly surface area and the proton load of yeast hexokinase as determined by ESI were reduced by ligand binding. The fact that the change of the Connolly surface area was greater than the change of the proton load may be explained as a partial dissociation of the extremely labile non-covalent complexes during the ionization process.

Detection of Peptide Aggregation by Pulsed-Field Gradient NMR and ESI-MS

S.L. Mansfield, T.D. Williams, D.A. Jayawickrama, L. Orfi, and C.K. Larive
University of Kansas, Department of Chemistry, Lawrence, KS 66045

Introduction: We are investigating the role of hydrophobic interactions in the aggregation of a family of peptides based on the b-amyloid peptide fragment b(12-28), VHHQKLIVFFAEDVGSNK (FF). Studies have shown this fragment undergoes amyloid fibril formation in vitro.^{1,2} We have reported the NOESY spectrum of FF³, which includes unusual NOE cross peaks in the aromatic region and suggests the formation of hydrophobic aggregates in the region of the sequence LVFFA.³ We have investigated the aggregation of the native FF peptide, and two substitutional analogs in which F19 and/or F20 have been replaced with glycine: GG and FG. Diffusion coefficients of the peptides are dependent on the hydrodynamic radius, which increases when aggregation occurs, and can be measured using pulsed-field gradient (PFG) NMR spectroscopy. Electrospray Mass Spectrometry (ESI-MS) has been used to study the noncovalent interaction of many classes of compounds, including drug/receptors.⁶ Two ESI experiments demonstrated MS measurable differences consistent with known binding affinity, the relative abundance of cluster ions and fragmentation as a function of collision energy in CAD.⁶ Peptide solutions characterized by NMR have been subjected to ESI-MS for a comparison of solution to ESI behavior.

Experimental: Diffusion Coefficient Measurements The peptides, synthesized at KSU Biotechnology Facility, were prepared in D₂O with the pD adjusted to approximately 2.9. A capillary containing TSP was used as both an external chemical shift reference and a concentration standard. Diffusion coefficients were measured with a Bruker AM500 spectrometer modified to accommodate PFG experiments, using the bipolar LED pulse sequence.⁴ The resonance intensity, *I*, is related to diffusion coefficient, *D*, by the relationship: $I = I_0 \exp(-DX)$, where *I*₀ is the intensity of the signal in the absence of a gradient pulse, and *X* is instrumental parameters. Diffusion coefficients were extracted from the NMR data using the Diffusion Ordered Spectroscopy (DOSY) methodology.⁵

Mass Spectrometry Mass spectra were obtained on an AUTOSPEC-Q (VG Analytical Ltd.) equipped with a "MARK III" ESI source. ESI spectra were acquired at 1:500 and 1:6000 (FF peptide) resolution. Peptides were dissolved in and sprayed from 80 mM HOAc, pH 4. A 34 gauge SS needle, was operated at 4 kV above the counter electrode and N₂ sheath gas. The instrument was operated at 4 kV and the ESI source elements optimized for maximum signal of the 2M3H³⁺ ion. CAD experiments were performed with precursor ions attenuated with argon in the collision quadrupole. The gas density was set on the low pressure side of a pressure maximum observed for the M2H²⁺ ion at 200 eV collision energy. This corresponded to 30% precursor attenuation. The analyzer quadrupole resolution was "wide-open". The collision energy ramp was 0 to 400 eV in 10 eV steps with MCA acquisition of 8 scans, 4 sec/scan at each step.

Results and Discussion: Concentration studies. To estimate the contribution of hydrophobic interactions to the aggregation of FF, we synthesized two analogs which substitutes G's for the two F's at residues 19 and 20, GG and FG. The diffusion coefficients of all peptides were measured in as a function of concentration. These results are depicted graphically in Figure 1. Because the diffusion coefficient of FF could not be measured at infinite dilution, the synthesis of a non-aggregating analog was critical to the analysis. The diffusion coefficient of GG remains constant throughout the concentration range and can be extrapolated to give a good estimate of the monomeric diffusion coefficient. In contrast, the diffusion coefficient of the FF decreases with increasing concentration, indicating aggregation of this peptide.

Mass Spectrometry. FF and GG peptide solutions produced cluster ions of 2M3H³⁺ and 3M4H⁴⁺. Clusters redundant with monomer (ie. M3H³⁺ vs 2M6H⁶⁺) not detected at high resolution. Peptide solutions of 0.3 to 2.6 mM, produced cluster ions that demonstrated a modest correlation with concentration (Figure 2). At a given concentration, the FF analog produced more abundant clusters, consistent with solution aggregation. CAD experiments were performed to determine if product ions, as a function of collision energy, could be used to differentiate aggregation strength. FF produces less fragmentation at a given collision energy than GG. The FG analog was not distinguishable from GG (Figure 3).

Modeling FF Solution Aggregation. The diffusion coefficients measured for FF as a function of concentration were fit to a mathematical model based on a monomer/dimer equilibrium which uses the following mass balance equations: $C_{tot} = C_m + 2C_d$ and $1 = f_m + f_d$ where C_{tot} , C_m , and C_d are the concentrations of the total, monomer, and dimer, respectively, and f_m and f_d are the fractions of monomer and dimer, respectively. The measured diffusion coefficient, D_{obs} , can be related to the fractional concentrations of the monomer, f_m , and dimer, f_d , and their respective diffusion coefficients, D_m and D_d , using the following equation: $D_{obs} = f_m D_m + f_d D_d$.

NLSQ Fitting. A monomer/dimer model based on the following equation: $f_d = [2K_{dimer}C_{tot} + 1 - (4K_{dimer}C_{tot} + 1)^{0.5}] / K_{dimer}C_{tot}$, where K_{dimer} is the equilibrium constant for the formation of the dimer, was fit to the data using the non-linear least squares method as shown in Figure 4. The generally good fit of this model to our data indicates that predominant aggregate species is the dimer. The parameters calculated from the NLSQ fit of this model to the data are $K_{dimer} = 295 \pm 40 \text{ LM}^{-1}$ and $D_d = 1.91 \pm 0.04 \times 10^{-6} \text{ cm}^2/\text{sec}$.

Conclusions: 1) The solution monomer/dimer aggregation of FF at low pH is driven primarily by hydrophobic interaction, similar interaction was not detectable for the GG analog.

2) The diffusion coefficients of FF vary with concentration in a manner that is consistent with a monomer/dimer aggregation equilibrium. The GG peptide does not aggregate in solution. However, the diffusion coefficients of the FG peptide indicate that this peptide has intermediate aggregation behavior (less than FF but more than GG).

3) ESI MS analysis of peptide solutions produced data suggesting the FF peptide forms stronger aggregates than the GG analog, however, both peptides clustered during ESI. The intermediate FG clusters were not distinguishable from GG in degree of fragmentation with collision energy.

Cu(II)-Peptide Complexes Studied by Mass Spectrometry and Capillary Electrophoresis

Siqing Song; Alison Z. Hu; Pavel V. Bondarenko; Ingrid Cruzado; Ronald D. Macfarlane
Department of Chemistry, Texas A&M University, College Station, TX 77843

In order to better understand the interaction of large peptides and proteins with transition metal ions, amino acids (Arg and His), tripeptides with Arg or His residue, and angiotensin II (AngII) were studied to characterize the role of individual residue and the termini. Biomolecules were mixed with Cu(II) solution at 1:1 ratio, and the mixture pH was adjusted to pH 10 by trimethylamine.

The Cu(II) complex ions with AAs and tripeptides, such as MCu^+ and $(MCu-H)^+$ ions, were detected using a ^{252}Cf -plasma desorption mass spectrometer (PDMS). The observation of the Cu^+ ion peak suggests that gas phase reduction takes place in the mass spectrometer. The binding abilities of Arg and His were compared. Table 1 listed the MCu^+ and MH^+ ion yields (calculated as the ratio of integrated ion intensity relative to that of H^+) for biomolecule plus Cu(II) samples. The higher MCu^+/MH^+ ratio for His and Gly-Gly-His indicating a higher binding strength of His residue than the Arg residue. Although the ion yields for pGlu-His-Gly amide are much higher than the corresponding ion yields for pGlu-His-Gly, the relative ratio of MCu^+/MH^+ is almost the same. The C-terminal modification doesn't affect the binding strength of the tripeptide. Figure 1 shows the fragment ion region for the NLE-Arg-Phe amide plus Cu(II) sample. The appearance of C-terminal fragment ions attached with a Cu(II) ion (x_1Cu^+ , y_1Cu^+ , z_1Cu^+) indicates that the binding of the Cu(II) ion involves Arg and Phe.

Table 1. Ion yields for biomolecule plus Cu(II) samples

Sample	MCu^+/MH^+
Arg	0.30/0.30 = 1
His	0.18/0.016 = 10
Gly-Gly-Arg	0.09/0.08 = 1
Gly-Gly-His	0.16/0.01 = 16
pGlu-His-Gly	0.07/0.03 = 2.3
pGlu-His-Gly amide	0.29/0.11 = 2.6

Figure 1. Fragment ion regions of NLE-Arg-Phe amide with (a) and without (b) Cu(II).

Figure 2 shows the PDMS and electrospray ionization (ESI-MS) spectra of AngII plus Cu(II). Complex ion peaks and fragment ion peaks attached with Cu(II) are present in the spectra. The fragment ion a_1Cu^+ , which has the His as the last residue, has high intensities in both spectra, again showing the strong bond between Cu(II) and the His residue.

Figure 2. Positive ion PDMS (A) and ESI-MS (B) spectra of AngII plus Cu(II) samples.

The feasibility of using capillary electrophoresis (CE) to analyze the Cu(II) complex ions was studied using a Beckman PACE 5510 system (Beckman Instruments Inc., Fullerton, CA). The running buffer is 50 mM 3-(cyclohexylamino)-1-propanesulfonic acid (CAPS) (pH 10 by tetrabutylammonium hydroxide). Table 2 compares the electrophoretic mobility of biomolecules and biomolecules plus Cu(II). His and NLE-Arg-Phe amide show large electrophoretic mobility changes after adding Cu(II) samples. Mobility change for other samples are quite small, probably reflects the equilibrium between the free biomolecules and the complexes

Table 2. Electrophoretic mobilities (μ^{eff}) of amino acids, tripeptides and their Cu(II) complexes

Sample	μ^{eff} (w/o Cu(II)) ($\times 10^{-5} \text{ cm}^2/\text{Vs}$)	μ^{eff} (w/ Cu(II)) ($\times 10^{-5} \text{ cm}^2/\text{Vs}$)
Arg (0)*	+2.4	0
His (-1)*	-18.74	-12
Gly-Gly-Arg (0)*	0	-1.6
Gly-Gly-His (-1)*	-15.36	-14.57
pGlu-His-Gly (-1)*	-14.02	-13.62
pGlu-His-Gly amide (0)*	0	-1.2
NLE-Arg-Phe amide (+1)*	+5.08	0

ESI-MS and MALDI-MS offer high sensitivity and high molecular weight measurement power, enabling the direct analysis of biomolecules with a minimum amount sample preparation. In this study, ESI-MS (home made) [4] and HP G2025A MALDI-TOF system (Hewlett-Packard Co., Palo Alto, CA) were utilized to analyze both apolipoproteins and whole lipoprotein particles. Lipoproteins were isolated from human plasma by ultracentrifugation and purified by desalting. Apolipoproteins were obtained by the delipidation of lipoproteins using the methanol-ether method [5]. Using sinapinic acid or α -cyano-4-hydroxycinnamic acid as the matrix, MALDI mass spectra of delipidated HDL samples show the ion peaks corresponding to (A-I)⁺, (A-I)²⁺, (A-I)³⁺, (A-II)⁺, (A-II)²⁺, (C-II)¹⁺, (C-II)²⁺, (C-II)³⁺, and (C-I)⁺. The negative ion spectrum has similar ion pattern. For delipidated HDL samples, a series of multiple charged (A-I)ⁿ⁺ ion peaks are present in the ESI mass spectra. The ionization of other apolipoproteins in the delipidated HDL samples, such as apo A-II and C's, are suppressed. Delipidated VLDL sample was also analyzed by MALDI, and apoC's were detected as shown in Figure 1. Due to its high sensitivity, MALDI technique has also been successfully used to analyze delipidated lipoprotein HPLC fractions for apolipoprotein identification.

The choice of running electrolyte was limited to 10% acetic acid at pH=2.3, or 10 mM ammonium acetate buffers at various pH values. The use of the acetic acid as an electrolyte allowed for good separations due to a low electro-osmotic flow (EOF) and increased sensitivity due to a low background signal at 214 nm for on-column UV detection. Use of low pH electrolytes was found to reduce the interaction of the digest products with the Si capillary walls. Fraction collection at the cathodic end of the CE capillary was carried out using Eppendorf tubes which were filled with 20 μ L of water.

In conclusion it was found that each method of separation and analysis possessed favourable attributes and that a combination of HPLC and CE coupled with off-line MS produced initial information with regards to the structure of human α -1 acid glycoprotein.

O-linked Glycosylation Site Identification by Pronase Digestion/MALDI-MS

Yi Yang, Todd Levin, Troy Austin, and Ron Orlando
Complex Carbohydrate Research Center and Department of Chemistry,
University of Georgia, Athens GA 30602

O-linked glycosylation is one of the most difficult post-translational modifications to locate. There is no known consensus sequence to predict *O*-glycosylation sites, and consequently any serine or threonine residue in a protein is capable of being *O*-glycosylated. Current mass spectrometric techniques have not been able to perform this analysis on a routine basis. In tandem mass spectrometry, the fragment ions that arise from peptide backbone cleavage have lost the carbohydrate chain. This prohibits the modified residue from being identified. Techniques involving carboxypeptidase or aminopeptidase digestion coupled with MS analysis can not determine *O*-linked glycosylation sites, since these enzymes are sterically blocked by the carbohydrate chain, and can not proceed past the modified residue.

We have developed a strategy based on pronase digestion coupled with MALDI-MS analysis of the digestion products. The *O*-linked glycopeptide is digested with pronase, which cleaves the peptide backbone in a random fashion. This produces a series of peptide/glycopeptide ions that permit the *O*-glycosylation site to be identified.

To demonstrate this methodology, an *O*-linked glycopeptide was isolated from the tryptic digest of Heparinase I by HPLC. It has a amino acid sequence of Val-Asn-Val-Gln-Ala-Asp-Ser-Ala-Lys. Comparing the experimental molecular weight obtained by ESI-MS to that deduced from cDNA sequence shows that the carbohydrate chain attached to this Heparinase I glycopeptide has a molecular weight of 1156. 10-20 picomoles of this glycopeptide was digested at room temperature with 2 μ g of pronase in 2 μ L buffer (50 mM NH_4HCO_3 , pH=8.0). 0.5 μ L aliquots of the digest were removed after digesting for 5, 10 and 15 minutes. These aliquots were immediately mixed with MALDI matrix and vacuum dried to stop the digestion. This was followed by MALDI analysis (Figure 1). These results clearly locate the site of *O*-glycosylation (Figure 2).

This method provides a rapid and sensitive procedure to identify the sites of *O*-glycosylation. Furthermore, our approach is applicable for determining the sites of other post-translational modifications, such as *N*-glycosylation, phosphorylation and sulfation. The primary advantages of our pronase digestion/MALDI-TOF approach towards *O*-linked glycosylation site identification is its speed (less than 30 minutes) and sensitivity (10-20 picomoles).

Analysis of Isoforms of Glycoproteins by CE-ESI MS

B. Yeung*, K. Yim and J. Vath

Biopharmaceutical Characterization and Analysis

Genetics Institute, Inc., Andover, MA 01810

INTRODUCTION

Intact glycoproteins were analyzed by on-line CE-ESI MS, using a low ionic strength acidic buffer and polyacrylamide coated capillary. Ribonuclease B (RNase B) was first examined as a model protein, then the method was applied to a recombinant glycoprotein, human bone morphogenetic protein 2 (rhBMP-2). Both proteins possessed carbohydrate structures of the N-linked high mannose type, and additionally, rhBMP-2 also contained three isoforms. Using CE-MS, the microheterogeneity of the proteins was observed, and the method was demonstrated to be a valuable tool for glycoprotein analysis. Moreover, evidence of protein aggregation in the reduced and alkylated rhBMP-2 was detected using CE-MS.

EXPERIMENTAL SECTION

CE-UV was performed using a BioFocus 2000 instrument (BioRad).

CE-ESI MS was carried out using a Spellman 1000R HV supply coupled to a VG Platform instrument (Micromass).

CE capillary was obtained from BioRad (LPA coated); dimensions = 50 μ m*65-70cm.

CE buffer = 50mM β Alanine/acetic acid (pH 3.5)

CE-MS liquid sheath = 75/25/0.1 (v/v/v) MeOH/H₂O/formic acid @ 3 μ L/min

CE running voltage: 360V/cm in CE-UV; 315-357V/cm in CE-MS

Injection: pressure in CE-UV; hydrodynamic in CE-MS (15cm of height)

Proteins: RNase B (X11-B) from Sigma; rhBMP-2 from Genetics Institute, Inc.

SUMMARY OF DATA

Fig. 1(a)

TIC of a CE-MS analysis of the reduced and alkylated rhBMP-2.

Both of these runs were carried out 17-19 days after initial sample preparation.

Based on migration time comparison between the two systems, Peaks I, II, III and IV in Fig. 1(a) are correlated to Peaks 2, 3, 4 and 1 in Fig. 1(b), respectively.

Peak identification by MS is shown in Fig. 2.

Fig. 1(b)

CE-UV profile of the same sample as in Fig. 1(a).

Fig. 2

Summed mass spectra from Peaks I-IV of the TIC in Fig. 1(a). I=extended form;

II=Gln form; III=pyroglu form;

IV=a mixture of Gln and pyroglu forms.

- Intact glycoproteins and their neutral glycan structures may be analyzed by CE-MS using low ionic strength acidic buffer without the need for glycan release or derivatization.
- Isoforms of rhBMP-2 have been identified by CE-MS. Based on MS data on Peak IV, as well as the behavior of Peak 1 in CE-UV, this peak has been deduced to be a protein aggregate composed of the Gln and pyroglu forms. The formation of this aggregate appears to be both time and sample concentration dependent.
- Despite the requirement by CE-MS for sample overloading, the microheterogeneity of the protein can still be observed in the RIC of each glycoform series. This information may be used to verify the heterogeneity observed for the protein by CE-UV.

Fig. 3

CE-UV analysis of rhBMP-2 performed on different days after initial sample preparation. Same peak identification as in the caption of Fig. 1.

Fig. 4

RIC of Peak I from Fig. 1(a), plotted using the most intense ion in each glycoform series, demonstrating the detection of microheterogeneity by CE-ESI MS.

Structural Characterization of the Glycoprotein α -N-Acetylgalactosaminidase

Alex Zhu[‡], Jack Goldstein[‡], James A. Carroll*, and Ronald C. Beavis
The Skirball Institute of Biomolecular Medicine
New York University Medical Center
[‡] New York Blood Center

Chicken liver α -N-acetylgalactosaminidase (α AGA) specifically removes terminally α -linked α -N-acetylgalactosamine from oligosaccharide chains on the surface of group A erythrocytes¹. This activity may be clinically useful for the conversion of blood group A to O. An active form of the enzyme can be produced recombinantly in yeast (*Pichia pastoris*) using chicken liver cDNA. However, the primary sequence must be verified and post-translational modifications of both the native and recombinant forms must be characterized before the enzyme can be used for transfusion therapy.

The primary sequence deduced from DNA indicates the presence of three potential sites for N-glycosylation of the type NxT. The glycosylation patterns for two of these three sites were observed in the MALDI mass spectra of the protease digests for both the native and recombinant forms. The top spectrum of figure 1 shows the V8 protease digest of the native form of α AGA. The peptide produced contains both of the potentially glycosylated Asn residues. The pattern suggests the presence of one N-acetylhexosamine at each Asn, with zero or one deoxyhexose present at each site. Further glycosylation is indicated as well, and is consistent with the pattern shown in scheme 1 below:

Scheme 1.

The bottom spectrum of figure 1 shows the glycosylation pattern present in the tryptic digest of recombinant α AGA. This pattern is consistent with a high mannose core structure which has been previously observed in glycoproteins expressed in yeast,² illustrated in scheme 2 below:

Scheme 2.

There is no evidence in these spectra as to the type of glycosylation present on the third potential glycosylation site in the protein.

2. Eppley Institute for Research in Cancer and Allied Disease, University of Nebraska-Medical Center

Mucins are glycoproteins that serve as lubricants in the ducts of many organs. Mucin-type glycosylation is an important post-translational modification of many proteins. The O-glycosylation of mucins by different normal epithelial tissues is critical to their function in the tissues (1). Alterations in the O-glycosylation patterns of mucins may play a role in the pathogenesis of several diseases in which there is evidence for altered mucin structure, including chronic inflammatory disorders. The altered glycosylation of mucins derived from tumors is believed to be a consequence of either truncation of oligosaccharide side chains or differences in the points of attachment of the oligosaccharide side chains to the core positions (1). Thus, it is important to determine both the extent of glycosylation and the points of attachment of oligosaccharide side chains to the protein backbone in mucins.

An LC/ESI-MS method was used to determine the extent of glycosylation of peptides. The LC/MS experiments were carried out with a Fisons VG Platform mass spectrometer for the analysis of products resulting from *in vitro* glycosylation of MUC1 epitopes using expressed forms of recombinant GalNAc transferases. The microbore HPLC was necessary to eliminate the salts and other interferences from the samples and to increase the sensitivity of detection by concentrating the glycosylated peptides. The ESI-MS spectrum shows glycosylation at a single serine or threonine residue of glycosylated AHGVTAPDTR peptide. The glycosylation is detected by the presence of a glycopeptide of 203 Da greater molecular weight than its corresponding native peptide. The addition of both one and two GalNAc was observed for RPAPGSTAPPA peptide. Multiple glycosylations were observed for larger mucin peptides. A maximum of 3, 6 and 10 GalNAc adducts was seen for the glycosylated MUC1 20-mer, 40-mer, and 80-mer peptides, respectively. **Figure 1** shows the transformed ESI-MS spectra of the MUC1 80-mer peptide, which was accomplished by using the maximum entropy processing in MassLynx. The molecular ion peak of the native MUC1 80-mer peptide was not observed, indicating that all of the peptide had at least two glycosylations take place.

Tandem mass spectrometry was used to identify the site of the glycosylation. Although the MS/MS spectra indicated some evidences on the site of the glycosylation, the position of the GalNAc addition could not be conclusively determined from the MS/MS data. The glycopeptide bond for GalNAc is quite labile and GalNAc is often eliminated before any peptide backbone cleavages occur. However, the glycosylation site of the O-GalNAc modified glycopeptides can be identified by using methods of β -elimination reaction and tandem mass spectrometry. β -Elimination specially alters the glycosylamino acid residue so that it can be distinguished as the site of glycosylation by tandem mass spectrometry (2,3). ESI-MS analysis of β -elimination products of glycosylated AHGVTAPDTR (*m/z* 1110) and RPAPGSTAPPA (*m/z* 1020) peptides showed protonated molecular ions of *m/z* 1093 and *m/z* 1003, respectively, indicating the successful removal of O-GalNAc followed by formation of a double bond. MS/MS spectra of the native RPAPGSTAPPA peptide and the β -elimination product of the glycosylated peptide are shown in **Figure 2**. The MS/MS spectra are dominated by N-terminal fragment ions due to the presence of Arg at the N-terminus. The series of ions in the two spectra have the same mass through amino acid 6 (see a, b and c series). Starting from position 7, however, an 18 Da mass shift is observed, indicating the original site of glycosylation was the threonine at position 7. The comparison of the CID-MS/MS spectra of both the native peptide and the glycosylated peptide after removal of the O-GalNAc by the β -elimination clearly provides information of the site of glycosylation.

Protein Glycosylation Analysis Using LC/ESI/MSⁿ on an Ion Trap Mass Spectrometer

Matt Sweeney, Jonathan Josephs, David Gale, Mark Sanders, and Tanuja Chaudhary
Finnigan MAT, San Jose, CA 95134

The high sensitivity of ESI/MS has led to this being one of the fastest growing techniques for the analysis of protein glycosylation. The recognition of the involvement of glycosylation in a wide spectrum of biological systems has meant that there is a growing need for affordable, simple, fast, and accurate techniques for the characterization of these post-translational modifications. ESI meets most of these requirements and with the recent introduction of new, more powerful, and easier to use affordable instruments this technique will lead to new discoveries in structure and function in this historically difficult realm of biochemistry. The LCQ is a dedicated LC/MSⁿ instrument which utilizes an ion-trap for mass analysis. The new ion trap offers improved MS/MS spectra over conventional linear quad instruments while simultaneously offering a much smaller (bench-top) physical size as well simplification of operation over prior technologies.

Work of the groups of Henion, Carr, Burlingame, and the Rheinholds (among many others) has led to the acceptance of ESI as one of the foremost tools for glycosylation analysis. This is because of the high sensitivity (low pico-mole or better) and the rich structural information obtainable. Bovine Fetuin is a well characterized glycoprotein which provides a means for comparing with previously available instrumentation and investigating the utility of MSⁿ in this field.

This poster demonstrates detection of glycosylations in tryptic digests by inducing fragmentations in the ion source and detecting ions characteristic of the N-linked carbohydrates. Full-scan MS/MS of glycopeptides in various charge states also produce a marker ion (656) which can aid in interpreting spectra. MS/MS/MS of the ions producing 657 (NeuAcHexHexNAc) results in the 204 (HexNAc), 292 (NeuAc), 366 (HexHexNAc) ion series characteristic of carbohydrate moieties comprising NeuAcHexHexNAc.

Methods

Bovine Fetuin was carboxymethylated and trypsinized (courtesy of Dr. George Hilliard, SKB Pharmaceuticals). Aliquots of 1200pmoles were reconstituted in 400ul and then portions were diluted to 300fm/ul prior to injection. A Michrom BioResources UMA LC was used with a 1x150mm Reliasil 300A C18 at 40-50ul/min ACN:H2O 0.1% TFA for LC/MS. A trap cartridge was used to remove urea and ammonium bicarbonate prior to injection. A Finnigan LCQ with an ESI source was used for all work. The instrument was operated as follows; sheath gas 85psi, aux gas 15 units, capillary temp. 200C, spray voltage 3.9 kV. The source CID was induced by off-setting the tube lens at the capillary exit by 70 Volts and adding 20 Volts to the capillary voltage.

Mass Spectrometric Characterization of Recombinant Human Factor VIII. ¹Besman, M.J., ²Medzhradszky, K.F., ²Maltby, D. and ²Burlingame, A.L. ¹Baxter Healthcare, Biotech Group, Hyland Division and ²University of California, San Francisco, Department of Pharmaceutical Chemistry.

The analytical characterization of therapeutic recombinant glycoproteins has presented significant technical challenges for the protein biochemist, particularly with respect to the elucidation of glycopeptide structure and microheterogeneity. Recombinate™, a recombinant human Factor VIII product used in the treatment of hemophilia A, was investigated from the standpoint of glycosylation microheterogeneity. Factor VIII, the cofactor for the activation of Factor X by Factor IXa in the coagulation cascade, is a protein of 2351 amino acids. Along with removal of a leader peptide, the nascent polypeptide is modified post-translationally at numerous sites by glycosylation and sulfation, and is processed proteolytically to give rise to a heterodimer of heavy and light chains which remain associated through chelation by divalent metal ion. The recombinant human Factor VIII (rhFVIII) product used in these studies was produced in Chinese hamster ovary cells under carefully controlled manufacturing conditions. Since glycosylation of recombinant protein therapeutics is a sensitive measure of production consistency, and is relevant to pharmacokinetics and immunogenicity, we have undertaken a structural investigation of rhFVIII glycopeptides by mass spectrometry.

The development of powerful mass spectrometric methods for the analysis of complex biopolymers has presented unique opportunities for the investigation of Factor VIII structure and function. In this report, we present the use of on-line LC-ES/MS in the confirmation of primary structure of this complex glycoprotein, as well as the structural elucidation of N-linked and Q-linked glycopeptides.

Recombinant human Factor VIII was incubated with thrombin, and the resultant rhFVIIIa polypeptides were isolated to homogeneity using reversed-phase HPLC. Each rhFVIIIa polypeptide was incubated with trypsin, and the peptide mixtures were resolved by RP-HPLC. On-line LC-ES/MS analysis of peptide mixtures was accomplished using an electrospray ionization source interfaced to a VG AutoSpec mass analyzer with EBE geometry. In-source fragmentation was enhanced through the application of suitable cone voltage, allowing for detection of ions characteristic of glycopeptides (e.g. m/z at 204 and 292 amu)

Peptide ions were assigned to the primary structure of rhFVIII where possible, allowing confirmation of 86% of the 73 kD polypeptide and 73% of the B-domain. Glycopeptides were identified through the presence of diagnostic fragment ions generated in the source; through the summing of appropriate scans, glycopeptide ions were identified by virtue of microheterogeneous structures with similar retention times

The TIC (Total Ion Current) elution profile for the tryptic digest of the 73 kD polypeptide is shown in Figure 1, as well as the reconstructed ion chromatograms for 204 amu (HexNAc) and 292 amu (Neu5Ac). The diagnostic ion elution profile for the 73 kD polypeptide was useful in the interpretation of the glycopeptides present, and could readily distinguish between the high-mannose and sialylated bi-antennary structures.

Three mass spectra exhibiting diagnostic fragment ions were analyzed for the presence of putative glycopeptides. The mass spectrum for the first glycopeptide-containing fraction exhibited diagnostic carbohydrate ions at m/z 204 amu (HexNAc), 274 and 292 amu (Neu5Ac), 366 amu (Hex-HexNAc), and 657 amu (Neu5Ac-Hex-HexNAc). Doubly-charged ions reflected the bi-antennary glycopeptides' structural differences due to microheterogeneity and fragmentation. The reconstructed ion chromatogram for m/z 292 amu (Fig. 1) indicated the absence of Neu5Ac in the second glycopeptide-containing fraction. Mass differences between the doubly-charged ions corresponded to hexose residues, suggesting the presence of a high-mannose glycopeptide. Low cone voltage data confirmed the presence of the Man₅₋₈ glycoforms. The third fraction, also containing a diagnostic ion at m/z 204 amu, indicated that the use of high cone voltage for the detection of glycopeptides also induced peptide fragmentation, in this case

resulting from peptide bond cleavage between the Asn and the penultimate Gly residues, with charge retention on the C-terminus (y₂)

The TIC (Total Ion Current) elution profile for the tryptic digest of the B-domain is shown in Figure 2, as well as the reconstructed ion chromatograms for 204 amu (HexNAc) and 292 amu (Neu5Ac). The B-domain elution profiles for the 204 amu and 292 amu ions were highly complex, and therefore of little utility in the identification of glycopeptides. However, glycopeptide ions with the same charge state were identified typically from the characteristic mass differences mirroring the microheterogeneity in carbohydrate structure corresponding to Neu5Ac residues, Neu5Ac-Hex-HexNAc or Hex-HexNAc structures. The structures of numerous N-linked and Q-linked glycopeptides were elucidated from this data.

The data presented herein indicate that the primary structure of Factor VIII, a heterogeneous glycoprotein, can be confirmed to a significant extent through LC-ES/MS analysis of peptide maps. The AutoSpec mass analyzer, with EBE geometry, produced sufficient mass resolution that charge assignment of multiply-charged ions was an infrequent complication in the interpretation of the data. Analysis of the 73 kD polypeptide indicate that in-source fragmentation to produce ions diagnostic of monosaccharides was generally useful in the identification of glycopeptides. However, for glycoproteins such as the B-domain which are extensively glycosylated (i.e. 20 potential N-linked glycosylation sites), detection of these ions may be of little utility; in these instances, characteristic mass differences arising from glycosylation microheterogeneity were of primary significance in the identification and elucidation of glycopeptide structures.

ESI-MS and MALDI-TOF Analysis of Zinc Binding by HIV-1 nc p7 Peptide

Sumpter, Terry; Sowder, Raymond, II, Kane, Bradley; Henderson, Louis
SAIC-Frederick, NCI-Frederick Cancer Research and Development Center, Frederick, MD
21702

The nucleocapsid protein p7 of the human immunodeficiency retrovirus contains two CCHC-type zinc binding "fingers". These regions are highly conserved structures, with the generalized sequence -C-X2-C-X4-H-X4-C-. Each finger is capable of binding a single zinc ion. These finger regions are nucleic acid binding domains which have been shown to be essential for viral replication and infectivity, making them attractive targets for therapeutic agents. It is therefore essential to have methods with which to evaluate the zinc binding status of the p7 protein as various modifications and manipulations are performed.

The purpose of this work is to determine the utility of MALDI-TOF for the observation of specific, non-covalent Zn^{2+} ion bonding by the p7 protein. Among the criteria used for evaluating this approach are the ability to both observe the bonding stoichiometry as well as the preservation of solution bonding stoichiometry. Results from ESI analysis of the same system are used as controls with which to compare the MALDI-TOF results. ESI is now well established in examining these types of interactions and has been previously used in this system.

Linear MALDI-TOF data were acquired using a Bruker Reflex II instrument with a 145 cm flight path. A variety of matrices were used (see below). A Nd YAG laser was used to irradiate the dried matrix/analyte mixtures at 355 nm. The source accelerating voltage was 28.5 kV. ESI data were acquired using a Vestec ESI interface in combination with a Finnigan MAT 4610 single quadrupole. Infusion flow rates were 1-2 $\mu\text{L}/\text{min}$ using 20 mM ammonium acetate at pH 6.8. The needle voltage was typically 2.20 kV, and the desolvation chamber temperature was 230 C. Data acquisition and reduction employed a Teknivent Vector system. The cloned HIV-1 nc p7 was released from a fusion protein by proteolysis with factor Xa and purified as apo-p7 by RP-HPLC. Two equivalents of ZnCl_2 were added to the purified fraction, followed by lyophilization.

When care was taken to maintain nearly neutral pH during reconstitution and ESI analysis, only the p7 containing two zinc ions was observed. This is also believed to be the physiologically active form. Under acidic conditions (pH ca. 2), only the apo-p7 is observed. When slightly acidic conditions are employed (pH ca. 5), a mixture of zinc-containing p7 species is observed, ranging from the apo to 2 or 3 zinc ions per p7. In contrast, a mixture of zinc-binding stoichiometries was always observed under MALDI-TOF conditions. Various matrix preparations were tried, including:

- (1) Saturated α -cyano-4-hydroxycinnamic acid (CCA) in 1.0 M ammonium bicarbonate/10% acetonitrile
- (2) Saturated 2,4,6-trihydroxyacetophenone (THA) in 10% acetonitrile
- (3) Saturated THA in water adjusted to pH 7 with ammonium hydroxide
- (4) 2,5-Dihydroxybenzoic acid in 1.0 M ammonium bicarbonate/10% acetonitrile
- (5) Solutions of (1)-(4) above containing 20 mM fucose

In some cases, the individual zinc containing species were sufficiently well resolved to be observed (Figure 1). In other cases, a broad peak centroided about the bis-zinc form was

observed, with the other species nearly hidden (Figure 2). It thus appears that while MALDI-TOF for this system can provide qualitative yes-or-no type information regarding the binding of zinc, stoichiometric information and other subtleties are better addressed by ESI mass spectrometry.

Structure determination and functional characterisation of succinylated Porin from *Rhodobacter capsulatus*

V. Schnaible¹, M. O. Glocker¹, M. Blüggel¹, M. Przybylski¹, U. Nestel², K. Diederichs², W. Welte²

¹ Universität Konstanz, Fakultät f. Chemie, P.O. Box 5560 M 731, 78434 Konstanz, FRG

² Universität Konstanz, Fakultät f. Biologie, P.O. Box 5560, 78434 Konstanz, FRG

The role of charges near the pore mouth has been discussed in theoretical work about ion channels¹. To introduce new negative charges in a channel protein, amino groups of Porin from *Rhodobacter capsulatus* 37b4 were succinylated with succinic anhydride. The extents and the sites of succinylations were determined by mass spectrometry. Molecular weight and peptide mapping analyses using matrix assisted laser desorption mass spectrometry identified succinylation of three lysine ϵ -amino groups (K-46, K-298, K-300) and the N-terminal α -amino group in tetrasuccinylated Porin respectively one ϵ -amino group (K-46) and the α -amino group in mono/di-succinylated Porin. The structure of tetrasuccinylated Porin was determined to 2.4 Å and was generally found unchanged in comparison to native Porin², to form a trimeric complex. All succinylated amino groups found in a mono/di- and a tetra- succinylated Porin are localised at the inner channel surface and are solvent accessible: K-46 is located at the channel constriction site, whereas K-298, K 300 and the N-terminus are all near the periplasmic entrance of the channel. The K-46 residue at the central constriction loop was modelled as succinyl-Lysine from the electron density data and shown to bend towards the periplasmic pore mouth. The electrical properties of the mono/di- and tetra- succinylated Porin were determined by reconstitution into black lipid membranes, and showed an increased single channel conductivity and an increased cation selectivity. The properties of a typical general diffusion Porin changed into those of a channel that contains point charges near the pore mouth. The single channel conductance was no longer a linear function of the bulk aqueous salt concentration. The substantially higher cation selectivity of the succinylated Porins compared to the native Porin is consistent with the increase of negatively charged groups introduced. These results show tertiary structure selective modification³ of charged residues as an efficient approach in the structure function evaluation of ion channels, and X-ray crystallography and mass spectrometry as complementary analytical tools for defining the chemically modified structures.

Mapping Phosphorylations by Precursor Scans of Unseparated Peptide Mixtures of Gel Isolated Proteins

Gitte Neubauer, Matthias Wilm and Matthias Mann

European Molecular Biology Laboratory, Meyerhofstr. 1, 69117 Heidelberg, Germany

<http://www.mann.embl-heidelberg.de>

Parent ion scans can be used to detect sites of posttranslational modifications (such as glycosylation, sulfation or phosphorylation) of peptides in unseparated digest mixtures (1). This technique takes advantage of the low flow rate of the nanoelectrospray ion source, which allows extensive experiments on minimal sample volume (2).

Kinases and phosphatases regulate the activity of many proteins quickly and reversibly by phosphorylation and dephosphorylation. Mapping of phosphorylation sites of proteins therefore provides an insight into the regulation of their activity. Here we use parent ion scans of m/z 79 (PO_3^-) to map the phosphorylation sites of src-kinase, a tyrosine phosphorylated protein expressed in *S.pombe* (3, see figure).

The pH of the spraying solution can be critical for the detection of phosphopeptides. Using the nano electrospray source, the pH can be changed during the experiment from neutral to basic (for parent ion scan in negative mode) or from neutral to acidic (for tandem MS sequencing).

We have further applied our method to gel isolated proteins, stained either with silver or Coomassie. In Lupus Antigen, which is serine and threonine phosphorylated, three phosphorylation sites were determined.

For quantitatively phosphorylated sites, low picomol amounts of protein on a gel is sufficient. We are currently working on the improvement of sequence coverage of gel isolated proteins, for example by using different enzymes for digestion.

FEMTOLE DETECTION OF PHOSPHORYLATED AND SULFATED PEPTIDES IN TOTAL TRYPTIC DIGESTS BY NEGATIVE-ION ESI-MS

Paul Jedrzejewski and Wolf D. Lehmann
Central Spectroscopy, German Cancer Research Center
Im Neuenheimer Feld 280, 69120 Heidelberg, Germany

Although positive ESI-MS has been adopted as one of the most productive MS tools for protein and enzymatic digest characterization, negative ion (NI) ESI-MS has seen only a limited applicability in this area. NI-ESI-MS has been successfully used for the detection of peptides and proteins.^{1,2} Neutral or basic solution conditions frequently have been recommended to enhance negative ion formation.^{2,3} These studies indicated that negative ion formation of peptides is favored by an increasing number of acidic residues (D and E) and a decreasing number of basic functions (mainly K and R), both influences being reflected in the pI value.³ In studies employing strongly acidic ion-pairing reagents (e.g. TFA in LC of peptides), adduct formation with anions is favored over deprotonation for negative ion formation.^{4,5}

We have applied NI-ESI-MS for the investigation of total tryptic digests of model mixtures consisting of phosphorylated peptides. Under these conditions we have observed negative ion spectra dominated by ion currents from phospho- and sulfopeptides. Thus, NI-ESI-MS from acidic solutions is another independent technique in the mass spectrometry toolbox for the detection of phosphorylation or sulfatation sites in a polypeptide sequence.

NI-ESI-MS was applied for the investigation of total tryptic digests of phosphorylated protein (β -casein) spiked with phosphorylated and sulfated peptides under strongly acidic conditions (1%HOAC). Under these solution conditions, both positive and negative spectra were acquired with 60 fm of digest mixture shown in Figures 1A and 1B, respectively. In the positive spectrum the main species are the non-modified peptides, however, a few of the modified peptides can be identified by a number of charge states. In contrast, the negative ion spectrum (Figure 1B) is dominated by ion currents from phospho- and sulfopeptides. Both singly and doubly charged ions were observed from these modified peptides with the doubly charged species being the most prominent whereas the triply charged species were not detected. In addition to the expected modified peptides, other modified peptides resulting from enzymatic cleavage of the spiked peptide (RDYsTGWIDF) and non-enzymatic peptide bond hydrolysis (Sp¹⁹-K²⁸) were observed. The selectivity of NI-ESI-MS for phospho- and sulfopeptides in acidic solution may be explained by the low pK values of a phosphate (pK₁ about 2) or a sulfate (pK < 1) group. At a pH of about 3, these groups still carry a negative charge, whereas the acidic residues of unmodified peptides are protonated (D: pK=3.65, E: pK= 4.25, C-terminal carboxyl group: pK=1.7-2.6) and thus give only a minor contribution to negative ion formation.

In addition to the modified peptides, the C-terminal tryptic peptide may be clearly identified in the negative spectrum although the difference for this peptide is not as dramatic between the polarities. Since this peptide (GPFPIIV) lacks strong basic or acidic residues other than the N-terminal amino or the C-terminal carboxyl groups, the response for this peptide is comparable between the polarities. It is likely that the detection of the C-terminal tryptic peptide which contains basic residue(s) will not be successful by this method nor in instances where the C-terminal peptide consists of a single amino acid. Similar results were obtained with tryptic digest of bovine serum albumin spiked with a phosphorylated peptide (Figure 2).

During the course of this investigation a number of different acidic conditions were explored (HOAC, FOA, TCA, TFA, HCl). Based on the arguments presented above, the optimum selectivity for the detection of phosphorylated and sulfated peptides should be obtained when these groups are the only ones still present in an ionized state (at a pH of about 2). Thus, the utility of HCl was investigated. Shown in Figure 3 is the negative spectrum for a 300 fm tryptic digest of β -casein spiked with an additional phosphorylated peptide. Although the selectivity is comparable to the data obtained

Figure 1A Positive ESI-MS spectrum for a 60 fm tryptic digest of β -casein spiked with phosphorylated and sulfated peptides. Solution conditions: 1%HOAC, 50% ACN

Figure 2 Negative ESI-MS spectrum for a 300 fm tryptic digest of bovine serum albumin spiked with a phosphorylated peptide. Solution conditions: 1%HOAC, 50% ACN

Figure 1B Negative ESI-MS spectrum for a 60 fm tryptic digest of β -casein spiked with phosphorylated and sulfated peptides. Solution conditions: 1%HOAC, 50% ACN

Figure 3 Negative ESI-MS spectrum for a 300 fm tryptic digest of β -casein spiked with a phosphorylated peptide. Solution conditions: 1%HOCl, 50% ACN

with a weaker acid (Figure 1B), the sensitivity has been dramatically reduced. The primary reason for the loss in sensitivity may be attributed to the extensive sodium adduct ion formation observed for all the phosphopeptides present in the mixture. It is reasonable to suppose that the elimination of the adduct ion problem would greatly improve sensitivity.

NI-ESI-MS from strongly acidic solutions is a useful tool for the specific detection of phospho- and sulfopeptides from total tryptic digest mixtures. This technique adds to the existing tool box of methods for the characterization of phosphorylated and sulfated proteins. The information obtained with this method should complement data obtained by other MS techniques, such as parent scans and LC-skimmerCID-MS, and it should match with sequencing data (ms/ms and Edman). Further improvements in the utility of this method may be gained by sample purification to remove the undesirable adduct ion formation and by background subtraction of appropriate blank solutions.

CHARACTERIZATION OF GASTROINTESTINAL PEPTIDES BY DESORPTION IONIZATION

Barbara S. Larsen, Richard G. McKay, Steven Gutteridge, and Martha Vestling
DuPont Central Research & Development
P.O. Box 80228
Wilmington, DE 19880-0228

Cholecystokinins (CCK) are bioactive peptides that control a multitude of processes from the functioning of the upper digestive tract to others localized in cerebral neurons.(1-3) An unusual feature of the members of the CCK family is the requirement for the post-translational modification of a specific tyrosine residue with a sulfate group. Physiologically, the sulfate ester is generated by the action of sulfotransferases, whereas, the chemical synthesis of the peptides with the tyrosine specifically sulfated is quite challenging.

The gastrointestinal peptide hormone of interest to these studies is an octapeptide (CCK) which has the following sequence: ASP-TYR-MET-GLY-TRP-MET-ASP-PHE-NH₂. The peptide was synthesized using automated Fmoc chemistry and purified using reverse phase HPLC. The octapeptide is only biologically active when the tyrosine is sulfated.

The sulfation of CCK was accomplished using a pyridinium acetyl sulfate procedure.(4) In view of the acid labile tyrosine sulfate, separations were performed with 0.1 M ammonium acetate. The reaction mixture can contain doubly sulfated material which elutes before the monosulfated peptides (chromatogram shown). By controlling the reaction time the amount of the doubly sulfated products can be controlled. In addition, the acid lability of sulfated tyrosine is shown with incubation in 0.1% TFA.

Mass spectrometry was critical to the identification of the presence of the sulfated tyrosine. Negative ion electrospray was the ionization technique of choice because no degradation or fragmentation of the peptide was observed. Doubly charged molecular ions dominated the spectra. The relatively labile tyrosine derivative does not degrade in the electrospray measurement provided the peptide is maintained at or near a neutral pH. The results from fast atom bombardment (FAB) show either the degradation or fragmentation of the doubly sulfated material. Using matrix assisted laser desorption ionization (MALDI), the molecular ion for the sulfated material can be observed provided a basic matrix is used.

Mapping of *In Vivo* Phosphorylation in Human VDR Protein by Phosphopeptide-selective Mass Spectrometry

George M. Hilliard, Michael J. Huddleston, J. Wesley Pike*, and Steven A. Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA
*Ligand Pharmaceuticals, San Diego, CA

The Vitamin D₃ receptor (VDR) is a member of a superfamily of genes which encode intracellular receptors for the steroid hormones. Occupation of these receptors by their cognate ligands results in transcriptional modulation of hormonally responsive genes. Receptor phosphorylation upon ligand binding has been observed to be an intrinsic step in the receptor activation process in numerous steroid receptor systems, although the specific function(s) of this modification remains elusive. The Vitamin D₃ receptor from a variety of animal species is also a hormone-modulated substrate for phosphorylation *in vivo*. A model system in yeast was initiated to detail the human VDR (hVDR) transcriptional activation process (Sone et al., 1990, McDonnell et al., 1989). The present data in this identical yeast system compliments detailed studies previously made of the ligand dependent hVDR phosphorylation observed in mammalian cells (Hilliard et al., 1994).

The hVDR cDNA was utilized to produce recombinant hVDR in 1,25-dihydroxyvitamin D₃-treated *S. cerevisiae* cells. This eukaryotic, yeast over-expression system produces hVDR which is functionally indistinguishable from recombinant hVDR produced in mammalian cells with regard to DNA or ligand binding, heterodimerization with cofactors, or transactivation of gene transcription activities. The human receptor protein was purified to >90% homogeneity utilizing DNA affinity chromatography. The purification recovery of functional hVDR protein (defined by DNA and 1,25(OH)₂D₃ hormone binding) was 0.15% of soluble, crude protein from yeast cell lysis. N-terminal sequencing of the ubiquitin-hVDR fusion protein showed intracellular processing of the recombinant protein leaving 4 residues from ubiquitin.

Tryptic peptides of the full-length receptor were first screened by negative ion LC-ESMS using a stepped orifice voltage scanning procedure (Huddleston et al., 1993) to produce and detect phosphopeptide marker ions and simultaneously obtain full scan mass data. ESMS, and MALDI-TOF of HPLC fractions, led to the identification of a large hVDR peptide (~7300 Da) which contained phosphate. Subsequently, chymotrypsin was used to further fragment this region of the hVDR and the peptides were re-screened by LC-ESMS single ion monitoring (SIM) at high orifice voltage to produce and detect phosphate marker ions only. A single region of the UV chromatogram which contained phosphate was identified. Molecular weight-related ions for the phosphopeptides in this fraction were selectively detected by a precursor scan of m/z 79 (PO₃⁻) using a "nanospray" ESI device (30-50 nanoliter/min., Carr et al., in press). Ions matching putative hVDR serine-rich phosphopeptides were detected. The phosphopeptides were sequenced by nanospray tandem MS and position 209 was identified as the location for a single phosphoserine residue. In contrast, earlier studies of recombinant hVDR over-expressed in mammalian cells (Hilliard et al., 1994) identified an adjacent serine position 205 as a single, hormone modulated phosphoserine residue contained within the hVDR protein.

In the yeast cDNA expression vector serine 209 was genetically engineered to an alanine residue, and the S209A hVDR was functionally compared to wildtype hVDR. The tests were functionally inclusive of receptor heterodimerization, DNA binding, hormone binding, and transactivation of gene transcription activities.

The resulting data showed no significant functional differences between the two hVDR constructs in yeast, mimicking earlier results of phosphorylation site mutants in mammalian cell versions of hVDR mapping experiments. The earlier studies in mammalian-expressed hVDR phosphorylation site mutants suggested an alternative, possibly compensatory, phosphorylation which occurred in the serine-rich area of the mutated phosphorylation site of hVDR. The phosphorylation state of the yeast-expressed mutant hVDR in the present experiments, and its potential compensation for receptor functional requirements for phosphorylation, remains unknown.

Future studies will address these questions directly and also chemically target known kinase pathways in various hVDR functional assays, as well as utilize "nanospray" MS technology to confirm and study the phosphorylation of endogenous human Vitamin D Receptor.

Selective Detection and Sequencing of Phosphopeptides at the Femtomole Level in Protein Digests

Michael Huddleston, Roland Annan and Steven Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

We describe a new procedure that enables selective detection and sequencing of Ser-, Thr-, and Tyr-phosphopeptides at the low femtomole level in protein digests (1). Radiolabeling with ^{32}P is not required, nor is prior chromatographic separation of the peptide mixture. This new strategy builds on earlier work from our laboratory on phosphopeptide selective detection (2,3). One-to-two microliters of the unfractionated protein digest is infused at basic pH into an electrospray mass spectrometer at a flow rate of 20 - 40 nanoliter/min using an ultra-low flow sprayer (4). The best sensitivity for detection of phosphopeptides and peptides in the negative-ion mode was obtained by spraying solutions at basic solution pH. A precursor-ion scan of m/z 79 (PO_3^-) produces a mass spectrum containing only the molecular ions of the phosphopeptides that are present in the sample (1). In cases where the protein sequence is known, the peptide molecular weights obtained are often sufficient to identify the specific sequences that are phosphorylated. If the protein sequence is not known, tandem MS with collision-induced dissociation of phosphopeptide precursor-ions may be used to obtain the amino acid sequences including the site(s) of phosphorylation. The approach described here, when combined with database searching algorithms, can be used to identify unknown phosphoproteins and to map the phosphorylation sites in these proteins. Phosphopeptides may be selectively detected using as little as 3 femtomole of a 10 femtomole/uL solution, and that sequence information for a phosphopeptide in the mixture may be obtained using as little as 3 femtomole of the same solution (Fig. 1). These procedures were used to identify and sequence phosphopeptides from α -casein, a milk-derived protein possessing up to nine phosphorylation-sites (Fig. 2). Numerous MS and tandem MS experiments were carried out on a single, 250 femtomole/uL loading of the phosphoprotein digest. Phosphopeptides derived from an unexpected variant of the protein were also observed (1). In addition, we show that the stoichiometry of phosphorylation at specific sites may be estimated from the ratio of the ion signals for the respective forms of the peptides observed in the normal full-scan mass spectra of the digest (1). We have successfully applied the precursor-ion scanning approach to characterize phosphorylation in the vitamin D receptor, a CSAID-binding protein homologous to ERK-2 and calmodulin. The results of these studies will be reported elsewhere.

Identification of Protein Phosphorylation Sites Using Capillary IMAC / LC / ESI-MS

Paul Russo*, Rocco Falchetto*, Ronald Hendrickson*, Gregory Smith*, Jeffrey Shabanowitz*, Donald Hunt**

*Department of Chemistry, #Department of Pathology, University of Virginia; **Department of Microbiology, University of Pennsylvania, School of Medicine

Introduction: Metabolic pathways and intracellular functions are to a large extent regulated by reversible protein phosphorylation. To gain a greater understanding of the role of phosphorylation, it is necessary to identify specific sites that have become phosphorylated. It has been shown that Fe^{3+} can successfully be used to reversibly bind phosphorylated proteins and peptides (1-3). In order to identify specific sites of protein phosphorylation a method was devised which utilizes Fe^{3+} capillary immobilized metal affinity chromatography / HPLC / electrospray mass spectrometry (IMAC/LC/ESI-MS) without the use of radiolabeling or 2D peptide mapping, which are time consuming and can lead to sample losses. The phosphorylated form of β -casein was used to develop the method.

It has been shown that the ActA protein from *Listeria Monocytogenes* is essential for bacterial movement through infected mammalian cells (4,5), and that this protein becomes phosphorylated during growth within the cells (6). Two phosphorylation sites have been identified using IMAC/LC/ESI-MS.

Experimental: IMAC columns were made by packing fused silica capillaries (180 μm OD x 75 μm ID) with Poros metal chelating beads. Fe^{3+} was bound to the beads by flowing 100mM FeCl_3 through the column. A 500 fmol aliquot of a 50 pmol β -phosphocasein tryptic digest was loaded onto the IMAC column, and 0.1 M acetic acid (pH 3) was washed through the column in order to elute the non-phosphorylated peptides. The IMAC column was then butt-connected to a C-18 packed fused silica capillary column of the same dimensions, which in turn was connected to a Finnigan TSQ 70u triple quadrupole mass spectrometer. The remaining contents of the IMAC column were then eluted onto the C-18 column with a known volume of 0.1% tetrabutylammonium acetate/50mM tetrabutylammonium phosphate, pH 8.2 (elution buffer). The two columns were disconnected, and a gradient of 0-80% B in 12 minutes was run over the C-18 at 500 nL/min, (B: acetonitrile; A: 0.1 M acetic acid). [See Fig. 1 for instrumental set-up].

ActA was isolated from *Listeria Monocytogenes* by immunoprecipitation using a monoclonal antibody specific for a part of the protein sequence - DFPPPTDEEL. One batch of ActA (ActA1) was phosphorylated *in vitro* while a second batch was left unphosphorylated (ActA2). ActA1 and ActA2 were run on 8% SDS PAGE, electroblotted onto PVDF membranes, and the bands digested with trypsin. Approximately 1 μL of each ActA digest was loaded onto a 75 μm ID x 180 μm OD Poros RII/H reverse phase column. A gradient of 0-80% B in 12 minutes was run over the Poros column directly into a Finnigan TSQ 70 triple quadrupole mass spectrometer in order to determine which cleavage fragments were present.

Approximately 1 μL of the ActA1 digest was loaded onto the IMAC column. The column was washed with 20 column volumes of 0.1M acetic acid, connected to a reverse phase Poros column, and washed with 2 column volumes of elution buffer. The columns were then disconnected and a gradient of 0-80% B was run over the Poros column directly into the mass spectrometer in order to determine which peptide(s) was (were) phosphorylated.

Results and Conclusions: Tryptic digestion of phosphorylated β -casein yielded only the singly phosphorylated fragment (MW 2063). Only a few peptides were retained by the IMAC column. However, only the phosphorylated peptide was recovered with a high abundance relative to the same amount of digest material loaded onto the C-18 column directly. After eluting the ActA1 peptides off of the IMAC column it was seen that only a few peptides were retained. Of the few remaining peptides, only the one with MW 2358 Da (787 $^{3+}$, 1180 $^{2+}$) had remained as abundant as when adding the digest directly to the Poros column. A collision activated dissociation (CAD) mass spectrum was obtained of 1100 $^{2+}$ from ActA2, which revealed the sequence $^{489}\text{NAGFLPLNPFISSPVPSLTPK}^{499}$ (Fig. 2). A CAD of the peptide 1180 $^{2+}$ from ActA1 (Fig. 3) revealed that it was phosphorylated at Ser 451 and Thr 457 . This technique can be applied to any phosphoprotein.

ANALYSIS OF PHOSHOPEPTIDES BY USING LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

Xirong Zhu and Chhabil Dass

THE UNIVERSITY OF MEMPHIS, DEPARTMENT OF CHEMISTRY, MEMPHIS, TN 38152, USA

INTRODUCTION: Protein phosphorylation is one of the most important and ubiquitous posttranslational events and serves to regulate the activity of many proteins, hormones, and enzymes. A group of kinases, collectively known as tyrosine kinases, catalyzes phosphorylation of tyrosine residues. A unique feature of enkephalin peptides is the presence of a tyrosine residue at the N-terminus. Enkephalins are distributed in several body tissues and are known to play a critical role in various physiological functions. It is of fundamental interest to know whether enkephalins exist in the phosphorylated form.

OBJECTIVE: The conventional approach of labeling of cells and tissues with ^{32}P -phosphate, coupled with Edman degradation for determination of phosphorylation state of proteins and peptides has a number of weak points. Therefore, an alternative approach is in order. MS techniques are increasingly becoming important in characterization of phosphopeptides. In this research, we have used an on-line combination of HPLC and ESI-MS to characterize several phospho and nonphosphoenkephalins. The objective is to develop a method that can be used to separate and characterize phosphoenkephalins from body tissues and fluids. A set of ten synthetic phospho and nonphosphoenkephalin peptides, including methionine enkephalin (MetEnk), leucine enkephalin (LeuEnk) and their C-terminally extended analogs such as MetEnk-K, MetEnk-RF, MetEnk-RGL, and LeuEnk-K and corresponding phospho derivatives such as phospho-MetEnk, -LeuEnk, -MetEnk-K, and -MetEnk-R, were used in this study.

EXPERIMENTAL: The MS measurements were made by using Fisons Platform II single quadrupole mass spectrometer. The quadrupole was scanned in the mass range of 550-990 Da at a scan rate of 1.5 s per scan. Chromatography separation was carried with an HP 1050 equipment (Hewlett Packard) consisting of a quaternary pumping system and a diode array UV-visible detector (DAD). A Vydac C-18 201HS52 column (250 x 2.1 mm, 5 μm particle size) and gradient elution with a mixture of 0.1% aqueous TFA (A) and acetonitrile (B) was used to separate the peptide mixture. For HPLC/ESI-MS analysis the outlet of the DAD was connected to a megaflo ESI probe and peptides were identified by their characteristic retention time and the molecular mass of a singly or multiprotonated ion specific to that peptide. The nonphosphopeptides were purchased from Sigma Chemical Co and phosphopeptides were synthesized in our laboratory.

RESULTS AND DISCUSSION: In the LC/ESI-MS set-up used in this study (see Dass in this volume), no flow-splitter is used. The eluents emerging from the UV detector are directly introduced to the megaflo ESI probe. The flow rate of the mobile phase was adjusted to 200 $\mu\text{L}/\text{min}$ and the gradient was set to 14-19% B in 0-10 min, 19-21% B in 10-20 min, 21-40% B in 20-30 min, and 40% B from 30-40 min. The eluents were monitored both by UV absorption and the positive ion current. Figures 1 and 2 illustrate the UV chromatogram and the corresponding total ion current chromatogram (the lowest trace), respectively. Figure 2 also shows extracted ion chromatograms of the individual peaks. It is obvious from these data that the integrity of the chromatographic run is maintained when ESI/MS is used as the detector. These data were acquired from an aliquot of the mixture containing 115 to 135 pmole of individual peptides. These are not the detection limits of the technique but the typical amounts used in this experiment. Sensitivity of the analysis can be improved by controlling the background ion current. Main contribution to the background arises from water clusters. Two types of water cluster ion series were observed; one due to clusters of the composition ($\text{H}_3\text{O}^+ + n\text{H}_2\text{O}$) and the other due to the ($\text{CH}_3\text{CN} + \text{H}^+ + n\text{H}_2\text{O}$) type of ions. The composition and rate of flow of the mobile phase determine the extent and type of water clusters. During gradient run, when the mobile phase becomes rich in acetonitrile, the former cluster series is less significant. Also, the background decreases with increase in the acetonitrile content. The formation of clusters can also be reduced by increasing the ESI source temperature, increasing the flow rate of drying gas, and increasing the sampling cone voltage. The effect of temperature was studied by increasing the source temperature from 60-180 $^\circ\text{C}$. At 180 $^\circ\text{C}$, the water clusters were not observed. However, at this temperature, fragmentation of the peptides was observed. Therefore, an optimum temperature of 150 $^\circ\text{C}$ is recommended.

NEW DEVELOPMENTS IN UNDERSTANDING AND EXPLOITING ELECTROSPRAY IONIZATION— A MECHANISM FOR LARGE ION FORMATION

*Richard D. Smith, Keqi Tang, Harold R. Udseth and Alan L. Rockwood
Environmental Molecular Sciences Laboratory
Pacific Northwest National Laboratory, Richland, WA 99352

The development of electrospray ionization has substantially changed the practice of mass spectrometry due to its versatility and broad applicability. A better understanding of the chemistry and physics of the electrospray ionization (ESI) process can provide the basis for the development of more sensitive and stable ion sources, and more flexible operation for specific applications (e.g., the characterization of fragile non-covalent complexes) and better quantitation. The chemical nature and abundances of ions formed in the ESI source are the result of a complex set of physical and chemical processes in an environment where droplet size, effective temperature, ambient pressure, and both solution and gas phase composition and properties may vary extensively. Strongly coupled with the ion formation process are the gas phase ion dissociation and particularly ion neutral collision phenomena (e.g., collisional activation, ion-molecule reactions) that largely determine the nature of the ions ultimately analyzed by the mass spectrometer.

A major and on-going question regarding electrospray ionization involves the mechanism of formation for large ions, such as from proteins. The most widely accepted mechanism is the field evaporation (desorption) model, first proposed for the case of small ions from liquid droplets by Iribarne and Thomson.¹ In this process, a high electric field at the surface droplet (estimated at $\sim 10^9$ V/m) causes ions to be spontaneously emitted to the gas phase. However, many features of the electrospray process appear to be somewhat difficult to rationalize in terms of this mechanism, including the ability to ionize high m/z species,² very high molecular weight compounds,^{3,4} and fragile non-covalent complexes.⁵ It is difficult to understand how such a process could be so broadly applicable, and simultaneously compete for desorption with small ions. However, this mechanism is often favored since (if one ignores these issues) it explains ion formation from liquid metals and offers a qualitative basis for rationalizing many characteristic features of ESI for small ions.

Alternative explanations face challenges. In particular, the variations in sensitivity between compounds, the relative lack of associated solvent residue, the apparent absence of analyte aggregation dominating the mass spectra, and the origin of the charge state distributions typically observed for large molecules all demand explanation.

We propose an alternative mechanism that does not invoke the desorption of small ions. In this model, the initial highly charged ions undergo asymmetric fission, a process that is well established for droplets that are large enough for direct observation.⁶ We also assume that this asymmetric fission process occurs for smaller droplets, a reasonable assumption unless other charge loss processes become competitive. The asymmetric fission process is known to produce much smaller droplets that have greater charge to mass ratios.⁶ An important aspect of our mechanism is that we assume that molecules enriched near the surface of the initial droplets disproportionately contribute to the smaller droplets as they are formed by shearing of the charged surface from the larger parent droplet. In our mechanism, the smaller droplets that may contain one or more large molecules (i.e., an analyte species of interest) now can shed both mass and charge by a variety of processes, leaving behind the solute and other "residue." Most mass loss is due to evaporation of neutral (e.g., solvent) species; however, processes requiring thermal activation for "residue" removal, dissociation of clusters, etc., will also be important depending upon the specific situation. (In this regard, it is important to remember the significant activation provided by interfacial processes in ESI.⁷) Charge may be lost by at least two processes. One may be the conventionally invoked field evaporation of small ions.¹ Also potentially important, we believe, is a second previously ignored process: field-assisted charge (e.g., proton) transfer to a molecule immediately adjacent to the surface charge site. On a smaller (i.e., molecular) scale, this corresponds to the well-established proton transfer processes that can result in charge state shifting,⁸ and that probably dictate the maximum possible charge

for large molecules.⁹ Regardless, it is apparent that both charge and mass can be removed from the shrinking nano-droplet by a host of processes that need not invoke large ion desorption. As noted above, the collisional activation of ions in the interface has been shown to allow the removal of at least some "residue,"¹⁰ as well as the dissociation of clusters.^{2,11,12} It should also be noted that recent results for spherical starburst dendrimer molecules extending to ~ 1 MDa show that the charge observed corresponds to an electric field at the surface of $> 2 \times 10^9$ V/m.¹³ This electric field is incompatible with formation by desorption from a larger droplet, as proposed by Fenn,¹⁴ since the larger droplet would be necessarily charged to well above the Rayleigh limit. In contrast, the data are consistent with formation by charge and mass lost from a larger droplet, where the high electric field that results as the droplet approaches the size of the spherical molecule, would facilitate both proton transfer and "desorption desorption" of small ions. Thus, the major remaining issue is: what determines the observed charge state distribution? In our mechanism, the shrinking nano-droplets would generally deposit the maximum number of charges feasible on the molecule; this is consistent with both experimental observation⁷ and the calculations of Williams and co-workers.⁹ It is also consistent with the fact that more well-defined structures, such as tetrameric proteins formed under gentle interface conditions, produce relatively narrow charge state distributions.^{5,11} But what defines the shape (i.e., width) of the charge state distribution? We believe the most likely explanation for the major part of the observed distribution, is charge site and/or structural heterogeneity, as we have suggested earlier.¹¹ The fact that constraints upon gas phase structure cause differences in the resulting electrospray charge state distribution is well established.¹² Thus, the more or less random distribution of energetically similar structures in solution is transformed (through the removal of the solvent and other electrospray-related phenomena) to create a mixture of species having a range of reactivities to ion-molecule processes (such as proton transfer). Other processes, including the dissociation of aggregates (particularly at higher solute concentrations), can also contribute to increasing the width of the charge state distribution and shifting it to higher m/z .¹⁵

The model we have outlined above is based upon established or physically plausible processes, and does not invoke the desorption of large ions (although at the molecular level distinguishing between ion desorption and charged aggregate or cluster dissociation may evolve to semantics). We believe that the mechanism proposed is capable of explaining existing observations related to electrospray ionization for large molecules. We are designing and conducting experimental studies aimed at further evaluation of this mechanism.

SOLVENT FRACTIONATION DURING EVAPORATION OF CHARGED DROPLETS

Pavel Kiselev, Joan Rosell and John B. Fenn
Department of Chemistry, Virginia Commonwealth University
1001 West Main Street, Richmond VA 23284-2006

Some of the most widely used techniques for producing ions from analyte species in solution involve the evaporation of solvent from small charged droplets. Frequently the solvent may comprise two or more components of differing volatility. Many Electrospray (ES) experiments have shown that both the relative abundances and the conformations of Electrospray (ES) ions can depend strongly on the nature of the solvent in the droplets from which they are formed. One can wonder, therefore, to what extent an ES droplet of multi-component solvent might vary its composition during the evaporation process and whether such variation can affect the nature of the product ions. It is well established that enrichment of higher boiling species can occur during evaporation of fuel droplets in combustion systems but such droplets are initially much larger than ES droplets and may be large enough to provide internal convective mixing. We know of no experimental data on the extent of enrichment in droplets as small as those characteristic of ES nebulization.

A major problem in measuring such enrichment is the difficulty of obtaining representative samples of droplet liquid for subsequent analysis. The exchange of species between ambient gas and very small droplets is so rapid that one must provide extremely fast removal of a sample droplet from its spray environment in order to avoid changes in its composition during the sampling process. We developed the probe shown in Fig. 1 which seems to overcome this difficulty. It comprises a length of glass tubing with a bore of 1.86 mm, one end of which was "pulled" to form a 10 to 20 mm length of capillary having an o.d. and i.d. respectively of about 280 and 150 microns. A tight bundle of 5 micron carbon fibers was inserted through the capillary, extending some 50 mm into the large bore region. At a point about 10 mm from its open end the small capillary was softened by heating and bent through 90 degrees. At the same time the glass was allowed to "collapse" around the fibers thus providing a seal that blocked any flow of gas or vapor but allowed liquid to pass through by capillarity. The large bore end of the probe was closed with two small metal tubes sealed into place with epoxy cement. One of the tubes introduced a flow of clean dry air into the resulting cavity. It also maintained contact with the carbon fibers thus serving as an electrode by which they could be maintained at a desired voltage. The entering air left through the other tube past a septum port at which a gas sample could be withdrawn for injection into a gas chromatograph equipped with a flame ionization detector.

This probe assembly was mounted on a translation stage that could position the inlet end at any desired location in the spray. By adjusting the voltage to some value intermediate between the spray needle and its counter electrode we could vary the flux of charged droplets to the end of the fiber bundle over a wide range. A portion of the deposited liquid passed by capillarity through the bundle into the wide bore region of the probe where it evaporated into the flow of air. That region of the probe could be heated to

insure complete evaporation of all the entering liquid. The following results relate to a liquid flow rate into the spray of 8.3 $\mu\text{L}/\text{min}$. Figure 2 shows the dependence of apparent solvent composition on probe voltage at several axial locations along a spray of methanol-chloroform droplets. We assume that where the composition becomes invariant with probe voltage the liquid deposition rate is so high that the sampled liquid has the same composition as that of the "free" droplets. Any species exchange between liquid and the vapor during sampling has then become negligible. Figure 3 shows results for droplets of several chloroform-alcohol mixtures. In each case the alcohol has a lower volatility than chloroform and clearly increases its concentration as evaporation of the droplet progresses. Data for the two ethanol-chloroform mixtures show that the droplets initially more dilute in ethanol lose chloroform more rapidly than those with a higher ethanol content. At an axial distance of about 6 mm the droplets from the two solutions reach the same composition and from then on follow the same enrichment-rate curve. Figure 4 shows results for droplets of an acetone-chloroform mixture for which chloroform is enriched because it is slightly less volatile. After the experiments were done we realized that these two components form an azeotrope at a chloroform mole fraction of 0.66 and a temperature of 338 K. It would be interesting to see if composition remains constant at or near that value even though the droplet temperature is uncertain in these experiments. We hope to continue these studies over a range of solvent combinations and electrospray conditions. The take home message from these preliminary results is that solvent composition can and does change during evaporation of ES droplets even though they are extremely small. The role and importance of such change in determining the nature of ES ions remains to be evaluated.

THE ELECTROLYTIC NATURE OF ELECTROSPRAY

Gary J. Van Berkel,¹ Feimeng Zhou,² and Joseph T. Aronson²

Claire, Eau Claire, Wisconsin 54702-4004

The fundamental electrochemical principles governing the operation of the ES ion source^{1,2} and the ability to use this electrolytic phenomenon to expand the range of compound types amenable to ES-MS³⁻⁵ are now common knowledge among most ES-MS practitioners. A major consideration for fundamental studies, and probably some analytical applications, that has not received attention, however, is the change in the initial solution composition entering the spray capillary caused by these electrolytic reactions. Discussed here are changes in the bulk solution pH that may result under certain ES-MS conditions. Charge-balancing redox reactions in the metal ES capillary that result in solution generation or elimination of H⁺, OH⁻, and other acidic or basic species, may have the end result, depending on ES operational parameters (e.g., solution flow rate, ES current, and metal capillary composition) and initial solution conditions (e.g., solvents, pH, and buffering capacity), of significantly increasing or decreasing the pH of the solution that initially enters the capillary. From a fundamental standpoint, this is important because it is believed that the gas-phase ions derived from acidic or basic species in ES-MS are, at a minimum, a qualitative reflection of the equilibrium ion concentrations in the original liquid sample solution. The equilibrium distribution of ions in solution is, of course, calculated on the basis of known analyte acid/base chemistry and bulk solution pH. From an analytical standpoint, the ability to control this pH change (or other electrolytically induced solution compositional change) might be used to enhance an analysis.

To directly show that the oxidation of water ($2\text{H}_2\text{O} \rightarrow \text{O}_2 + 4\text{H}^+ + 4\text{e}^-$, $E^\circ_{\text{red}} = 1.23 \text{ V vs SHE}$) in the ES capillary might actually change solution pH, we carried out a set of experiments with an ES-diode array detector (ES-DAD) setup that allowed the solution exiting the ES capillary to be monitored by UV/visible spectrophotometry prior to the spraying process.² As shown by the data in Figure 1, the pH of the solution exiting the capillary was monitored by continuously infusing a water/methanol solution (9/1 v/v, 1.0 mM KCl) of the pH indicator bromophenol blue (15 μM , $\text{pK}_{\text{in}} = 3.85$) at several solution flow rates. The change in the absorbances measured for the basic (In_B) and acidic (In_A) forms of the indicator clearly show that the pH of the solution does change and that the resulting solution pH (as estimated from the spectra using the Henderson-Hasselbach equation) correlates nicely with the pH value calculated on the basis of the measured ES current and Faraday's law, assuming the electrolytic oxidation of water to be the only reaction taking place.

Unambiguously detecting the effect of an electrolytic induced solution pH change on the ES mass spectrum of an analyte can be difficult. This is because the phenomena associated with charged droplet evaporation and the liberation of ions from the droplets might also alter the appearance of the ES mass spectra. The data in Figure 2 show, however, that the ES mass spectrum of cytochrome c is drastically different if conditions are such that the electrolytic oxidation of water (and therefore a pH decrease) is promoted (Figure 2a) or inhibited through the addition of a redox buffer to the solution (Figure 2b). Relatively good signal for the multiply-charged protein is observed in the former case, but the signal levels are over an order-of-magnitude lower when the

redox buffer I⁻ is in the solution. The presence of a relatively large amount of the easily oxidized iodide anion ($3\text{I}^- \rightarrow \text{I}_3^- + 2\text{e}^-$, 0.53 V vs SHE) serves to "buffer" the potential at the metal/solution interface within the ES capillary to a value below that necessary to oxidize water. Thus, the electrolytic induced reduction in pH does not occur, the concentration of the protonated-protein in solution remains relatively low, and the gas-phase signal levels are also low. We also noted that the gas-phase signal for the protein was much less if a stainless steel capillary was used rather than a platinum capillary. This can be explained by the electrolytic corrosion of the stainless steel capillary supplying a major portion of the charge-balancing current that might otherwise have been used to oxidize water and therefore decrease pH. The lessened solution pH change with added I⁻ and with the use of a stainless steel capillary were corroborated by experiments carried out with the ES-DAD.

A NOVEL THREE-ELECTRODE SYSTEM FOR FAST ELECTROCHEMISTRY / ELECTROSPRAY MASS SPECTROMETRY

Richard B. Cole*, Wenzhe Lu, Xiaoming Xu

Department of Chemistry, University of New Orleans, New Orleans, LA 70148 USA

The coupling of electrochemistry to other analytical techniques can offer valuable, difficult to obtain information to aid in the characterization of intermediates and reaction products from redox processes. The analysis of short-lived intermediates and products of electrochemical reactions has presented the greatest challenge. Electrochemistry coupled on-line with mass spectrometry offers particular advantages of high sensitivity and specificity. The electrospray ion source itself has been described as a special type of electrolytic cell [1]. Since that time, several groups [2-5], especially Van Berkel and coworkers [3,5], have been engaged in coupling electrochemical devices to electrospray mass spectrometry. Results stemming from the coupling of three-electrode electrochemical systems to electrospray mass spectrometry (ESMS) first appeared in 1995 [2,3]. The current report describes a novel three-electrode electrochemical device which has been coupled on-line with electrospray mass spectrometry (EC / ESMS) to enable analyses of nonpolar, nonvolatile neutral compounds which are not typically amenable to ESMS, and to offer the possibility for real-time monitoring and identification of intermediates and products generated by electrochemical reactions.

The novel device for on-line "Fast Electrochemistry / Electrospray Mass Spectrometry" [6] is shown in Figure 1 where an electrochemical flow cell has been constructed inside the electrospray probe. The three-electrode cell consists of a platinum microcylinder working electrode (2), flame-sealed inside a fused silica capillary (4). The fused silica postpones electrical contact between the working electrode and the sample solution until the electrospray region. It also insulates the working electrode from the auxiliary electrode (8), a stainless steel capillary which surrounds both the working electrode and the fused silica layer. This auxiliary electrode also functions as the electrospray capillary. The above electrode assembly is mounted on a "cross fitting" (7), and is held in place by ferrules (9), as is the Ag/Ag⁺ reference electrode (6). Sample is infused in port (10), and a carrier gas to pneumatically-assist the electrospray process is introduced in port (12) of a stainless steel tube (14). The low volume cell (~ 0.125 μ L) has been designed with a minimum distance between the working electrode and the "Taylor cone" inherent to the electrospray process. This configuration minimizes the time between electrochemical generation of ions and mass spectrometric analysis.

The novel EC / ESMS probe has been used to perform on-line linear sweep voltammetry with real-time monitoring of the products of: 1) oxidation of diphenyl sulfide; 2) anodic pyridine addition to 9,10-diphenylanthracene; and 3) the reduction of nitrobenzene. Shown in Figure 2 are the 'Ion Abundance vs Potential' curves for the oxidation of diphenyl sulfide, indicating the appearance of: a) diphenyl sulfide radical cation; b) protonated diphenyl sulfoxide; c) pseudodimer sulfonium ion; d) further oxidized pseudodimer sulfonium ion; and e) m/z 217, possibly (Ph-S-S-Ph - H)⁺. The signal intensity of the diphenyl sulfide radical cation (Fig. 2a) was relatively low compared to other signals, suggesting that this intermediate was relatively unstable. Figures 3(a-c) show averaged EC / ES mass spectra for the reduction of nitrobenzene, obtained at progressively later intervals during linear sweep voltammetry. At increasingly negative voltages, the relative abundance of the singly charged radical anion ($M^{\cdot-}$) of nitrobenzene (m/z 123) is observed to diminish in favor of M^{2-} (m/z 61.5). Moreover, the latter reacts to form increasing abundances of the protonated dianion MH^- (m/z 124) at progressively negative applied voltages.

On-line Fast Electrochemistry / Electrospray Mass Spectrometry employing the novel probe has thus allowed monitoring and identification of ionic intermediates (radical and even electron) and products of electrochemical oxidations and reductions. The probe design offers the shortest possible distance between the working electrode and the ES 'Taylor cone', thus minimizing the time between electrogeneration of ions and their release into the mass spectrometer. While Fast EC / ESMS can enable the analysis of nonvolatile, nonpolar neutral compounds which are otherwise difficult to ionize by ESMS, electrochemically-generated permanent gases, free radicals, or other neutral products that cannot be ionized by acid/base chemistry or redox reactions within the applied potentials will not be detected by EC / ESMS. The technique should thus be viewed as providing information complementary to EC / EI-MS and EC / EPR.

ION MOBILITY SPECTROMETRIC / TOF-MASS SPECTROMETRIC INVESTIGATION OF ELECTROSPRAY IONS

R. Guevremont, K.W.M. Siu, and L.Ding, Institute for National Measurement Standards, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6

A commercially available IMS/MS instrument (PCP Inc., West Palm Beach Fla.) was converted from a quadrupole to a time-of-flight mass spectrometer. Ion lenses and grids for pulsed, space-focus acceleration, linear TOF were installed. A diffusion pump below the IMS/TOF orifice, and a second diffusion pump below the TOF flight tube provided two stages of pumping. Ions were generated by electrospray in a Plexiglas chamber connected to the IMS via a 15 cm stainless steel tube 1/8 in. od. The tube ended in the 'reaction zone' of the IMS instrument and was held at approximately +2000V in order to match the voltage level within the IMS instrument. The electrospray chamber was flushed by 5L/min N_2 which entered the chamber concentrically to the exit tube leading to the IMS. Of this gas 2L/min carried the electrospray ions into the IMS, and 3L/min exited directly from the cell. This countercurrent of gas minimized the entrance of neutrals and large droplets into the IMS instrument. Because of the low mobility of electrospray ions of interest, the gating function was extended from the usual 1ms up to 5ms (note wide peaks in Figure 1). This permitted good sensitivity detection of ions with mobility as low as $0.2 \text{ cm}^2/\text{V}\cdot\text{s}$ (such as cluster ions). The interface between the IMS and MS was an orifice approximately 25 μm in diameter. The mobility cell in the IMS/MS instrument was held at 150°C . The TOF was operated at a vacuum below 1×10^{-5} torr. The acceleration voltage was 1350V.

Figure 1 illustrates the IMS spectra from electrospray of tetraoctylammonium bromide. The spectrum is characterized by ions of mobilities ranging from over $1.6 \text{ cm}^2/\text{V}\cdot\text{s}$ to as low as $0.16 \text{ cm}^2/\text{V}\cdot\text{s}$. The ions of high mobility include the tetraoctylammonium ion (M^+) and several adduct species, $M(\text{MBr})_n^+$. Heavier cluster ions appear in the spectrum. Figure 2 illustrates IMS/TOF-MS spectra acquired with gating of selected regions of the IMS spectrum shown in Figure 1. As expected, tetraoctylammonium ion and other adduct ions appeared in the TOF spectrum, whereas the heavier cluster ions were not detected. It appears that this type of ion is too massive to be detected with the present instrument. IMS, with electric current detection, provides quantitative measurement of the flux of ions presented to the IMS/TOF interface. Figure 3 illustrates the ratio of measured TOF signal intensity to IMS peak height for ions derived from electrospray of a series of tetraalkylammonium compounds ranging in size from tetraethylammonium, to tetraoctylammonium. The variation of the ratio of TOF/IMS signals with ion mass illustrates the degree of possible mass discrimination in the IMS/TOF interface. Figure 4 illustrates the integration of signals from IMS (top) and IMS/TOF (bottom) as a function of the temperature in the IMS cell (electrospray cell at room temperature). The IMS drift velocity of the tetraalkylammonium ion, and its adduct ions increased with increasing temperature while that of the cluster ion decreased. Moreover, the intensity of the tetraalkylammonium peak remained constant with increasing temperature, while that of the small adduct ion increased and that of the cluster ion decreased. Despite these changes, the total integrated electrical current detected by IMS remained constant (top trace). On the other hand the IMS/TOF the total integrated signal increased with increasing temperature. The large cluster ions (not detected by TOF-MS) appear to be undergoing conversion at elevated temperature, via charge expulsion, to yield increased flux of low mass ions (in this case $M(\text{MBr})^+$ ions, lower trace Figure 4).

Figure 1 Ion Mobility Spectrum of electrospray ions from a 2.5mM solution of tetraoctylammonium bromide. Selected segments of the spectrum were gated for IMS/TOF. TOF spectra appear in Figure 2.

Figure 2. TOF spectra acquired with gating of selected regions of the IMS spectrum of tetraoctylammonium bromide. The selected regions are shown in Figure 1.

Figure 3 Ratio of measured TOF signal intensity to IMS peak height for a series of ions from ES of tetraalkylammonium salts.

Figure 4. Signals from IMS (top) and IMS/TOF-MS (bottom) were integrated as a function of time. Electric current is conserved in IMS, but signal intensity increased with temperature in TOF.

Quantitative Characteristics and Matrix Effects of Electrospray Mass Spectrometry

Zhanying Stacy Ho, Zhenyu Shou and Richard F. Browner
School of Chemistry and Biochemistry
Georgia Institute of Technology, Atlanta, GA 30332-0400

Electrospray mass spectrometry has received considerable interest in recent years.

Knowledge of the factors affecting the ionization efficiency and sensitivity is therefore becoming more and more important for reliable operation in analytical applications and for a better insight into the applicability of electrospray to new and interesting fields. Despite the importance of the technique, there have only been limited studies to establish factors that affect dynamic range and linearity, and to determine the existence and extent of matrix effects.

In these studies, the quaternary ammonium salts tetramethyl (Me_4N^+), tetraethyl (Et_4N^+), tetrapentyl (Pe_4N^+) and tetrahexyl (He_4N^+) were chosen to investigate quantitative characteristics and matrix effects of electrospray and to gain insight into ionization mechanisms. Quaternary ammonium ions already exist in solution and are not affected by the presence of different background ions or by pH conditions. They are free of ion/molecule reactions such as proton transfer in the gas phase. Hence this class of compounds can be considered a good starting point for fundamental studies of electrospray.

The experiments were done using an Extrel Benchmark mass spectrometer. All the experiments involved through infusion with a mobile phase of 1:1 methanol-water mixture. The electrospray sensitivity of pure quaternary ammonium ions increases as the chain length increases. The dynamic range expands over 5-7 orders of magnitude, depending on the specific ions, and the linear range is 2-3 orders of magnitude for all the ions.

Four 1:1 binary mixtures of quaternary ammonium salts were studied: (1) Me_4N^+ and

Pe_4N^+ , (2) Me_4N^+ and Pe_4N^+ , (3) Et_4N^+ and Pe_4N^+ , (4) Et_4N^+ and He_4N^+ . In terms of general analytical response curves, the signals for Me_4N^+ or Et_4N^+ in binary systems are much lower than those for pure solutions and the signals level off at much lower concentrations. In the meanwhile, the signals for Pe_4N^+ or He_4N^+ in binary systems are somewhat higher than those for pure solutions and the shape of the analytical curve remains unchanged. For all four ions, when the concentrations are very low, the signals for binary systems are higher than for pure solutions.

The results can be explained on the basis that the ions detected by mass spectrometry are generated from the surface of the charged droplets. The concentration ratio of ions on the surface of the aerosol is different from that in the bulk solution. For example, in binary mixture 2, there probably exists a competition for surface migration between the Me_4N^+ and He_4N^+ , leading to less Me_4N^+ movement to the surface of the aerosol than for the single component system, and resulting in a decrease in signal for Me_4N^+ . As for He_4N^+ , the concentration on the surface of the aerosol is almost the same as in the single component system, so that the signals are quite similar. In the binary mixtures, there are more ions in solution, resulting in higher conductivity, and thus higher charge density on the drop surface. This is probably the reason that the signals for Pe_4N^+ and He_4N^+ in the binary system were even higher than those for their pure solutions.

Bruce Thomson; Perkin-Elmer Sciex, Concord, Ontario L4K 4V8.

It is commonly observed that the charge distribution envelope in the electrospray or ion spray spectrum of a multiply charged protein shifts toward lower charge state as the voltage in the orifice-skimmer region is increased. Because structural or other properties of proteins in solution are sometimes inferred from the shape of the charge distribution envelope, it is useful to seek an explanation for the origin of this effect. In addition, it seems likely that ions desorbed from solution are significantly clustered, and the transport, drying/heating and declustering processes which the ions undergo before mass analysis need to be considered in any consideration of mechanistic/structural/solution effects.

At least five possible explanations for the shift in charge state with declustering voltage can be proposed: (1) It is a focusing artifact, in which low voltage better focuses low m/z ions, and vice versa. (2) Protons are stripped from the protein ions in the collision process. (3) Proton-bound solvent clusters are stripped from heavily clustered protein ions. (4) Protons are transferred to other neutrals by ion-molecule reactions, activated by increased collision energy. (5) As the declustering voltage is increased, high charge state ions are fragmented while low charge state ions are more effectively declustered. A triple quadrupole system has been used to explore these five possible explanations, recognizing that it has a second region for declustering/fragmentation - the Q2 collision cell. This allows exploration of the processes in a region with greater control over energy, pressure and gas composition, with an additional stage of mass analysis where needed.

Experimental An API III triple quadrupole uses a high capacity cryopump, which obviates the need for differential pumping. A nitrogen gas curtain or barrier separates the ion source from the interface, so that the expansion into vacuum contains only ions plus nitrogen - solvent and other neutrals (except for those attached to the ions) are excluded. The declustering region is between the orifice and the RF-only transfer rods ("Q0"). The potential between OR and Q0 controls declustering and fragmentation, and produces the same effect as the orifice-skimmer potential on a differentially pumped system. All experiments were performed with a solution of apomyoglobin, 20 pmol/L in MeCN/H₂O 0.1% formic acid, infused at 5 μ L/min. CAD in Q2 was performed with nitrogen as a collision gas.

The possibility of a focusing artifact was investigated by applying no declustering voltage between OR and Q0, operating Q1 in and RF-only mode, declustering in Q2 and mass analyzing in Q3. The Q1 spectrum observed with no declustering is weak and noisy, and exhibits a characteristic tail on all the peaks attributed to cluster and adducts, and shows a charge envelope which peaks at the 18+ charge state. When declustered in Q2 (resolving with Q3 instead of Q1), the behavior is similar to that observed under more normal conditions of OR/Q0 declustering - as the collision energy (now controlled by Q2 rod offset) is increased, the intensity increases, adduct tails are removed, and the spectrum shifts toward lower charge state. Since there is no applied field in the OR/Q0 region, the shift in charge state does not appear to be associated with focusing effects in this region, but rather with CAD processes which are similar in both regions.

The question of whether individual charge states lose protons during the up-front CAD process is readily answered by CAD of each of the mass selected ions in Q2. Under good up-front declustering conditions (thus ensuring that only the bare protein ion is introduced through Q1 into the collision cell), there appears to be no evidence of proton loss under any CAD energy condition (low to high). As the collision energy is increased, the ion fragments by processes which all represent loss of neutral or charged fragments of the molecule, but not individual protons. This is consistent with expectations that reaction pathways would favor retention of the proton on some part of the molecule as it fragments, rather than loss of the proton. However, the picture changes when CAD is performed on undeclustered ions. In this case, weak peaks appear which correspond to both lower and higher charge states. These have been observed by others when performing CAD on so-called "cold" ions¹, and attributed to charge stripping (loss of an electron to explain the higher charge state) and charge loss (loss of a proton to explain a lower charge state). The fact that the same processes are not observed for the well declustered ions, however, suggests alternative explanations (see below).

There appears to be no evidence for either protonated solvent clusters nor protonated nitrogen in product ion spectra of the heavily clustered ions. All of the low mass fragments are alkali ions (eg sodium,

potassium), or organic fragments of the parent. This suggests that charge loss by processes (3) and (4) above is not significant or favorable.

This finally leaves the explanation that increasing the declustering voltage causes high charge state ions to be fragmented (their intensity decreasing as the voltage is raised) while lower charge state ions are more effectively declustered (their intensity increasing until the point of fragmentation). Thus for each charge state there is an optimum voltage for declustering without fragmentation, and each charge state peaks at a different voltage (since the laboratory-frame collision energy increasing with charge of the ion). This explanation is supported by the following experimental results: (1) As the Q2 voltage is raised to the point where high charge state ions start to decrease in intensity, low mass organic fragments begin to appear. (2) Allowing only ions <1600 Da through Q1 (operating in RF-only mode), and declustering in Q2, results in the observation of many high charge state ions which clearly are greater than 1600 Da when sampled and passed through Q1, but much lower (down to < 1000 Da) after declustering in Q2; this indicates the fact that a very long tail of clusters/adducts exists for each charge state.

In the course of the experiments, it became clear that under low declustering conditions, CAD of ions in any mass window within the protein ion charge state envelope, leads to products which are clearly protonated protein ions of lower and higher charge state (as seen in Figure 2). Further investigations have suggested the following explanations: (1) Dimers and higher multimers fragment to monomers with a range of charge distribution. (2) Alkali ion adducts, which are often present, fragment by loss of the alkali ions, and hence lower charge state (eg an ion with two K⁺ fragments by sequential loss of K⁺). (3) A continuum of clusters and adducts exists, which upon declustering, leads to a series of declustered ions of lower mass. For example, the parent mass of the declustered 12+ charge state (m/z 1413 for apomyoglobin) may contain a contribution from the clustered 13+ charge state, particularly under low declustering conditions. CAD of m/z 1413 thus may lead to some formation of m/z 1304 purely as a declustering process, rather than due to loss of a proton. Thus the appearance of higher and lower charge state ions observed in Figure 2 may be due to a the presence of a complicated overlay of multimers, alkali ion adducts and solvent clusters which exist within every parent mass window, and which fragment/decluster by the means described above.

Figure 1. Apomyoglobin spectrum declustered in Q2, showing the shift in charge state with collision energy.

Figure 2. CAD spectrum of m/z 1020-1030 window of apomyoglobin adduct/cluster, with no declustering in the OR/Q0 region. (Vertical expansion = 16x).

Assessment of hydrogen bonding contributions in a gas phase protein by mass spectrometry.

Christie L. Hunter¹, A. Grant Mauk², and Don J. Douglas²
¹Dept. of Biochemistry and Molecular Biology, ²Dept. of Chemistry,
 University of British Columbia, Vancouver, Canada

With the development and application of electrospray mass spectrometry and its application to proteins, the relationship between the structure and properties of protein ions in the gas phase and their behavior in solution has become an issue of extensive discussion. A particularly attractive strategy for assessing this correlation would be to compare the stability of a series of protein-small molecule complexes in the gas phase with their stability in aqueous solution. Here, this correlation has been evaluated through the investigation of horse heart myoglobin variants and bovine liver cytochrome *b₅* derivatives in which the stabilizing hydrogen bonding interactions between the propionate groups of the non-covalently bound heme have been modified through genetic or chemical means. Previous work has demonstrated that the rates of heme dissociation from these proteins in solution vary systematically with the number of hydrogen bonds formed between these propionate groups and the corresponding apo-protein (1).

Figure 1. Hydrogen bonding interactions (dotted lines) of the heme propionate groups of horse myoglobin and bovine liver cytochrome *b₅*.

In the present study, the stability of heme binding to each of the reference proteins in solution is represented by the activation energy for heme dissociation, measured by the kinetic method of Hargrove *et al.* (2). The stability of the heme binding to the apoprotein in the gas phase was determined by collisionally-activated dissociation in the differentially pumped ion sampling interface (Figure 2). The voltage difference between the orifice and skimmer that caused 50% dissociation of the complex for four different charge states was taken as a measure of the binding energy (V_b). Differences in V_b (4 - 10 V) could be detected between the variants differing by just one hydrogen bond. The dissociation voltages measured in the gas phase exhibited a linear correlation with the activation energies of dissociation in solution for the myoglobin variants involving changes in the hydrogen bonding structure to the heme propionates (Figure 3). The myoglobin variants in which the amino acid substitution also eliminated a hydrogen bond to the proximal histidine residue and thereby weakened the proximal histidine-Fe bond in solution, however, appeared to stabilize heme-apoprotein association in the gas phase. The dissociation voltages for the cytochrome *b₅* derivatives also correlated with stability in solution (Figure 3).

Figure 2. The mass spectra of wild-type myoglobin at various orifice-skimmer voltage differences and the relative abundances of holo and apo myoglobin as a function of the orifice-skimmer voltage difference.

Figure 3. The dissociation voltage (V_b), measured in the gas phase, is correlated to the activation energy of heme dissociation (E_A), measured in solution, for the myoglobin and cytochrome *b₅* derivatives.

The implications of these results are twofold. First, hydrogen bonding interactions present in solution are maintained in the gas phase under these mild conditions. The protein cannot be grossly misfolded in the gas phase and retain linear correlation with behavior in solution. Second, this work suggests that small differences in protein-small molecule stability may be evaluated in the gas phase in a manner that (through automation) is more rapid, more sensitive, and more generally applicable than conventional methods used in solution.

On the origin of spray current pulsations in ES MS

R. Juraschek, R. Paulig, M. Böhmer and F. W. Röllgen
Institut für Physikalische Chemie, Universität Bonn, Wegelerstr. 12,
D-53115 Bonn, Germany

Low frequency pulsations of electrospray currents are a well known phenomenon. Recent investigations of capillary spray current pulsations under ES MS conditions showed "low" frequency pulses consisting of bunches of "high" frequency pulses which were attributed to the rate of droplet formation [1].

We have investigated spray current pulsations for a water/methanol (vol. ratio 1:1) solution and ES MS conditions by combining the measurement of the capillary current pulsations with optical microscopy and flash photography to monitor the disintegration of the liquid at the end of the capillary. In these experiments a capillary of 240/110 μm (O.D./I.D.) was used with a capillary/counter electrode distance of 1 cm, and a flow rate of $F \approx 2 \mu\text{l/min}$ was generally applied.

Three different axial spray modes, i.e. spraying of the liquid via formation of a cone jet, could be distinguished by increasing the capillary potential (U_{cap}): At lower U_{cap} , "low" frequency pulsations appear which group together "high" frequency pulses as shown in Fig. 1. With increasing U_{cap} the low frequency pulsations increase up to a spray mode with a single high frequency pulsation. This frequency, which is also observable in mass spectral ion intensities, further increases with U_{cap} (The maximum frequency observed was less than 4 kHz). Microphotography revealed the correlation between a single high frequency pulse and the transient emission from a cone jet which accordingly appears and disappears at this rate (Fig. 2). The origin of the high frequency pulsations is an imbalance between the loss of liquid via emission and the supply of the liquid to the apex of the cone. The time period between subsequent pulses is needed for rebuilding the cone jet after its disrapture and relaxation of the surface of the liquid. In contrast, the low frequency pulsations arise from an imbalance between the integral emission of a series of pulses and the supply of the liquid through the capillary to the cone. Both pulsation phenomena are related to field and capillary forces acting on the surface of the liquid cone, and to pressure differences in the cone. The third spray mode appears at a critical U_{cap} at which the capillary current increases by approximately a factor of two and at which current pulsations disappear. A continuous cone jet is observed under these conditions. There is no evidence of the emission of droplets directly from the apex of the cone. This finding is supported by electrohydrodynamic considerations.

NOVEL ELECTROSPRAY SOURCE DESIGN

Edward W. Sheehan and Ross C. Willoughby
Chem-Space Associates, 575 Epsilon Dr., Pittsburgh, PA 15238 USA

In recent years electrospray (ES) have successfully demonstrated capabilities for ion production with both labile and high molecular weight compounds. Typically ES ion sources are operated at atmospheric pressure because of the efficient heat transfer at these pressures to the charged droplets which results in the evaporation of the primary droplets and concomitantly causes efficient ion production. Unfortunately, at atmospheric pressure:

1. only a fraction of the ions produced are actually sampled into the low pressure mass detectors because of the difficulty of focusing and sampling ions into high vacuum systems through small sampling apertures.
2. the threshold of an electrical discharge across the gap between the high electrical potential capillary and the counter-electrode is low. The operating voltages for a stable ES liquid cone-jet are limited by this discharge threshold due to partial or complete degradation of the electrospray process during an electrical discharge.

The possibility of operating ES at pressures other than at atmospheric pressure is illustrated in Figure 1. The hashed areas show that there are two distinct regions for ES operation, Regions I and III. Region I is the low pressure electrospray (LPE) regime where no discharge occurs and stable liquid cone-jets occur (Electrospray cones at these pressures are generally referred to as electrohydrodynamic ionization, EHD, when the liquid flow is on the order of several nanoliters. With EHD, ions are generally emitted directly from the cone). Region II is the discharge region where no liquid cone-jets are observed because the current is dissipated through the gas phase. Region III is the atmospheric pressure regime associated with most conventional ES systems. The dotted line is the onset voltage for a typical liquid cone-jet formation; below which no ES occurs.

In the present work a new electrospray source has been developed that operates at the reduced pressures of Region I. The system consisted of a fused silica electrospray needle; a heated high pressure region (0.1-100 torr); and a ion-optics stack, all residing in the front chamber of a differentially pumped commercially available quadrupole mass spectrometer system (Benchmark LC/MS, Extrel/Waters, Pittsburgh, PA). Upon the application of a high potential (~2 KeV) to the liquid following, at ~ 3 microliters/min, through the fused silica needle an electrospray cone-jet was observed at the end of the fused silica. The pressure of the front chamber was $2-3 \times 10^{-4}$ torr. The electrified liquid jet emitting from the apex of the electrospray liquid cone was stabilized and directed, with the aid of electrostatic and mechanical adjustments, through a small aperture into the higher pressure region (0.1-100 torr). In the higher pressure evaporation region, the droplets undergo evaporation and desolvation resulting in the formation of ions. The ions were extracted from the higher pressure evaporation region and were subsequently mass analyzed.

Analysis was performed on the quaternary ammonium salt, tetramethylammonium chloride and the purine, caffeine. The preliminary results from this LPE interface were itemized as follows:

- a reasonably stable ion signal;
- the mass spectra were qualitatively the same as conventional atmospheric electrospray: the presence of a prominent singly charged molecular specie (the cation M^+ , m/z 74, for tetramethylammonium ion and the protonated ion $[M+H]^+$, m/z 195, for caffeine);
- a symmetrical ion profile and a narrow energy spread for the ion species,
- a lack of fragmentation; and
- a lack of higher mass solvent-analyte cluster ions

MALDI-MS of Polymeric Materials

Camille M. Kassiss¹, Anna M. Belu¹, Joseph M. DeSimone¹, Richard W. Linton¹, Gary W. Lange² and Robert M. Friedman²

¹Department of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-3290

²Monsanto Company, St. Louis, MO 63141

MALDI-MS has the potential to become a powerful "routine" analytical tool for the characterization of synthetic polymers up to very high molecular weights. However, some very important sample preparation issues must first be overcome before MALDI-MS can be universally applied.

Role of the matrix

Because the sample preparation protocol, namely finding a suitable matrix-polymer combination, is essential to the success of the experiment, it is necessary to investigate what role the matrix plays in aiding the desorption and ionization of the polymeric species. Aside from absorbing at the wavelength of the laser and exhibiting apparent miscibility with the polymer in a particular solvent system, no universal criteria has been outlined for choosing a matrix. Some have suggested that the polymer-matrix homogeneity and microstructure play a role in the success or failure of the MALDI experiment.¹⁻² In our research, we have focused on the miscibility between the matrix and polymer. If the lack of miscibility between the polymer and matrix is one of the causes contributing to the failure of the MALDI-MS experiment, then finding a way to overcome this problem may be a major step toward understanding the role of the matrix. The use of surfactants has been investigated in this work as a potential means by which previously "unsuccessful" polymer-matrix systems can be significantly improved. We have utilized non-ionic surfactants, such as Triton X-100, reduced, n-Octyl- β -D-Glucopyranoside, and n-Octyl- β -D-Thioglucopyranoside in the analysis of 5K Da Polymethyl methacrylate (PMMA) in a matrix that has been previously shown to give poor results.

As we have reported previously, *trans*-3-Indoleacrylic acid (IAA) is a "suitable" matrix for producing parent molecular ions in the MALDI-MS analysis of PMMA. Dithranol, however, is not "suitable" as a matrix for the observation of molecular ion signals.¹ After first determining that the addition of these surfactants at concentrations at or below their critical micellar concentrations to the "successful" PMMA-IAA system resulted in no degradation of the oligomer signals, we investigated their use with the PMMA-dithranol system. Using the same plate loadings of polymer and matrix as in the PMMA-IAA system (0.16 nmol PMMA, 0.1 μ mol dithranol), the addition of 0.6 nmol of Triton X-100 to PMMA and dithranol resulted in the appearance of PMMA molecular ions. Concentrations up to 1.0 nmol produced comparable results. A marked improvement in the signal to noise is observed with the use of n-Octyl- β -D-Glucopyranoside (Fig. 1) and n-Octyl- β -D-Thioglucopyranoside in the PMMA-Dithranol system. For the case with glucopyranoside, PMMA molecular ion signals are observed at 1 nmol of surfactant and produce signals of significant intensities from ca. 10 - 70 nmol. For the case with thioglucopyranoside, the appearance of analyte molecular ions is observed upon the addition of 0.5 nmol of surfactant, albeit of low intensity, with concentrations from ca. 5 - 50 nmol producing results comparable with glucopyranoside. (Note: All spectra contain oligomer peaks cationized by Na⁺.)

Effect of Molecular Weight Distribution

Because MALDI-MS has the capabilities of fast and precise analysis to determine molar mass absolutely,¹ much interest has been generated in improving the utility of this technique for all classes and types of polymers. For materials with narrow polydispersities (> 1.05), molecular weight measurements agree quite well with those of other more conventional tools, such as GPC. However, a polymer with a broader molecular weight distribution (> ca. 1.1) has been shown to affect the accuracy of the MALDI-MS results. Significant differences between molecular weights measured by GPC and MALDI are observed as the polydispersity increases.^{3,4} In an effort to overcome this limitation, researchers have begun to couple GPC prior to MALDI analysis by collecting and subsequently analyzing fractions from the progression of a standard GPC run. The overall molecular weight and polydispersity of the original sample can be obtained from the collection of spectra of the fractions.⁵

In our research, we have attempted to build on the success of this idea by simplifying the overall sample preparation scheme. The polymer effluent from a GPC is pumped through an HPLC pump and spray deposited directly onto a rotating matrix-coated disk. The disk is inserted into the instrument and the resulting polymer "trail" is analyzed by MALDI-MS.

Both narrow and broad polydisperse PMMA samples were spray deposited onto IAA coated disks and various spectra were acquired along the "trail." The molecular weight at each point was observed to shift to lower values with each acquisition (Fig. 2). Molecular weight information was determined for each point, and subsequently for the entire sample. The overall calculated Mn and MWD values were lower than manufacturer's estimates. Optimization of this protocol is underway.

Analysis of Low-Molecular Weight Polymer Blends by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

Robert Goldschmidt and Kevin G. Owens, Department of Chemistry, Drexel University
Scott D. Hanton* and David M. Parees, Air Products and Chemicals, Inc.,

Introduction

Matrix-Assisted Laser Desorption/Ionization (MALDI/I) techniques have recently been extended to determine the chemical structure of a variety of industrial polymers. Important information that can be determined includes the monomer mass, end group mass, and molecular weight distribution. Previous work has shown that average molecular weights obtained from many MALDI/I experiments essentially agree with the average molecular weights determined by Gel Permeation Chromatography (GPC).¹⁻⁴ We would, however, like to extend MALDI/I to the quantitative analysis of polymer blends.

Results

We have analyzed a series of polymer blends including: polyethylene glycols (PEG), amine terminated polyethers, polytetramethylene glycols, polymethylmethacrylates, polystyrenes, and perfluoropolyethers. The goal of these analyses is to characterize each component of the blend by its chemical structure and average molecular weights, and to quantify the relative amounts of each of the blend's components. These experiments have demonstrated that MALDI/I can analyze the chemical structure and average molecular weights of the individual components, but that we cannot rely on the values for the relative composition of the blend. Figure 1 demonstrates these results. It is a MALDI/I-TOF mass spectrum of an equimolar blend of PEG 1500 and PEG 4600. The ratio of peak area PEG 1500/PEG 4600 = 0.30.

Figure 1

To further investigate the analysis of polymer blends by MALDI/I, we designed three factorial experiments. Factorial experiments are planned experiments used to objectively discover the interdependence of experimental variables and their cross terms.⁵ For these experiments we chose to examine PEG blends, to minimize the complication of the analyte polymer. The factors for these experiments contain the number of moles of PEG 1500, PEG 4600, and matrix (2,5-dihydroxybenzoic acid, DHB), and the laser power.

The factorial experiments show that the area/mole ratio of PEG 1500/PEG 4600 is critically dependent on the experimental conditions. We observe seven significant factors and cross terms: PEG 1500(-), PEG 4600 (+), DHB (+), laser (-), PEG 1500 x PEG 4600 (-), PEG 1500 x DHB (-), and DHB x laser (-). Figure 2 is a graphical representation of the set of results showing the interdependence of the numbers of moles of PEG 1500, PEG 4600, and DHB on the above ratio. Analytically, this ratio = 1.0. From these relationships we can clearly see two important trends: increasing the moles of DHB tends to increase the ratio, indicating that more DHB assists PEG 1500 better than PEG 4600, and increasing the moles of PEG 4600 tends to increase the ratio, indicating that additional PEG 4600 inhibits itself more than it inhibits PEG 1500.

Figure 2

Conclusions

These experiments demonstrate that the results of analyzing polymer blends with MALDI/I - TOFMS is critically dependent on the sample preparation method. The sample preparation must be tuned to the particular chemistry of the blend components. Currently, we know optimized sample preparation conditions exist for the pairs we have studied, but we cannot predict these conditions in advance. Without optimized blend sample preparation conditions, MALDI/I cannot be expected to properly quantify polymer blends.

Polymer analysis by MALDI - Rapid Molecular Weight and Chemical Modification Data

Kuang Jen Wu and Robert W. Odom

Charles Evans & Associates, Redwood City, CA 94063

Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry has been applied to the analysis of industrial polymers. The studies were performed on a high resolution triple electrostatic sector analyzer (ESA) time-of-flight mass spectrometer. These ESAs provide complete first order energy focusing of ion flight times which correct and compensate flight time variation due to kinetic energy aberration at the acceleration region as well as flight time differences arising from angular variances. No delay extraction was applied to the sample stage, therefore, the improved mass resolution is carried out entirely by the flight time compensation effects of the electrostatic sectors. A N_2 laser ($\lambda=337$ nm) with a pulse width of 600 psec is used for desorption/ionization. The routine mass resolution has been demonstrated to be in the range of 5,000 - 7,000 for m/z up to ca. 6,000. The matrix survey of different matrix/analyte combination indicated that dithranol with Ag trifluoroacetate as an ionization agent in TFH is the best sample preparation protocol for polystyrene analysis. A number of industrial polymers as well as co-polymers were investigated. Fig. 1 shows a polystyrene 8k standard. The oligomer peaks are clearly resolved when the sample was irradiated at threshold laser power density. Mass accuracy is determined to be < 50 ppm throughout the entire MW distribution. Such high mass accuracy permits a direct verification of the end group. The MALDI results confirm that each oligomer of the 8k polystyrene sample contains one butyl end group and a silver atom attachment (cationization agent). The mass distribution does not shift under various desorption laser intensities. However, both the mass resolution and accuracy deteriorate at higher laser irradiance. The presence of impurities can significantly hinder the ionization, therefore, affects the measured MW distribution. Fig. 2 is a positive ion spectrum of polystyrene 29k standard. The individual oligomers can still be resolved at this mass range, and the mass resolution is limited primarily by the width of the isotopic envelope. The weight averaged MW and calculated polydispersity values are in general good agreement with those measured by GPC and light scattering. Although M_w values determined by MALDI are consistently lower. These polystyrene 29K ion peaks also contain one butyl end group and a Ag atom attachment as indicated by the measured m/z values at each oligomer peaks. Due to the fact that higher MW components have less ionization yields as well as less detection sensitivity. An unnormalized mass distribution can result in false calculated M_w and polydispersity values. The future improvements include establishing a mass dependent ionization/detection calibration coefficients for various polymeric compounds.

ICI Research and Technology Centre, PO Box No 90, Wilton, Cleveland, England TS90 8JE
Keith Jennings, Michael Deery
University of Warwick, Coventry, England
Glen Critchley
Micromass Floats Rd, Manchester, England

Introduction

The use of matrix assisted laser desorption/ionisation mass spectrometry (MALDI) has enabled synthetic polymer formulations to be studied directly with much greater ease than was previously possible. A further advantage is that the mass range that can be analysed can be significantly extended. Early results have been promising, particularly when characterising narrow molecular weight distribution polymers. The use of the approach to give information regarding end groups has also been effective with polymethylmethacrylate (PMMA), polystyrene (PS), polyethylene glycol (PEG) and a number of polyester systems having been studied. Interesting results have also been obtained in a number of studies of polymer kinetics and polymer degradation. The technique continues to evolve however and a number of issues are still under active investigation by a number of groups.

Current issues

The resolution that may be obtained using the approach, using time of flight analysers, has recently been significantly extended using delayed extraction procedures. In this approach the ions in the source are initially allowed to spread out in a near zero electric field. The distance travelled by the ions depends on the initial velocities. At an appropriate time an electric field is applied to the ions. Faster ions, which have travelled further, receive less energy from the applied field than the slower ions. Velocity focusing can therefore be achieved and ions of the same mass arrive at the detector at the same time independent of their initial velocities. Second order focusing can be achieved by correct arrangement of the pulse time, pulse intensity and source geometry. The study of polymer systems with differing end groups has led to significant differences being observed in the relative sensitivities of the oligomeric species. The source of this variation, which is strongly compound dependant, continues to be studied. It has also been observed that, for some polymers, the molecular weight distribution that is measured can depend on the nature of the cation used in the experiment. This is obviously of significant practical importance and raises issues regarding the nature of the cation attachment process. Of perhaps the most significance however is the difficulty of obtaining spectra from samples of high polydispersity. When M_w/M_n reaches a value significantly above ~1.5 the MALDI experiment gives results that do not reflect the whole sample but rather predominately the lower oligomers. Preparative GPC methods followed by obtaining separate MALDI spectra and reconstruction of the data has led to more representative results but direct analysis would offer significant advantages.

Results

Experiments have been carried out on a number of polymer samples of mixtures of narrow polydispersity to mimic higher polydisperse systems. Representative results were obtained for mixtures of equal weights. These results are shown in Figures 1-3. Attempts to obtain the same results with equal molar ratios of the mixtures were unsuccessful. This indicates the current limitation of the direct experiment. The experiments were carried out using a ToFSpec E instrument (Micromass UK Ltd., Floats Rd, Manchester, England) employing delayed extraction in linear mode with a hybrid MCP-electron multiplier detector.

CHARACTERIZATION OF SYNTHETIC POLYMERS BY INTERNAL MALDI FT- ICR MASS SPECTROMETRY

Pitsenberger, Cynthia C.; Easterling, Michael, E.;
Danis, Paul O.; Amster, I. Jonathan

Matrix assisted laser desorption (MALDI) mass spectrometry has shown great promise as an alternative method to gel permeation chromatography for characterizing synthetic polymers. MALDI MS has been used to measure molecular weight distributions and the masses of the repeat units of synthetic polymers. In principle, the elemental composition of the end groups of a polymer can be derived if the masses of series of oligomers can be measured with high accuracy. End group analysis is directly related to the mass resolving power, and hence, mass accuracy of the mass spectrometer. TOF mass spectrometry, which has been used previously for MALDI measurements of polymers, does not have sufficient mass measurement accuracy and mass resolution to be able to perform end group elemental analyses. Here we show examples of high resolution measurements of polymers and copolymers by MALDI Fourier transform ion cyclotron resonance spectrometry

Using MALDI FT-ICR, linear regression of a plot of exact masses of the repeat units of a homopolymer, poly(methyl methacrylate), externally calibrated to PEG 2000, yields values of 100.0524 ($m_{\text{calc}}=100.0524$) for the repeat unit mass and 125.0351 ($m_{\text{calc}}=125.0578$) for the endgroup mass including sodium. These data are consistent with endgroups of 2 hydrogens. High resolution mass analysis of a commercial polyester sample, an alternating copolymer of a diol and a mixture of adipic and isophthalic acids, revealed regions of the mass spectrum that show statistical distributions of the two acids, as shown in Figure 2. The mass difference in the binomial distribution corresponds to the difference in mass of the two acids, adipic acid and isophthalic acid, comprised in the polymer. The mass spectrum contains five peaks, as expected for all the possible masses for 4 acids and 4 alcohols present in the polymer. When fitted to a binomial distribution, the constituents closely approximate 50% acid and 50% alcohol representation.

Figure 1. MALDI FT-ICR mass spectrum of poly(methyl methacrylate). Top spectrum shows the distribution of the monomer repeat masses. The bottom spectrum is an expansion of the x-axis showing the isotopic resolution of two sodiated oligomers, differing in mass by the monomer unit.

Figure 2. MALDI FT-ICR mass spectrum of a polyester copolymer of an acid (adipic acid and isophthalic acid) and a diol, diproxylated bisphenol-A (PBPA). Represented here is the region of the mass spectrum comprised of 4 acids and 4 alcohols.

FTICR-MS characterisation of (co-)polymers

FOM-Institute for Atomic and Molecular Physics,
Kruislaan 407, 1098 SJ Amsterdam, The Netherlands.

Strategies for the mass spectrometric characterisation of complex polymeric systems are generally divided in direct and indirect analyses. Both strategies have been employed in our external ion source 7T FTICR-MS and can answer most of the questions posed by polymer chemists. We have used MALDI-FTICR-MS for the determination of molecular weight distributions of both homo-polymers (derivatised Polyethyleneglycol, Polystyrene and Polymethylmethacrylate) as more complex co-polymers (EO-PO). The high resolution of our FTICR-MS, is used to characterise several polymers consisting of a complex permutation of two monomeric units and five different end-groups. In figure 1 we have shown an example of a MALDI-FTMS

Figure 1 MALDI -FTICRMS spectrum of mono-amine terminated ethyleneoxide-propyleneoxide copolymer. The sample was mixed with the 2,5 dihydroxybenzoic acid matrix in a 1:1000 molar ratio, dissolved in EtOH and subsequently electrospray deposited on a flat stainless steel probe. Average resolution is approximately 30000 for this 128k dataset.

spectrum of a mono-amine terminated 1,2-polyoxyalkylene. We have used the individual monoisotopic peaks for the identification of the different end-group distribution. The analytical method used was described earlier [1,2]. From figure 1 it is obvious that contrary to the specifications of this product, not

one single polymeric system is found, but that there are several distributions present. Here we benefit from the resolution of our FTMS data, enabling us to identify the monomeric composition as well as the exact end-group distributions. In the higher part of the molecular weight distribution, we find $\text{CH}_3\text{O}-(\text{C}_2\text{H}_4\text{O})_x-(\text{C}_3\text{H}_6\text{O})_y-\text{C}_3\text{H}_5\text{N}$ to be the dominant distribution. The distribution around $M_w \sim 1000$ is identified to be $\text{CH}_3\text{O}-(\text{C}_2\text{H}_4\text{O})_x-(\text{C}_3\text{H}_6\text{O})_y-\text{C}_3\text{H}_5\text{O}$. These unsaturated endgroups can be formed due to dehydration of the hydroxylethyl endgroup of the polymer during the base-catalysed polymerisation. Note that the exact mass of the low M_w distribution found can also be described with $\text{CH}_3\text{O}-(\text{C}_2\text{H}_4\text{O})_x-(\text{C}_3\text{H}_6\text{O})_y-\text{C}_3\text{H}_5$. In this case the monomeric constitution of the copolymer does not agree well with the ratio of ethyleneoxide and propyleneoxide used in the polymerisation process. Another aspect of the analysis of these complex polymeric system is the occurrence of components with identical elemental compositions which could possibly be differentiated by studying the MS/MS fragmentation behaviour.

The flight time of ions between ion source and ICR-cell is of great influence on the determination of the molecular weight distribution. The spectrum in figure 1 was taken at an interval of 1000 us between laser shot and the end of the trapping event. Increasing this interval to 1200 us eliminates the low M_w part of the spectrum. In order to circumvent this distortion of the measured M_w distribution, several measurements at different intervals have to be performed. A good representation of the full M_w distribution is achieved by overlaying all measured spectra, provided that MALDI and experimental conditions are identical. By coadding 100 transients at each interval time we have averaged MALDI efficiency and laser intensity fluctuations. Also the appearance of magnetron motion can severely hamper a correct interpretation of these molecular weight distributions. Due to the magnetron motion, the ion detection efficiency becomes a function of their respective m/z value. The high mass contribution of the molecular weight distribution is underestimated compared to the lower part of the molecular weight distribution, leading to a misrepresentation of the M_w distribution.

Next to MALDI as a direct analytical method for polymer analysis, direct temperature resolved mass spectrometry (DTMS) is used to identify additives, residual oligomers and catalysts used in the polymerisation process. This indirect approach thermally degrades the polymer system before it is analysed in the mass spectrometer. This technique can be a valuable tool in the analysis of complex polymeric systems, particularly in combination with FTICR-MS. DTMS benefits from the high resolution as well as the high repetition rate of our FTICR-MS. We have identified brominated fire retarding additives [3] as well as UV-stabilizing additives in commercial polymeric blends. The minimal sample requirements for this techniques makes it especially suitable for microscale analysis.

TANDEM ELECTROSPRAY MS FOR ASSESSMENT OF COPOLYMER COMPOSITION

Kelsey D. Cook, Albert A. Tuinman, and Jeremi D. Johnson

Department of Chemistry, University of Tennessee, Knoxville, TN 37996-1600

Anionic copolymers are commonly employed as additives in engine lubricants and coolants. In conjunction with a problem with such a formulation, we were asked to assess the feasibility of qualitative distinction among several such additives. Negative ion electrospray MS was employed with collisional activation to characterize the composition of eight commercial oligomeric (MW ca. 2,000 - 20,000) terpolymers containing styrene sulfonate (SS), 2-acrylamido-2-methyl propane sulfonic acid (AMPS), and acrylic acid (AA) (Figure 1). Spectra of the polymer samples (ca. 20 µg/ml in 50/50 water/methanol) acquired under "normal" conditions (20 V cone voltage, infusion of 5 µl/min) on the VG Quattro II were extremely complex, comprised mainly of a broad, unresolved "hump" centered on a few hundred Da, and a few low-mass ions associated mainly with the solvent (Figure 2a). When the same samples were run with collisional activation (CA) by increasing the cone voltage to 100 V, additional low-mass ions *characteristic of individual monomers* emerged (Figure 2b). These ions were not present with significant intensity without CA. Peaks at m/z 183 and 206 were attributed to formation of SS and AMPS monomers, respectively, via collisional activation of the polymers. Under these conditions, at best a weak signal was observed at m/z 71 for the AA monomer. Addition of 75 µM NaOH enhanced the signal attributable to AA by promoting ionization of this weakly acidic compound (Figure 3). Signals due to the other two monomers were not adversely affected.

As a test of the validity of these assignments, a sample of a pure polystyrene sulfonate (PSS) oligomeric (nominal MW 1600) homopolymer was examined by negative ion ES MS (Figure 4). This relatively low-mass sample gave an interpretable spectrum comprised of several homologous, overlapping series each corresponding to oligomers of varying degrees of polymerization and charge states. (Although incidental to the current study, these data allowed confirmation that the polymer end group mass was 58 Da (C_4H_{10})). Collision-induced dissociation ($E_{lab} = 25$ eV, $\sim 2 \times 10^{-4}$ torr Ar) of an arbitrary oligomer (pentamer with two sodium ions attached, for a 3- overall charge) generated predominantly the monomer at m/z 183 (Figure 5), with very little other fragmentation

The next step was to acquire and compare spectra of all eight samples under identical (collisional activation) conditions. As a measure of the monomer composition of each, fractional intensities ($\% \Sigma_{monomer} = 100 i_{monomer} / (i_{71} + i_{183} + i_{206})$) were calculated and compared for each of the three monomer signature ions (Figure 6). For comparison, the variability of the ratio of two fragments from the same monomer (m/z 135 and 206 from AMPS) was also assessed (Figure 7). Some scatter persists in Figure 7, and some of the eight samples had no detectable AMPS (so that the i_{135}/i_{206} ratio could not be assessed). Nevertheless, it is clear that the differences among the $\% \Sigma$ values for the various samples are significant, relative to the uncertainty in the data (as estimated either from the run-to-run variability represented in Figure 7, or from the standard deviation of replicate measurements, used with permutation of errors calculations to generate the error bars shown). More detailed quantitation will require substantially more work, including studies with standards of known monomer ratios and/or calibration of MS data against alternative methods. This has proven difficult for the samples of interest.

COUPLING GEL PERMEATION CHROMATOGRAPHY TO MALDI MASS SPECTROMETRY

Xun Fei and Kermit K. Murray

Department of Chemistry
Emory University
Atlanta, GA 30322

Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry is well known as an excellent method for molecular weight determination of biopolymers and is seeing increasing use for the analysis of synthetic polymers. However, speed and ease of use make gel permeation chromatography (GPC) the method of choice in most polymer applications despite problems with calibration of the molecular weight scale. MALDI mass spectrometry is an obvious choice for a GPC detector because it provides an internal molecular weight calibration and an additional dimension of separation. A aerosol liquid introduction technique has been developed that can be used to couple GPC to a MALDI mass spectrometer. In aerosol MALDI, the UV absorbing matrix is mixed with analyte in a solution that is sprayed directly into the mass spectrometer. The solvent is evaporated when the aerosol passes through a heated drying tube.^{1,2} Ions are formed by pulsed UV laser radiation and mass-selected using a reflectron time-of-flight mass spectrometer. Coupling aerosol MALDI to GPC simply involves mixing the column effluent with a matrix solution prior to nebulization.

Figure 1. Representative mass spectra from approximately 100 obtained during an on-line GPC-MS separation of PEG 1000.

Five representative mass spectra from approximately one hundred obtained throughout a GPC-

MS separation of the polyethylene glycol PEG 1000 are shown in Figure 1. Each mass spectrum is the result of an average of 100 laser shots at a pulse energy of 105 mJ, and the spectra were 10 point boxcar averaged for plotting. The PEG spectrum contains oligomer peaks extending from approximately $m/z = 600$ to 1200 . The more intense distribution of peaks is associated with protonated analyte $[M+H]^+$ at mass $44.05n + 19.02$ where n is the number of polymer repeat units. The less intense set of peaks is associated with the sodium ion adduct of the form $[M+Na]^+$ at mass $44.05n + 41.01$. The mass resolution for all of the oligomer peaks is approximately $m/\Delta m = 300$. The PEG oligomers began eluting from the column after approximately 42 min and elution continued until 55 min had elapsed. The largest molecular weight polymers elute first: the number average molecular weight for the mass spectrum at 43 min is 1320 u whereas by 51 min the number average molecular weight has decreased to 760 u.

Figure 2. Weight and number average molecular weight plotted as a function of retention time for PEG 1000. The open circles correspond to number average molecular weight, M_n , and filled circles correspond to weight average molecular weight, M_w .

Number average (M_n) and weight average (M_w) molecular weights were extracted from the GPC mass spectra by integrating the individual oligomer peaks. The retention time behavior of the weight and number average molecular weight based on the $[M+H]^+$ peaks of PEG 1000 is shown in Figure 2. A 600 ns window about the calculated flight time was used for integration of the peaks and a 2 MHz second order Bessel function smooth was applied to improve baseline subtraction. The lines through the data points in Figure 6 correspond to the function $\log(M) = A + B t_r$ where M is the weight or number average molecular weight, t_r is the retention time and A and B are constants varied in a least squares fit. Deviation from the expected $\log(M)$ dependence can be seen in Figure 2 between 43.5 and 44.5 min. It is likely that the deviation from $\log(M)$ dependence is due to differences in separation efficiency for the different PEG oligomers.

The GPC-MS experiment represents a new and powerful method for polymer characterization, allowing for the direct correlation of size and mass. Two types experiments can be performed using the aerosol MALDI GPC-MS apparatus: characterization of unknown polymers or fundamental studies of the GPC process using polymers of well known size distribution.

Role of MS techniques in the characterisation of fresh and aged natural and synthetic varnishes used for paintings.

MOLART, FOM Institute for Atomic and Molecular Physics, Kruislaan 407, 1098 SJ Amsterdam, The Netherlands. (2) National Gallery of Arts, Scientific Department, Washington, USA.

Paintings are multicomponent multilayer systems of high complexity. A painting is usually composed of a support material (wood or canvas), priming ground, various paint layers and a finishing varnish. Our research groups study these systems using various MS techniques in order to determine distribution, state of oxidation, molecular weight distribution and spatial distribution of the various organic compounds in the painting materials. DTMS, FABMS and MALDIMS are used for direct fingerprinting. Compound resolution is achieved with GCMS and LCMS techniques. Spatially resolved studies on cross sections are planned with SIMS and LD-ITMS.

Natural resins based on di- and triterpenoids have long been the traditional and mostly praised varnish for paintings despite the fact that they age considerably over short periods of time. The redox regime on and in the painting rapidly leads to higher oxidation states of these natural products. Ageing changes the mechanical and optical properties of varnishes and hence leads to the necessity to restore the art work. Aged varnishes require higher polarity solvents (isopropanol or ethanol) for removal. MS studies were performed to investigate the changes in chemical structure of natural resins used in paintings.

Diterpenoid resins which can be found on the painting as varnish and copper resinate glaze, in the painting as resin oil paint, inside the paint layers and at the reverse when wax/resin lining has been carried out. The oxidation state of these diterpenoids changes rapidly (see contribution TPE 150). The state of oxidation of the dammarane type skeletons in Dammar and Mastic triterpenoid varnishes changes rapidly. Ocotillone becomes a relatively dominant compound in aged Dammar varnishes. Reverse phase C18 HPLC using acetonitrile/water [1] is a good technique to characterise Dammar varnishes. Compared to the fresh dammar resin, a new mixture of well resolved strongly UV light absorbing compounds of higher polarity is observed in aged Dammar varnishes from paintings. HPLCMS(MS) using an APCI interface gives a crisp TIC for the fresh material but a very broad "trailing hump" with a few small peaks above the "background" for aged varnish. Mass chromatography demonstrates that the peak form is fine: the mixture of compounds is clearly too complex. HPLC-APCI-MSMS data of main peaks could be obtained and show similarities to the EI DTMS data obtained on HPLC cuts. Identifications require further work.

In the last decades various synthetic resins have been developed. The polymethylcyclo-hexanone varnishes have been used in the period between 1950 and 1970 [2]. DTMS of such resins is a rapid method of determination of such resins in small microgram scale paint/varnish samples. FABMS of Laropal K80 and AW2 in NBA gave relatively low molecular weight ranges with high peaks around m/z 800 and a tail towards m/z 2000. The ketone resins are clearly not "pure" compounds, but mixtures. MALDI MS of the resins tried in various matrices did not give good results until now.

Several new synthetic resins were tested in weatherometers at the NGA to investigate their performance under visible light ageing conditions [3]. Direct temperature-resolved MS (DTMS) combined with multivariate analytical techniques was performed to identify these resins and to investigate their ageing behavior. The resulting principal component map shown below demonstrates that ageing in a weatherometer leads to chemical changes that can be detected by MS. The various resins (control marked by a circle) are easily discriminated and plot in different multivariate regions. The cluster of Arkon-90 samples plots as a separate cluster in PC3 below the PC1PC2 plane.

The aged samples are identified by the number of exposure hours. The geometric distances in the map are a measure of the differences in chemical structure. Addition of a HALS (Tinuvin 292) prevents extensive photo-oxidative damage: the samples marked with a superscript T plot relatively close to the controls. The DTMS spectra and TIC data confirm these observations. Ageing is found to increase the relative abundance of polymerised fractions. The ions yield measured with respect to an internal standard (perylene) drops dramatically as ageing progresses. This suggests that (thermo)chemically stable bonds are being synthesised in the course of the photo-ageing process.

PRIMARY THERMAL DEGRADATION MECHANISMS IN POLYIMIDES¹
Michael A. Grayson, McDonnell Douglas Aerospace Corporation, St Louis MO 63166

Polyimides are an important class of polymers for use in high temperature environments. The application of such materials for long periods of time (years) under extreme conditions of temperature (177°C) requires a means of accelerating the aging of the polymer system. It is essential, therefore, that the thermal degradation of polyimides be understood in order to devise and validate accelerated aging conditions. In particular, it is critical that we determine and understand the thermal degradation mechanism for the reaction that occurs in the use-environment temperature range. For purposes of discussion, I will define this reaction as the primary thermal degradation reaction. The polymer in this study is based on a research polyimide LaRC™ -SI¹. The compounds used to synthesize the polymer are a 50/50 mixture of Biphenylcarboxylic dianhydride (BPDA) and 4,4'-Oxydiphthalic anhydride (ODPA) reacted with 3,4'-Oxydianiline (ODA). Phthalic anhydride (PA) was used to cap the amine terminus of the polymer chain⁽¹⁾. Structures for these compounds are shown in Figure 1. The amine stoichiometry was offset from 0 to 6% to make a series of polymers with different chain lengths. In this work, the 0 and 4% stoichiometric offset polymers were studied. The polymerized structure will consist of a random copolyimide with a structure like that shown in Figure 2. This structure is idealized in the sense that all of the amine terminations have been endcapped with phthalic anhydride.

Figure 1. Starting materials for synthesis of copolyimide.

Figure 2. Idealized copolyimide structure

to separate thermal degradation product ions from fragmentation ions. The thermal degradation of high performance polymer systems is characterized by a complex series of degradation pathways. This comes about because these polymer systems tend to be highly aromatic in structure and consequently very hydrogen deficient. As an example, for the polyimide in this study less than 4% of the molecular weight of the copolymer repeat unit is accounted for by hydrogen. While the study of these complex degradation pathways is of academic interest, it is more critical in this work to focus on only those degradation processes that occur at the very beginning of thermal degradation; i.e., the primary degradation mechanism. The initial thermal degradation of the 0% amine stoichiometry copolyimide begins with the production of carbon

dioxide. The onset temperature for this process is in the neighborhood of 330°C. The production of carbon dioxide in the thermal degradation of polyimides is commonly observed. Zurakowska-Orszagh and Chreptowicz⁽²⁾ determined the mechanism for this process using phthalimide as a model compound. The nitrogen bond in the imide ring is attacked as shown (I). A complex rearrangement process then occurs among the imide ring atoms that results in the formation of benzonitrile and carbon dioxide in phthalimide.

This would suggest that volatile products containing the benzonitrile group might be found in the degradation of a polyimide. The compounds that are observed evolving from the polymer immediately after the appearance of carbon dioxide ion are not consistent with that conjecture. At 345°C several amine containing compounds and an imide containing compound are observed.

All three of these compounds can be accounted for by attack of the phenyl-ether bond in the polymer chain. This suggests that although carbon dioxide may form, other volatile products from the polymer degradation are different from those observed in the phthalimide; at least for this polymer structure. The appearance of the amine containing compounds III (m/e 330 daltons) and IV (m/e 346 daltons) indicates that not all of the polymer chain ends were capped with phthalic anhydride. If such were the case, II (m/e 239 daltons) would be observed and neither III or IV would be present. The thermal degradation of the 4% amine offset stoichiometry begins in the same way; with the production of carbon dioxide at the same temperature as for the 0% case. However, the only common primary degradation product between the two stoichiometries is compound III. The evolution profile for III differs significantly between the two stoichiometries; the onset of its appearance in the 4% stoichiometry being approximately 30°C lower than in the 0% stoichiometry. One other primary product is observed in thermal degradation of the 4% stoichiometry polymer; compound V which can arise either from a chain terminus (structure Va), or from successive inter-chain cleavages (structure Vb). It is interesting to note that both of these primary degradation products arise from cleavage of the phenyl-ether portion of the polymer chain. In addition there is an indigenous volatile compound at m/e 460 daltons that evolves prior to the onset of thermal degradation. This can be accounted for by one 3,4'-ODA end-capping with two phthalic anhydride molecules. Such a reaction is indeed likely given the excess diamine in the 4% stoichiometric offset formulation. This work indicates that in addition to the previously observed degradation mechanism responsible for the generation of carbon dioxide, the phenyl-ether portion of the polymer chain is also attacked at the onset of thermal degradation. It is also apparent that the shift in polymer chemistry in the higher stoichiometric amine offset formulations has a deleterious effect on the thermal stability of the polymer chain. Such information is valuable not only in the development of accelerated aging conditions for these material systems, but also in guiding the formulation of new resin systems.

of the polymer chain. Such information is valuable not only in the development of accelerated aging conditions for these material systems, but also in guiding the formulation of new resin systems.

INVESTIGATION OF T-CELL RECEPTOR INDUCED SIGNAL TRANSDUCTION PATHWAYS USING ELECTROSPRAY IONIZATION TANDEM MASS SPECTROMETRY

Aebersold, R., Figeys, D., Gu, M.² Kerwin, J. M., Bures, E.J.,¹ Wange, R.L.,¹ Samelson, L.E., Watts, J.D.

Departments of Molecular Biotechnology and ²Botany, University of Washington, Box 357730, Seattle, WA 98195; ¹Cell Biology and Metabolisms Branch, NICHD, National Institutes of Health, Bethesda, MD, 20892.

Introduction. It has been known for some time that a cell's ability to respond to external stimuli, be they chemical, physical or hormonal, is regulated to a large part by a wide range of cell surface receptor complexes, which in turn are linked to a variety of intracellular protein complexes and enzymes. The biochemical mechanism by which the triggering of a cell surface receptor is interpreted by the cell, resulting in a defined biological response, is often referred to as signal transduction. These receptors and their ligands elicit discrete sets of intracellular biochemical responses, many components of which overlap, with the desired downstream physiological response apparently being determined by engagement of a subset of these receptors along with the relative extent to which each individual receptor pathway is being activated. Important aspects of receptor-mediated intracellular signaling include protein phosphorylation/dephosphorylation of key signal transduction pathway components, events carried out by protein kinases and phosphatases, respectively and the generation and release of small organic signaling molecules generally referred to as second messengers. Within T cells, a wide variety of cell surface receptors and co-receptors have been identified, known to play roles in the regulation of a variety of T cell biological responses, such as cell killing and interleukin-2 (IL-2) production, as well as regulating a range of differentiation and proliferative responses, such as positive and negative selection in the thymus, clonal expansion, anergy and programmed cell death (apoptosis). Based on the conviction that the most useful, comprehensive and biologically and potentially medically significant information in these areas of study would be the direct analysis of the state of protein phosphorylation and the establishment of quantitative profiles of second messengers in cells at different stages of activation, we have focused on the establishment of suitable, highly sensitive analytical methods. Since it was both biologically and medically significant in addition to biochemically challenging, we selected TCR-induced signaling pathways as a model system on which to test any new methodologies.

Results. Following TCR engagement, a number of its subunits, in particular the ζ and CD3 ϵ chains, become multiply tyrosine phosphorylated on a conserved motif, referred to as an immunoreceptor tyrosine-based activation motif (ITAM). The PTK ZAP-70 binds specifically to the doubly tyrosine

phosphorylated ITAMs of the TCR ζ and CD3 ϵ subunits subsequently becoming itself both tyrosine phosphorylated and activated. Applying Fe³⁺ metal affinity chromatography in series with capillary RP-HPLC-ESI-MS/MS we have shown that all six of the cytoplasmic tyrosine residues of the TCR ζ chain which constitute three complete ITAM motifs and Y292, Y492 and Y493 of ZAP-70 are major sites on *in vivo* phosphorylation in TCR-stimulated Jurkat T cells [1,2]. Subsequent mutagenesis demonstrated that phosphorylation of ZAP-70 at Y493 was a required event for the activation of ZAP-70 catalytic activity [3]. We have also shown that TCR ζ is a good substrate for the T cell specific tyrosine kinase p56^{lck} whose activation precedes the activation of ZAP-70, but is not a substrate of ZAP-70. Together these data are consistent with a mechanism of early TCR-induced activation events in which the rapidly activated tyrosine kinase p56^{lck} phosphorylates tyrosine residues in the ITAM motif of TCR ζ . Phosphorylation of TCR ζ results in the recruitment of ZAP-70 to the TCR structure through binding of the ZAP-70 tandem SH2 domain to TCR phospho ζ and activation of ZAP-70 catalytic activity by phosphorylation of key regulatory residues by p56^{lck}.

At least three receptors on T cells, CD28 and the receptors for TNF α and the Fas ligand have been implicated in the activation of sphingomyelinases. Among the products of sphingomyelinases, ceramides have recently received much attention as putative second messengers for apoptosis. Using precursor ion scanning in an ESI triple quadrupole mass spectrometer we have demonstrated that we can establish quantitative and qualitative profiles of the ceramide content of biological samples [4]. We have used the method to determine the ceramide profile from non-stimulated Jurkat cells. Lipid extracts from as little as 10⁶ cells partially purified by simple silica gel chromatography was sufficient to clearly detect and differentiate the ceramide species present.

Discussion. We have shown that advanced techniques based on capillary chromatography and mass spectrometry for the analysis of the phosphorylation state of proteins and precursor ion scanning protocols for the analysis of ceramides now have the sensitivity to start to unravel intracellular signaling pathways by direct biochemical analysis. Further increases in sensitivity of such analyses by the introduction of microspray ionization techniques and the extension of profiling capabilities to additional types of second messengers will make mass spectrometry the method of choice for the comprehensive analysis of intracellular signaling pathways.

Understanding the Role of Protein Phosphorylation in Signal Transduction with the Aid of Mass Spectrometry

Roland S. Annan, Michael J. Huddleston, and Steven A. Carr
Department of Physical and Structural Chemistry
SmithKline Beecham Pharmaceuticals

Protein phosphorylation plays a critical role in transmitting signals from outside the cell into the nucleus. The first step in many signalling pathways is multiple phosphorylation of a receptor following ligand binding. This generally touches off a phosphorylation cascade, which continues, until the signal reaches the nucleus resulting in activation of transcription factors. Identifying the substrates for a particular protein kinase, and mapping the phosphorylation sites within a protein are essential for understanding the signal transduction pathway. MS based methods developed in our laboratory and by others now make it possible to unambiguously identify and sequence phosphopeptides at levels of a few hundred femtomoles. In our laboratory, LC-electrospray MS with phosphate selective scanning is used to identify candidate phosphopeptides in protein digests. An aliquot from the selected fraction from the LC-MS experiment is then analyzed by MALDI-TOF MS to confirm the presence of a phosphopeptide, and establish an accurate molecular weight. When using a reflectron time-of-flight mass spectrometer, MALDI can distinguish tyrosine phosphorylation from serine and threonine phosphorylation for peptides containing a single phosphate group. Phosphopeptides are identified in the (+) ion MALDI reflector spectrum by the presence of $[MH-H_3PO_4]^+$ and $[MH-HPO_3]^+$ fragment ions formed by metastable decomposition. An abundant $[MH-H_3PO_4]^+$ ion, accompanied by a weaker $[MH-HPO_3]^+$ ion indicates that the peptide is most likely phosphorylated on serine or threonine. In contrast phosphotyrosine-containing peptides generally exhibit $[MH-HPO_3]^+$ fragment ions, and little, if any $[MH-H_3PO_4]^+$. If it is necessary to establish the specific residue which is phosphorylated, the peptides are sequenced using either MALDI post source decay (PSD), or nanoelectrospray (nanoES) CID MS/MS. Using either method, we can distinguish between single phosphorylation at serine/threonine or tyrosine, and in many cases, determine the exact site of phosphorylation. Nearly complete sequence coverage and phosphorylation site mapping is often possible using PSD on ca. 300 fmol of peptide.

For nanoES, 25–100 fmol is all that is required. In general nanoES also provides better sequence coverage for larger peptides. Figure 1 shows the nanoES CID spectrum of a 23 residue tyrosine phosphorylated peptide, isolated from a tryptic digest of calmodulin after *in vitro* reaction with recombinant insulin receptor kinase. LC-MS with phosphate selective detection was used to identify fractions containing phosphopeptides. This peptide was also suspected to contain two oxidized methionines. The sequence of 21/23 residues can be deduced from this spectrum. The location of the phosphate is clearly established as Tyr¹³⁸, and both methionines are confirmed as being oxidized.

Endogenous phosphorylation is often present at very low stoichiometries. Therefore, even though an abundant amount of protein may be available, the yield of phosphopeptides from

a protein digest may be quite small. In the strategy we normally employ for phosphopeptide mapping, outlined above, we frequently encounter HPLC fractions which are believed to contain phosphopeptides, but we cannot identify the candidate peptide molecular weight. In response to this all too common problem we have developed a new 2D phosphopeptide mapping methodology which is based on orthogonal scanning techniques employing an ES triple quadrupole MS. In the first dimension we employ LC-ESMS in the SIM mode detecting PO_3^- product ions. In the second dimension, the targeted HPLC fractions are analyzed for precursors of PO_3^- using a nanoES source. The combination of the two scan routines makes this methodology very selective, and the use of the nanoliter flow device allows us to detect even very low levels of phosphorylation. If sufficient material is present, we can sequence the phosphopeptide using the same sample. We have used this strategy to successfully map the phosphorylation sites in several recombinant proteins including osteopontin, vitamin D receptor, CSBP (a MAP kinase homolog), and calmodulin. During the analysis of the milk protein alpha S1 casein we identified several phosphopeptides molecular weights which did not map to any part of the S1 sequence. One of the S1 phosphopeptide fractions also contained a nonphosphorylated peptide which we could not map to the S1 sequence. We sequenced this peptide by nanoES CID and performed a data base search using a short sequence tag (NXEN). The search identified a second casein protein, alpha S2 as being part of our sample. S2 casein bears little sequence homology to S1 casein, and contains 10 known phosphorylation sites in four tryptic peptides. Using this information, we identified all but one of the remaining phosphopeptides found in our HPLC fractions. Although very little of this remaining peptide was present in the fraction, we obtained an excellent nanoES CID spectrum. Based on this data, we report a new variant of alpha S1 casein, in which residues 92–95 have been replaced with XGY (where X is either Leu or Ile) yielding the peptide YXGYLEIVPNSAEER (M_r 1831.8). This sequence appears to be quantitatively phosphorylated on Ser¹⁰¹.

MS Sequencing of Novel Invertebrate Gonadotropin Releasing Hormone Peptides from Tunicate *A.G. Craig, W.H. Fischer, J.F.F. Powell†, S.M. Reska-Skinner†, M. Park, J.E. Rivier and N.M. Sherwood†. The Salk Institute, La Jolla, CA and †University of Victoria, B.C. Canada.

Gonadotropin releasing hormone (GnRH) is a neuropeptide secreted by hypothalamic neurons which acts in concert with other signals on the anterior pituitary gland to control reproduction in vertebrates. Previously we and others have traced the structural changes in the evolution of this neuropeptide within vertebrates including mammals and primitive species such as Russian sturgeon (*Acipenser gueldenstaedti*) and spiny dogfish (*Squalus acanthias*) (D. Lovejoy *et al.* PNAS (1992) 89, 6373-7). In phylogenetic terms, these species are located close to two different lineage bifurcations, one leading to bony fishes and the other cartilaginous fishes. We are interested in continuing to trace the phylogeny of this neuropeptide and to establish whether a homolog exists in invertebrates. To address this issue we have investigated whether a GnRH like molecule was present in tunicate (*Cheilosoma productum*). Protochordates such as the tunicate or sea squirt are at an evolutionary junction because they possess a notochord during early stages of development. Extracts from 1200 adult tunicates were found to contain compounds which cross-reacted with antisera raised against lamprey GnRH. Two active components were purified to homogeneity, and characterized with MS.

All known forms of GnRH contain a blocked amino terminus (pyroglutamic acid) which renders them resistant to Edman sequencing (R. Burgus *et al.* PNAS (1972) 69, 278-82), while the C-termini are resistant to carboxypeptidase treatment (D. Patterson *et al.* Anal Chem. (1995) 67, 3971-8).

Using matrix assisted laser desorption (MALD) we determined the sequences as follows. Figure 1 shows (A) the post-source decay (PSD) spectrum measured on a Bruker Reflex TOF instrument of tunicate GnRH I. The sequence assignment is based on a series of b-type ions and other fragment ions including y-type ions marked with asterisk. The insert shows the resolved isotope distribution of the [M+H]⁺ measured on a Jeol HX110 equipped with MALD and a -20 kV point detector (measured m/z 1246.58 c.f. calc. mono. [M+H]⁺ of 1246.564 Da).

(B) The MALD-TOF spectrum of tunicate GnRH II. The insert shows the HX-110 resolved isotope distribution of the [M+H]⁺ (measured m/z 2232.14 c.f. calc. mono. [M+H]⁺ of 2231.977 Da). (C) The MALD-TOF spectrum of tunicate GnRH II after reduction with tris(2-carboxyethyl) phosphine. The insert shows the resolved isotope distribution of the intact [M+H]⁺ (measured m/z 1117.52 c.f. calc. mono. [M+H]⁺ of 1117.50 Da). (D) The PSD spectrum of reduced tunicate GnRH II.

Tunicate GnRH I contains a salt bridge between residues 5 and 8 straddling a proposed beta turn which may serve to stabilize a bioactive conformation. When synthetic replicates of these hormones are injected into the visceral hemocoel (located near the gonads) in tunicates, an increase in estradiol was detected in a fluoroimmunoassay. Tunicate GnRH II represents the first occurrence of cysteine in a GnRH. The dimeric structure has no precedent.

Monitoring Changes in Calcium-Induced Conformational Changes in Recoverin by ESI-MS

Richard S. Johnson, Thomas A. Neubert, Kenneth A. Walsh, James B. Hurley
Department of Biochemistry, University of Washington 98195-7350

Recoverin is a calcium-binding protein involved in visual signal transduction, and is thought to regulate the duration of the photoresponse in a calcium-dependent manner via interactions with rhodopsin kinase. Recoverin is N-terminally acylated by a family of C12 and C14 fatty acids, and these acyl groups are known to play a role in the calcium-induced structural changes observed for this protein. The interplay between the calcium-binding sites and the N-acyl group has been termed a "calcium-myristoyl switch". This switch is thought to operate via a conformational change that results in the acyl group being extended away from the protein in the presence of calcium, thereby allowing for interactions of the acyl group with membranes or other proteins. In the absence of calcium, the acyl group is drawn into the recoverin molecule. Here we use the fragmentation method described by Zhang and Smith (1993) to measure the hydrogen isotopic exchange for calcium-bound and calcium-free recoverin that had been N-acylated with either myristic acid (C14:0) or lauric acid (C12:0), as well as the unmodified protein.

In the case of N-myristoylated recoverin, calcium-binding sites (EF-hands) were found to have a reduced rate of deuterium exchange in the presence of calcium, which was interpreted as a stabilization of hydrogen bonds resulting from metal chelation (Fig. 1). In contrast, certain hydrophobic regions exhibited a marked increase in the rate of deuterium exchange (Fig. 2). This effect may be due to the removal of hydrophobic stabilization of the regions that is otherwise provided by the myristoyl group when calcium is absent. Nearly identical results were obtained for N-lauroylated recoverin, except that the hydrophobic regions were not stabilized by the acyl group to the same extent. Similar studies of unacylated recoverin yielded results that were quite different from the acylated protein in that no regions were found to have an increased rate of deuterium exchange in the presence of calcium. Thus, it is clear that the N-terminal acyl groups play a critical role either in maintaining an appropriate conformation or controlling protein dynamics. The influence of both calcium-binding and N-acylation were clearly evident from data obtained using ESI-MS to monitor changes in hydrogen isotopic exchange rates.

Zhang, Z., & Smith, D. L. (1993) *Prot. Sci.* 2, 522-531.

Figure 1: MH^+ ion corresponding to the peptic peptide encompassing residues 85-89 from N-myristoylated recoverin after 180 minutes of deuterium exchange. In the top panel, 1 mM EGTA was used to remove any residual Ca^{2+} ions, whereas in the bottom panel, 1 mM $CaCl_2$ was present.

Figure 2: MH_2^{+2} ion corresponding to the peptic peptide encompassing residues 64-80 from N-myristoylated recoverin after one minute of deuterium exchange. In the top panel, 1 mM EGTA was used to remove any residual Ca^{2+} ions, whereas in the bottom panel, 1 mM $CaCl_2$ was present.

Sequencing MHC Class I K^b Peptides Isolated from Mouse EL-4 Cells by Membrane Preconcentration - Capillary Electrophoresis - Mass Spectrometry (mPC-CE-MS/MS)

Andy J. Tomlinson¹, Stephen Jameson² and Stephen Naylor^{1,3}

¹Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN 55905, USA. ²Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN 55415, USA. ³Department of Pharmacology and Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN, USA.

Peptides that bind to major histocompatibility (MHC) class I molecules are important signals of the immune system. However, characterization of individual sequences presents a formidable challenge to analytical chemistry.¹ First, the MHC class I glycoprotein complex can bind in excess of 10,000 cellular derived peptides. Second, these biologically important peptides are extracted in low concentrations (typically <picomolar). In addition, only a few of the peptides presented by MHC class I molecules exhibit antigenic activity and most are of unknown sequence.

The complexity of the analytical challenge of MHC class I peptide sequence determination warrants minimal handling of isolated peptide fractions. This we have achieved by development of a strategy that uses membrane preconcentration-capillary electrophoresis-mass spectrometry (mPC-CE-MS) and tandem MS techniques as the final stages of analysis.² In this methodology a small piece of impregnated membrane (e.g. a styrene-divinyl benzene copolymer impregnated 3M Empore™ membrane) is inserted at the inlet of the CE capillary. Such approach enables the analysis of large sample volumes (>100 µL) in a CE capillary of total volume of <350 nL, thus effectively overcomes the major limitation of CE for this application, namely the poor concentration sensitivity of conventional CE methods.

Other aspects of the strategy we have developed for sequencing MHC class I peptides include peptide isolation by immunoprecipitation, molecular weight filtering (<10,000 kDa.) and reversed phase HPLC. Acetonitrile is removed from these fractions under vacuum to yield aqueous solutions (~40 - 70 µL) of HPLC isolated components. Peptide-rich fractions are then diluted to ~150 µL with CE Separation buffer (2 mM NH₄OAc : 1% acetic acid in water, pH 2.9). In a systematic study we found this approach minimizes peptide losses to the wall of the Eppendorf vial.³ An aliquot (50 µL) of the resultant sample is applied to an mPC-CE cartridge, washed with CE separation buffer and analyzed by mPC-CE-MS to screen for peptide signals. The remainder of the sample (~100 µL) is then applied to the mPC-CE cartridge and analyzed by mPC-CE-MS/MS. In both analyses moving boundary transient isotachopheresis (ITP) as voltage is applied across the mPC-CE capillary by the elution of analytes between zones of a basic leading stacking buffer (typically 1-5% NH₄OH) and an acidic trailing stacking buffer (typically the CE separation buffer).⁴ Ultimately peptide sequences are determined by searching raw MS/MS spectra against an appropriate peptide/protein library using the Sequest algorithm developed by Yates *et al.*⁵ This approach is demonstrated by isolation and sequencing MHC class I peptides that were derived from a K^b immunoprecipitation of mouse EL-4 cells.

It has become clear in recent years that MHC protein molecules are peptide transporters. T-cell recognition of MHC antigens is strongly influenced by the associated peptide in both positive and negative ways. Thus certain MHC protein/peptide combinations will activate T-cells while others termed TCR antagonists will block T-cell stimulation. TCR antagonists are also capable of inducing a critical stage of T-cell development in the thymus, which is termed positive selection. In the present study, we utilize a TCR transgenic model system in which the TCR is specific for an ovalbumin peptide (SIINFEKL) in the context of the mouse class I molecule K^b.

Specifically, a K^b precipitate of 3x10⁹ mouse derived EL-4 cells was immunoprecipitated and coarsely fractionated using reversed phase HPLC. The HPLC separation was monitored at 214 nm and ~100 µL fractions were collected. Acetonitrile was subsequently removed under vacuum and each fraction was diluted to ~150 µL with CE separation buffer. These resultant samples were then analyzed by mPC-CE-MS as described above. In a specific example a peptide detected at MH₂²⁺ = 503.6, was subjected to mPC-CE-MS/MS and the spectrum shown in Figure 1 was obtained. These data were interpreted using the Sequest algorithm to search the OWL protein database. This search revealed that the peptide was derived from F-actin and found to be of self origin. The peptide sequence was determined to be ISFKFDHL, and expected MS/MS ion series were in good agreement with the data shown in Figure 1.

Figure 1 mPC-CE-MS/MS Analysis of a K^b Associated MHC Class I Peptide Isolated from 3 x 10⁹ EL-4 Mouse Cells

Structural Characterization of Non-Peptide Antigens: Is the Presentation Paradigm Different?

Vernon N. Reinhold, Bruce B. Reinhold, Branch Moody, § Steven A. Porcelli, § Michael B. Brenner, §
Boston University Medical School, 80 E. Concord Street, Boston, MA 02118, and §Harvard University
Medical School, Longwood Avenue, Boston, MA 02115

A paradigm has been long established that T cells recognize peptide antigens presented by major histocompatibility complex (MHC) molecules. This binding and presentation is necessary for activation and subsequent lysis of the cell carrying the specific antigenic peptide. Recent reports suggest, however, that non-peptide antigens can be presented to T cells by human CD1 molecules and their isotypes (1,2). The human CD1 family is encoded by five nonpolymorphic and closely linked genes on chromosome one, and at least four human CD1 proteins (CD1a, -b, -c, and -d isoforms) are expressed on the surface of cells in association with β 2-microglobulin. It is therefore anticipated that CD1 has a functional role in immune recognition.

A major class of microbial antigens associated with pathogenicity are lipoglycans, and studies of a mycobacterial antigen recognized by CD1b-restricted human T cell line has led to the discovery that this antigen was protease resistant (3). The antigen was subsequently characterized to be a cell wall component called mycolic acid. This surprising and unexpected observation has been extended to *M. leprae*-specific CD1b-restricted human T cell line by the recognition of lipoarabinomannan, a glycolipid from the cell wall (2). Additional TLC fractions have been observed to induce comparable activity and it has been the goal of our efforts to support and extend the structural aspects of this work by direct mass spectral analysis.

Mycobacteria possess highly antigenic fractions responsible for humoral immunity. These are the agents of toxicity and importantly, the very antigens implicated in protective immunity. The discovery of nonpeptide lipid and glycolipid antigen recognition by CD1-restricted T cells defines a new paradigm for immune recognition and provides a distinct mechanism for host responses to infection. The existence of this MHC-independent pathway for T cell activation may substantially expand the immune repertoire and could have important implications for many aspects of cell-mediated immunity.

In this preliminary investigation, lipophilic extracts from the bacterium *M. phlei* were purified by TLC and checked for cell proliferation activity. Active and non-active fractions were both submitted to MS and CID analysis before and after chemical modification. Partial chemical degradation of extracts was undertaken to evaluate the detailed structure. One active lipophilic fraction produced an envelope of ions centered at m/z 1382.3 with satellite ions, (increments of 14 Da), suggesting alkane heterogeneity characteristic of a mycolic acid component (Fig. 1). Co-analysis of cord factor standards indicated that the source of charge for these compound types is proton and not alkali metal ion adduction. This was unexpected since there are no basic sites in the molecule and alkali metal adduction in carbohydrates is the most common method of ionization by electrospray. This conclusion was reached after the addition of LiOAc, NaOH, and KOH all produced the same molecular ion while addition of HCl produced the best sensitivity. Further pursuit of these fractions and detailed characterization of saponified mycolic acid fractions are underway to define component structures responsible for activation. These preliminary studies will provide a basis for understanding fractions isolated from CD1 molecules that may support a presentation paradigm. This active fraction was acetylated and reanalyzed indicating the incorporation of five acetyl groups. Partial base degradation (Fig. 2) provided important integral components of structure, while CID of the major ion (m/z 1382.3) indicated a terminal ester loss, all supporting the structure shown in Scheme 1.

Accurate Peptide Sequencing for Cloning and Homology Searching

Matthias Wilm, Andrej Shevchenko and Matthias Mann
Protein & Peptide Group, European Molecular Biology Laboratory (EMBL)
D-69012 Heidelberg, Germany
<http://www.mann.embl-heidelberg.de>

Microcharacterization of proteins important in signalling requires extreme sensitivity because of the low abundance of these factors. Frequently, it is practically impossible to obtain the 10 - 50 pmole of gel isolated protein required for Edman degradation. We have recently developed a robust and sensitive procedure for the mass spectrometric sequencing down to sub picomole levels of protein starting material (1). This procedure uses the nano electrospray ion source (2,3) and does not require chromatographic separation of the peptide mixture. Using four recent examples of previously unknown proteins we show here that it is feasible to obtain enough sequence information to allow cloning of the corresponding gene. In each of the cases the amino acid information obtained agreed completely with the translated DNA sequence of the coding region.

To shorten the time of interpretation of tandem mass spectra of unknown proteins, we have developed the isotopic labelling technique to be applicable to subpicomole levels of gel separated protein. Crucial practical developments were redistillation of the ^{18}O water used in the labelling as well as the use of high resolution Q1 scans to determine the isotope distribution and hence the charge state of the peptides.

The developed techniques were applied in the study of the CD95 receptor mediated signalling pathway of apoptosis (programmed cell death). This signalling pathway is of central importance in many normal and abnormal cell states (it has recently been implicated in p53 mediated apoptosis and apoptosis of T cells induced by the AIDS virus). Two dimensional gel electrophoresis of intracellular proteins bound to the receptor in its activated and non activated form produced several protein candidates for the signalling factor (see figure 1A). Less than 50 ng of protein from a silver stained gel were digested and six peptides sequenced completely (figure 1C). A search of a human genomic database yielded a match for one of these peptides. The full length clone contained all six peptides and a seventh via a peptide sequence tag. The sequence of the clone immediately led to a model for the mode of action of this "missing link" in apoptosis (4).

ESI-MS Evaluation of the Post-translation Modifications to Histones upon Induction of Apoptosis

Mary S. Weir Lipton, R. Clinton Horan, Brian D. Thrall, David L. Springer and Charles G. Edmonds
Macromolecular Structure and Dynamics; and Molecular Biosciences Departments
Pacific Northwest National Laboratory, Richland, WA 99352

Apoptosis is biochemically programmed cell death that plays an important role in development of normal adult tissues and in cellular response to physical or chemical insult. This is a type of cell death based on an internal genetic mechanism triggered by low dose physiological stimuli, contrasting with necrosis which results from a pathological factors (trauma, etc). Effective triggers include a range of stimuli from physical, toxic exposures, viral infection, immunologically relevant factors, and mixed growth signals which may aid in the removal of precancerous cells.

Apoptosis occurs in normal biological processes including differentiation, development, cell maturation, and immunological function and plays a number of physiological roles including immune surveillance and the removal of target cells to neurological development. This phenomena is mainly found in rapidly dividing cells and is thought to counter balance mitosis to maintain a stable cellular population. There is recent data to suggest that the induction of apoptosis is dependent upon the same signals that regulate the cell cycle through mitosis, particularly at the G1/S border. Regardless of the origin, the most recognized event in the apoptotic progression is the margination and condensation of the chromatin.

The fundamental subunit of chromatin is the nucleosome made up of double stranded DNA wrapped approximately one and a half times around an octamer of four core histone proteins to form a "beads on a string" structure. During the apoptotic process, the chromatin is cleaved between the nucleosomes into discrete segments containing multiples of 180 to 200 base pairs of DNA, which when run on an agarose gel migrates in a characteristic ladder pattern. The DNA fragmentation is the result of a controlled nuclease reaction which may be a part of a receptor mediated response. This pattern occurs with such frequency that it has become a hallmark technique for distinguishing between apoptosis and necrosis. Within the nucleosome the interaction between the DNA and the histones is dependent in part upon the reversible post-translational modifications to the histone proteins. These modifications modulate the availability of the positive charges on the tails of the histones which interact with the strongly acidic DNA backbone.

In our experiments, the cells were allowed to grow to a density of 3×10^5 cell/ml, and then were dosed with novobiocin and harvested at 0, 1, 2, and 4 hours. Novobiocin, a promising antibiotic the clinical trials for cancer chemotherapy, induces apoptosis in HL60 cells. The histones were isolated by hydroxyl appetite chromatography and reversed phase HPLC and analyzed by mass spectrometry. Shown in the figure below are the spectra of the 16+ charge state of histone H2A isolated from control cells and cells harvested at 1, 2 and 4 hour time points, respectively. The major component (a) in each of these spectra, appearing at m/z 877 represents histone H2A with a basal level of one acetylation. The second peak (b) represents a further methylation protein (or alternatively a sequence variation), and the third (c) an additional acetylation. The level of acetylation to histone H2A dramatically increases after 2 hours of exposure. After four hours of exposure the levels of protein acetylation have returned to near normal. This reduction in acetylation

is thought to be the result of an incomplete induction of apoptosis to the HL-60 cells by novobiocin. At this time point, the cells which have undergone apoptosis have already lysed and the cells remaining are similar to the control cells.

In conclusion, in the widely studied field of apoptosis, little is known about the biochemical processes underlying the morphological changes to the cell, though one of the most recognized features of apoptosis is chromatin condensation and margination. We are using ESI-MS to analyze the modifications to histone proteins that accompany apoptosis in an attempt to unlock some of the mysteries of the biological events. We have found that the modifications to histone H2A and H4 increase 2 hours after induction of apoptosis only to return to normal levels at four hours after induction. We believe that the increase in histone modification accompanies the chromatin margination and DNA fragmentation, although more studies are necessary to clarify this.

PROTEIN IDENTIFICATION WITH TANDEM MASS SPECTROMETRY AND SEQUEST

John R. Yates, A. McCormack, Jimmy Eng, and David Schieltz

Department of Molecular Biotechnology, University of Washington, Seattle, WA 98195

Introduction

Genomic and EST sequencing projects are providing a sequence infrastructure that is greatly benefiting protein biochemistry. In particular, the growing databases has triggered the development of integrated methods for mapping proteins isolated by using 2-D gel electrophoresis as well as the development of new methods for protein identification. We have developed a fully automatable system that combines micro-scale separation techniques, tandem mass spectrometry, and the SEQUEST database searching software (1-3) for mapping and other studies. This approach is also useful for the analysis of proteins contained in mixtures and the direct identification of interacting proteins without the use of gel electrophoresis.

Recent developments in the use of automated data acquisition employing data dependent computer algorithms has significantly improved the efficiency for the acquisition of tandem mass spectra. Analysis of the larger volumes of data produced by automated data acquisition can best be performed by the computer algorithms designed to correlate tandem mass spectra to protein or nucleotide databases. The ability to acquire and then quickly analyze large numbers of tandem mass spectra by using the growing sequence databases has enabled the analysis of increasingly complex problems. For example, the identities of proteins contained in proteolyzed protein mixtures can be determined by comparing the tandem mass spectra of individual peptides to sequences in the database and identifying the proteins from which the amino acid sequences originated. This approach has been applied to the study of protein antigens processed in the class II antigen pathway (4).

Experimental

Electrospray ionization mass spectra were recorded on a Finnigan MAT (San Jose, CA) TSQ700 equipped with atmospheric pressure ionization as previously described (12, 23). Atmospheric pressure ionization was performed using the following conditions. The needle voltage was set at 4.6 kV. The sheath and auxiliary gases consisted of nitrogen gas (99.999%) and were set at 20 psi and 5 L/min., respectively. The heated capillary temperature was set at 150°C and a potential of 70 V was placed on the capillary. The first mass analyzer was tuned to a 2-3 u (FWHM) wide window for precursor ion selection and peak widths in the second mass analyzer ranged from 1.5-2.0 u.

Automated tandem mass spectrometry. Tandem mass spectra were acquired using Instrument Control Language (ICL). The ICL program acquires two mass spectra, scanning Q3 over 550-1500 m/z in 1 sec. If an ion is present in the scan and the calculated signal-to-noise is above a specified value (10/1), then four product ion spectra are acquired using the m/z value of the base peak in the last mass spectrum. Using the m/z value and the assumption that the parent is doubly-charged, the program calculates the scan range and the collision offset. Product ion spectra are generated using argon as the collision gas (4-5 mtorr) and collision energies (laboratory frame) on the order of 10 to 30 eV. The spectra are acquired by scanning Q3 over the specified range in 2 sec.

Immunoprecipitation of Ras and the formation of the GST-Sla2 gene fusion were performed following standard protocols. Cell lysates were created as previously described (1) and incubated with the Ras antibody or passed over the GST-Sla2 column. In both experiments the cell lysates were precleared by passing the material over control columns. A fraction of the bound material was analyzed by gel electrophoresis and an additional aliquot was removed for proteolysis and LC/MS/MS.

Computer Analysis of MS/MS data. An *S. cerevisiae* sequence specific database was obtained from Saccharomyces Genome Database Center at Stanford (<http://genome-www.stanford.edu>). The sequence of

trypsin was added to the database to screen for autolysis products. Database searches were performed with the SEQUEST software on a DECstation 3000/300 (1-3).

Results and Discussion

The strategy employed to identify proteins in the mixtures involves first performing a gel electrophoresis separation with high sensitivity silver staining. The next step involves proteolysis of an aliquot of the mixture and then LC/MS/MS analysis of the peptides. Table 1 shows the proteins identified as bound to GST-Sla2 column. Under the conditions employed during washing steps it is expected the interactions are specific. Further biological studies such as gene deletions can be used to induce phenotype changes. The proteins identified as part of the Ras isolation are shown in Table 2. In this case the proteins identified are expected to be non-specific interactions under the conditions of the washing steps. The methodology employed to identify the proteins contained in the mixtures is highly efficient and reasonably sensitive. In the Ras experiments an aliquot corresponding to 1/50th of the sample was used for identification and an aliquot of 1/10th was used for the gel electrophoresis experiment.

Table 1: Proteins identified as bound to the GST-Sla2 column.

Access.	MW	Protein Identity
NFS1	54 kDa	Similarity to NIFS from Nitrogen Fixing Bacteria
DED1	65 kDa	Similarity to "dead" box family helicases, P110 Subfamily
DBP1	68kDa	Putative ATP-dependent Helicase
NHPA	10 kDa	Related to mammalian non-histone protein HMG
SSB1	66 kDa	Heat shock protein
SSA2	69 kDa	Heat shock protein
HS72	66 kDa	Heat shock protein
ACT	41 kDa	Actin
SLA2	108 kDa	Talin-like Protein involved cytoskeleton

Table 2: Proteins identified in the immunoprecipitation of Ras.

Protein Identity	MW
RAS1	36 kDa
RAS2	40 kDa
Human Keratin	65 kDa
Alcohol dehydrogenase	10 kDa
Heat shock protein 82	81 kDa
Glyceraldehyde-3-phosphate	35 kDa

COUPLING MATRIX ASSISTED LASER DESORPTION IONIZATION MASS SPECTROMETRY TO LIQUID SEPARATIONS

Kermit K. Murray

Department of Chemistry
Emory University, Atlanta, GA 30322

The advantages of matrix-assisted laser desorption/ionization (MALDI) mass spectrometry for the analysis of biological and synthetic polymers are well known. These include compatibility with time-of-flight (TOF) mass spectrometers, high tolerance for impurities, low detection limit, and an upper mass limit in excess of 500,000 Da. A disadvantage of MALDI is the difficulty in coupling to liquid separations such as liquid chromatography (LC) and capillary electrophoresis (CE). Various approaches have been used for MALDI liquid introduction including off-line methods, continuous flow probes, and aerosols. With the off-line method, fractions are collected and later run on a standard MALDI mass spectrometer. This method is the easiest to implement, but can be slow and inconvenient. The MALDI continuous flow probe is similar to a continuous flow fast atom bombardment (FAB) probe and uses liquid MALDI matrices such as 3-nitrobenzyl alcohol at flow rates of 5 $\mu\text{L}/\text{min}$ or less.¹ In an aerosol MALDI apparatus, a solution containing matrix and analyte is introduced into the mass spectrometer using a pneumatic nebulizer at a liquid flow rate of approximately 1 mL/min .² Solvent is removed in a heated drying tube and the aerosol particles are irradiated with a pulsed UV laser. The resulting ions are mass analyzed in a TOF mass spectrometer.

An aerosol MALDI apparatus has been constructed at Emory University that incorporates a reflectron TOF mass spectrometer for improved mass resolution.³ The LC-MS configuration of the aerosol MALDI apparatus is shown in Figure 1. The LC column eluent and matrix solution are combined in a mixing tee and delivered to the nebulizer. In a typical experiment, mass spectra are averaged for 100 laser shots at 10 Hz and downloaded from the oscilloscope to the microcomputer hard disk throughout the chromatography run. File downloading requires approximately one second per mass spectrum, thus 10% of the mass spectra are not recorded.

Figure 1. Aerosol MALDI reflectron TOF configured for on-line LC-MS.

The improved mass resolution of the Emory aerosol MALDI apparatus has recently been exploited in the size exclusion LC-MS analysis of synthetic polymers. Details of this experiment are given elsewhere in this volume;⁴ Figure 2 depicts a grayscale map of a polyethylene glycol (PEG 1000) separation that serves to illustrate the utility of the technique. The grayscale map is

similar to a topographic map or false color image with a shade of gray representing the ion signal data value at a particular flight time and column retention time. In the figure, dark vertical stripes separated by 1.6 μs between 60 and 90 μs flight time correspond to protonated PEG oligomers. The lighter vertical stripes between dark stripes correspond to the sodium ion adduct peaks of the form $[M+\text{Na}]^+$. The shift in the polymer peak distribution from longer to shorter flight time with increasing retention time (corresponding to a shift from high to low mass) can be easily seen in the figure. This two-dimensional separation by size and mass is a potentially powerful tool for synthetic polymer analysis.

Figure 2. Gray scale intensity plot of a GPC-MS analysis of PEG 1000. Ion signal at a particular flight and retention time is represented by a gray scale intensity with darker areas corresponding to larger signal.

Further improvements in aerosol MALDI are necessary before it becomes a viable analytical technique. Mass resolution has been improved by a factor of ten with the addition of a reflectron, however, the mass range must be extended beyond the current limit of several thousand Da. The limit of detection must also be improved. The approach to improved detection limit currently underway is to convert from a continuous nebulizer to single droplet generator. If a single particle is delivered to the point of laser ionization with high efficiency, the resulting detection limit is fmol or lower. The lower flow rate for single aerosol MALDI will be compatible with both microbore HPLC as well as CE.

On-line High Speed Countercurrent Chromatography / Electrospray Ionization Mass Spectrometry (HSCCC/ESIMS) in Natural Products' Chemistry

Zhengrong Kong,[§] Kenneth L. Rinehart,[§] Richard M. Milberg,[§] Walter D. Conway[†]

[†] School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14260

Introduction

High speed CCC offers advantages over other chromatographic methods in that it is free from all complications arising from the use of solid supports. Adsorptive loss, denaturation of samples, contamination or tailing of solute peaks are minimized in this technique. High speed CCC has been developed with short running time and good resolving power. Unfortunately, it is incompatible with common optical detectors, *i.e.* UV/Vis and refractive index detectors, due to bleeding of the stationary phase. This produces a chaotic emulsification in the solution stream. On-line mass spectrometric detection, which avoids the solvent problems associated with conventional detectors, provides a universal detector with high sensitivity.

The combination of CCC with thermospray MS has been reported. The coupling of CCC with FABMS through a moving belt interface has also been accomplished by our group. Interfacing HSCCC with ESIMS provides a new analytical methodology. This technique is suitable for thermally labile compounds with continuous detection at high sensitivity. High speed CCC associated with MS/CID/MS can provide valuable structural information. In this paper, the interface of HSCCC/ESIMS has been developed and was employed in the separation and detection of two sets of natural products.

Methods

Analytical high-speed CCC separation was performed on a P.C., Inc. (P. C., Inc., Potomac, MD) High Speed Countercurrent Chromatograph, equipped with a small-volume (16.8 ml) analytical coil, which was wound with 30.0 m of 0.85 mm i.d. polytetrafluoroethylene (PTFE) tubing in two layers on a core of 8.59 cm radius ($b=0.85$). The system was capable of revolution up to 1400 rpm. A mixture of hexane/ethyl acetate/methanol/H₂O (4/7/4/3, v/v) was equilibrated overnight, and two phases were separated. The coil was first filled with the stationary phase (heavy phase). The mobile phase (light phase) was pumped by a Beckman 114M HPLC pump (Beckman, Fullerton, CA) through the coil at 0.8 ml/min while the coil was spun at 800 rpm. Stationary phase retention varied from 60% to 80% estimated by measuring the amount of stationary phase eluted in the mobile phase during equilibration.

A VG Quattro mass spectrometer with quadrupole-hexapole-quadrupole configuration was employed to acquire ESI mass spectra. The mass spectrometer was operated in the threshold continuum mode and calibrated with CsI. The resolution was adjusted to resolve isotopic peaks at *ca.* m/z 600. The mass range was scanned from m/z 100 to 1500 for high speed CCC/ESIMS and from m/z 60 to 950 for HSCCC/ESIMS/CID/MS in 4.9 sec. MS/CID/MS spectra were obtained on the (M+H)⁺ ions with argon employed as the collision gas.

Erythromycins (ErA, ErEst and ErSucc, in equal amounts, 5.0 nmol) were dissolved in 20 μ l methanol and injected into the chromatograph when the system attained equilibrium. Erythromycins were chromatographed at 0.8 ml/min. The elution was split at a 1:8 ratio so that about 100 μ l/min reached the ionization source.

Didemnins (Did A, Did B and Nordid A, in equal amounts, 5.0 nmol) were dissolved in 20 μ l methanol and injected into the chromatograph when the system attained equilibrium. A fraction of didemnins obtained during the isolation of Did B was also subjected to HSCCC/ESIMS analysis.

Result and Discussion

Two sets of model compounds, didemnins and erythromycins, were employed for this study. Erythromycins are important antibiotics in the treatment of Gram-positive bacterial

infections. These antibiotics have weak chromophores and low extinction coefficients, and can't be detected by conventional optical methods. Didemnins are cyclopeptides isolated from the marine tunicate *Trididemnum solidum*. Did A is the precursor for the synthesis of other didemnins showing antiviral, antitumor activities. However, large-scale purification of Did A is difficult due to the presence of Nordid A.

HSCCC/ESIMS has been successfully applied to the separation and detection of erythromycins and didemnins. The total ion chromatogram (TIC) of didemnins is illustrated in Figure 1. The identity of each peak in the TIC was deduced from the molecular ions and the characteristic fragment ions in the corresponding mass spectra. The mixture was resolved well enough that each peak in the TIC contained only a small amount of other components. Thus, Did A can be purified from Nordid A by high speed CCC.

Figure 2 shows the TIC of erythromycins. Interestingly, the first peak in the TIC before the three erythromycin peaks does not belong to any compounds in the mixture. The mass spectrum indicated that this peak contained two compounds with ions at m/z 844, 772. These two ions corresponded to the molecular ions of dehydrated ErSucc and dehydrated ErEst. Obviously, these two compounds were produced during their solvolysis in methanol, but not from erythromycins during the ionization process. We have been able to assign the structures of these two dehydrated erythromycins.

High speed CCC/ESIMS enables the direct analysis of compounds dissolved in solution by mass spectrometry, and uses the specific utility of ESIMS for the production of mass spectra of relative large, polar, thermally labile molecules. When high speed CCC is associated with MS/CID/MS, structural information on molecular ions and fragment ions can be obtained.

Novel Statagies For The Coupling Of Capillary Electrochromatography With Mass Spectrometry; Lane, Steve; Bought flower, Robert; Paterson, Clare; Underwood, Tim; Morris, Michael; GlaxoWellcome, Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY UK.

Capillary Electrochromatography (CEC) is an emerging technique employing small diameter, packed, fused-silica capillaries that couples the very high efficiencies of Capillary-Zone Electrophoresis (CZE) and Reversed-Phase Liquid Chromatography (RPLC) to effect the separation of both neutral and charged species. The flow within the capillary is driven electrically and results from the ionisation of the surface silanol groups and silica based packing giving rise to an electrical double layer that in turn leads to a net flow toward the cathode termed electro-osmosis (EO). This EO flow gives rise to a favourable "plug-type" flow profile in contrast to the parabolic Poiseuille flow of pressuredriven systems. A further advantage is that the flow is independent of particle diameter and with no theoretical restriction on column length provides the opportunity of using very small diameter particles to obtain very high efficiencies approaching the theoretical maximum. This is in contrast to pressure driven capillary liquid chromatography where practical constraints result in lower achievable efficiencies with smaller particle diameter. Selectivity in CEC is identical to that for conventional RPLC for neutral analytes and electrophoresis also contributes for ionised species.

These properties allow very high efficiencies to be achieved with neutral mixtures demonstrating in excess of 150,000 plates per metre on 3µm C18 columns packed inhouse. Results from the early interfacing of CEC with a quadrupole mass spectrometer using a modified commercially available CZE electropherograph and CE/MS mass triaxial probe highlighted the need to pack the column completely to the ESI probe tip. By avoiding open tube sections after the packed bed excellent chromatographic efficiencies can be translated through to the mass spectrometer. Fig 1 shows the separation of Cefuroxime Axetil diastereoisomeric pairs spiked with the E-isomer. Following this work the goal became to devise an interface that facilitated separations of high efficiency but with short analysis times using high field strengths and short packed capillary columns. A prototype CEC/MS integral probe system was built and demonstrated capable of achieving these goals and high efficiency separations with short analysis times are shown for

mixtures of Pharmaceutical compounds. Future directions for the technique are include the use of CEC specific phases to promote higher EO flows at lower pH. A mixed mode column of strong cation exchange resin and C18 gives higher EOF at lower pH whilst maintaining reversed phase selectivity.

Columns: 90-95cm long, 50µm i.d, 375µm o.d slurry packed with ~~3µm~~ Hypersil ODSA to its full depth.
CEC Buffer: 80% CH₃CN/5mM sodium tetraborate at pH9
Make up flow: 10µL/min of 50:50 MeOH/0.3% Formic acid
Injection: 30kV for 5s or 10s of 1mg/ml Cefuroxime Axetil in buffer spiked with the E-Isomer (ANTI).

ADVANCES IN HIGH-SPEED GAS CHROMATOGRAPHY

Richard Sacks, Department of Chemistry,
University of Michigan, Ann Arbor, MI 48109

Gas chromatography (GC) is the most widely used method for the analysis of mixtures of volatile organic compounds (VOCs). The popularity of GC is the result of a favorable combination of high selectivity, a very large concentration range, and the potential for high accuracy and precision. Despite these very attractive features, the protracted analysis time of GC, typically several minutes to several tens of minutes, has limited applications in some critical areas and has prompted much interest in more rapid analysis methods. However, for complex VOC mixtures spanning a wide range of concentrations, a time-consuming separation step is usually required.

The possibility of high-speed GC (HSGC) was noted shortly after the first demonstration by Golay of the wall-coated open tubular (capillary) separation column. However, the lack of practical inlet systems which can generate the necessary narrow injection bands and the lack of separation strategies to accommodate the reduced resolving power of HSGC have limited its application until quite recently. In the last decade, dramatic advances have been made, both in inlet system design (1) and in the development of separation strategies (2). The current state of the art allows for the complete separation of mixtures containing 20-30 components in as little as 30 s.

Analysis time t_a for a GC separation is equal to the elution time of the last component of interest as given by equation 1.

$$t_a = (L/\mu)(k_n + 1) \quad (1)$$

where L is the column length, μ is the average velocity of the carrier gas in the column, and k_n is the capacity factor of the last component of interest. For HSGC, short columns at high flow rates and relatively small capacity factors are required. All result in reduced peak capacity and thus much greater co-elution probability. The use of conventional inlet systems, which typically have injection band widths of 50-100 ms, results in further reductions in resolving power of short capillary columns.

Cryofocusing inlet systems, which can inject 5-10 ms wide vapor plugs, recently have been developed (3). These inlet systems are robust, reproducible and do not significantly degrade the resolving power of short capillary columns. In addition, these inlet systems can integrate sample vapor from an extended, low-concentration source, and thus can achieve detection limits in the low and sub ppb range using a flame ionization detector. These inlet systems will be discussed.

The price paid for high speed is a significant loss in resolving power and peak capacity. This results in a much greater probability of peak overlap and has restricted the use of HSGC to relatively simple mixtures. Recently, the use of

tunable selectivity (2) has allowed for much greater control of the local positions of component peaks in the chromatogram with the result that mixtures containing 20-30 components now can be completely separated in a time frame of 30-60 s. Continuously adjustable selectivity is achieved by the use of tandem (series coupled) capillary columns of very different selectivity. The junction point between the columns is connected to an auxiliary carrier gas supply, and the pressure at the junction point is adjusted to tune the selectivity for a specified set of target compounds. As the tuning pressure is changed, a corresponding change occurs in the fractional contribution that each column makes to the overall column selectivity. For a tandem column ensemble, an overall capacity factor k can be computed for every mixture component.

$$k = k_1 + f_2(k_2 - k_1) \quad (2)$$

where k_1 and k_2 are the capacity factors for the mixture components on the two separate columns, and f_2 is the fractional contribution of column 2. If k_1 and k_2 are known, either from libraries or empirically determined for the components in the mixture, the fraction f_2 can be computed directly from a tandem-column chromatogram using equation 2.

Tuning optimization algorithms are based on computing the separation quality of all component pairs as the tuning pressure is adjusted. The separation of the worst-case component pair (critical pair) is then plotted versus the tuning pressure producing a window diagram. Separation quality is estimated by a relative resolution function (4) as described in equation 3.

$$R_{rel} = \Delta k / (k_{ave} + 1) \quad (3)$$

In equation 3, Δk is the difference in overall capacity factor values for a component pair using a specified phase fraction f_2 , and k_{ave} is their average value. When the minimum value of R_{rel} (critical pair value) is plotted vs. f_2 , a series of zero values is observed, corresponding to the phase fractions where co-elution of each critical pair occurs. Between each pair of zero values, a "window" with a local maximum occurs. The phase fraction corresponding to the global window maximum gives the best separation of the worst case (critical) pair. The use of window diagrams where both phase fraction and isothermal column temperature are optimized for minimum separation time will be described.

High Speed, High Throughput GC-MS Using Time-of-Flight Mass Spectrometry with Time Array Detection

Ben D. Gardner¹ and John F. Holland²

Departments of Chemistry¹ and Biochemistry², Michigan State University,
East Lansing, MI 48824

The power of any analytical procedure lies in its ability to produce reliable qualitative and quantitative information within reasonable time frames. In the case of gas chromatography, a *power factor* can be defined as the number of compounds successfully separated and analyzed per second. This is an excellent reference measurement as one considers the various types of chromatography being employed and/or developed at the present time. For example, packed column chromatography typically exhibits power factors in the range from 0.01 to 0.1, while capillary column chromatography typically covers the range from 0.1 to 1. The newer techniques of fast chromatography have documented power factors in the range from 1 to 5 with the potential to go higher. We use this factor as a reference for our investigations in rapid separations and detection.

The use of classical single channel detection for GC presents a situation where only the time axis can furnish reliable qualitative information. Here analytical resolution rests upon the ability of the column to produce temporal separation of the eluting components. Isolated peaks are easy to quantitate and deconvolution routines are applied to co-eluting species to obtain area estimates for quantitation. Theoretically, power factors approaching 1 are possible, practically, this level is seldom documented.

The use of multi-channel detection for GC engenders a distinction in the concept of chromatographic resolution. While for the single channel detector chromatographic resolution and column resolution are virtually the same, with multi-channel detection it is only necessary for a single channel to be unique to one species over an elution window for the compound represented by that channel to be chromatographically resolved. In these cases, chromatographic resolution may have a dual meaning: column (temporal) resolution and analytical (fully characterized) resolution. In the end, it is the analytical resolution that counts.

The most competent multi-channel detector for gas chromatography is the mass spectrometer. However, to take full advantage of its power, it should produce spectral data at rates compatible with the band widths of the chromatography being monitored. Packed column chromatography requires spectral acquisition in the range of 0.2 to 1/sec which is readily accomplished by modern commercial mass spectrometers. To take full advantage of the power of capillary GC, spectral generation rates from 20 to 40/sec are required; far beyond the range of the magnetic, quadrupole, and ion trap mass spectrometers in common usage. In fact, due to the finite time requirements of scanning mass spectrometers, such rates are not possible. At the present level of technology, only array detectors, where all of the ions are measured simultaneously, have the potential for such speed. Of the array detectors available, only time-of-flight (TOFMS) with time array detection (TAD) has the speed, sensitivity, resolution, range and cost to be a viable multi-channel detector for gas chromatography. With this type of instrumentation, new approaches to gas chromatography are enabled.

Classical gas chromatography, where column resolution dominates parameter considerations, can now be referred to as resolution optimized chromatography. When the high spectral generation rate is combined with the fact that the TOF produces unskewed mass spectra, which are amenable to rapid, effective

deconvolution routines, classical parameters may be altered to yield faster analyses. These include the use of short, narrow bore columns with thin stationary phases and high carrier flow rates. The extent of temporal (column) resolution suffers, but full chromatographic information can be retrieved in a process called time-compressed chromatography. Power factors in the range from 0.4 to 2/sec can be realized with this technique. Further increases in power can be achieved with techniques involving sample compression by cryogenic means with fast desorption onto the column resulting in injection band widths of 100 msec and less. There are several types of sample compression, and those designed specifically for rapid analysis are often referred to as "fast" chromatography.

The data illustrated in the figure were collected using a LECO FCD-650 GC-TOFMS system with TAD and a fast chromatographic technique. A 0.2 μ L VOC mixture was cryofocused at the head of a 2-m Rt_x-5 (0.1 mm i.d., and 0.1 μ m film thickness) column. The sample was released into a 150 cm/sec hydrogen carrier gas by convective heating in an HP 6890 GC oven, heated from 80 to 120 °C at 60 °C/min. The TOFMS system is capable of generating up to 500 spectra/sec with a mass range and resolution of 650 u and a sensitivity in the low picogram range. Well defined and individually discernible profiles (analytically resolved), were obtained for 21 compounds from this mixture in 3 seconds. For this portion of the run the power factor is 7, which is a clear indication of the potential of fast chromatography and its possible future impact on the arts and practices of gas chromatography.

With the true multi-channel detection capability of TOFMS with TAD, power factors have been increased over two orders of magnitude for capillary column GC with no loss of analytical information. This instrumentation provides the platform upon which future advances in fast separations may rest.

Figure 1: Selected mass chromatograms from a Fast GC-TOFMS analysis of 21 VOCs in 3 seconds. The data were collected at 200 spectra/second.

Fast GC and Comprehensive 2DGC Coupled to HRMS and TOFMS for
Environmental Toxicant Analysis

John R. Barr¹, Donald G. Patterson¹, Jr., Vaughn E. Green¹, James Grainger¹, Ben D. Gardner², and John F. Holland²

1. Centers for Disease Control and Prevention, 4770 Buford Highway, NE, Atlanta, Ga, 30341
2. Department of Biochemistry, Michigan State University

In order to increase the statistical power of epidemiologic studies by increasing the number of participants, faster and less costly analytical methods must be developed for the measurement of persistent organic pollutants in human samples. The current HRGC-HRMS analytical method for dioxins, furans, and coplanar PCBs is very time consuming requiring a full 8 hours to analyze a five sample analytical run (3 of which are unknown study samples; one blank, and one QC sample). We recently have developed methods which greatly increases the sample throughput by using a comprehensive two-dimensional gas chromatography system (C2DGC) or fast chromatography. The C2DGC technique is much faster than a one-dimensional GC system, more specific (two retention indices) and more sensitive (narrower peaks in the second dimension). Comprehensive two-dimensional separations differ from conventional multidimensional separations in that all substances are subjected to both dimensions of the separation processes. The theoretical peak capacity obtained from an orthogonal two-dimensional separation process is the product of the peak capacities obtained on each dimension. Unlike conventional heart-cutting techniques, comprehensive two-dimensional separations do not sacrifice any analytical range covered by a given sample.

We are currently developing methods to analyze PCDDs, PCDFs, cPCBs by C2DGC/HRMS. Preliminary results indicate that we can separate and analyze these toxicants an order of magnitude faster (Figure 1) with attogram on-column sensitivity (Figure 2). This new system should allow us to dramatically speed-up the analysis in human samples and thereby reduce the cost of these analyses. The normal 1 hour chromatogram for the HRGC/HRMS analysis of PCDDs/PCDFs/cPCBs on a 60 meter DB-5 capillary column is shown in Figure 1A. The analysis time can be dramatically reduced by using a 2 meter column with a 0.1 mm ID and 0.1 μ m film thickness. The same 24 compounds can be analyzed in just over 7 minutes (see Figure 1B) with the shorter column.

Fast chromatography employing shorter narrow bore GC columns has also greatly increased the speed of analysis. The PCBs can now be analyzed in 10 minutes by employing the shorter narrower columns. GC/MS analysis of pesticides can also be dramatically reduced by employing either fast GC or C2DGC techniques. Our current serum pesticide methods currently require 40 minutes but by using fast and C2DGC all compounds 16 compounds in our analysis can be separated in 3-5 minutes. Coupling this technique to mass spectrometry has yielded a very fast yet highly specific analysis. The increased sensitivity that results from the use of fast and C2DGC/MS will also allow the use of smaller serum samples. This again allows us to miniaturize and increase the speed of the sample cleanup procedures. The higher throughput and reduced cost will allow larger epidemiologic studies to be conducted with higher statistical power to find any potential association of body burden with health effects.

Figure 1. PCDDs, PCDFs, and cPCBs can be adequately separated and analyzed in about 1 hr using high-resolution gas chromatography/high-resolution mass spectrometry (HRMS) (A). By interfacing fast chromatography with HRMS, the same compounds can be separated and analyzed in less than 8 min (B).

Figure 2. Using high-speed comprehensive 2D gas chromatography, peak volumes (instead of only peak areas or heights) can be obtained. By measuring peak volumes, attogram detection is achievable.

ON-LINE DETECTION OF FAST CHROMATOGRAPHIC EVENTS BY ELECTROSPRAY IONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY

Erol E. Gulcicek, B. Andrien, J. F. Banks, J. G. Boyle, T. Dresch,
P. Haren, and C. M. Whitehouse

Analytica of Branford, Inc., Branford, CT 06405

One of the most significant advantages of a TOF mass spectrometer over conventional scanning mass spectrometers is the ability to acquire a complete mass spectrum 2 to 3 decades of m/z wide in tens to low hundreds of microseconds. It allows one to study and observe fast-changing chemical events in real time. Faster liquid chromatographic and electrophoretic separations can be captured with all of the mass spectral information available at all times with high sensitivity levels. This is contrary to scanning mass spectrometers where broader mass spectral scan information is sacrificed in order to achieve more sensitive results by using the single ion monitoring (SIM) acquisition mode.

The subject TOF mass spectrometer is equipped with an API source containing both electrospray and atmospheric chemical ionization sources. A well collimated ion beam from the API source is delivered orthogonally into the TOF pulsing region via an RF-only hexapole ion guide with a narrow kinetic energy distribution. The TOF mass spectrometer flight tube has the capability to quickly interchange between the linear and ion mirror configurations allowing both the high sensitivity and high resolution aspects of the instrument to be accessed. The data acquisition system can continuously acquire and sum over 10,000 mass spectral sweeps per second.

The above features of the TOF Mass Spectrometer is tested with CZE and fast HPLC applications. Using a consistent three protein and five peptide mixtures, results with CZE, perfusion chromatography, and Non Porous Silica (NPS) HPLC separations are demonstrated. All separations are completed under 200 to 300 seconds. With the NPS column, the five peptide mixture is separated in less than 40 seconds with elution peak widths approaching as low as 300 ms (FWHM). In addition, Myoglobin tryptic digest run with the NPS column under 300 seconds is shown. Figure 1 shows the recent fast HPLC separation of the five peptide mixture using a 4.6 x 33 mm column with 1.5 μ m particle size Non Porous Silica coated with C18. To capture all of the information in such a short separation and peak elution times, an acquisition rate of 8 spectra per second consisting of 1024 averaged mass scans each was used. Figure 2 shows the respective single mass spectrum (1024 averaged mass scans) of each peptide under the separated peaks.

In summary, this study demonstrates the importance of the TOF MS technique for its ability to detect faster liquid chromatographic and electrophoretic techniques.

Some Observed Phenomena of a Linear Quadrupole Under Fast/GC Conditions

Casey C. Grimm and Steven W. Lloyd
USDA-ARS-SRRC
1100 Robert E. Lee Blvd.
New Orleans, LA 70124

A quadrupole mass spectrometer has been fitted with a short narrow bore capillary column (0.1 mm ID) and a data acquisition system capable of acquiring data at scan speeds in excess of 25,000 amu/s. The scan speed of the quadrupole is limited by the flight time of the ion through the quadrupole and not the data system. By limiting the mass range, sampling only once/amu, and increasing the offset potential between the source and the quadrupole, the mass spectrometer can be used to identify compounds that GC peak widths of less than 50 ms. Chromatograms of only a few seconds are required to separate and detect volatile compounds. Operating the quadrupole mass filter at these extreme conditions results in some predictable phenomena.

When ramping the quadrupole at high speeds, high mass ions of greater mass than the upper limit of the scan range may possess sufficient momentum to breakthrough the fields at low voltages. This occurs after dropping the rods at the top of the scan when the RF and DC potentials are at their greatest back down to low mass. The heavier ions have sufficient momentum to breakthrough the low fields after the quadrupole has been reset to the bottom of the scan range. This results in an artifact peak during the first part of the next scan (Figure 1). The artifact peak can be eliminated by scanning in a downward mode, or by de-tuning (Figure 2) the quadrupole rods.

Typically quadrupole mass filters are scanned from low mass to high mass. The RF and DC voltages are placed on the rods permitting low mass ions to pass, then are raised at a constant ratio to allow successively higher mass ions to pass through. Upon reaching the highest voltages equal to the upper end of the mass range, the voltages are then dropped back to the low mass for the next scan. A 5 millisecond settling time is generally incorporated into the scan cycle. In order to conserve time, an alternating scan was developed, which scanned from low mass to high mass on odd scans and high mass to low mass on even scans. While scanning at normal speeds (<500 amu/s) no difference was observed in the TIC intensities of PFTBA leaked into the source. Upon

scanning at higher rates, TIC intensities increased in the upward scan and decreased in the downward scan. If multiple samples were taken at each step (signal averaging), this phenomena decreased. A possible explanation is based upon the change in size of the acceptance angle of ions entering into the quadrupole.

As the quadrupole is scanned from low mass to high mass, the acceptance region in front of the mass spectrometer becomes smaller. When making small steps <0.125 amu, only a slight difference is observed in signal intensity when going from m/z 68.875 to m/z 69 vs m/z 69.125 to m/z 69. Upon going to larger steps >0.5 amu, appreciable difference is observed which becomes larger, the faster the quadrupole is scanned. Figure 3 shows the TIC's of six different scans. PFTBA was leaked into the source to provide a constant analyte. The relatively constant TIC at the top is the result of scanning the quadrupole from m/z 50-250 m/z. Scan times were adjusted by varying the number of samples signal averaged.

COMPATIBILITY OF FAST GC WITH TOFMS: HOW FAST CAN WE GO?

Ritchard Parry, Viatcheslav B. Artaev, Nancy Brichford, Kevin McNitt and Joel Mitchell
LECO Corporation, 3000 Lakeview Avenue, St. Joseph, MI 49085 USA

Demands for greater productivity in the workplace has placed greater emphasis on reducing analysis time. As a result, a variety of fast gas chromatographic systems have been introduced. The fast data collection rates obtained on time-of-flight mass spectrometers (TOFMS), when compared to scanning systems such as quadrupoles or magnetic sectors, also provides opportunities for further reduction in analysis time. The use of TOFMS as a detector for a fast gas chromatograph would appear to be the optimum combination of current technologies to provide fast and accurate analysis. But, how fast can we go?

A Fast GC accessory from Chromatofast installed on a Varian 3400 GC was used to provide the fast chromatography. This system significantly tightens analytical bands prior to sample introduction into the analytical column through a unique combination of cryotrapping and ballistic heating. This system was interfaced to a Pegasus™ TOFMS system manufactured by the LECO Corporation. This system consists of an electron impact ionization source, reflectron mass analyzer and a chevron type multi channel plate detector. The data acquisition system is based upon a proprietary fast data collection system capable of up to 500 summed spectra per second for a mass range from 1 to 1000 u. A Pentium platform system was used for data processing and output.

The interface of the Fast GC to the Pegasus TOFMS presented one minor problem. The Fast GC uses vacuum to draw the sample from the injection port to the cryotrap. This approach works well with GC detectors at atmospheric pressure. However, the vacuum from the mass spectrometer created another avenue of sample flow during the GC sampling process. As a result, a significant portion of the sample was drawn directly to the analytical column effectively bypassing the cryotrap. The chromatogram resulting from the two different modes of sample introduction unnecessarily complicated the data analysis. Figure 1 represents a schematic of the solution used to correct this problem. A "T" was introduced between the end of the analytical column and the mass spectrometer. The third leg of the "T" was connected through a solenoid and needle valve to the injection port carrier gas supply. The solenoid

Figure 1: Schematic of a modified Fast GC system.

was opened during the sampling cycle to provide gas flow to the mass spectrometer and analytical column. This minimized the vacuum draw on the analytical column from the mass spectrometer allowing all of the sample to be drawn toward the cryotrap.

A series of documented flavor mixtures, including Nutmeg Oil, Lemon Oil and Tea Tree Oil, were chosen to evaluate the system. The flavor mixtures offer an interesting challenge for the system in that they contain a large number of structurally similar analytes that provide very similar electron impact mass spectra. Therefore, a high degree of chromatographic resolution had to be maintained while attempting to decrease the analysis time.

Several criteria were chosen to monitor the performance of the system including GC cycle time, spectral quality and the number of data points obtained to define a chromatographic peak. Successful chromatographic resolution or mass spectral deconvolution of all analytes in the sample was also required. Figure 2 shows a comparison of traditional GC analysis and Fast GC analysis of Nutmeg Oil. The chromatographic analysis time has been successfully reduced from 40 minutes to 3.7 minutes. The GC cycle time is also significantly reduced with the traditional GC analysis having a cycle time of 48.7 minutes versus 6.9 minutes for the Fast GC. The TOFMS system was also able to easily generate 75 points across the 1.5 second wide chromatographic peaks when a 50 spectra/second acquisition rate was selected. Faster rates could have been used for narrower peak widths. Mass spectral quality was also well maintained at this acquisition rate with all of the documented analytes easily identified by mass spectral comparison with the NIST database.

The combination of the Fast GC with the Pegasus TOFMS was shown to successfully reduce the analysis time of several flavor mixtures by approximately 1 order of magnitude while maintaining the described criteria for data quality. Total analysis time for other applications will be dictated by the degree of chromatographic resolution required for each specific application. The fast data acquisition rates obtained with the TOFMS are more than adequate for the Fast GC making the time of the chromatographic separation the limiting factor in the further reduction of analysis time.

ELECTROSPRAY FTICR STUDIES OF ISOLATED GAS PHASE PROTEIN CONFORMERS

Benjamin J. Bolanos, Richard Arkin and David A. Laude

Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

Of interest in this work is the question of whether selected trapping at the FTICR trapped ion cell can be used to distinguish between gas phase conformers of electrosprayed ions on the basis of ion mobility differences in the ESI/FTICR interface. To be presented is evidence that the selective trapping experiment can distinguish at least four gas phase conformers of electrosprayed cytochrome-c. These ion mobility results are supported by gas phase H/D exchange experiments performed in the trapped ion cell on isolated gas phase cytochrome-c conformers.

A magnetic field focusing ESI/FTICR is used to minimize the kinetic energy spread of electrosprayed ions. In data to be shown, the kinetic energy spread of individual charge states is about 0.5 eV FWHH. Conditions in a heated capillary/skimmer source are carefully controlled to select desired post-capillary collision conditions for desolvated electrosprayed ions. In particular, the distance between the capillary and skimmer, D_{c-s} , can be adjusted over a few mm range to produce significant differences in the kinetic energy of cytochrome-c ions delivered to the cell. In general it is found that at a D_{c-s} of 1 mm, the optimal trapping voltage for ions is independent of the charge state. As the D_{c-s} is increased to 3 mm and larger, a charge dependent nature to the optimal trapping voltage is observed.

A model developed to determine the optimum FTICR V_{trap} for electrosprayed ions contains a

$$V_{trap} = K_{slip}(v^2/2Ac)(m/z) + K_{eff} V_{skim}$$

contribution in the first term from gas dynamics and a contribution in the second term from the skimmer potential. The model suggests that in an experiment examining optimal trap potential as a function of charge state, different conformers should show distinctions in slope corresponding to different velocities.

Experiments were performed to evaluate V_{opt} vs. cytochrome-c m/z at 1 mm and 3 mm D_{c-s} values. From the 1 mm data, three clear distinctions optimum trap voltage (Ia = *6; Ib = *7, *8; II = *9 through *14) are observed. These results are shown in the plot below. Spectra are also shown in which trapping parameters are optimized to best isolate each conformer. Data was also acquired at D_{c-s} = 3 mm which revealed an additional conformer for higher charge states (III = *15 through *18)

Comparison of ion mobility and H/D exchange methods for conformer assignment in ESI/FTICR. Solid data points are from ion mobility work and unfilled points are from H/D exchange data.

ESI-FTICR of Isolated Cytochrome C Conformers at D_{c-s} = 1 mm

In order to validate these ion mobility results, gas phase H/D exchange data were acquired for the isolated conformers in the trapped ion cell. These results are in excellent agreement with the ion mobility results and also with H/D exchange results on cytochrome-c from McLafferty. The only distinction is that our H/D exchange work further resolved conformer II into two distinct conformers, IIa and IIb.

research	cytochrome-c conformation		
	I	II	III
McLafferty 1993 H/D exchange	*6 - *7(*8) least reactive	*8 - *14 most reactive	*12 - *16 intermediate reactivity
present work FTICR ion mobility	*7 - *8 (*6)	*9 - *14	*15 - *18
present work H/D exchange	*7 - *8 (*6) least reactive	*9 - *11 most reactive	*12-14 most reactive
			*15 - *18 intermediate reactivity

In future work we intend to reduce the kinetic energy spread by an order of magnitude (less than 0.1 eV FWHH) in order to better evaluate selected conformers within single charge states and to develop a quantitative collision model for ion mobility in the ESI/FTICR interface.

Structural Analysis of Polysaccharides and Peptides by MALDI FT-ICR Mass Spectrometry

Touradj Solouki, Bruce B. Reinhold, Catherine C. Costello, Matthew O'Malley, Shenheng Guan*, Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab, Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

* Member of the Department of Chemistry, Florida State University

Matrix-assisted laser desorption/ionization (MALDI) provides a rapid means of generating peptide, protein, and polysaccharide ions for direct FT-ICR mass spectral analysis. In addition to the usual advantages of MALDI FT-ICR mass spectrometry, namely, accurate mass measurement and high mass resolving power, we have recently demonstrated that combined use of ion axialization and ion remeasurement makes possible orders-of-magnitude improvement in sensitivity to the low-attomole detection level.[1] A critical issue in solving many important research problems in biology and medicine is the sample amount required to perform structural mass spectrometry.

Here, we demonstrate two approaches for FT-ICR structural mass spectrometry on samples of biological interest. First, we illustrate that MS/MS of a peptide mixture by stored-waveform ion modulation (SWIM) [2] two-dimensional FT-ICR tandem mass spectrometry helps to elucidate the structures of biological molecules in multi-component samples in an automated fashion. Second, we present gas-phase sequence and structural information provided by MSⁿ experiments. We use stepwise sustained off-resonance irradiation (SORI) collisionally induced dissociation (CID) to obtain MS and MSⁿ mass spectra from a single laser shot to obtain molecular weight and to assign glycosyl linkages. We report a highly efficient quadrupolar axialization method that allows the trapping of collision-induced small fragment ions for multiple remeasurements. Figure 1 shows normalized ion signal data for a disaccharide CID fragment ion (axialized or not axialized) from [M+Na]⁺ permethylated maltoheptose parent ion. After 100 remeasurement cycles, efficiency for remeasurement of the axialized fragment ions at m/z 463 is 99.22%.[3] Figure 2 shows SWIFT-isolated (400 < m/z < 540) CID_{Ar} fragment ions of isolated [M+Na]⁺. Remeasurement of the same ion packet in presence of 2 x 10⁻⁷ torr N₂ collision gas for 80 cycles enhances the S/N ratio; hence, ring-opening fragment ions that are not observed in a single measurement experiment may be assigned. We employ the same methodology to perform stepwise gas-phase sequencing of peptides.

A Top Down Approach to Sequence Verification of Large Proteins

Neil L. Kelleher, Einar K. Fridriksson, Gary A. Valaskovic, Hong Y. Lin,
David J. Aaserud, Ziqian Guan, Fred W. McLafferty
Cornell University, Dept. of Chemistry, Ithaca, NY 14853-1301

Mass Spectrometry is now established as a unique complement to classical methods for characterization of large proteins. (1) The high resolution ($>10^4$) and mass accuracy (ppm) possible with FTMS provide extensive mass data from complex mixtures from enzymatic or molecular ion dissociation. In our "top-down" approach to verification and refinement of DNA-deduced sequences, the intact MW value characterizes heterogeneity and possible sequence discrepancies, which then are positioned by ion or enzymatic dissociation. By using a varying degree of dissociation one can work rationally through the data verifying big portions of the sequence and then by increased fragmentation characterize smaller portions of the sequence. Complementary fragments that add up to the MW of the protein or of bigger fragments are especially helpful in locating causes of mass discrepancies (see figure 1). We have used Carbonic Anhydrase (29 kDa) for model studies. Figure 2 shows a single spectrum of human carbonic anhydrase after a mild digestion with a cathepsin-like protease present in the blood cells used for sampling. A single scan shows in addition to molecular ions 15 distinct peptides, up to 25.4 kDa. With α -chymotrypsin digestion we identify 62 peptides in one mixture without a chromatographic separation. With one additional protease (Lys C) and ion fragmentation we are able to break a total of 155 bonds out of 258 and locate to within 10 residues a 1 Da mass shift as compared to the sequence MW, caused by a deamidation of a Glutamine residue in the proteolysis process.

The top-down approach is applicable to proteins >100 kDa. Fig 3 shows spectra with unit resolution of two related 112 kDa proteins, verifying the cDNA derived sequence. The spectra were acquired on a 9.4 T FTMS instrument at NHMFL with A. G. Marshall and M. W. Senko. We have also analyzed proteins electroeluted from SDS PAGE. IR laser heating removes buffer and detergent adducts very efficiently and simplifies sample preparation for ESI MS. This is shown in figure 4 for Horse Myoglobin, 16950 Da.

Blackbody Infrared Radiative Dissociation: From Dissociation Energetics to Structural Elucidation

William D. Price, Paul D. Schnier, Rebecca A. Jockusch, Evan R. Williams
Department of Chemistry, University of California, Berkeley CA 94706

One of the fundamental issues confronting biological mass spectrometry is the relationship between gas-phase ion structure and dissociation energetics and dynamics. It has recently been shown that small weakly bound cluster ions, stored in an FTMS cell at pressures below 10^{-8} torr, are activated exclusively by the absorption of blackbody photons from the chamber walls, i.e., dissociation rates are independent of the pressure¹. Arrhenius activation energies (E_a) in the zero-pressure limit can be obtained from the temperature dependence of the unimolecular dissociation rate constants. For small weakly bound systems, the absorption of blackbody photons is the rate limiting step. Thus, the Arrhenius pre-exponential factor (A) reflects only these up-pumping rates and reveals nothing of the structure of the transition state. From modeling, Dunbar² found that the energy of a population of ions is given by a truncated Boltzmann distribution. True dissociation energies E_0 can be obtained by adding a large correction to the measured activation energy.

Using blackbody infrared radiative dissociation (BIRD), the dissociation energetics of several proton-bound amino acid dimers was investigated. Arrhenius plots for the dimers of glycine, alanine, lysine and the cross-dimer of alanine-glycine are shown in Figure 1. Also shown is the proton bound dimer of N,N-dimethylacetamide which has a dissociation endothermicity (ΔH_0°) of 1.35 eV³. The measured activation energies and calculated E_0 are compiled in Table 1. Using Dunbar's method, the calculated E_0 for N,N-dimethylacetamide overestimates the measured E_0 by 0.3 eV. Curiously, the dissociation rates of alanine-glycine cross-dimer are faster than both the glycine dimer and the alanine dimer, i.e., has a larger measured A value. In the truncated Boltzmann picture, larger ions should dissociate faster than smaller ones with similar threshold energies. However, the entropy of activation for alanine-glycine dimer is more favorable than for a symmetric dimer such as alanine. These results indicate that the dissociation rates include both information about the transition state as well as the up-pumping rates and that the truncated Boltzmann treatment breaks down.

Thus, more accurate master equation model is necessary to extract meaningful information from these experiments. With this method, the detailed rate constants for all activation, deactivation and dissociation processes are calculated. These values are then used to construct the transport matrix from which the time dependence of the ion population is calculated. Radiative pumping rates are given by the Einstein A and B coefficients. The transition frequencies and transition dipoles are calculated at the AM1 semi-empirical level. The blackbody energy density is given by the Planck distribution law at the experimental temperature range and the microcanonical occupation probabilities are calculated exactly by systematically eliminating each transition frequency from the density of states calculation. Microcanonical unimolecular dissociation rates are calculated using RRKM theory. A "loose" transition state is assumed for the proton bond dimers. Transition state frequencies for all species were varied to provide a high pressure Arrhenius pre-exponential (A^∞) of $10^{14.5} \text{ s}^{-1}$. A scaling factor for transition dipoles was determined by matching the ratio of measured rates between ala-ala and gly-gly, and was then applied to all transition dipole magnitudes. By varying E_0 , the experimental activation energies and A factors are recovered (Table 1). Thus, the master equation model appears to accurately reproduce the experimental data with reasonable parameters.

The rate equation for thermal unimolecular dissociation is given by equation 1.

For a polymer, the rate of blackbody photons exchanged with the chamber walls increases linearly with size. Whereas, the microcanonical dissociation rate constants, k_d , decreases. When $k_{1,c} \gg k_{-1}$, the measured reaction rates will reflect only the dissociation kinetics and the energy distribution of a population of ions will be given by a Boltzmann distribution. This is the high pressure limit of the classical Lindemann-Hinshelwood mechanism.

Dissociative activation parameters for biomolecules as large as ubiquitin (8.6 kDa) can also be obtained using BIRD⁴. Figure 3(a and b) shows the BIRD spectra of ubiquitin 11+ and 5+, respectively, formed by electrospray ionization. The 11+ ion dissociates predominantly to the y_{7+}/b_{5+} complementary pair, whereas, the 5+ ion only loses water. The Arrhenius activation energies of 1.6 and 1.2 eV and pre-exponentials of 10^{17} and 10^{12} s^{-1} are measured for the 11+ and 5+ ions, respectively.

To determine if these are "high pressure" values, dissociation rates of ubiquitin were calculated within the formalism of the master equation, modeled using the generic peptide, (ala-gly)₈ (8.4 kDa). The backbone C-N stretch of the first ala-gly subunit was used as the reaction coordinate, transition state frequencies were varied to provide A^∞ of 10^{12} and 10^{17} s^{-1} . With $E_0 = 1.52 \text{ eV}$ and $A^\infty = 10^{17} \text{ s}^{-1}$, the calculated E_a and A very closely match the measured values for ubiquitin 11+, and the ion population is very close to that of a Boltzmann distribution (Figure 2). This, as well as the large measured A value strongly indicates that these ions are in thermal equilibrium with the chamber walls. Similar results were obtained for the 5+ ion.

The thermal equilibration depends on a number of factors including the ion size, E_0 , A^∞ and temperature. For the small peptide bradykinin (1.1 kDa) 1+ which dissociates by loss of NH_3 with a measured E_a of 1.3 eV and $A = 10^{12} \text{ s}^{-1}$, master equation modeling shows that the high pressure limit approximation is valid to within the error of the experiment ($\pm 0.1 \text{ eV}$ and $10^{\pm 1} \text{ s}^{-1}$).

Molecular activation by blackbody photons becomes increasingly important in the unimolecular dissociation of large ions. Evidence presented above indicates that ubiquitin ions come to thermal equilibrium with the blackbody field of the vacuum chamber. The resulting activation energies (E_a) are a true reflection of the dissociation energy (E_0) and the pre-exponential factors reflect the dynamics of the dissociation process. This information, which has not been accessible via other methods, should greatly improve our understanding of the dissociation processes of large ions.

Non-destructive, broad band FT detection using dc dipolar excitation in a quadrupole ion trap R. G. Cooks, M. Soni, V. Frankevich, M. Nappi, H. Wei, R. E. Santini and J. W. Amy Department of Chemistry, Purdue University, West Lafayette, IN 47907

A new method of ion detection is demonstrated for a quadrupole ion trap. In this experiment, a collection of trapped ions of different masses is impulsively accelerated by application of a dc dipolar field so as to cause ion z-direction excursions from the center of the trap at their mass-characteristic frequencies; the image current due to the approaching ions is measured using a pin detector electrode set into but isolated from one end-cap electrode. The image current is Fourier transformed to produce a frequency domain (i.e. mass) spectrum. Signal intensities after amplification are on the order of 1 volt and resolution is up to 1500 (50% valley) but is strongly dependent on the number of trapped ions and on the exact trap geometry, including the position and size of the detector electrode. Measured ion frequencies are different to those calculated for a pure quadrupole field but the measured ion frequencies are linear with ion mass, allowing ready mass calibration. Remeasurement can be performed by re-application of the dc pulse to re-excite the ion population; the transients are averaged to record the final spectrum. Fig. 1 illustrates the individual transients recorded in a remeasurement experiment. The FT-ITMS technique can be used to perform MS/MS experiments simply by isolating the parent ion using SWIFT or a reverse-forward rf scan prior to collisional activation achieved using either a resonant ac signal, or a SWIFT excitation pulse, or a dc pulse. After cooling, the resulting product ion population is measured non-destructively using the dc excitation and image current methods already described. This capability is illustrated in Fig. 2 which shows an experiment in which a reverse-forward rf scan was used to isolate the parent ion of interest, m/z 120, and ac excitation was employed for CID. The degree of fragmentation observed can be controlled by adjusting the time or amplitude of the CID signal.

A variant on the experiment shown to improve signal strength is to use a dc offset in order to operate with an off-center pseudopotential well. By placing the ion cloud closer to the detector electrode, stronger signals are recorded. Experiments using double-ended detection (pin electrodes in each of the end-cap electrodes) should null out noise. Experiments in which ac excitation is used instead of dc give similar but inferior results; signals depend on the exact frequency and amplitude chosen and relative ion abundances are not as accurate. Nevertheless, non-destructive broad band detection with ac excitation shows good mass resolution (Fig. 3). ITSIM simulations suggest that improved resolution is possible by minimizing ion-ion interactions using dc pulses applied in the x-direction as well as in the z-direction; under such conditions the ions undergo almost cycloidal motion (with associated rf-induced ripple).

OPTIMIZATION OF ION TRAPPING AND MASS MEASUREMENT IN FT-ICR MASS SPECTROMETRY

KENT J. GILLIG, BRIAN K. BLUHM, AND DAVID H. RUSSELL
LABORATORY FOR BIOLOGICAL MASS SPECTROMETRY
DEPARTMENT OF CHEMISTRY
TEXAS A&M UNIVERSITY

INTRODUCTION

A goal of FT-ICR mass spectrometry is to extend the obtainable mass range while maintaining the high resolution capabilities of the method, and improving the mass measurement of high mass ions. Our view is that the limiting factors involved are the excess kinetic energy of the ions resulting from ionization methods used and the dispersion of ions in the FT-ICR cell. A solution (other than increasing the magnetic field strength) is to modify cell geometry to create a favorable trapping environment for high mass ions. The strategy resulted in the implementation of the wire ion guide cell which approximates a Kingdon trap and has been used to successfully trap and detect high mass ions formed by MALDI.¹ Experiments have continued with this cell geometry focussing on mass measurement capabilities and improvement in ion trapping duration.

EXPERIMENTAL

The experiments were performed using an FT-ICR spectrometer consisting of a 7 T Oxford magnet, an Extrel-2001 data station, and a homebuilt cylindrical cell. Ions were formed by laser desorption at 355nm with a Nd:YAG laser.

RESULTS

Figure 1 contains a SIMION plot of electrostatic field lines of a cylindrical wire ion guide cell with a length and diameter of 1.5". By adjusting the voltages on the wire and trap plates the field lines can approximate those of an ideal Kingdon trap.² The field lines are defined by $\phi = A(z^2 - r^2/2 + B \ln r)$ where A and B are

constants for a given cell, z is the length of the cell and r is the radius of the cylinder. A major advantage of the ideal Kingdon trap is that it gives rise to harmonic motion in the z direction, extending trapping times and stabilizing the ion motion, which is given by the frequency $\omega = \sqrt{\frac{kq}{m}}$

Figures 2,3, and 4 are graphs of resolution, frequency shifts, and constant cyclotron frequency; respectively, for data obtained on laser desorbed Fe ions using an ideal Kingdon trap cell. The trapping voltage was maintained at 1V

for the data in figures 2 and 3, while the voltage on the wire during the beam event and trapping delay (VBB) and excite and detect period (VBN) were varied.

CONCLUSIONS

The parameters of the wire ion guide cell can be adjusted to approximate an ideal Kingdon trap and provide harmonic motion in the z-direction. The results indicate that for a wire ion guide cell with an aspect ratio of one and 1V applied to the endplates there exists a maxima in resolution and a common shift in the observed cyclotron frequency when 3V are applied to the wire during the excite and detect event. This result is independent of the voltage applied to the wire during the trapping delay. It is also possible to adjust the observed cyclotron frequency to a constant value by varying the trap and wire voltages. Effectively, the combination of quadrupole and logarithmic fields can form a field free detection environment.

Characterization of an Electrostatic Ion Guide for Transfer of Electro sprayed Ions into a FTICR MS

Michelle Buchanan, Robert Hettich, and Liang Tang

Organic Mass Spectrometry Group, Chemical and Analytical Sciences Division
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365

In previous reports (1,2), we have demonstrated the ability to obtain spectra using an electrostatic ion guide (EIG) for the transfer of ions from an external electrospray (ES) ion source and into a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer even though the source was displaced 46 cm from the EIG (See Figure 1A). In the present study, the EIG interface has been more fully characterized to allow its performance to be optimized. Initially, the EIG (5 cm OD cylinder with central wire) was studied outside the strong field of the 3T magnet, as shown in Figure 1B, to measure ion current densities and radial distributions with and without the EIG. A Faraday plate, fashioned like a bullseye with a 6 cm OD and three concentric rings and a center disk, was placed in three locations: (1) immediately after the skimmer cone, (2) 100 cm behind the skimmer (no EIG in place), and (3) 100 cm behind the skimmer with the EIG in place. The pressures in this region were approximately 10^{-4} torr. With no EIG in place, at 100 cm from the skimmer, approximately 40 percent of the current density fell within the center disk (1.27 cm diameter) and about 80 percent fell within a diameter of 2.5 cm. With the EIG in place and with potentials of 5 V and -15 V placed on the cylinder and central wire of the EIG, respectively, the current density on the central disk increased to 74 percent and the density within 2.5 cm was greater than 98 percent.

Once initial operating parameters for the EIG was established, the system was reconfigured to obtain mass spectra, as shown in Figure 1a, which is the configuration we previously reported (1,2). Under these conditions, the EIG is positioned 46 cm behind the skimmer cone orifice and extends to within 7.6 cm of the trapped ion cell of the FTICR. Ions from Gramicidin S could be trapped at low static accumulation voltages on the FTICR cell, 0.5 to 2 volts, without a high pressure pulse of buffer gas. Spectra could be obtained with 50 femtomoles of compound consumed per 10 msec scan. In this configuration, however, when voltages on the EIG were removed spectra could still be obtained, with signal intensities reduced only by a factor of two compared to when the voltages were applied. Further, current measurements on the rear electrode of the EIG showed that significant ion current was lost to this electrode. Changing the voltages on the cylinder and central wire had little effect on reducing this loss, suggesting that the EIG was not operating optimally.

The system was then altered to the arrangement shown in Figure 2, with the EIG located approximately 10 cm from the skimmer cone orifice. In this configuration, the pressures in the EIG region were in the mid- 10^{-5} torr range. The observed signal levels improved by an order of magnitude compared to previous arrangement. Further, in this new configuration, the observed signal decreased about by a factor of ten when no voltages were applied to the EIG. In contrast to what we had observed with the other configuration, the current on the rear electrode could be readily altered by changing the potentials on the cylinder and wire of the EIG.

From these experiments, the effectiveness of the EIG interface to transport ions from an external ES to the trapped ion cell of the FTICR has been improved over previous configurations. The high pressures.

in the analyzer region (low 10^{-6} torr) currently prevent high resolution spectra from being obtained. We plan to increase differential pumping in the source and interface regions to improve base pressures in the trapped ion cell and, thus, mass resolution. Also, our current electrospray source produces relatively low currents compared with other sources and we plan to modify the source to improve detection limits in the system.

Rapid Air Oxidation of Organothiol Self-Assembled Monolayers in Normal Laboratory Environments

Charles L. Wilkins, Jill R. Scott, and Jie Yao, Department of Chemistry, University of California, Riverside, Riverside, CA 92521 and W. Russell Everett and Ingrid Fritsch, Department of Chemistry and Biochemistry, University of Arkansas, Fayetteville, AR, 72701.

Self-assembled organothiol monolayers (SAMs) on gold or silver surfaces are widely advocated as important materials with many potential useful applications. Recently, alkanethiolate monolayers upon gold have been proposed as "inert" model surfaces for investigation of the fundamentals of biointerfacial science¹. Thus the stability of such monolayers to air oxidation is an important issue. In this paper, we report the rapid and complete air oxidation of *clean* dodecanethiol and 10-(ferrocenylcarbonyl)decanethiol self-assembled monolayers on gold in the dark and under normal laboratory fluorescent lighting. This oxidation does not require ultraviolet radiation. Previously, Hemminger and co-workers demonstrated that 193 nm laser desorption, with a Fourier transform mass spectrometer (FTMS) for detection as a rapid and sensitive means for characterization of alkanethiol SAMs².

The present results, unexpected in light of numerous previous literature reports, are the result of careful studies employing 308 nm laser desorption mass spectrometry (LD-FTMS). The MS results are corroborated by polarization modulation Fourier transform infrared mass (PM-FTIR) spectrometry, where a broad sulfonyl band at 1120 cm⁻¹ is used to monitor oxidation of dodecanethiol SAMs. As figure 1 shows, oxidation of self-assemble monolayers, as monitored by LD-FTMS is rapid and complete within 5 minutes.

Thus, we conclude that previous reports of air oxidation stability of such materials may result from sample preparation conditions and should be reevaluated.

Analysis of Harmonics for an Elongated FT ICR Cell with Multiple Electrode Detection

Eugene N. Nikolaev*, Institute for Energy Problems of Chemical Physics, Moscow, Russia
V. Sergey Rakov and Jean H. Futrell, University of Delaware, Newark, DE

Harmonics in FT ICR signals are of interest for two intrinsic reasons. Incorrect mass assignments can be made because of harmonics, especially for multiply-charged ions and fragment ions from large molecular ions. More importantly, resolution for higher harmonics increases n times, where n is the order of harmonic. Resolution in ICR is the ratio of the peak width, (which is inversely proportional to signal detection time) to its frequency, and the detection time for the signal is the same for all harmonics. For this reason it may be desirable to introduce new methods in FT ICR experiments which emphasize higher frequency harmonics in detected signals. One way to obtain a harmonically-rich signal is to use ICR cells with multiple electrode detection geometry, first proposed by Nikolaev *et al.* in 1985 [1] and later by Ridge *et al.* [2]

One source of harmonics in detected signal is the detection method itself. It has been shown that for any kind of detecting geometry large orbit ICR trajectories result in non-sinusoidal form of detected signals, which leads to *odd harmonics* in the spectrum. Analytical derivation and experimental verification has been presented previously [3]. Another cause of harmonics is electronic signal processing, which is not discussed here.

If we include magnetron motion in ion trajectories the induced charge density on the detection plates becomes a complicated function of time, cyclotron and magnetron radii and frequency are the main parameters. The total induced charge on each detecting plate is the integral of this function over the plate coordinates and detected current is the time derivative of the total induced charge on the plate. The expression for induced current can be expanded into a frequency Fourier series. The general equation for the induced current in case of $2M$ detecting plates is found to be

$$J(t)_{\text{synch}} \sim \sum_n \frac{1}{n} \sum_{k=0}^n C_n^k r^k \rho^{n-k} (k\omega + (n-k)\Omega) \cos(k\omega t + (n-k)\Omega t)$$

$$n = M(2p+1), p = 0, 1, 2, \dots$$

where ω , Ω , r , and ρ are the cyclotron and magnetron frequencies and radii, respectively. Thus we obtain a simple series in which each term's *cosine* argument indicates the frequencies of all the harmonics and their coefficients predict their amplitudes. In most physically realizable cases, such as a non-synchronized magnetron motion (1), two detecting electrodes cell, i.e. $M=1$ (2) or magnetron motion, when $\omega \gg \Omega$ and $r \gg \rho$ (3) some terms in the expansion become insignificant and a simpler picture emerges. The above formula includes as a special case the results published in [3] and satisfactorily explains the harmonics amplitudes distribution as a function of excitation time (i.e. the cyclotron radius) presented in [4].

Thus the present work explains the presence of *even harmonics* in the spectrum along with their amplitude distribution for common cells and for cells with multiple electrode detectors. Also the phenomena of harmonics shifting and splitting can be explained in terms of the general equation. In real life experiments these spectral features depend on the cyclotron and magnetron motion parameters.

The principal criterion for the maximum number of detecting electrodes follows from the convergence of the series:

$$J(t)_{\text{non-synch}} \approx Mr^M \omega \cos(M\omega t) + M(M-1)r^{M-1}\omega \rho \cos((M-1)\omega t) + \\ + M(M-2)r^{M-2}\omega \rho^2 \cos((M-2)\omega t) + \dots$$

$$M-1 < \frac{r}{\rho}$$

Our conclusion from this analysis is that maximum number of electrodes for a practical cell with traditional ion excitation/injection scheme is 16 (8 pairs).

Computer modeling using MATLAB 4.2 software has been performed on a Pentium-100 computer to illustrate the effects of synchronized and non-synchronized magnetron motion. The results show that for magnetron frequencies comparable with cyclotron frequency (which fortunately is never the case), and/or when the magnetron and cyclotron radii become of the same order the spectrum is very complex, becoming almost uninterpretable even for a single mass ion and as few as 8 detecting electrodes (four pairs).

The method of multiple electrode detection along with the mathematical analysis presented here becomes a powerful strategy for increasing the resolution in FT ICR. Practical limitations apply to the maximal number of detecting electrodes (probably about 8 pairs). We also show how higher harmonics can be distinguished from fundamentals, thereby reducing the probability of errors in designing M/Z when working with high mass multiply charged ions.

Characterization of ESI-FTICR Performance at Low Magnetic Fields

Michael V. Gorshkov[†], Qinyuan Wu, Harold R. Udseth, Gordon A. Anderson, and Richard D. Smith[‡]
Pacific Northwest National Laboratory[§], P.O. Box 999, Richland, WA 99352

Fourier Transform ion cyclotron resonance mass spectrometry (FTICR-MS) in combination with an electrospray ionization (ESI) source provides the highest achievable resolution and accuracy for the characterization of biologically important molecules and/or non-covalent complexes¹⁻³. The routine use of this method is partially limited by the current state of the art implementations based on expensive high field superconducting magnets. From another hand, the use of low magnetic field brings additional problems because of increasing scale of artificial factors such as magnetron frequency, space charge interactions, magnetic field inhomogeneity, phase locking, and critical mass. Thus, a comprehensive characterization of FTICR-MS performance at low magnetic field and evaluation of design solution to overcome those negative factors is of practical interest as a potential basis for benchtop instrumentation with performance characteristics exceeding alternative approaches. In this work, we evaluated a 1 tesla FTICR mass spectrometer built recently at Pacific Northwest National Laboratory. We also discussed several design approaches which could overcome the low field constraints. Among those approaches are: (i) large 4" size FTICR trap; (ii) "in-field" ESI source; and (iii) pulse magnetic shutter. The large size of the trap leads to decreased effects from electric field inhomogeneity and space charge interactions, and it increases the critical mass-to-charge ratio. "In-field" ESI source brings the compactness in design, and it makes possible to better overcome the low focusing effect from the magnetic field used. Pulse magnetic shutter developed at this lab as an alternative to permanent current electromagnetic, or slow pneumatic shutters provides better differential pumping, can be located close to the trap, and does not introduce undesirable field perturbations. To achieve the goal of comprehensive instrument characterization we performed ultra high resolution and precise mass measurement in electron ionization mode, as well as high resolution and tandem mass spectrometry measurements of electrosprayed ions of different peptides and proteins as well as weak binding organometallic complexes. In the first set of routine experiments using EI, we were able to achieve 10⁷ mass resolution for N₂ ions and to perform a new consistency test of the atomic mass table for xenon isotopes (Figure 1) with ppb mass accuracy which is the highest obtained in FTICR-MS up to date. In another set of experiments we performed CID analysis of a non-covalent complex [18-Crown-6...SrNO₃⁺] obtained by using ESI. In this study we achieved ppm level of accuracy in the analysis of MS/MS products. Finally, we demonstrated that ultra high resolution can be achieved for ESI ions and the characteristic isotopic pattern can be routinely obtained in a 1 tesla magnetic field for higher molecular weight peptides and proteins as well. Figure 2 and 3 show the spectra for bradykinin (M_r 1,060) with mass resolution of 850,000 for 2+ charge state ions and ubiquitin bovine (M_r 8,565) with completely resolved isotopes and the mass resolution of 110,000, respectively. The highest molecular weight protein for which we obtained a resolved isotopic pattern to date was cytochrome c (horse heart) with M_r 12,360 (see Figure 4). Studying the factors limiting instrument performance we found that ion frequency drift during detection (which is longer than that in higher magnetic fields) is the major one. Among different contributors to the frequency drift which is in the range of 0.1-10 Hz, we found that ion-ion interactions are most responsible for the drift and the amplitude shape of the time-domain signal. In order to correct the drift, we developed programming tools based on instantaneous phase rotation of acquired time-

domain data. We have received 2-100-fold spectral enhancement depending on the quality of original time-domain spectra.

Accurate Mass Measurements by using Multiple Ionization Techniques Simultaneously with FT/MS

Brian E. Winger, John A. Castoro, Diane Tutko and Joseph E. Campana, Finnigan FT/MS, 6416 Schroeder Rd., Madison, WI 53711-2424.

Presently, the most accurate mass measurement for any type of mass spectrometer is obtained by using an internal mass reference. Fourier transform mass spectrometry (FT/MS) is capable of accurate mass measurements less than 5 ppm with an external calibrant and less than 2 ppm with an internal mass reference. The difficulty in achieving this mass measurement accuracy, when an internal reference is necessary, is finding an appropriate mass reference that will co-mix and ionize without interfering with the ionization of the analyte. In addition, the ion abundances of the two materials should be relatively similar, therefore adjustment in the molar ratio's is typically necessary, but not always possible.

NewStar FT/MS (illustrated in Figure 1) is a Fourier transform mass spectrometer equipped with multiple ionization sources concurrently and consists of a dual-cell in the center of a 3 (or 7) Tesla superconducting magnet. On the source side is the N_2 laser accessory and an Autoprobe system used for MALDI. The analyzer side is equipped with UltraSource, Finnigan FT/MS's external ion source, equipped with an electrospray ionization (ESI) source. In addition to ESI, UltraSource is equipped with a filament that is mounted on a linear feedthrough that allows for electron ionization (EI) when the filament is inserted, and for ESI when the filament is extracted.

An accurate mass measurement method based on the use of multiple ionization techniques simultaneously, or MITS, was developed where the analyte and mass reference compound are introduced into the mass spectrometer independently. The possible MITS combinations that exist with the NewStar FT/MS configuration include EI-MALDI, EI-LDI, MALDI-ESI and LDI-ESI. Unlike with traditional methods for obtaining accurate mass measurements by using an internal mass reference, the relative abundances of the reference and analyte ions can be controlled simply by varying experimental parameters such as ionization time and emission current (EI), suspended trapping time (MALDI or LDI), and ion injection time (ESI).

The data illustrated in Figure 2 demonstrates the true versatility of the NewStar FT/MS. Mass reference ions were generated by both MALDI (m/z 1209.6527) and by ESI (m/z 380.2180, 523.7745, 556.2766 and 574.2330) while the analyte, Insulin β -chain, was injected into a loop that was in series with the ESI calibrant mixture. The RMS mass error for the $[M+4H]^{4+}$ monoisotopic species (m/z 874.4190) was 1.07 ppm with a standard deviation of 0.45 ppm based on a set of five measurements. Using this same MITS protocol, an RMS mass error of 0.80 ppm with a standard deviation of 0.38 ppm was obtained for the $[M+4H]^{4+}$ monoisotopic species of melittin (m/z 712.1963). These results demonstrate that routine accurate mass measurements can be obtained by using MITS.

To summarize, we have developed a method for obtaining routine accurate mass measurements that involves the use of multiple ionization techniques simultaneously, MITS, on a NewStar FT/MS system.

Real-Time Characterization of Individual Particle in Ambient Aerosols in Riverside, California

Christopher A. Noble and Kimberly A. Prather*

Department of Chemistry, University of California, Riverside, California 92521

In order to enhance our understanding of the role of aerosols in atmospheric processes and to identify aerosol sources, the ability to characterize ambient aerosol particles in real-time is necessary. Many researchers focus on particle size and/or chemical composition, since these two features of aerosol particles are of primary importance in heterogeneous reactions and source allocation.

Experimental Section

Our research group has recently developed aerosol time-of-flight mass spectrometry (ATOFMS), a technique which allows for real-time determination of the size and chemical composition of individual aerosol particles. Particle analysis is performed in one instrument using two laser aerodynamic particle sizing prior to time-of-flight mass spectral analysis. Two laser aerodynamic sizing allows for size analysis of polydisperse aerosol samples over the size range of ~ 0.1 – 10 μm in diameter.

Results and Discussion

The ATOFMS system has been used to study particles in ambient aerosol systems in Riverside, California during May 1995. The time-of-flight mass spectrum of each particle is used to manually classify particles into chemically specific categories. Samples of two types of particles are shown in Figure 1. The inorganic/organic particle class is typified by the presence of (1) carbon ions extending out

to C_5^+ or C_6^+ , (2) CH_3^+ , NH_4^+ , H_3O^+ and NO^+ , as well as (3) the presence of peaks due to metal cations. In Figure 1a, the metals which are evident are lithium, aluminum and iron. Other metals which are commonly present in this category are: sodium, potassium, calcium, lead and vanadium. It is speculated that this type of particle is the result of emission processes, possibly from an automobile. The peaks due to NH_4^+ and NO^+ indicate the presence of ammonium and nitrate in the original particle, possibly due to some secondary heterogeneous process involving gas phase ammonia and nitric acid. The inorganic oxide class is represented by the presence of metal cations and associated metal oxides. Figure 1b demonstrated a particle containing sodium, aluminum, potassium and titanium as well as some related metal oxides. Also found in particles assigned to this category are: silicon, calcium, chromium, iron and lead. Based on both the chemical composition of the inorganic oxide particles as well as the size range this type is found in, it is likely that these particles are of soil origin or dust which has been suspended into the atmosphere.

Plotting the size distributions of the distinct categories, it is evident that particles of similar composition are specific to certain size modes. This implies that there is a direct correlation between particle size and chemical composition. As shown in Figure 2, the majority of inorganic particles are coarse (i.e., greater than 1 μm in diameter). Similarly, the majority of organic particle types are smaller than 1 μm in diameter. Because ATOFMS is a single particle method, it is possible to distinguish between chemically different particle types within the same size mode. This measurement capability contrasts that of bulk aerosol methods, which cannot specifically differentiate between multiple particle classes in a single size mode. This is important because chemical speciation within a particle determines its environmental and biological reactivity. Time-variable data as well as size dependent data from atmospheric studies using ATOFMS will be presented.

Figure 1: Representative positive ion spectra of two different particle categories. (a) Inorganic/organic. (b) Inorganic oxide.

Figure 2: Size distributions of inorganic particle types. Total size distribution of all particles sampled also shown.

Single Particle Analysis by On-line Bipolar Laser Mass Spectrometry and Multivariate Data Analysis

Klaus-Peter Hinz¹, Frank Drews², Ronald Lange²,
Raimund Kaufmann¹, Bernhard Spengler^{1*}

¹ Institute of Laser Medicine, University of Düsseldorf, PO Box 101007,
D-40001 Düsseldorf, Germany

² IUF GmbH, Rudower Chaussee 5, D-12489 Berlin, Germany

A laser based mass spectrometrical system for physical and chemical analysis of individual particles from various aerosol sources is described. Particles are investigated in an on-line mode by means of a differentially pumped direct-inlet system. Artifacts from preparation and complete loss of volatile compounds can thus be avoided. The instrument used is a home-built bipolar time-of-flight mass spectrometer, allowing us to simultaneously obtain a positive and a negative ion spectrum from the same particle for each laser shot [1]. Using both polarities the reliability of a chemical characterization by mass spectrometry is highly improved.

After entrance into the ion source, particles are detected by a light scattering system. About 1 mm downstream the detected particle is vaporized and partly ionized by a UV laser pulse. Particles of different size classes can be discriminated by their velocity, using different trigger delays between particle detection and laser ionization. Time-of-flight spectra are acquired by a transient recorder, transferred to a computer and evaluated for on-line statistical analysis. Figure 1 shows, as an example, the positive and negative ion spectrum of a single particle characterized by a high contents of nicotine

Figure 1: Positive (A) and negative (B) ion spectrum of a 0.5 µm diameter indoor aerosol particle containing nicotine.

In the "learning mode" multivariate calibration methods on the basis of classical techniques, fuzzy logic or neural networks are used to transform ion spectra into data bases of typical particle populations, characterized by sets of main particle classes.

In the "evaluation mode", after setup of main particle classes, newly recorded mass spectra are immediately classified by on-line pattern recognition procedures, and degrees of membership to certain particle classes are calculated. Thus for each detected particle a chemical classification is displayed on the computer screen promptly and statistical evaluation of the complete particle population is updated. Figure 2 shows the histogram of a population of particles from ambient laboratory air (black bars) together with the membership coefficients of an individual nicotine-containing particle (white bars).

Figure 2: Classification diagram with the degree of membership for the single nicotine-containing particle in Figure 1 (□) and for the complete particle population (■) of 299 particles with 0.5 µm diameter.

On-Line Analysis of Aqueous Aerosols

K.R. Neubauer, M.V. Johnston, Department of Chemistry and Biochemistry
A.S. Wexler, Department of Mechanical Engineering
University of Delaware, Newark, DE 19716

Sulfur compounds, important in acid deposition and the earth's energy balance, enter the atmosphere from both natural and anthropogenic sources. However, in many instances, sulfur aerosols can exist in aqueous droplets resulting from sea spray, deliquescent growth, and/or reactions in cloud, fog, or haze droplets. For example, hydroxymethanesulfonic acid (HMSA) forms from the aqueous phase reaction of formaldehyde and sulfur dioxide, while methanesulfonic acid (MSA) occurs in the marine environment and, therefore, may exist in sea spray droplets. For these reasons, it is important to understand the effects of water on distinguishing various forms of sulfur.

Conventional particle analysis techniques are off-line, thereby allowing the opportunity for evaporation of volatile species and changing of the particle's composition from its form in the atmosphere. To minimize this problem, we use rapid single-particle mass spectrometry (RSMs) to analyze particles in real time. This technique involves drawing particles directly into the source region of the mass spectrometer and detecting them by light scattering before ablating them with a single laser pulse. With this sequence of events, each mass spectrum results from a single laser pulse ablating a single particle in flight. In this study we generate dry aerosols of known size and composition and pass them through a humid environment so that they undergo deliquescent growth to form aqueous droplets. Our goal is to observe the effects of water on the mass spectra of single particles of atmospherically relevant sulfur aerosols.

Our results indicate that aqueous particles differ from dry aerosols in several aspects. As typified by sodium chloride in Figures 1 and 2, peaks attributable to water appear in the spectra of aqueous particles, while dry aerosols exhibit higher mass cluster ions resulting from the solute. Another difference is the threshold laser fluence necessary for ablation - higher fluences are necessary to produce ions from wet particles than from dry particles. Above thresholds, only minimal peak broadening occurs with increasing laser fluence. In Figure 1 unit mass resolution is observed for the aqueous particle at a fluence 3.5 times greater than threshold.

When extended to aqueous sulfur aerosols, the same spectral differences arise as described for sodium chloride particles: peaks attributable to water, fewer cluster ions due to solute, and higher ablation thresholds. However, despite these differences, we can distinguish MSA, ammonium sulfate, and (HMSA) aerosols on the basis of peaks characteristic of the each compound.

We also attempted to extract quantitative information by examining particles of mixed composition. Figure 3 displays the results for a simplified urban aerosol consisting of the sodium salt of HMSA and ammonium sulfate. As evident in this plot, the peak area ratio scales with relative concentration in the particle, thereby demonstrating that semi-quantitative analysis of aqueous aerosols is possible.

INSTRUMENTATION FOR TROPOSPHERIC AEROSOL CHARACTERIZATION

Z. Shi, S. Young, C. Becker, M. Coggiola
SRI International, Menlo Park, CA 94025

H. Wollnik
University of Giessen, Giessen, Germany

A new instrument has been developed to determine the chemical composition of tropospheric and low stratospheric aerosols with the size down to 0.2 μm in diameter. The first deployment of this instrument is in conjunction with the NASA-sponsored SUBsonic aircraft Contrail and Cloud Effects Special Study (SUCCESS) field program. Utilizing NASA's DC-8 research aircraft as an experimental platform, aerosols, both in contrails and clouds, are studied with this aerosol mass spectrometer near Clouds And Radiation Testbed (CART) site in Oklahoma.

The instrument is a thermal volatilization, electron impact ionization time-of-flight mass spectrometer coupled with an aerosol sampling system and an optical particle detector. It is dedicated to studies of volatile and semi-volatile aerosols.

The spectrometer consists of three parts: aerosol sampling, vaporization and ionization, and data acquisition. A conical-shaped probe isokineticly brings the sample into the interior of the aircraft. An aerosol beam is formed after passage through a capillary sampler and a two-stage differential pumping system which is based on D. Murphy's design (NOAA, Boulder CO). Particles are then intersected by a laser scattering particle sensor, and a trigger will be sent to start the mass scan if aerosols in the size range of interest are detected. In order to maximize the applicability to various aerosols with different compositions, shapes, and velocities, a thermal volatilization method has been adopted. The temperature of the heated surface is adjusted to around 900K which is sufficient to vaporize volatile aerosols generated by jet airplanes. The resulting vapors enter the ionization region where they are ionized by electron impact

The storage-type ion source is based on the design of H. Wollnik and co-workers at Giessen, Germany. Experimental results show that ions can be stored in the ion source for up to 1 ms before extraction into the TOF drift tube, which increases the instrumental sensitivity. Ions are analyzed by a reflectron-TOFMS in a single scan. With a 500MHz digitizer, a resolution of 1000 can be obtained at mass of 600 amu. Results show that the separation of vaporization and ionization steps increases the accuracy of quantitative measurement. It is found that the delay time between the particle detection and ion extraction depends on the vaporization/ionization processes and the ion storage time, rather than the transit time for aerosols travel from the optical sensor to ionization region. Therefore, the delay time is independent of the velocity of aerosols.

During NASA's SUCCESS field mission, more than 30,000 aerosols in various environments have been sampled with this instrument: aerosols in the clouds at altitude from 5,000 ft to 42,000 ft; aerosols in contrails formed by jet airplanes using various types of fuels; aerosols in the atmosphere over mountain, desert, and ocean. Aerosols rich in sulfate, nitrate, ammonium, and sulfuric acid have been observed. Our preliminary results of *in situ* aerosol characterization are important to reveal their sources, properties, and evolution processes.

This work is supported by AEAP under grant NAG 2-963

Real-Time MS/MS of Organic Airborne Particulates

P. T. A. Reilly, R. A. Gieray, M. Yang, W. B. Whitten, and J. M. Ramsey
Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN 37831-6142

In the past, particulate analysis was performed in bulk. In other words, particles were collected on a filter, extracted, and then subjected to exhaustive chemical analysis. All information about the composition of the individual particles was, of course, lost. Recently real-time mass spectrometric techniques have permitted the chemical analysis of individual airborne particles with much success.^{1,2,3} However, because native airborne particulates are not pure, attempts to identify organic components have not been very successful due to matrix interference. Here we present the proof of principle that standard MS/MS ion trap techniques may be used to positively identify organic components of airborne particulates even when there is matrix interference.

Airborne particulates coated with bis-ethylhexyl hydrogen phosphate (HDEHP) were created by nebulizing a slurry of 0.5 g of particles ($\leq 3 \mu\text{SiC}$ or $\leq 1 \mu\text{kaolin}$) with 0.1 ml of HDEHP in 50 ml of methanol. The solvent surrounding the particles was evaporated by passing them through heating and cooling tubes. The dried particles then enter the apparatus through a differentially-pump injection system consisting of a 2 cm 500 μID capillary, a 500 μ and 250 μ skimmer, respectively. Upon entering the main chamber, the particles pass through two focused CW lasers. The scattered light is collected by fiber optics and detected by two separate PMT's. These signals determine the particle flight time and trigger timing electronics that fire an excimer laser (308 nm) when the particles reach the center of the trap regardless of their velocity. The ablated ions are then subjected to standard ion trap techniques for identification.

The top panel of Figure 1 shows the negative ion spectrum of HDEHP on $\leq 3 \mu\text{SiC}$ particles. The middle panel shows isolation of the parent HDEHP ion and the bottom panel reveals the daughter ion spectrum after collision induced dissociation (CID). SiC was chosen in this case because it does not interfere with the HDEHP spectrum. However, not all naturally occurring matrices are as non-interfering as SiC. One example would be kaolin (hydrated aluminum silicate), the major component in clay dust. Its negative ion spectrum is shown in the top panel of Figure 2. The middle panel shows the mass spectrum of HDEHP on $\leq 1 \mu\text{kaolin}$. The only hint that there might be a phosphated component is the presence of a peak at mass 79. The bottom panel shows the daughter ion spectrum of mass 321 after isolation and CID. It positively identifies HDEHP by the characteristic fragments at 209 and 79 Da. This clearly demonstrates the feasibility of organic component analysis of individual airborne particles using standard ion trap techniques.

Fate Studies of 3,3'-Dichlorobenzidine in Contaminated Lake Sediment
by a Small Low Field FT-ICR MS

Marianne C. Nyman, James Pérez, Arto K. Nyman, Ernest R. Blatchley III, and
Hilkka I. Kenttämää, Purdue University, West Lafayette, IN 47907

Many carcinogenic and toxic compounds are hydrophobic and have a high affinity for sediment particles. Transport of such compounds in lake systems is thought to be predominantly attributed to episodic resuspension events.¹ Other factors that influence the fate of hydrophobic organic compounds in a sediment/water environment include sorption/desorption and microbial and photochemical transformations. This study focuses on the biodegradation and photodegradation pathways of one such compound, 3,3'-dichlorobenzidine.

The fate and transport of 3,3'-dichlorobenzidine (DCB) and its congeners, 3-monochlorobenzidine (MCB) and benzidine, present a problem in the environment due to their carcinogenic nature. DCB is an amino-substituted biphenyl compound that is used as an intermediate in the manufacture of industrial dyes. A single point source of DCB is known to exist in Lake Macatawa (Holland, MI) in the form of a permitted effluent diffuser. No other sources of DCB or related compounds are known to exist in this lake. Therefore, this lake was selected for the field investigations included in this study.

Analytical measurements were carried out by reversed phase high performance liquid chromatography (HPLC) with ultraviolet (UV) and electrochemical (ECD) detection. Confirmation of the analytes' identities were achieved with a small custom built low field (0.4 T) Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR) equipped with a solids probe.² Preliminary results obtained with the low field FT-ICR indicate excellent sensitivity toward these environmental contaminants. A lower limit of detection of 28.7 pg on the solids probe (based on a signal to noise ratio of 2:1) for DCB was measured by collecting 70 eV electron impact mass spectra of standard methanol solutions of different concentrations.

DCB was identified in sediment and water samples collected throughout the eastern basin of lake Macatawa. DCB and benzidine were identified and quantified in water and sediment samples collected over an area of approximately 10 km² in Lake Macatawa. These findings suggest that DCB is being transported over long distances and that dehalogenation is taking place. The most likely dechlorination pathways include microbially-mediated and photochemical reactions.

Biodegradation of DCB was examined using sterile glass serum bottles containing 50 g of wet sediment and 180 mL of water and closed with open closure caps and teflon septa. The headspace was flushed with N₂ gas to create an anaerobic environment. As a result of the addition of a stock solution of DCB in methanol, initial concentrations of approximately 10 mg DCB/kg of sediment or 50 mg DCB/kg of sediment were established. Autoclaved (121 °C, 150 min) samples spiked with DCB in methanol served as controls. The bottles were incubated in the dark at 4 °C, 20 °C, or 30 °C for several months under

separately. Analysis carried out by HPLC and FT-ICR provided evidence for reductive dechlorination of DCB into MCB and benzidine.

Preliminary photodegradation experiments were conducted using 3 mg/L DCB in Lake Macatawa water exposed to two GE Chroma 50 lamps at wavelengths of 360 to 750 nm for up to five hours (Figure 1). The mass spectra demonstrate that DCB undergoes photo-dechlorination to benzidine, with MCB as an unstable intermediate.

In conclusion, the observation of more efficient transport than expected for DCB, and the demonstration of its transformation into more soluble benzidine, raises questions about the safety of discharge of toxic hydrophobic organic contaminants in lake systems. These studies also demonstrate the feasibility of the low field FT-ICR to solve problems of environmental relevance.

Figure 1. Photodegradation results of DCB in Lake Macatawa water.

Optimization of Trace Analysis by Ion Trap MS/MS

Bert C Lynn, Jr.,

Department of Chemistry and MS State Chemical Laboratory,
Mississippi State University, MS State, MS 39762

The availability of powerful bench-top quadrupole ion trap mass spectrometers has brought power of tandem mass spectrometry (MS/MS) to the trace analytical chemist. The MS/MS technique, when used for target compound analysis, promises ultimate selectivity and sensitivity. The first level of MS/MS selectivity is achieved by isolation of a unique precursor ion (equivalent to a selected ion monitoring experiment). An additional level of selectivity is obtained through conversion of the precursor ion to a unique product ion by collisionally induced dissociation (CID). The sensitivity of MS/MS results from the elimination of matrix interference (chemical noise) thus increasing signal to noise ratios. Also, since chemical noise is eliminated, the multiplier gain can be increased and large volume injections can be employed to increase the signal. The following questions are the basis of this study. Can the parameters involved in the MS/MS experiment be optimized for trace analysis and does it really matter?

Data discussed in this paper were obtained on a Varian Saturn 3 ion trap mass spectrometer equipped with the Waveboard® options of MS/MS, selected ion storage (SIS), automated method development (AMD), multiple reaction monitoring (MRM) and MS³. Four types of MS/MS experiments are available on the Varian instrument. The first type is referred to as nonresonant CID that involves injection of a variable frequency square wave onto the end caps of the ion trap. This pulsed DC waveform causes a rapid displacement of the ion cloud in the trap. Collisions between the ion cloud and the He bath gas induce dissociation. Three types of resonant CID are also available including single frequency (traditional), multiple frequency and secular frequency modulation. Nonresonant and resonant (secular frequency modulation) were compared in this study.

The parameters of the MS/MS experiment that require optimization are precursor ion selection, width of the mass isolation window, RF level (low mass cutoff), CID time, CID voltage. The precursor ion should be unique and as intense as possible since this is the available ion current. The stability of this ion should also be evaluated since stable ions are difficult to fragment. The base peak in a spectrum, while providing the greatest amount of ion current, are often too stable to fragment with good sensitivity. Communications with Varian and experiments in our laboratory indicated that CID time was not a critical parameter when a minimum of 20 msec was employed (default value). The low mass cutoff determines the location of the precursor ion on the q_z axis which in turn determines the depth of the trapping pseudopotential well. A balance must be achieved between the depth of the well and avoidance of the higher order octapole ($q_z=0.64$) and hexapole ($q_z=0.78$) fields. The CID voltage determines the amount of energy imparted to the precursor during the CID process.

The parameters low mass cutoff and CID voltage were selected for optimization in this study. The parameter space for these two variables is quite large, greater than 20,000 parameter pairs in a typical nonresonant experiment. To address this large parameter space, a simplex method of optimization was employed. The simplex method¹ is a rapid method capable of optimizing a parameter set using a limited number of experiments. A simplex is a geometric figure defined by a number of points equal to one more than the number of dimensions of parameter space (e.g., a two parameter set will produce a triangle). Optimization maximizes a response which has a user defined

value. The response is used to determine the next simplex by reflection, expansion, or contraction of the figure.

In this study, the parameters low mass cutoff and CID voltage were optimized using a variable size triangular simplex. The first three parameter pairs (vertices of the triangle) were set as large as possible to cover all reasonable parameter space. The response used in this study was the ratio of intensity of the desired product ion or ions divided by the intensity of the precursor ion (at 0V CID). Optimum parameters were usually obtained in less than 18 experiments. Three compounds, atrazine, chlorpyrifos-methyl, and the ethyl derivative of an hydroxylated PCB, were studied in detail.

Atrazine was used as a model for easily fragmented compounds. Parameters were optimized for the conversion of m/z 215 (molecular ion) to m/z 200 (loss of a methyl group). Data from the nonresonant simplex indicated a very broad ridge of equivalent responses extending from a q_z value of 0.20 to 0.59. Thus, optimization would not improve the sensitivity of this analysis. However, the resonant simplex indicated a significant improvement in response at q_z 0.19 and 0.25V CID. Resonant CID would therefore greatly benefit from simplex optimization. The optimum parameter set would have been easily missed using conventional optimization techniques.

Recently, the hydroxylated PCBs have gained considerable attention due to their estrogen activity. Since we are currently developing trace methods to address this class of compounds, we were interested in including an example in the current MS/MS study. The full scan EI spectrum of 2-chloro-4-ethoxybiphenyl is remarkable since the molecular ion (m/z 232) eliminated ethylene upon ionization to produce m/z 204, the molecular weight of the underivatized PCB-OH. The conversion of m/z 204 to m/z 139 was subjected to simplex optimization. Data from the nonresonant experiment indicated an extremely sharp response maximum centered at q_z 0.36 and 87V CID. Deviation of $q_z \pm 0.1$ produced virtually no response. The resonant simplex experiment also indicated a sharp response maximum at q_z 0.39 and 0.45V CID. This response clearly demonstrates the need for parameter optimization in trace analysis. The nonresonant and resonant MS/MS spectra obtained from the parameter pairs at the maximum response were nearly identical. The conversion efficiencies (precursor to product ion current) obtained from this compound were the largest obtained for any compound studied, 72% and 60% for nonresonant and resonant CID, respectively.

Chlorpyrifos-methyl (Reldan) was included in the study because of the unusual EI spectrum obtained from this organophosphorus insecticide. The EI spectrum contains very few fragment ions and the base peak is the molecular ion (m/z 286). Therefore, m/z 286 was selected for CID even though this ion was considered quite stable. The nonresonant simplex optimized for conversion of m/z 286 to m/z 241 indicated an extremely sharp maximum response at q_z 0.33 and 95V CID. Virtually no response was obtained at q_z values on either side of the maximum. Extensive fragmentation observed in the spectrum obtained at the optimum parameter pair, possibly resulted from product ion fragmentation. The resonant simplex however indicated a rather broad response which maximized at q_z 0.59 and 1.05V CID. Fragmentation in the optimized spectrum was greatly reduced compared to the nonresonant spectrum.

Data from this study clearly indicated the applicability of the simplex method for parameter optimization. The need for optimization was also demonstrated. For certain compounds, significant increases in sensitivity (>10 fold) were obtained through optimization.

The Study of PAH Transformations on Single Micrometer-Sized Particles Using TOF-SIMS

Thomas F. Fister¹, Stacie S. Summers², Gregory S. Strossman¹, Richard W. Linton², Robert W. Odom¹

1. Charles Evans & Associates, 301 Chesapeake Dr., Redwood City, CA 94063

2. Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290

Polycyclic aromatic hydrocarbons (PAHs) are found adsorbed on many different types of atmospheric particles. Interest in these compounds exist because of their toxic nature. PAHs undergo chemical transformations via reactions such as photolysis and nitration. These reactions are important as they alter the toxicity of the adsorbed PAHs. Both PAH lifetimes and transformations are dependent on the particle composition and morphology¹. A knowledge of PAH lifetimes and transformations on atmospheric particulates is necessary to understand potential health risks of different particle types. The current research describes preliminary results using time-of-flight secondary ion mass spectrometry (TOF-SIMS) to monitor PAH transformations on single particles.

Benz[a]anthracene (BaA) and benzo[a]pyrene (BaP) were adsorbed onto SiO₂ particles by pumping a PAH solution through a column packed with SiO₂. The 5 µm, spherical SiO₂ particles had surface areas of 500 m²/g. PAH coverages on the particles were approximately 0.1 monolayers. The particles were placed on Si wafers for TOF-SIMS analysis and photolysis. PAH was adsorbed onto coal flyash particles by solution evaporation. These particles were placed on polished graphite plachets for study.

Two methods were used to study PAH photolysis on particles. In the first method, several particle-laden substrates were photolyzed for different lengths of time (5 min-5 hrs) using a 254 nm UV lamp (≈ 4 mW/cm²/s). TOF-SIMS analyses on random particles were performed on each of the different substrates. The second method followed PAH photolysis on single particles. Samples were photolyzed in the ambient atmosphere and then introduced into the TOF-SIMS for analysis. This sequence was repeated with a mass spectrum obtained from the same particle after each photolysis event.

The TOF-SIMS in this study used a pulsed liquid metal ion gun (⁶⁸Ga⁺, 25keV, 600 pA DC, 1 ns pulse width, 10⁴ kHz pulse rate) that was rastered across the sample surface. The time-of-flight analyzer consisted of three 90° quasihemispherical electrostatic analyzers in the ion flight path and a dual microchannel plate for ion detection. Fields of view and analysis times were 25-40 µm and 2-3 min, respectively. Mass spectra were obtained from each particle within the field of view.

The photolysis of random BaA coated SiO₂ particles exhibited a rapid 1st order decay of the PAH. The BaA half-life under these conditions was approximately 6 min. One photolysis product, benz[a]anthracene-7,12-dione (BaAD), was detected. The BaAD intensity reached maximum after about 25 minutes and then underwent a decay as well.

Photolysis studies on single particles displayed similar results. Figure 1a plots the BaA intensity (normalized to the total ion signal and scaled accordingly) vs photolysis time for the photolysis of BaA on three individual particles. The BaA decay is similar on all three particles and little remains after 10 min of photolysis. The decay on the particles is 1st order with half-lives ranging from 2.1-2.3 min. Figure 1b shows a plot of the normalized BaAD intensity vs photolysis time. The BaAD intensity increases and then undergoes a gradual decay on all three particles. A small amount of BaAD is present on the particles before photolysis which may result from a BaA aging reaction as these coated particles were prepared 6 months prior to this study.

BaA photolysis on 14 individual SiO₂ particles was studied. The average half-life on 13 of the particles was 2.5 min with a relative standard deviation of 14%. The half-life of the 14th particle was

considerably higher (7 min). The average half-life of the individually analyzed particles was considerably shorter than for the analysis of photolyzed random particles. This discrepancy did not result from ion dose differences as the successive analysis of unphotolyzed BaA coated SiO₂ particles exhibited little change in BaA intensity for doses typically necessary for following 15 min of photolysis on an individual particle. The difference most likely resulted from cycling the individual particles in and out of the vacuum for the TOF-SIMS analyses following each photolysis event. The decay in BaA intensity when cycling a sample in and out of vacuum is two times faster than the decay in BaA intensity for particles remaining in vacuum in between analyses.

Photolysis of BaP coated SiO₂ particles displayed considerably different results. While a 1st order BaP decay was observed, no photolysis products were detected. The analysis of photolyzed random particles yielded a BaP half-life of 8 min. The analysis of 18 photolyzed single particles found a variation in half-lives ranging from 3-27 min. The nature of this variation is currently undetermined.

A preliminary investigation of PAH photolysis on flyash was begun. Thus far the photolysis of BaA on four single flyash particles was studied. The BaA underwent an initial 1st order decay on the flyash particles with half-lives ranging from 4-15 min. However, a considerable amount of BaA remained on one of the particles following the initial decay. The remaining BaA subsequently underwent a very gradual decay in intensity. Ion images showed that the particle with remaining BaA was considerably rougher in appearance than the other three flyash particles. In addition, mass spectra of the particles showed the particle with the high BaA intensity had relatively higher Al and Si intensities. While the BaA half-lives on the flyash particles is longer than the half-lives on SiO₂, the effects of the substrate on this difference is uncertain. UV absorption by the dark graphite plachet may effectively reduce the light intensity around the particle relative to that in the SiO₂/Si wafer system. Further studies on substrate effects are planned.

Research was supported by DOE SBIR grant #410960.

Figure 1. Photolysis trends for BaA coated SiO₂ are shown. The intensities have been normalized to the total ion intensity and scaled accordingly. The left plot is the trend for BaA while the right plot shows the formation and decay of BaAD.

STATIC SIMS STUDIES OF ORGANOPHOSPHATE ADSORPTION ON METAL OXIDES

Jani C. Ingram, Gary S. Groenewold, Randy B. Wright, Anthony D. Appelhaus
Idaho National Engineering Laboratory, P. O. Box 1625, Idaho Falls, ID 83415-2208

Static secondary ion mass spectrometry (SIMS) investigations of the adsorption of pinacolyl methylphosphonic acid (PMPA) on metal substrates will be described. PMPA is a degradation product of the nerve agent soman (GD). The purpose of these studies is to investigate the utilization of metal substrates as selective adsorbents for passive sampling of a specific class of compounds from aqueous samples. Utilization of an adsorptive approach offers the advantages of 2-dimensional dispersion of the target compound which requires less of the compound to be present for analysis as compared to absorptive materials in which 3-dimensional dispersion occurs. Additionally, the surface can be directly analyzed using static SIMS which is advantageous for compounds which are difficult to desorb due to strong adsorption or low volatility.

The motivation for the present study was based on previous studies of tributyl phosphate (TBP) on mineral surfaces which showed that iron-bearing phases of the mineral surface are responsible for tenacious organophosphate adsorption,^{1,2} and the detection limit³ for TBP analyses is ca. 0.001 monolayers of TBP or ~ 2 pg/mm².

The SIMS instrument used in these experiments was constructed using a modified quadrupole mass analyzer (2 - 2000 amu instrument, manufactured by Extrel (Pittsburgh, PA)).⁴ The primary beam employs ReO₄⁺ as the bombarding particle.⁵ ReO₄⁺ is produced by heating a Ba(ReO₄)₂ ceramic in vacuum, and the ions emitted are accelerated to 10 keV. The ion gun was typically operated at 80 pA; a typical primary ion dose was 2.8 x 10¹² ions/cm². Also unique to this instrument is the pulsed secondary ion extraction technology which mitigates charge buildup on the surface of the sample.⁴

One of the objectives of this study was to investigate a range of metal substrates. The metal substrates used for the study were chosen based on availability. In these experiments, the following metal powders were exposed to 100 ppm aqueous PMPA solution: CeCu₄, Fe, FeCr, FeO, Fe₂O₃, FeSi₂, FeTiO₃, TiCeCu, TiCu₃, Y₃Fe₅O₁₂, ZrFe, ZrFe₂, ZrO₂. Approximately 10 mg of the metal powder was attached to a sample planchet with double-sided tape; then 30 µl of the PMPA solution was spiked directly on the metal powder. The water was allowed to

Figure 1

evaporate in the laboratory air; then, the sample was inserted into the instrument.

An anion SIMS spectrum of PMPA on ZrFe₂ along with the structures of the fragment ions observed are shown in Figure 1. This spectrum is similar to the spectra of PMPA on the other metal substrates investigated in this study.

The signature ions of interest are the quasimolecular ion, [M-H]⁺ m/z 179, and the ion m/z 95 [M-H-(C₆H₁₂)⁺].

The results from this study were evaluated by calculating the ratio of the ion abundances of [M-H]⁺ (m/z 179) to PO₂⁺ (m/z 63) (see Figure 2). This ratio is an indication of the effect that the substrate has on fragmentation, with better detection being achieved with less fragmentation which is denoted by a large ratio value. The results indicate that ZrFe₂ and the copper-containing substrates are the best metal substrates for PMPA detection. Interestingly, all the copper-containing substrates gave similar results (less fragmentation). However, the Fe and Zr containing substrates with the exception of the ZrFe₂ contribute to high fragmentation which suggests that the surface chemistry of the ZrFe₂ is somewhat unique. This issue is currently under investigation.

In addition to metal substrates, another strategy for PMPA detection being pursued involves the development of a basic substrate for the acidic target compound. A preliminary experiment was performed in which aluminum foil was rinsed with 1 M NaOH, allowed to dry, then exposed to PMPA. In Figure 3, the results from the PMPA on this basic surface are compared to PMPA on the untreated foil (marked neutral). These results indicate that the basic surface increases the production of higher mass fragment ions (m/z 95 and 179) by a factor of 3 as compared to the untreated foil.

Investigations are currently in progress which are directed toward taking advantage of this phenomenon as a basis for a selective adsorptive material for acidic target compounds.

This work was supported by the Department of Energy under contract DE-AC07-94ID13223 through the LDRD program of Lockheed Martin Idaho Technologies Co.

**(A NEW INSTRUMENT FOR) ON-LINE APPLICATION OF HYPHENATED GC/MS
ANALYTICAL TECHNIQUES IN FIELD AND PROCESS SITUATIONS**

Neil S. Arnold, William H. McClennen¹ and Henk L.C. Meuzelaar¹

FemtoScan Corporation, 747 East South Temple, #101, Salt Lake City, UT 84102

¹Center for Micro Analysis & Reaction Chemistry, University of Utah, Salt Lake City, UT 84112

Many field and process analytical problems require on-line solutions with limited time for sample preparation to obtain near real-time results. The ability to limit sample preparation is greatly improved by the application of a high speed (chromatographic) separation method and the use of an effective automated sampling system that limits operator intervention requirements. One approach to problems involving gas phase analytes developed by the authors involves the use of high speed, transfer line gas chromatography/mass spectrometry (TLGC/MS) and a unique, pneumatic, automated vapor sampling (AVS) device for direct, non-mechanical sample introduction [1,2]. This approach preserves three important criteria for in-situ analyses: (1) high speed for near real-time response; (2) reliable, automated analysis which requires a minimum of sample preparation but still responds well to chemical mixtures; and (3) compatibility with portable operation for in-situ analysis.

To date, we have constructed three different portable or transportable AVS-TLGC/MS concept instruments - with additional variations - to address different niches based on the currently available technology. A transportable instrument based on an Ion Trap MS and a backpack portable instrument based on quadrupole MS have previously been discussed [3,4]. Figures 1 and 2 illustrate the concept for a "roving" GC/MS system capable of operation for extended periods via a remote analytical operator. Like its predecessors, this system provides powerful capabilities for analyzing complex mixtures.

Figure 2. Concept drawing of the roving system for local mapping of environmental contamination concentration gradients.

Figure 1. Roving AVS-TLGC/MS instrument demonstrated indoors on a small cart for laboratory evaluation.

This instrument utilizes a commercially available Enviroprobe™ AVS-TLGC module from FemtoScan Corp. coupled to a Hewlett Packard 5972A mass spectrometer (MSD) with only minor modifications. Modifications include a ruggedized, low power turbo-molecular/molecular drag pumping system (with a lightweight plastic diaphragm backing pump) and a shortened GC interface. The MSD is controlled by a notebook PC computer system with PCMCIA based interfacing to the MS system and an integrated global positioning system (GPS) unit for simultaneous data acquisition and analyte mapping. Additionally, the entire instrument may be operated remotely using a wideband radio modem (or cellular phone) and remote

PC-Windows software (PC Anywhere). Such remote operation allows one trained analytical "expert" to operate a number of remote instruments. Figure 3 illustrates one application of this instrument to gradient mapping of a toluene spill. Fig. 3a illustrates a (smoothed) concentration gradient around the spill along with a portion of the travel path of the instrument during the mapping effort. Fig. 3b shows the selected ion response (m/z 91) of the instrument as it traversed the path in Fig. 3a. During this time the instrument is repetitively sampling every 6 seconds from the air and performing a rapid GC

Figure 3. (a) "Roving" path of system through toluene from "A" to "B"; (b) Toluene response sequence from "A" to "B".

separation. In the figure, the sequence of peaks observed are the toluene response from each successive rapid chromatogram taken during the run. GC/MS conditions: 2.0 mm x 100 μ m i.d. x 0.1 μ m film, 5% phenyl methyl silicone (Quadrex), isothermal at 65 C, sampling pulse 200 ms/6.0 s, scan SIM 40, 91, 92 at ~6 scans/s.

A clearer illustration of the peak sequence data is shown in Fig. 4. In this figure, a mixture of 5 ketones is being separated every second providing real time data which allows for process monitoring. A sample is taken every second so that the MS response to m/z 57 is plotted through the sequence of chromatograms. This figure provides on-line analysis of a separation process involving these ketones so that the progress of the process can be monitored at a glance by the changing ratios of constituents. Conditions: 0.8 m x 100 μ m i.d., CP Sil 8 CB, isothermal at 70 C, sampling each 1.08 s, pulse duration scan m/z 56-60 at 35 scans/s.

Figure 4. Ultra high speed separation of a mixture of 5 ketones. 1- acetone; 2- MEK (methyl ethyl ketone); 3- DEK (diethyl ketone); 4- MIBK (methyl isobutyl ketone); 5- MBK (methyl butyl ketone).

Speed can be critical to both on-line and roving applications of the instrument. Such systems provide analytical firepower at the location of the problem. They also provide the means for distributing the analytical expertise required to operate the instrument over a large number of instruments by providing a number of remote data processing and control options. A distributed analytical network, involving a number of instruments and a remote data interpretation center, allows the power of such instruments to be fully exploited by analytical professionals without requiring a trained chemist at every site.

Capillary Electrophoresis/Electrospray Mass Spectra of the Herbicides Paraquat and Diquat

Xinbei Song

Oak Ridge Institute for Science and Education Postdoctoral Research Fellow
26 W. Martin L. King Drive
Cincinnati, OH 45268

and

William L. Budde
U. S. Environmental Protection Agency
Office of Research and Development
National Exposure Research Laboratory
26 W. Martin L. King Drive
Cincinnati, OH 45268

The herbicides paraquat and diquat have similar structures with each having two quaternary nitrogens. The two dications differ in mass by just 2 Da.

Paraquat

Diquat

The maximum contaminant level for diquat in U. S. drinking water is 20 µg/L and although paraquat is not currently regulated, it has been under consideration for regulation in recent years. A conventional separation and measurement technique for these herbicides is liquid chromatography on a reverse phase column using an

ion pairing reagent and detection with an ultraviolet detector. Given the usual ambiguities and uncertainties of UV detection, a specific method utilizing mass spectrometry is desirable for general environmental monitoring, research in human and ecological exposures, and drinking water compliance monitoring. Because the herbicides are cations in aqueous solution, separation by capillary electrophoresis (CE) and measurement by electrospray (ES) mass spectrometry would appear to be the perfect analytical technique. Paraquat and diquat were separated in about ten minutes by CE using six different acetic acid/salt buffers in 50% (v/v) methanol-water. Paraquat gives positive electrospray ions at M/z 93, 185, and 186 and diquat gives similar ions at 92, 183, and 184. The relative abundances of these ions depend on the buffer compositions. The ions at 93 and 92 are the expected dications. The ions at 186 and 184 are singly charged molecular ions. The singly charged ions at 185 and 183 are formed by deprotonation of the doubly charged cations in the electrospray process. Since the presence of an ammonium ion in the buffer promotes the deprotonation reaction, the mechanism shown below for paraquat is proposed to account for its role in the process. This reaction may take place during the process of desolvation of charged particles or in the gas phase.

A similar mechanism can account for the deprotonation of diquat. The singly charged deprotonated ions at M/z 185 and 183 are the base peaks in the ES spectra in the presence of ammonium salt electrolytes used in the CE separation buffer and these ions were used to evaluate the quantitative potential of this technique.

Development of a New Benchtop Double-Focusing Magnetic Sector Instrument For LC/MS

A new LC/MS has been developed with the goal of providing high resolution capabilities of a sector instrument in a compact, benchtop instrument. In order to reduce the total size and weight of the instrument, Matsuda type QQQHCQ(Q: quadrupole lens, H: homogeneous magnetic field, C: cylindrical electric field) double focusing ion optics are employed with a small magnet(radius: 150mm, angle: 27.8 degrees). As a result, the total footprint of the instrument is as small as 850mm by 950mm. In addition, the ion optical bench of the mass spectrometer is designed with an image magnification of 0.18, which permits the use of a source slit setting 5 times wider than that of conventional ion optics with the same size magnet. Therefore, high sensitivity is preserved, since the ion trajectory is optimized to enhance ion transmission through the narrow magnetic field gap. The ion optical geometry is shown in the figure 1.

Figure 1. Ion optical geometry of the benchtop LC/MS

The mass spectrometer has an atmospheric pressure ionization source with both ESI and APCI capabilities. The source has three differentially-pumped stages. The first stage is pumped by a rotary pump whereas the second and third stages are pumped by two turbo-molecular pumps. An RF-only multipole ion guide is used in the second stage for efficient ion transport to the third stage. The charge state distribution of protein ions are comparable to those obtained with quadrupole-based mass spectrometers, indicating that the charge exchange due to collisions with neutrals at the ion acceleration region has been minimized because of the very low pressure at the third pumping stage.

A newly developed desolvating plate is used for electrospray ionization. Figure 2 was obtained under several different flow rate conditions, showing that efficient desolvation has been achieved even at high flow rate of 1 ml/min with the desolvating plate heated to 250 degrees Celsius.

The mass spectrometer is controlled by a PC based data system, and ion source tuning parameters can be optimized automatically by the data system.

Design and performance of a hybrid tandem mass spectrometer with BE/ion trap configuration

W. Huels, H. Muenster, R. Pesch, E. Schroeder.
Finnigan MAT GmbH, Barkhausenstr. 2, D-28197 Bremen, Germany

Introduction

Since the introduction of the first hybrid tandem mass spectrometers with EBQ geometry, many other combinations of magnetic sector field analysers with dynamic mass spectrometers like quadrupoles and time-of-flight systems have been reported.¹ All those instruments are basically intended to do MSⁿ operations with n=2 only.

In addition, the quadrupole based systems suffer from low or bad sensitivity particularly at higher resolutions of the sector mass spectrometer. Meanwhile, the sensitivity issue has been addressed by a TOF analyser as the second mass spectrometer.²

Experimental

We report here on the design and the performance of a hybrid EB-ion trap tandem mass spectrometry system based on research reported by Cooks et al. in 1990.³ The transfer optics from the sector instrument into the ion trap consists of an electrostatic deceleration lens system and a dual-octopole assembly facilitating a very effective transfer of the ions into the ion trap. The ion trap itself is floated on the acceleration potential of MS1 to compensate for the high kinetic energy the ions have when they leave the sector mass spectrometer.

Results:

At high resolution of MS1, optimised duty cycles with extended collection of ions into the ion trap improve the total sensitivity by orders of magnitudes. Full scan product ion mass spectra show typically one order of magnitude higher sensitivity compared to conventional EBQ configurations.

This allows for the separation of nominal isobaric ions with resolution greater than 20 000. Figure 1 shows the part of the ESI mass spectrum where the isobaric protonated molecular ions of Quercetin-3-O-β-glucuronide and Isorhamnetin-3-O-β-glucoside appear. Both ion species are well separated with a resolution of m/Δm 14 000 (10% valley).

The lighter ion corresponds to the protonated Quercetin-3-O-β-glucuronide. The heavier ion is the protonated Isorhamnetin-3-O-β-glucoside. MSⁿ spectra of the two ions in the ion trap show the loss of the sugar moiety and subsequent fragmentation related to the structure of the aglyca (e.g. Fig. 2 for MS⁴ of the protonated Isorhamnetin-3-O-β-glucoside).

Can Ion Trap LC/MS/MS Replace Quadrupole LC/MS/MS in Quantitative Drug Analysis?

Jack Cunniff¹, Jan Paulson², and Jae Schwartz¹

¹Finnigan MAT, San Jose, CA 95134 USA

²Astra Draco AB, Lund, Sweden

Introduction

The introduction of the modern ion trap has introduced powerful and practical **qualitative** solutions unequaled by previous generally affordable MS systems. Investigation of the modern ion trap's capability to provide practical solutions for **quantitative** determinations has only recently begun.

Along these lines, a comparison between the Finnigan LCQ, a newly developed benchtop ion trap mass spectrometer for LC/MS/MS and a Finnigan TSQ-7000 using budesonide as a model compound will be presented. Budesonide (MW 430), is a topical glucocorticosteroid used in the treatment of asthma and rhinitis. The key issues examined are 1) linear dynamic range, 2) the effect of varying the amount of co-eluting compounds, 3) sensitivity, and 4) reproducibility

Methods

All ion trap experiments were performed on an LCQ ion trap mass spectrometer (Finnigan MAT, San Jose, CA). All quadrupole experiments were performed on a TSQ 7000 triple quadrupole mass spectrometer (Finnigan MAT, San Jose, CA). Both instruments were fitted with an APCI source and were operated in the negative ion mode. The LCQ used an isocratic mobile phase of 60:40 MeOH/Water + 1% acetic acid at a flow rate of 1 mL/min through a 4.6 X 33 mm Supelcosil LC-8-DB column. The TSQ used an isocratic mobile phase of 56:44 MeOH/Water + 1% acetic acid at a flow rate of 1.5 mL/min through a 4.6 X 33 mm Supelcosil LC-8-DB column.

The acetic acid adduct ions were selected as the parent ions (m/z 489.3 and 497.3). The scanning parameters used were

Ion trap (LCQ).		Triple quadrupole (TSQ 7000):
budesonide.	full scan MS/MS 489.3 → [150-505]	(SRM) 489.3 → 356.996-357.796
budesonide d_4 .	full scan MS/MS 497.3 → [150-505]	(SRM) 497.3 → 356.996-357.796

ion ranges monitored for quantitation: 338-340, 356-359

Results

Experiment 1: Effect of large quantity of coeluting compound.

Figures 1-4 illustrate the effect on linearity on the budesonide calibration curve (40pg-40 ng) from the introduction of 430 pg and 430,000 pg of coeluting internal standard on both the ion trap (Figure 1 and Figure 2) and the triple quad (Figure 3 and Figure 4)

Experiment 2 : RSD's and LOQ's on an ion trap vs. Triple quadrupole

The RSD's for multiple injections (on-column) of budesonide and its d_4 internal standard are displayed in TABLE 1. The contribution of non-deuterated compound from the 4300 pg of labeled internal standard has been taken into account.

Table 1. picograms injected on-column

Instrument	picograms injected on-column	n	%rsd
TSQ	34.1	10	6.1%
TSQ	63.9	10	3.0%
TSQ	183	10	3.4%
TSQ	660	10	1.2%
TSQ	2570	10	0.7%
TSQ	10200	10	3.8%
TSC	40800	10	1.1%
LCQ	34.1	9	32%
LCQ	63.9	9	17%
LCQ	183	9	9.7%
LCQ	660	9	4.0%
LCQ	2570	9	2.7%
LCQ	10200	9	3.5%
LCQ	40800	9	6.4%

Conclusions

- The results from the current study indicate that the linear dynamic range for both the modern ion trap (LCQ) and the triple quadrupole (TSQ) mass spectrometer are similar and are defined by the source.
- Both instruments adequately provided linear calibration over three orders of magnitude.
- For the current assay, the triple quadrupole (TSQ) afforded lower levels of quantitation and smaller rsd's.
- Upon the introduction of increasing quantities of co-eluting internal standard, no noticeable quenching was observed with either instrument.

PHOSPHOPEPTIDE ANALYSIS BY MICROSPRAY IONIZATION - HYBRID QUADRUPOLE/ION TRAP MASS SPECTROMETRY

K.R. Jonscher and J.R. Yates, III
Dept. of Molecular Biotechnology
Box 357730, University of Washington, Seattle, WA 98195-7730

Mass spectrometry, coupled with liquid chromatography, has been increasingly applied to the analysis of biological molecules and systems. Conventional ESI-LCMS techniques may fail to provide structural information for many of the components in these mixtures due to the combination of co-elution of species from the LC and the slow scan times of quadrupole mass filters. Previously, we analyzed the performance of a novel hybrid quadrupole mass filter/quadrupole ion trap [1]. In this work we use a microspray ionization [2,3] source to characterize the sensitivity of the instrument and to investigate its utility for the analysis of phosphopeptides.

APPARATUS: An electrospray ionization source (Analytica of Branford) was modified to incorporate a heated capillary (Finnigan MAT). The microspray source consisted of a lucite sample stage with a high voltage feedthrough attached to an X,Y,Z manipulator. Several needle configurations were investigated. The configuration that seemed to provide the highest sensitivity coupled with longevity was a combination of the methods used by Mann [4] and Lee [5]. A diagram is shown in **Figure 1**. A pulled glass micropipette was trimmed to provide a tip ~ 1 cm in length. A fused silica transfer line with the polyimide coating at the tip removed was inserted into the tip of the micropipette needle along with a platinum wire. The voltage, ~ 1 kV, was applied to the sample via the wire. Needles of this configuration typically lasted many days without clogging.

RESULTS: The sensitivity of the instrument was investigated using serial dilutions of a mixture of human angiotensin I (MW 1296) and melittin (MW 2847). Sample was infused at 50 nL/min using a Harvard syringe pump and the quadrupole was operated in rf-only mode. Signal from both peptides was easily detected using a sample concentration of 50 fmol/ μ L and the resulting mass spectrum, representing the consumption of 75 amol of material during the course of 3 scans, is depicted in **Figure 2**.

A limitation of the ion trap technique is that neutral loss and parent ion experiments are very difficult to implement. We developed a neutral loss scan as follows: the quadrupole mass filter was used to mass-select an ion of interest, the ion was fragmented in the ion trap, then data was acquired over a narrow mass range 49 u below the m/z of the mass-selected ion. This mass difference corresponds to the loss of phosphoric acid from a doubly-charged phosphopeptide. Two peptides resulting from a tryptic digest of α -casein were investigated. One of the peptides was phosphorylated, the other was not. Results illustrated in **Figure 3** clearly indicate the utility of the approach. A signal was obtained for the loss of H_2PO_4 from m/z 831, a phosphorylated peptide, while no signal was observed at the mass corresponding to the loss of H_2PO_4 from m/z 692, an unphosphorylated peptide.

CONCLUSIONS: Microspray ionization using a novel needle configuration proved to be a sensitive and powerful technique for the analysis of phosphopeptides in biological mixtures. A neutral loss scan was successfully developed to locate phosphopeptides. This technique can be automated to enable the analysis of complex mixtures of molecules.

Figure 1: Novel microspray needle configuration used in this work.

Figure 2: Mass spectrum resulting from microspray infusion of angiotensin I and melittin. S/N of m/z 712 was 30.

Figure 3: Experiment to detect phosphopeptides using a novel neutral loss scanning technique. The resultant signal is compared for the case of (a) an unphosphorylated peptide at m/z 692 and (b) a phosphorylated peptide at m/z 831. A neutral loss of 49 u was chosen, corresponding to the loss of phosphoric acid from a doubly-charged phosphopeptide.

IMPROVED MS/MS PERFORMANCE ON THE NERMAG R 3010 TRIPLE QUADRUPOLE MASS SPECTROMETER

Andries P. Bruins, University Centre for Pharmacy, 9713 AW Groningen, The Netherlands

Our NERMAG triple quad equipped with a custom built atmospheric pressure ionization source for APCI and IonSpray[1] has very good sensitivity in the single MS mode but very poor sensitivity in the MS/MS mode. Extensive variation of collision gas pressure, collision energy and retuning of lenses did not improve sensitivity. Ion transmission with both Q1 and Q3 resolving is good in the absence of collision gas. In the presence of collision gas the parent ion drops but daughter ion intensity is extremely low. Four factors may play a role: 1. poor parent ion transmission into Q2, 2. poor parent ion containment in Q2, 3. poor daughter ion containment in Q2; 4. poor daughter ion extraction from Q2 and injection into Q3. A simplified diagram of the NERMAG R 3010 is given in Figure 1. The operator can select rod offset voltages for Q0, Q1, and Q2. Collision energy (in the laboratory frame) is determined by Q2 and Q0 rod offsets. Q3 rod offset is generated from Q2 offset, parent mass, and daughter mass by a hardware multiply and divide circuit. The lenses between Q2 and Q3 and at the exit of Q3 ride on a floating common controlled by the aforementioned Q3 rod offset circuit. Q3 rod offset has to match the kinetic energy of daughter ions: if too low a voltage (i.e. too much negative for positive ions) is applied, daughter ions move too fast through Q3 and show poor resolution; if too high a voltage (too little negative for positive ions) is applied, daughter ions are pushed back into Q2.

In the absence of slowdown by collisions daughter ions have a kinetic energy according to

1. A.P. Bruins and C. Beaugrand, Proceedings ASMS San Francisco 1988, pp 1241,1242

Figure 1. Schematic diagram of the NERMAG R 3010 triple quad with API source

$$E_{kin, daughter} = \frac{1}{2} m_{daughter} v_{parent}^2 = \frac{m_{daughter}}{m_{parent}} E_{kin, parent}$$

NERMAG has used this equation for making Q3 rod offset proportional to daughter ion mass in order to decelerate the ions. If ions are slowed down by collisions however, daughter ion kinetic energy is lower than anticipated by the hardware circuit and ions may be pushed back into Q2. An experimentally derived equation uses a quadratic dependence of daughter ion kinetic energy on daughter ion mass [2]. Under condition of very high pressure in Q2 daughter ions have almost come to a standstill, and have to be accelerated into Q3 [3]. We have disabled the hardware control circuit and have applied external control voltages. It appeared that a 2 to 3 fold increase in sensitivity can be obtained. A second variable not accessible to the operator is the RF amplitude applied to Q2 rods. By overriding the circuit that generates the control voltage for the Q2 RF amplifier a much higher control voltage could be used for the generation of a high Q2 RF amplitude. Here, a 3 to 5 fold increase in sensitivity is obtained. It should be noted however that the RF amplifier (and its 50V DC supply), the RF transformer, and cable connections to Q2 cannot deliver a very high RF amplitude. Figure 2 demonstrates the gain obtained for CID of m/z 609 of reserpine (see also ref. 3). **In conclusion:** there is poor ion containment in Q2 and poor injection into Q3; a tenfold increase in sensitivity was obtained by the use of external control voltages. A further improvement is necessary.

Conformation of Gas-Phase Myoglobin Ions

B.A. Collings and D.J. Douglas
Dept. of Chemistry, University of British Columbia
Vancouver, British Columbia
V6T 1Z1, Canada

The observation of noncovalent complexes of proteins with substrates and prosthetic groups¹, by mass spectrometry, suggest that the folded tertiary structure of proteins and interactions binding noncovalent complexes survive the ionization process and that the gas-phase protein may retain some memory of the solution structure. The extent of folding or unfolding of a protein can be interpreted through a measurement of its collision cross section in the gas phase. In this work² the collision cross-sections have been measured for ions of gas-phase myoglobin (Mb) and for apomyoglobin (apoMb) formed by collisionally activated dissociation (CAD) of the heme-apoMb complex in the orifice-skimmer (OS) region of an electrospray mass spectrometer.

Experiments were performed on a triple quadrupole mass spectrometer constructed in house. Ions formed by pneumatically assisted electrospray of horse heart myoglobin (5 μ M in 10% MeOH/90% water) were passed through a dry nitrogen "curtain" gas, a 0.25 mm diameter sampling orifice, a skimmer (0.75 mm orifice diameter) to a radio frequency quadrupole and then to the first quadrupole of a triple quadrupole mass spectrometer system. The extent of CAD was controlled by varying the potential difference between the orifice and skimmer.

The figure above shows the results of mass spectra taken potential differences of a) $\Delta OS=30$ V giving mainly the heme-apoMb complex, b) $\Delta OS=110$ V giving a mixture of heme-apoMb and apoMb and c) $\Delta OS=180$ V giving only apoMb.

Collision cross sections with argon were determined by measuring the ratio of energies of ions leaving the collision cell, E , to the incident energy, E_0 .³ The energy E_0 was determined by the difference in rod offset potential between the first RF quadrupole and the collision cell quadrupole. Collisions with the background gas in the RF quadrupole region served to moderate the ion energies and energy spreads to < 1 eV.⁴ The slope of a linear plot of $\ln(E/E_0)$ vs target gas thickness, S , (number density $\times$ cell length) gives the collision cross section. Collision cross sections for each of the major ion species in the above figure were measured and are shown in the figure below.

Comparison of the cross sections for Mb at $\Delta OS=30$ V with those for apoMb at $\Delta OS=180$ V, shows that for a given charge state, the Mb ions have smaller cross sections, corresponding to a more compact structure while the apoMb ions have larger cross sections corresponding to a more extended or unfolded structure. This provides direct physical evidence that the gas-phase ion has unfolded on loss of heme. The mechanism of heme loss appears to be Mb $\rightarrow$ unfolded Mb $\rightarrow$ apoMb. Unfolding of the Mb can also be partially induced by increased charging of the ion. For example, the cross sections for Mb +13,14 are greater than those for apoMb +7,8, formed by CAD of Mb +8,9. (Calculations have shown that the increased cross section with charge state is unlikely to be due to an increased ion-induced dipole. The different cross sections observed for Mb and apoMb in the same charge states indicates that it is the structure of the protein and not solely the charge state which determines the collision cross section.) The gas phase ions have an average cross section (averaged over charge states) of 2239 $\text{\AA}^2$ and 2638 $\text{\AA}^2$ for the Mb and apoMb respectively indicating an increase of $\times 1.2$ on loss of the heme.

Extended Mass Enhancement for a Commercially Available Quadrupole Mass Spectrometer Series

Scott Niemann* and Alexander Schilling**

* CSS Analytical Company, Shawnee Kansas

** The Hewlett Packard Co., Naperville Illinois

Introduction

The development of techniques for studying peptides, proteins and synthetic polymers by mass spectrometry such as fast atom bombardment (FAB) and electrospray have made the use of extended mass ranges above 1000 amu essential. Most commercially available research grade mass spectrometers possess mass ranges to at least 2000 with some allowing ranges to 3-4000 amu. This higher mass range can be useful as there are occasions when a specific peptide or other large polymer (synthetic dendrimers etc..) will not produce sufficient multiple charges in electrospray to allow observation of the molecule below 2000 amu. Experiments in FAB, which does not typically produce multiple charges also depend on the mass range of the instrument to allow observation of the high mass ions.

Instrumentation:

A HP 5989B MS Engine equipped with a 59987A electrospray interface, 10-2000 amu mass range and an IRIStm ion guide was modified with a CSS Company xxMass[®] upgrade kit. A HP 1090L LC was used to perform chromatography on a peptide sample using a 90:10:0.05% TFA:Acetonitrile mobile phase using a gradient to a final concentration of 10:90 in 15 minutes at a flow rate of 0.350 mL/min on a Vydac 300A C-18 column. A sample of polyalanine was also infused at 20 μ L/min in order to allow mass axis adjustment on the extended mass range.

Discussion:

As the figures shown illustrate, the CSS xxMass upgrade allows the use of a 5989B (or a 5989A) mass spectrometer to scan to mass ranges as high as 2600 amu, which extends the MS capability to samples with molecular ions above the 2000 amu mass range of the current instrument series. The chromatogram demonstrates that the modifications employed produce stable operation for use with chromatography. The upgrade kit includes all needed hardware modifications and software drivers.

Resolving Isobaric Masses Using a Quadrupole Operated in the Second Mathieu Stability Region

Randall E. Pedder and Richard A. Schaeffer

ABB Extrel, Quadrupole Mass Spectrometry, 575 Epsilon Drive, Pittsburgh, PA 15238

Operation of a quadrupole in the second Mathieu stability region offers dramatic improvement in resolution compared to normal first stability region operation. This presentation explores the utility of high resolution second stability operation for the separation of isobaric compounds such as CO and N₂ at m/z 28, and CO₂ and NO at m/z 44. Practical aspects of tuning and optimization in the second Mathieu stability region are discussed.

INTRODUCTION At the 1995 ASMS conference, (1) we presented high resolution mass separation of helium and deuterium at m/z 4, using both the first and second Mathieu stability regions. In that work, we demonstrated peak widths at half height for m/z 4 approaching 0.001 amu (resolution = 3600) with remarkable abundance sensitivity. Previous researchers have identified similar high resolution performance (2). Such high resolution is not limited to m/z 4. Indeed, this year, we have demonstrated the separation of other isobaric doublets and triplets such as CO and N₂ at m/z 28, and CO₂ and N₂O at m/z 44, through quadrupole operation in the second Mathieu stability region. The operation of a quadrupole in the Second Mathieu Stability Region requires fourteen times the DC voltage and 4.5 times the RF voltage compared to normal operation, thus limiting the usable mass range due to power requirements. In this presentation, we demonstrate high resolution experimental results measured at various masses, and provide hints for practical implementation of second stability operation for high resolution separation of isobaric compounds.

EXPERIMENTAL In these experiments, a standard ABB Extrel 3/8" quadrupole probe with 041-11 Axial Ionizer and analog electron multiplier was controlled using the ABB Extrel Merlin data acquisition and control electronics, with RF frequency of 2.1 MHz. The nominal mass range of this configuration is 500 amu when operated in the traditional first stability mode, and 56 amu when operated in the second Mathieu stability region. Because in this implementation, the switch between first and second stability regions involves a change in the gain resistor for the resolving DC command circuit from 10 kOhm to 29 kOhm (1), the correlation between mass command and actual mass is directly proportional to the 4.5-fold increase in required RF voltage. The required 13 to 14-fold increase in DC voltage is derived from a combination of the 2.9-fold gain in the DC circuit switch and the 4.5-fold increase in RF mass command.

The 150-QC quadrupole control electronics were modified to set the full scale mass command voltage to correlate with 250 amu in the first stability region to allow better matching of the mass command voltage to the second stability region mass range of 55 amu. The resolution from the Merlin 16 bit mass command DAC is therefore approximately 0.001 amu per step. Tune voltages were critical in maximizing high resolution

performance. Dramatic changes in peak width at the base of the mass peak were seen as the quadrupole entrance potential was adjusted, with little change in the width of the peaks at half height. Similar to first stability region high resolution operation of a quadrupole, highest resolution corresponded with ionizer lens voltages which did not deviate far from the ion region potential. The tune voltages which yielded the best abundance sensitivity and highest resolution at the base of the peaks were: Ion Region, +10, Extraction Lens, -7; Lens 1 and 3, -7; Lens 2, -12; Quadrupole Entrance Lens, -86; and Quadrupole Exit Lens, -80 Volts. Pole Bias was set to 0 Volts, with 1.5 to 2.5 kV applied across the Multiplier and the Dynode grounded.

RESOLUTION AND TRANSMISSION Figure 1 is an expanded view of the second stability region of the stability diagram. The scan lines labeled 'A', 'B' and 'C' represent the three possible types of boundary crossings during a scan across a wide mass range. 'A': $\beta_x=1, \beta_z=1$, 'B': $\beta_x=0, \beta_z=1$, 'C': $\beta_x=0, \beta_z=2$. The β values associated with these boundaries correspond to the frequencies of ion motion at boundary crossing (fundamental frequency of ion motion is directly proportional to β). Mass peaks measured via scan line 'A' have characteristic peak fronting on the low mass side of the peak. Mass peaks measured via scan line 'B' have excellent sensitivity and abundance sensitivity, but have a peak width limited to the narrowest scan line that can be contrived to pass through these two boundaries. Mass peaks measured using scan line 'C' have the highest possible resolution, presumably due to the focusing effects of the higher frequencies of ion motion near the $\beta_x=3$ boundary.

Figure 1. Close-up view of second Mathieu stability region showing three possible families of scan lines.

Figure 2 illustrates the resolution and transmission characteristics of first and second stability operation, with the labels 'A', 'B' and 'C' corresponding to the three scan lines indicated in Figure 1. Note that the relative sensitivity of second stability operation is approximately one seventh that of first stability operation at unit mass resolution for m/z 28. The same ratio was identified in reference 1 for m/z 4 measured using a 3/4 inch quadrupole operated at 2.9 MHz. The dotted line labeled 'single peak' corresponds to the estimated resolution for the resolved m/z 28 peaks where the valley was > 50% of peak height.

Figure 2. Resolution - Transmission curves for the analysis of m/z 28 on a 3/8" quadrupole operated at 2.1 MHz, using first and second stability regions.

RESOLVING ISOBARIC MASSES Figures 3 and 4 represent high resolution second stability separation of two sets of isobaric doublets. The peaks in figure 3 correspond to CO and N₂ from a 50-50 mixture leaked into the chamber. These mass peaks are separated by 11.2 milli-amu. The peaks in figure 4 correspond to CO₂ and N₂O from a 50-50 mixture leaked into the chamber. These mass peaks are also separated by 11.2 milli-amu. An important feature of these spectra is the fact that for a given system, the minimum possible peak width increases with increasing mass. That is, while resolution (m/Δm) increases with increasing mass, the more important figure of merit of minimum peak width (Δm) goes up slightly with increasing mass as well. This phenomenon is illustrated by the fact that the m/z 28 and 44 examples require the same mass separation, but the valley between the two m/z 28 peaks is much deeper than

Figure 3. High resolution second stability spectrum of m/z 28

for the two m/z 44 peaks. There is a similar increase in minimum peak width in normal first stability operation.

Figure 4. High resolution second stability spectrum of m/z 44

CONCLUSIONS AND FUTURE WORK Isobaric compounds can be readily resolved using high resolution second stability quadrupole operation. As with normal quadrupole operation, fine adjustment of ionizer and quadrupole entrance lens voltages is critical for ultimate resolution to maximize abundance sensitivity and minimize the broadening of the base of the peak. Second stability operation sensitivity at unit mass resolution as measured in this work, using a 3/8" quadrupole operated at 2.1 MHz, is approximately one seventh that of first stability operation. This correlates well with the results presented last year (1) for a 3/4" quadrupole operated at 2.9 MHz. We predict that resolution and abundance sensitivity may possibly be improved through the addition of an energy analyzer between the ionizer and the quadrupole. In our lab, we have found that abundance sensitivity improves by an order of magnitude or more when either an axial energy analyzer or a quadrupole deflector is used between an ionizer and a quadrupole operated in the normal first stability mode of operation.

Optimizing Quadrupole Performance When Coupled With High Voltage Ion Sources

Randall E. Pedder and Richard A. Schaeffer

ABB Extrel, Quadrupole Mass Spectrometry, 575 Epsilon Drive, Pittsburgh, PA 15238

Some applications require the ion birth potential to be elevated far from ground. In these cases, the quadrupole pole bias must be elevated far from ground to allow for reasonable quadrupole ion energies, but most system designs have a grounded quadrupole housing. **Problem:** When operating with quadrupole pole bias different from quadrupole housing potential, poor performance results. Sensitivity can diminish by more than an order of magnitude. The housing potential asserts itself into the quadrupole field yielding split mass peaks due to octapolar and dodecapolar non-linear resonances. **Solution:** These effects can be avoided by electrical isolation of the quadrupole housing, with the housing potential maintained within ten to twenty volts of the pole bias.

INTRODUCTION Quadrupole performance is generally optimum when the ion energy through the quadrupole is limited to five or ten eV. At higher ion energies, abundance sensitivity, resolution and peak shape suffer. In certain applications it is inconvenient or impossible to force the potential at which the ions are born to be at or near ground. Examples of such applications are SIMS, hybrid MS/MS instruments (BEQ), plasma monitoring, flow tubes, and other specialized ion sources. One is therefore given the choice of settling for non-optimum quadrupole performance or floating the quadrupole pole bias to within five or ten volts of the ion region potential. Quadrupoles are typically mounted inside a grounded cylindrical housing. If the pole bias differs more than twenty volts from the quadrupole housing potential, peak splitting due to even order non-linear resonances is evident in the spectra. This presentation includes an experimental and theoretical treatment of the problems associated with optimizing quadrupole performance when the ion source potential is by necessity elevated far from ground.

EXPERIMENTAL A standard ABB Extrel 3/8" quadrupole probe with 041-11 Axial Molecular Beam Ionizer and counting electron multiplier was modified to allow electrical isolation of the multiplier housing. This isolation was effected by the addition of a Vespel (polyamide) insulator between the quadrupole exit lens mounting hardware and the multiplier housing. The quadrupole exit lens was modified by the addition of a short tube lens, which penetrates into the multiplier housing. The bias potential was applied to the circuit common connectors at the back of the Extranuclear Labs (ABB Extrel) 020-2 ionizer control electronics, 0-11 QPS quadrupole power supplies with Model 15 High Q Head, Faraday aperture plate and quadrupole housing. The tune voltages were Ion Region, +5; Extraction Lens, -1; Lens 1 and 3, -19; Lens 2, -153; Quadrupole Entrance Lens, 0; and Quadrupole Exit Lens, -2 Volts. Pole Bias was set to 0 Volts, with 1.7 kV applied across the Multiplier and the Dynode grounded. A bias voltage

was summed with all of these voltages through the electrical common of the control electronics. The quadrupole housing was alternately grounded or biased using this bias voltage in these experiments.

FLOATING THE QUADRUPOLE WITH GROUNDED HOUSING When ionizer and quadrupole pole bias are floated from ground, but the housing is grounded, quadrupole performance is adversely affected. In the spectra of masses 27 to 33 (m/z 28 and 32 from an air leak, m/z 31 from perfluorotributylamine) shown in figure 1 below, one can see that absolute sensitivity drops rapidly as the pole bias differs from the housing potential by more than twenty volts. Indeed, with a two hundred volt positive or negative potential difference, the sensitivity of the analyzer drops by a factor of twenty. Peak shape changes dramatically as well, yielding characteristic peak splitting and broadening. The relative intensities of the various mass peaks distort as well, with m/z 28 relative intensity reduced with increasingly negative voltage deltas.

Figure 1. Quadrupole peak shapes with grounded quadrupole housing and biased control electronics

WHAT CAUSES THIS PEAK SPLITTING Dennison (1) demonstrated that the grounded field of a quadrupole housing alters the effective radius of the quadrupole rods, even when the pole bias matches the housing potential. When the housing potential differs greatly from the pole bias, the housing potential penetration into the quadrupolar field is more dramatic, yielding octapolar and dodecapolar field distortions. The effects of such field distortions were calculated theoretically by Dawson in 1972 (2). In this work, Dawson correlated fourth order (octapolar) and sixth order (dodecapolar) field distortions with split peaks. The Mathieu stability diagram in figure 2 is adapted from reference 2. The peak splitting evident in the spectra can be rationalized as follows: When the housing potential is more positive than the pole bias, as is the case of a negative system potential and grounded housing, the negative DC voltage offset corresponds to a positive Mathieu 'a' parameter, with peak splitting characteristic of the upper half of the stability diagram, namely octapolar peak splitting. For the case of the housing potential more negative than the pole bias (positive system potential), the peak splitting is characteristic of the negative 'a', bottom half of the stability diagram, with peak splitting attributed to both octapolar (split top) and dodecapolar (pre-cursor with peak broadening) field distortions.

Figure 2. Mathieu stability diagram showing characteristic octapolar and dodecapolar non-linear resonance lines. These non-linear resonance lines correlate well with experimental peak shapes shown. Stability diagram adapted from reference 2.

FLOATING BOTH THE QUADRUPOLE AND HOUSING If the housing potential is maintained at the same bias potential which elevates the rest of the analyzer, analyzer performance returns to normal levels, independent of bias potential. From figure 3, it can be seen that the non-linear resonance effects are eliminated through the elevation of the housing potential, with no loss in sensitivity as the bias potential goes to more and more positive voltages.

When the bias potential is elevated to more negative potentials, a slight reduction in sensitivity is

Figure 3. Quadrupole peak shapes with biased quadrupole housing and control electronics.

evident, which is attributed to a reduction in detection efficiency. Since detection efficiency is dependent on the acceleration of ions exiting the quadrupole to an off-axis detector, a reduction in the acceleration potentials results in both a reduction in ion energy as the ion strikes the multiplier surface and a slight change of the focusing of the ions into the multiplier cone. Both of these effects contribute to a loss in sensitivity as the voltages are changed from optimum values. These effects can be eliminated by biasing the multiplier and dynode supplies similar to the biasing of the ionizer and quadrupole supplies, and the use of a high voltage on the conversion dynode.

CONCLUSIONS AND FUTURE WORK This presentation identifies the symptoms and sources of some of the problems associated with analyzing ions whose birth potential is elevated far from ground, specifically poor peak shape and sensitivity. By biasing the potential of the complete analyzer including the quadrupole housing, these problems can be minimized. In these data, the dynode potential was maintained at zero volts to emphasize the importance of the bias potential on detection efficiency. Maintaining the dynode potential at 5000 Volts from ground should minimize this effect.

This work was performed using vintage vacuum tube electronics, which has a maximum bias offset of 400 Volts. Similar results can be obtained using current vintage solid state electronics, with the integral pole bias offset limited to the 200 Volt internal pole bias supply.

RF-Only Quadrupoles with Axial Fields

Bruce Thomson, Chuck Jolliffe and Reza Javahery; Perkin-Elmer Sciex, Concord, Ontario L4K 4V8.

Quadrupole devices are used both for mass filtering (typically in an RF/DC mode) and for ion focusing or confinement (in an RF-only mode). Conventionally formed of four extended parallel electrodes, they are explicitly designed to produce electric fields in the interior region in only two dimensions (x and y). Absence of any electric field in the axial direction (at least in regions which are not close to the entrance or exit), is ensured by making the electrodes parallel to one another, and preventing any stray external field from penetrating into the center of the device. Once ions are through the fringing field, they move at a constant axial velocity which depends on their entrance energy.

RF-only quadrupoles operated at a pressure of a few millitorr provide efficient ion containment and collisional focusing, and are used both as transfer optics from a high pressure source into the API 100 and 300 single and triple quadrupole systems, and as a collision cell in the API 300. When the pressure is .01 Torr and above, gas drag on the ions can be significant, slowing passage of the ions through the device. We have developed methods of applying an electric field along the axis of an RF-only quadrupole in order to control the ion energy and the drift time of ions through a high pressure RF quadrupole. Four methods have been developed and characterized.

Method 1: A quadrupole is constructed of several sections or segments, insulated from each other. RF voltage is applied to each segment, with separate DC offset voltages. Control of the individual DC offset voltages (which control the center axis potential for each segment) allows an axial field to be created. An approximately constant field is created by maintaining a constant voltage difference between each of the segments. Other non-constant field can be created by tailoring the voltage on the segments. RF quadrupoles with up to 20 segments approximately 1 cm in length have been built and characterized.

Method 2: A case surrounding a conventional quadrupole is divided into separate segments, each with a separate DC voltages applied. The potential from each case segment adds (slightly) to the rod offset (center DC) potential of the quadrupole, allowing control of the potential along the axis as above. This method is less effective than that of Method 1 since the case electrodes are further from the center of the quadrupole, and somewhat screened by the rod electrodes.

Method 3: A small diameter insulating rod electrode coated with a resistive material is located between each of the quadrupole rods, extending along the length. Each of the four resistive electrodes has a DC potential applied between the ends (identical for all four), which produces a potential gradient along the axis in the center of the quadrupole. The strength of the gradient (electric field) can be varied by adjusting the potential difference between the ends of the electrodes.

Method 4: The quadrupole is constructed with one pair of (opposite) rods tilted inward toward the exit, and the other pair of rods tilted outward toward the exit. This results in one pair of rods being closer to the axis at the entrance, and the other pair being closer to the axis at the exit. With a separate DC rod offset potential applied to each pair of rods, the potential at the center of the quadrupole is closer to the potential on one pair of rods at the entrance, and closer to that on the other pair of rods at the exit. The result is a potential which varies linearly from one end of the device to the other, creating an axial field with a strength controlled by the voltage difference between the rod pairs. Ion confinement and fragmentation (when used as a collision cell) has been experimentally shown to be unaffected by the asymmetry of the electrode spacings, which can differ by as much as 25%.

All four methods of producing an axial field have been constructed and characterized, with the segmented quadrupole being explored in the most detail. A 10-segment quadrupole, with segments 0.9 cm long separated by 0.1 cm gaps, has been characterized as the collision cell in a triple quadrupole. Equal RF voltages were applied to all segments, and a potential divider was used to separately control the gradient along the axis. Ions were gated into Q2 with by pulsing the entrance lens, and drift times to the detector were recorded with a multichannel scalar triggered by the gating pulse. The output of the normal pulse counting detector (after Q3) was connected to the MCS. Gated ion pulses were 60 μ s wide, and 5 μ s bin widths were used to record the arrival time spectra. Q3 (the mass resolving quadrupole following the segmented collision cell) was used to provide mass resolution for the ions of interest. A low entrance

energy (4 eV in the examples which follow) was used to avoid fragmentation in Q2, which was operated at a pressure of .008 Torr.

Figure 1 shows the arrival time spectra for m/z 59, 175 and 907 (from PPGs ionized by IonSpray) at the detector with no axial field applied. Figure 2 shows the same three ions with a field of 0.8 V/cm (8V applied along the 10 cm length). The long tail in the arrival time spectrum is removed even by this weak field. Median drift times have been recorded for field strengths of up to 3 V/cm. At much higher field strengths, scattering losses begin to become apparent.

Figure 1

Figure 3 shows how the arrival time (measured at the peak in the spectrum) varies with axial field for each of the three ions. The asymptote represents the drift time through Q3, which is unaffected by the axial field.

Conclusion: An electric field can be applied along the axis of an RF-only quadrupole in order to control the drift time of ions through the background gas. Effective control of the time dispersion can be achieved without reducing performance as an ion confinement device.

The combination of an axial field with a high pressure RF quadrupole could find application in mobility separation, measurement of cross-sections, and efficient transfer of ions through much higher gas pressure where drag effects become deleterious. The ability to control the axial field in the quadrupole can also be used to store ions (in an axial potential well), and then quickly eject them into another device. In addition, the axial field should allow better control over collisional activation and/or reaction processes in a collision cell than is possible in a conventional quadrupole.

STATIC SECONDARY ION MASS SPECTROMETRY UTILIZING THE ION TRAP

A. D. Appelhans, D. A. Dahl, J. E. Delmore, G. S. Groenewold and J. C. Ingram

Idaho National Engineering Laboratory¹, P O Box 1625, Idaho Falls, ID 83415-2208

We have designed, constructed and tested a secondary ion mass spectrometer using an ion trap mass analyzer along with two other unique technologies, pulsed extraction sample neutralization and a heavy molecular anion gun. The instrument has been tested with a wide range of samples, including non-conducting materials such as polymers, vegetation, and minerals. While secondary ion mass spectrometry (SIMS) has historically not been used extensively for environmental analyses, there have been related studies that demonstrate its potential.^{1,2,3} The extreme sensitivity for detecting trace levels of adsorbed molecular species makes SIMS attractive for environmental sample analysis.

Environmental samples present unique challenges to SIMS: they are mostly non-conducting and thus charge under ion bombardment, their physical shape varies widely, and they are chemically complex and "dirty". Sample charging can be overcome utilizing a molecular negative ion for sputtering the sample coupled with pulsed secondary ion extraction.^{2,3} The remaining challenge is the chemical noise present on environmental samples. The SIMS spectrum of these samples contains a peak at virtually every mass up to 400 d, and thus obtaining a unique spectral signature is problematic. The ion trap mass spectrometer offers one solution to this challenge: mass spectrometry/mass spectrometry (MS/MS). By isolating the target compound (mass) and dissociating it, a unique spectral signature can be generated and the chemical noise effectively filtered out.

In our ion trap SIMS, illustrated in Figure 1, the ion gun, detector assembly, ion trap mass

Figure 1 Layout of ion trap SIMS instrument.

spectrometer, and sample probe are all aligned colinearly. The sample is positioned 2mm behind one end cap of the ion trap, and the endcap aperture has been enlarged to 5mm and covered with a 1-mm-spaced grid. A cylindrical lens, located 3 mm behind the sample, is biased to ~100 volts at the same

polarity as the ions to be analyzed. Helium gas is introduced directly into the ion trap via a port in the end cap spacer. The 4 keV, 500 pA, ReO_4^- sputtering beam passes through the detector assembly and ion trap, and is focused to a spot of ~1mm on the sample. A white noise source can be applied to the end caps during sputtering to exclude all ions except those in a chosen mass range. Once the secondary ions are collected in the trap, the sputtering beam is turned off (electrostatically). A mass spectrum is generated by scanning the ions out of the trap sequentially by mass; alternately, for MS/MS, specific ions are collisionally excited and dissociated within the trap and the dissociation products and remaining parent ions are scanned out by mass. The deflection grids direct the ions into the channeltron detector. The kinetic energy of the ejected ions is a function of their mass, and ranges from a few eV up to thousands of eV, and the mirror lens corrects for this wide energy spread. Both negative and positive ions can be detected, and by adding a second detector (mirror image of that shown) both polarity ions can be detected simultaneously.

As an example the system's performance, we examined the sensitivity for detecting a contaminant present on soil. The soil was exposed to successively lower levels of tri-n-butyl phosphate (TBP) resulting in a surface concentration ranging from 3 monolayers down to 0.001 monolayers. Two mg of soil was attached to a 3mm square of double sided sticky tape. Using filtered noise fields ions were collected in the mass range m/z 263-272, and the ions at m/z 267 (the TBP molecular ion) were then collisionally dissociated. The

Figure 2 MS/MS provides specificity to separate target ions in the presence of isobaric ions (chemical noise), even at levels of one-thousandth of a monolayer.

TBP daughter ions at m/z 99, 155, and 211 were used as the markers to determine detection. By using MS/MS the TBP signal could be isolated from the background signal at m/z 267, even when the peak at m/z 267 contained less than 1% TBP ions. Utilizing the ion trap in secondary ion mass spectrometry provides significant advantages in sensitivity, specificity, ease of sample analysis, and sample analysis time that make it an attractive alternative for environmental sample analysis.

TOF-SIMS Using Metal-Oxide Clusters As Primary Ions*

Center for Chemical Characterization and Analysis
Department of Chemistry
Texas A&M University, College Station, TX 77843-3144.

INTRODUCTION

The use of polyatomic or cluster ions as primary projectiles in secondary ion mass spectrometry (SIMS) has been shown to significantly improve the yield of secondary ions from inorganic and organic samples. For the case of cluster projectiles ranging in size from 2 to 6 constituents, the increase in yield has been shown to be non-linear, and the secondary ion yield due to the impact of a three atom cluster is greater than the collective yield due to the impacts of three single atomic projectiles (1). The increased secondary ion yield possible when using a cluster primary ion will be a benefit as the concentrations of chemical species, for instance dopant concentration in semiconductor devices, that mass spectrometrists are called upon to determine continues to decrease.

In light of the enhancement yields observed using cluster projectiles, we are investigating the use of a variety of heavy atom cluster beams for use in static Time-of-Flight-SIMS for chemical characterization.

EXPERIMENTAL METHOD

The cluster ions primary ions are produced by the impact of a fission fragment from a ^{252}Cf fission foil on a target composed of the nitrate of the respective metal species. The positive cluster ions produced are primarily of the type $(\text{M}_2\text{O}_3)_n\text{MO}^+$ and $(\text{M}_2\text{O}_3)_n\text{H}^+$. These ions are accelerated and separated by Time-of-Flight before successively striking the sample target to initiate the desorption of secondary ions. Using a low primary ion fluence, event-by-event bombardment and detection with coincidence counting methods, the mass spectra of the secondary ions produced by each type of cluster ion projectile can be recorded in one run under the same experimental conditions.

RESULTS

Figure 1 shows the relative ion yield distribution due to the impacts of various

bismuth oxide cluster ions onto a vapor deposited CsI target. The percent relative yield of I^- is plotted as a function of primary ion energy per mass unit to facilitate comparison of the primary ions at the same velocity. The primary ion energy for this experiment ranged from 12 to 22 keV. The sample was biased negatively to 7kV.

CONCLUSIONS

The secondary ion yields observed from the impacts of these cluster ions on a CsI target are higher than from the impact of Cs^+ , a primary ion commonly used in SIMS. For example, using the $(\text{M}_2\text{O}_3)_3\text{MO}^+$ cluster projectile, the yield of I^- is 15-20 times greater than from Cs^+ when compared at .02 keV/amu. Yield enhancements (i.e. the yield due to a 3 atom cluster is higher than the collective yield due to 3 monoatomic projectiles) also are observed for these cluster ions, consistent with earlier studies of cluster ion induced desorption.

TOF-SIMS Using KeV Energy C₆₀ Primary Ions

R.D. Harris, M.J. Van Stipdonk, and E.A. Schweikert
Center for Chemical Characterization & Analysis, Chemistry Department
Texas A&M University, College Station, TX 77843-3144

Time-of-flight static secondary ion mass spectrometry (TOF-static SIMS) has been used to characterize and image a diverse selection of samples, such as pharmaceuticals, polymers, semiconductors and car paints [1]. TOF analysis requires pulsing the primary ion source while the static limit restricts the primary ion dose. Analysis of small quantities of material in the sub-micrometer domain becomes a challenge because of the low ionization probabilities of many species in SIMS. One approach to improve the secondary ion (SI) yields in TOF-static SIMS is to use a primary projectile with increased sputter/ionization efficiency while remaining within the static limit and maintaining the ability to produce a tightly focused primary ion beam. Polyatomic primary ions have been shown to produce higher SI yields when compared to monatomic ions [2, 3, 4]. For this reason, we have examined the use of C₆₀, Buckminsterfullerene, as a primary projectile.

Data was acquired on a SIMS instrument built in-house. Primary ions are produced by impacting MeV ions from a ²⁵²Cf source onto a coated mylar foil. The foil coating is a segregated vapor deposit of C₆₀ and CsI. Primary ions are accelerated and separated by their TOF in a 15 cm primary ion flight tube and then successively impact a negatively biased analyte target at an angle of 23° to 27°. Electrons produced from this impact strike a microchannel plate (MCP) electron detector, while secondary ions traverse a 50 cm secondary ion flight tube toward a secondary ion MCP detector. The TOF of all primary ions can be calculated using ²⁵²Cf fission fragments to start timing and electron impacts at the electron detector to stop timing. An event window can be placed around the arrival of each primary ion of interest at the sample target. Secondary ion mass spectra are produced using arrival signals from the SI stop detector in coincidence with primary ion event windows at the electron detector. Using a low primary ion fluence, event-by-event bombardment and detection, and coincidence counting methods, the mass spectra of secondary ions produced

from each primary ion impact can be recorded simultaneously under the same experimental conditions.

Figure 1 shows the yields of the 164 u, (M-H)⁻ phenylalanine secondary ion as a function of primary ion energy. C₆₀⁺ primary ions at 0.02 KeV/amu yield 3.5% to 4.5% of (M-H)⁻. Extrapolation of the Cs⁺ primary ion data to the same projectile energy gives a (M-H)⁻ relative yield of 0.1% to 0.2%. Future projects include modification of the SIMS instrument so that lower and higher impact energies can be investigated.

WATER CLUSTER FORMATION IN A NOVEL LOW POWER RADIO FREQUENCY GLOW DISCHARGE

Ian A. Mowat⁽¹⁾ John FJ Todd⁽¹⁾ and Marian L Langford.⁽²⁾

⁽¹⁾ Chemical Laboratory, University of Kent, Canterbury Kent, England, UK, CT2 7NH,

⁽²⁾ Building S18, DRA Fort Halstead, Sevenoaks, Kent, England, UK, TN14 7BP

(1) Introduction.

Glow Discharge Ionization has been used extensively for monitoring trace amounts of atmospheric contaminants (1,2). DC glow discharges have successfully been used for the detection of explosive materials using both quadrupole mass filters (3) and quadrupole ion trap mass spectrometers (4). DC and RF discharges have also been utilized as the ionization method for an atmospheric pressure source coupled to an LC column (5,6).

The aim of this current work was to replace the DC discharge with a radio frequency (RF) discharge, which would be operable to a higher overall pressure, thus increasing the sensitivity of the instrument by increasing the number of molecules available to be ionized in the discharge itself.

(2) Experimental.

All the experiments were carried out on a modified ITMS system which has previously been described (4,7). In the first series of experiments, the RF discharge was mounted on a 6" flange directly connected to the ion trap chamber. However, a number of modifications were necessary in order to be able to couple a high pressure source (up to several hundred Torr) with a low pressure mass spectrometer (the ion trap operating most favourably at about 1.5×10^{-4} Torr in this configuration). This involved the construction of a differential pumping region between the ion source and the trap chamber itself. This was mounted through a standard 6" CF flange between the discharge region, on an identical flange, and the trap chamber. The differential pumping was accomplished by a compact 55Ls⁻¹ turbo pump backed by a rotary pump.

Among the compounds studied were:

(1) Water clusters, (2) perfluorotributylamine (FC-43), (3) 1-octene, (4) heptachloropropane, (5) naphthalene, (6) 1,2-dinitrobenzene, (7) 2,6-dinitrotoluene, (8) 2,4,6-trinitrotoluene

(3) Results.

Positive ion mass spectra were successfully obtained of all the compounds listed above. Furthermore, it was possible to control the degree of fragmentation by changing the power dissipated in the discharge. This could be done in three ways: (i) Varying the output of the signal generator; (ii) varying the gain of the RF amplifier; (iii) varying the settings of the impedance matching circuit, hence changing the ratio of forward to reflected power.

Figure 1 shows two spectra of heptachloropropane obtained in the RF discharge. It can be seen that there is a clear change in the relative peak intensities obtained at different discharge powers. This is shown by the ratios between the peaks around m/z 166 and m/z 201 increasing as the discharge input voltage increased, from 3V to 7V, suggesting an increase in the harshness of the discharge conditions. In all cases, the discharge conditions are apparently 'softer' than for 70eV EI ionization, for which the base peak is m/z 83.

The use of water clusters as a probe of the RF discharge behaviour has previously been described (8). A saturated vapour pressure of water was created by heating a damp tissue in the inlet tube to about 35°C. This vapour was then pulled into the RF discharge region, where

cluster formation occurred.

Figure 2 shows two mass spectra, acquired after attempting to isolate $H^+(H_2O)_{10}$. It can clearly be seen that efficient isolation was not achievable, even with a very short time (100 μ s) after isolation, prior to the scanning the ions out of the trap.

(4) Conclusions.

This work with an atmospheric sampling RF glow discharge ionization source has successfully demonstrated the production and analysis of positive and negative ions. The fragmentation was controllable through variation of the discharge conditions and pressure. Further improvements in the gas flow through the differential region and hence the sensitivity are anticipated, thus enabling the study of ion production in RF and DC discharges at pressures of several hundred Torr.

Ion Kinetic Energy Distributions in a Radio Frequency Glow Discharge Source

Steven J. Christopher, Yuancai Ye, and R. Kenneth Marcus
Department of Chemistry, Clemson University, Clemson, SC 29634

Glow discharge mass spectrometry has become a well established technique for the elemental analysis of trace constituents in solid matrices. However, GDMS still suffers from the fact that it is difficult to characterize ion transport from the source to the spectrometer. Certain phenomena which may influence ion transport include ion kinetic energies, ion optics, and discharge parameters.

A simultaneous evaluation of ion kinetic energy (IKE) distributions and their dependence on fundamental plasma parameters is currently under investigation. These fundamental studies may help give insight into various ion transport and sampling mechanisms in glow discharge sources.

Langmuir Probe Technique

Fundamental plasma parameters including ion density, n_i , electron density, n_e , floating potential, V_f , plasma potential V_s , and electron energy distribution function, EEDF, are obtained using a Langmuir probe circuit and a LabView 2.2 program (National Instruments, Austin, TX) developed in house. Basically, a -100 V to +100 V potential is placed on the Langmuir probe which will either repel or attract plasma electrons and ions. Based on the resulting current voltage (*i*-*V*) curves, one can obtain information on the aforementioned fundamental parameters.

Ion Kinetic Energy Distributions

Ions emanating from the rf-GD source pass through a grounded sampling cone which provides a stage of differential pumping. Located directly behind the sampling cone is a Comstock (Oak Ridge, TN) 902 electrostatic energy analyzer (ESA), equipped with a three-element einzel lens mounted to the entrance aperture. A diagram of the system is located in figure 1. Ions which successfully traverse the ESA impinge upon a copper plate which feeds the ion current to a picoammeter for measurement. Average ion kinetic energies can then be determined to better than 3% RSD for repetitive scans.

All data obtained with the Langmuir probe-ESA system demonstrate an intimate relationship between V_f and average IKE, with respect to discharge power, pressure and sampling distance. Figure 2 shows the effect of sampling distance on V_f and average IKE. EEDF's tend to shift towards higher energy values at longer sampling distances and may serve to increase both V_f and average IKE.

Microsecond Pulsed Glow discharge Time-of-Flight Mass Spectrometry: Characteristics

Wei Hang, Cynthia Baker, B. W. Smith, J. D. Winefordner, W. W. Harrison*
Department of Chemistry, University of Florida, Gainesville, FL 32611

Since the start of our microsecond (μ s) pulsed glow discharge (GD) studies, it has been clear that the combination of a pulsed GD with a time-of-flight mass spectrometer (TOFMS) would be an ideal situation.

A μ s-GD permits the application of high instantaneous power up to several hundred Watts. In an argon gas discharge with a copper cathode, such a high power turns the normally observed pink glow into a green glow, which is the characteristic emission from copper metastable atoms and ions. Both the ionization yield and sputter rate are greatly enhanced during a pulsed operation. Since the μ s-GD can work at a low average power (depending on the pulse-magnitude, pulse-width, and frequency), overheating of the cathode can be avoided, which results in a good stability.

The TOFMS is an ideal mass analyzer in dealing with a pulsed ion source. It has the highest ion transmission among all mass spectrometers. In addition, because the TOFMS is able to operate at a high repetition rate, a large number of spectra can be acquired and integrated (or averaged) in a short period of time, resulting in a significant signal-to-noise enhancement. For the observation of pulsed events, TOFMS offers the distinct advantage of multiplex detection of a high percentage (several tens percent) of ions of all masses during each pulsed event.

Besides the efficient sampling of the μ s-GD-TOFMS, this system has the potential for temporal separation of discharge gas species from sputtered sample components. It is believed that mass spectrometry samples ions primarily near the vicinity of the orifice. Gas Species (argon, nitrogen, oxygen, water, etc.) are ionized basically by electrons due to their high ionization potential. These species can not be ionized after the termination of the discharge because of the fast scattering of electrons. On the other hand, sputtered particles have to diffuse across the cathode-orifice distance before they are ionized by long-life metastable argon atoms through Penning collisions, and successfully sampled by the mass spectrometer. Thus, sputtered sample ions reach the repelling region several hundred microseconds later than gas species. By setting a delay time of the repelling pulse in favor of the sample ions, gas species interferences can be greatly reduced. Although this property can not separate deposited gas particles from true cathode particles, and gas species interference can not be reduced to zero (due to their spatial and energy distributions), it can reduce all the gas species peak intensities up to 3 orders of magnitude (depending on the source pressure, cathode-orifice distance and the repelling pulse delay) without losing any analytical signal. Therefore this advantage paves a new way for the analysis of such samples that contain small amounts of "troublesome" elements, such as C, Al, Si, S, P, K, Ca, Fe, etc..

A μ s pulsed source also has higher resolution and sensitivity compared with a continuous source. In the repelling region, TOFMS only extract a certain volume of ions present in front of the extraction grid (in the flight tube direction). These ions have been sorted to a certain level according to their speed when they move from the source to the repelling region. The ion optics (including the three-cylinder lenses, steering plates, and

slit) can shape the ion beam for less spatial distribution in the repelling region. The TOFMS actually extracts an ion package of different masses with limited spatial distribution and lateral energy distribution, which is easy for the deflect plates to guide the ion package to the detector. Sputtered sample ions are sampled several hundred microseconds later after the termination of the plasma. Their speed passing the repelling region is most likely to be determined by their diffusion speed in the source instead of the plasma potential, a slower speed across the repelling region further improves the transmission in the orthogonal extraction. On the contrary, for a continuous source, ion optics after the skimmer can not efficiently focus the ion beam without any selection of energy. TOFMS extracts a volume of ions with a larger spatial distribution and energy distribution, which make it difficult for the deflect plates to guide this ion package; part of the ions will hit the flight tube wall, which decreases the signal and increases the noise.

The main problem of this instrument is its detection and data acquisition system. The high sampling efficiency of the system results in the non-linear response of the microchannel plate detector, which blocks the quantitative analysis of the sample. The analog-to-digital converter has the minimum sensitivity of 40 μ V, thus all signals below 40 μ V is simply not sampled. Another problem rises from the poor vacuum in the last stage (1.5×10^{-5} torr), which introduces a dark current of 80 μ A at the microchannel plates.

Even with these limitations, This approach shows the potential as a powerful analytical technique. The system shows a detection limit of sub-ppm level, and a resolution of 1600 in the reflectron mode (360 in the linear mode). Mass discrimination of this system is also very small. Further works including instrumentation improvement, GD parameter optimization, relative sensitivity factors, and isotope ratio measurements are under consideration.

Glow Discharge FTICR Mass Spectrometry at High Magnetic Fields

Goodner, K.L.; Milgram, K.E.; Dejsupa, C.; Watson, C.H.; Eyler, J. R. University of Florida, Gainesville, FL 32611-7200; Barshick, C.M.; Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

Introduction Glow discharges are a valuable analytical tool for the analysis of solids. However, like many elemental techniques, interferences from polyatomic ions and isotopes of other elements make many analyses difficult, if not impossible. As part of the Eyler group's continued advancement of elemental sources coupled with FT-ICR/MS, a glow discharge ion source has been designed for use in the high magnetic field of the superconducting magnet in order to take advantage of the ultra-high mass resolving power of FT-ICR/MS to discriminate the interferants.

Experimental

- Concentric tube design for differential pumping (Figure 1)
- 3D representation of the glow discharge sample probe (Figure 2)
- 128k transient, 50 scans, 1 zero fill, Hamming apodization
- 99.998% pure Ar discharge gas, NIST SRM 1261a stainless steel sample pin

Results and Discussion The concentric tube design in Figure 1 provides for three stages of differential pumping. Region A is maintained at ~1 torr of Ar for the discharge by 2 mechanical pumps. Region B, pumped by an 800 L/s (N₂) cryopump, is maintained at 1-5x10⁻⁵ torr. Two 300 L/s oil diffusion pumps keep Region C at 5x10⁻⁶ torr (shutter open) and 4x10⁻⁷ torr (shutter closed). Lastly, Region D has a pressure of 6x10⁻⁷ torr (shutter open) and 5x10⁻⁸ torr (shutter closed) maintained by a 700 L/s oil diffusion pump. The conductance limits are 0.5, 4, and 4 mm (labeled 3, 4, and 6 respectively) in diameter.

Figure 2 shows objects 1, 2, and 3 from Figure 1 in more detail. A 1/4" stainless steel tube, A, is threaded on one end to hold the GD probe. Argon is supplied through the polyethylene tube labeled B. It is coupled via a 1/8" to 1/4" adapter (D), along with the high voltage connection (E) to the electrical feed-through (part #FTT 1213251, Kurt J. Lesker Co.) which has been modified with a threaded piece for assembly with part A. The actual sample holder, G, is removable to facilitate multiple sample shapes (e.g. pin, hollow cathode, planar, or disk). The sample, H, is held in place via a set screw in part G. There is a ceramic sample cap that protects the feed-through from sputter loss so as to not interfere with the analysis. This is slid into the discharge area, L, which has a removable conductance limit, N. This is all attached to a Delrin piece, J, with slots cut into it to facilitate pumping. This entire assembly (J-N) is attached to a 2 1/4" diameter tube which has guides for the probe assembly (A-I).

Figure 3 shows the results of measuring power supply voltage as the probe/source was progressively inserted into the concentric tube assembly at various pressures. Metal probe guides, located at 58 and 38 cm, caused a perturbation of discharge operating conditions as the probe passed these points. The decrease in voltage beginning at about 30 cm did not coincide with the presence of a guide, but did occur simultaneously with a rapid increase in the magnetic field strength.

Various methods were employed to improve the Limit of Detection (LOD) [1] from 38 ppm to 6 ppm as can be seen in Table 1. The last entry in the table is from Barshick and Eyler [1] using the same system, but with an external source/probe. The most analogous LOD as compared to the external injection is 11 ppm since the pulsed valve serves the same purpose as the decelerator assembly employed by Barshick and Eyler.

Conclusions

- Improved ion transport
- Same concentration LOD (11 ppm) as external source with 1/30th sample consumption
- Current detection limit of 25 pg

DEVELOPMENT OF A PORTABLE HIGH RESOLUTION FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETER

Gregory Miller, Mathias Koch, J.P. Hsu, Frank Ozuna

Southwest Research Institute, 6220 Culebra Road San Antonio, Tx. 78228

The need for small, compact, portable, high-resolution mass spectrometers for on-line, real-time monitoring of compounds of interest to the semiconductor industry and for environmental monitoring has prompted us to design a field-portable bench top instrument based on the principle of Fourier transform ion cyclotron resonance (FTICR). The high resolution capabilities inherent in FTICR allow us to more accurately ascertain the identification of chemical species based on their exact mass. The mechanical simplicity of this instrument and the lack of complex ion-optical components allowed the construction of a very rugged device ideally suited for harsh environments.

By limiting the mass range to $M/Z = 15 - 300$ g/mol, a low field $B = 0.5$ T rare-earth neodymium-iron permanent magnet was chosen which decreased the size and weight of the instrument with the added advantage of no power consumption due to the permanent magnet. Since the primary anticipated use of this instrument is for continuous on-line monitoring, a high conductance ICR cell (fig.1) was designed with good accessibility for gas sample introduction. By maintaining the physical size of the vacuum system to a minimum (fig.2), and by the use of Summa passivation of the vacuum chamber, high vacuum requirements needed for high resolutions up to $M/\Delta M = 7500$ were able to be achieved with a constant flow of gas into the cell.

The ion cyclotron cell chosen is a screened cell of cubic geometry made up of alternating layers of beryllium-copper shims separated by ceramic insulators and assembled on ceramic posts to make up four faces of the cube. The two additional faces of the cubic cell comprise of trap plates, gating electrodes filament support, collector and the screen plates. The alternating layers of shims isolate electrically the two sides used for the excitation electrodes and the two sides for the detection electrodes. The gap left between the alternating beryllium-copper shims allows for high cell conductance and provides for accessibility for sample introduction.

(fig.1)

(fig.2)

All instrument control, from SWIFT waveform generation through mass spectral data acquisition was achieved using Virtual Instruments (VI's) written using LabVIEW graphical programming language running on an Intel Pentium-90 with 32 Mb of main memory. The interface consisted of National Instruments NI-DAQ data acquisition board with a total of six separate channel inputs and outputs, and a general purpose interface bus board (GPIB). The time-domain digital SWIFT waveform was generated in LabVIEW and sent to an Analogic 2040 arbitrary polynomial waveform generator via the GPIB interface card for analog waveform generation. The RF-waveform was clocked out to the excitation electrodes of the ICR cell from a timed pulse sequence. The detected transient waveform was amplified and captured on a LeCroy digital storage oscilloscope (DSO) which sends the digitized waveform to the PC for post signal processing and display. A single time-domain transient and its Fourier transform mass spectra are shown in (fig.3) below for room air from a constant leak.

(fig.3)

Quantification of Detection Limits in FTICR-MS

The sensitivity of any analytical technique is often a limiting factor in its application. An explicit definition of detection sensitivity and the parameters that affect sensitivity, such as transient lifetimes, frequency stability, and preamplifier performance in Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS), is crucial to characterization and further instrumental improvements which will promote more challenging applications. We have recently initiated experiments based on two independent approaches that are aimed at the quantification of instrumental sensitivity. The detection of single or individual ions for the mass measurement of very large molecules has been previously reported¹. As one approach, this presentation will report on the use of these techniques for the quantification of FTICR-MS detection sensitivity. Time-resolved ion correlation (TRIC) is used to establish the exact mass, and thus charge, of a series of high molecular weight molecules. An example 132,000 Da Albumin Dimer spectra and its time domain signal can be seen in figure 1. The peak areas resulting from normalized time-domain signals are used to produce an estimate of detection sensitivity. A second approach involves the statistical analysis of isotopic distributions as the population is gradually reduced, similar to a method previously reported². A two ion (26 charges) peak is shown in figure 2. Both these approaches allow the determination of parameter effects on sensitivity and further the understanding of detection limitations. Finally, a comparison is made between the detection limits produced by both methods, as well as that predicted by theory.

Theoretical sensitivity of a capacitively dominated detection circuit can be expressed as:

$$V_s = \frac{Nqr}{\sqrt{2dCt}}$$

Detection sensitivity results:

Statistical method.	88 nV rms/charge
TRIC method:	.7 nV rms/charge
Theory	96 nV rms/charge

With the present electronics a detection limit of 26 charges (bandwidth)^{1/2}, for a 3 to 1 signal to noise ratio, has been shown

Quantitation Methods in Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT/ICR-MS)
 Goodner, K.L.; Milgram, K.E.; Watson, C.H.; Eyler, J.R.; University of Florida, Gainesville, FL 32611-7200
Introduction Fourier transform ion cyclotron resonance mass spectrometry (FT/ICR-MS) has been used primarily for qualitative analytical chemistry in such applications as sequencing, structure elucidation, and fragmentation pathways. When using FT/ICR-MS for quantitation, a myriad of methods for determining peak intensity have been utilized involving differing apodization windows, zero filling, peak interpolation, and number of scans. Most studies have concentrated on exact mass determination. We seek to determine the optimal method of quantitating peak intensities rather than masses, in order to maximize precision and accuracy while minimizing analysis time.

Approach In order to determine the best method for quantitation, we opted for simulated data in order to have more control over the variables of interest. Simulated transients were generated for Pb^{+1} and Pb^{+2} using the natural abundances for the intensities. Noise and signal damping were varied to simulate differing experimental conditions. Since the intensities were known, percent errors for each peak could be calculated. By varying groupings, each variable could be investigated. The variables we investigated were: number of scans, apodization function, zero filling, peak height, and peak areas.

Given three data points X_1, Y_1 ; X_2, Y_2 ; X_3, Y_3 , three equations can be written for the parabolic fit:

$$\begin{aligned} a(X_1)^2 + bX_1 + c &= Y_1 \\ a(X_2)^2 + bX_2 + c &= Y_2 \\ a(X_3)^2 + bX_3 + c &= Y_3 \end{aligned}$$

$$\begin{bmatrix} X_1^2 & X_1 & 1 \\ X_2^2 & X_2 & 1 \\ X_3^2 & X_3 & 1 \end{bmatrix} \begin{bmatrix} a \\ b \\ c \end{bmatrix} = \begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \end{bmatrix}$$

$$A^{-1}AV = A^{-1}H$$

$$V = A^{-1}H$$

A

V = H

$$Y = aX^2 + bX + c$$

$$Y' = 2aX + b$$

$$0 = 2aX + b \quad (\text{for maximum})$$

$$X_{\text{max}} = -b/2a$$

$$Y_{\text{max}} = a(-b/2a)^2 + b(-b/2a) + c$$

$$Y_{\text{max}} = -b^2/4a + c$$

Similar methods can be employed for the other interpolations.

In Figure 1, the absolute percent errors are plotted vs. the number of zero fills and the various methods of determining peak heights. The absolute percent error was calculated by averaging the absolute error for each peak where the absolute error is giving by

$$\%err = |\text{exp. value} - \text{known value}| / \text{known value} * 100\%$$

The important point of the Figure 1 is that with one zero fill and using the Comisarow method of peak height determination the same average absolute percent error is obtained as with the other methods after two and three zero fills. Keep in mind that each zero fill doubles the transient length so three zero fills increases the workload on the computer eight fold!

Figure 2 shows what has been known for many years: signal averaging decreases the errors associated with quantitation. For each group of scans, the trends seen in Figure 1 are again seen. However, a larger pattern is also apparent: from "single scan" to "100 scans" to "infinity scans" there is a noticeable jump at each boundary.

Graphs similar to the ones displayed can be generated for peak area measurements instead of peak heights. The same trends can be seen, using one zero fill and the integrated Comisarow method for area determination gives the best results. The trapezoidal+ method consistently gives better results than the plain trapezoidal method, although improvements are small. The Max*FWHM technique is very erratic. In some cases the approach works well, but in many it is radically worse than the Comisarow method. Due to this instability, it is not recommended as a quantitation technique. Also the absolute percent error using the integrated Comisarow method is higher than that obtained using peak heights (0.956 vs. 0.835 and 0.423 vs. 0.187).

Conclusions The most efficient method of determining peak intensities is to apodize using the Hanning, 3-term Blackman-Harris, or 3-term Kaiser-Bessel windows, and subsequently using the Comisarow polynomial fit described in this poster to determine peak height. If peak areas are to be used, the procedure is the same, except the integration of the Comisarow polynomial is necessary.

Absolute Percent Error for Peak Height

Absolute % Error for Peak Height

A New Dual ICR Cell for Studying Cation-Anion Reactions and Surface Induced Dissociation

Fu Cheong Man, M. Kirk Green, Sharron G. Penn, and Carlito B. Lebrilla
University of California, Davis, CA 95616

A dual ICR cell has been built for an external source Fourier transform mass spectrometer in our laboratory. This new ICR cell is designed for studying cation-anion reactions and surface induced dissociation.

The design (Figure 1) consists of two cells (each 5 x 5 x 5 cm) and four trapping plates that can be independently controlled. Trapping plates 1 and 2 make up cell A, and trapping plates 3 and 4 make up cell B. Trapping plate 1 is mounted at the opening of the quadrupole rods and contains a 3 mm diameter aperture to allow ions from the electrospray ionization (ESI) source to enter the cell. Trapping plates 2 and 3 are made of stainless steel mesh and both contain a 3 mm diameter aperture in the center to allow ions to travel unimpeded between cells A and B. Trapping plate 4 is made of solid stainless steel and contains a 1 cm diameter aperture to allow electrons to enter the cells. A filament mounted on a Macor block sits on trapping plate 4 as an electron source for electron impact ionization (EI). Each cell has a set of transmitter plates and receiver plates. However in the present configuration, cell A is the detector and cell B is used for ion storage.

In the cation-anion reactions, multiply charged anions of macromolecules (e.g. proteins, nucleotides and saccarides) are produced by negative mode ESI and trapped in cell A. Cations are produced by EI in cell B from a background pressure of a small organic gas (e.g. bromobenzene or pyridine). Singly charged cations are trapped in cell B and are transferred to cell A by placing the appropriate voltages on trapping plates 3 and 4, allowing the cations to react with the anions. The anionic product are detected in cell A.

Surface induced dissociation can be performed by accelerating the ions to a high kinetic energy and passing them through the trapping plates 3 and 4 (metal mesh) to induce dissociation.

SIMION simulation and preliminary studies including experiments on ion transport between cells A and B were performed at the first stage of our project. Results (Figure 2 and 3) show that the dual cell can be used for ion trapping and ion transport in both modes.

Some cation-anion reactions have been studied, including reaction between ubiquitin and bromobenzene, lysozyme and bromobenzene, and trisialoganglioside and pyridine. Initial results are promising, but some difficulties still need to be addressed, such as obtaining good signals in negative mode ESI without using a transmitter offset or a nitrogen pulse, and investigation of the conditions needed for the ions to react. A more intensive study is planned.

An External Source 7 Tesla FT-ICR Mass Spectrometer with Electrostatic Ion Guide

Forest M. White, Jarrod A. Marto[†], and Alan G. Marshall^{*}

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab,
Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

^{*} Department of Chemistry, Florida State University

[†] Department of Chemistry, University of Virginia, Charlottesville, Va

A novel-design 7 Tesla Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer with external source has been constructed (see Figure 1). The ions are formed in a 9-way ion source cross, allowing for a variety of different ion sources to be attached simultaneously, thereby minimizing "downtime" for changing ion sources. An eight-inch bellows allows for the movement of the ion guide relative to the ion source, providing compatibility to a variety of ion sources having a variety of focal lengths.

An electrostatic (wire-in-cylinder) ion guide transports ions approximately 60 inches from the ion source to the ion trap for mass analysis, through a large magnetic field gradient. The front half (furthest from the magnet) of the electrostatic ion guide consists of a 0.5 inch perforated stainless steel tube (0.43 inch I.D.), whereas the back half consists of a 0.5 inch O.D. titanium tube (0.43 inch I.D.). A coaxial central gold-coated tungsten wire electrode (50 micrometer diameter) runs the entire distance. The small ion guide diameter allows for a smaller conductance limit, and therefore greater pressure differential between pumping stages. The first of three pumping stages is currently equipped with a 520 L/s turbopump (the ion source cross), while the second two stages are both equipped with 1500 L/s cryopumps.

Figure 2 demonstrates the experimental performance of external matrix-assisted laser desorption/ionization (MALDI) on the new instrument. The luteinizing hormone releasing hormone (LH-RH) positive-ion FT-ICR mass spectrum was obtained from a single laser desorption/ionization event from a standard Finnigan FTMS probe tip containing 15 μ L of a crystallized DHB/LH-RH (1000:1 mole ratio) solution. The most efficient transmission of ions from the ion source to the ion trap occurred with a -40 V potential on the ion guide tube, and a -55 V potential on the central wire. These conditions reduced the ion flight time by approximately 50%, while also narrowing the spread in arrival time, allowing for more efficient capture of the ions at the trap. On reaching the ion trap, the ions were decelerated by an 8 V potential on the back trap plate, with the front trap plate gated to allow the ions to enter the trap. The ions were subjected to single-frequency resonant quadrupolar excitation (1.4 V_{p-p} @ 91.5 kHz) for 10 ms at 1.0×10^{-7} torr, and after an additional 60 seconds, dipolar excitation and broadband detection were carried out at 2.0×10^{-9} torr. The time domain data was subjected to FFT and Blackman-Harris apodization and displayed in magnitude mode.

This work was supported by the National Science Foundation (CHE 93-22824), and the National High Magnetic Field Laboratory at Florida State University.

Combining FT-ICR Mass Spectrometry with Ion Mobility Spectrometry

Kent J. Gillig, Brian K. Bluhm, David H. Russell
Laboratory for Biological Mass Spectrometry
Department of Chemistry
Texas A&M University
College Station, TX 77843

Introduction

Structural elucidation of gas phase ions is regarded as an important next step in the advancement of mass spectrometry. Most structural information derived from mass spectrometry comes from fragment ions which are produced during the ionization process or by collisions with gas molecules or photons. Hydrogen deuterium exchange or clustering (solvation) experiments are also performed to give structural information about the molecular ion. Recently Bowers and Jarrold introduced to the mass spectrometry community the use of the well established ion separation capabilities of ion mobility¹ as a general method for structural characterization of gas phase ions^{2,3}. The ion mobility apparatus is capable of separating electronic states of transition metal ions as well as different protein conformations.^{4,5}

Experimental

We are constructing an instrument which combines the high resolution and ion manipulation capabilities of FT-ICR mass spectrometry with the structural characterization capabilities of ion mobility experiments as shown in Figure 1. FT-ICR offers the ability to perform ion-molecule reactions, collisional activation, and collisional cooling prior to the drift cell which is not present in previous instrumental designs. Ions are produced, isolated and reacted within a two-section ICR cell, then a single mass is injected into the drift cell where different structures are separated according to their respective mobilities (K), as shown in equations 1-4.

$$v_d = KE \quad (1)$$

$$K = \frac{3}{16} \frac{q}{N} \left(\frac{1}{m} + \frac{1}{M} \right)^{1/2} \left(\frac{2\pi}{kT} \right)^{1/2} \frac{1}{\Omega_p} \quad (2)$$

$$\Omega_p(T) = \frac{1}{2(kT)^{3/2}} \int_0^\infty e^{-5/4 \pi E^2} Q_p(E) dE \quad (3)$$

$$Q_p(E) = 2\pi \int_0^\pi (1 - \cos \theta) f(\theta) \sin \theta d\theta \quad (4)$$

Since an ion's mobility is dependent on its collision cross section (Ω_p), isomeric forms of ions can be resolved, provided the mobilities are sufficiently dissimilar. Upon elution from the drift cell each ion packet is continuously extracted down a flight tube to obtain the arrival time distribution (ATD). Subsequently in a second experiment the ions are pulse extracted upon elution from the drift cell to verify that no ion-molecule reactions or clustering occurred in the drift cell. Structural information is extracted from the arrival time distribution by fitting the peaks with a theoretical flux equation (5) which is dependent upon the ions specific collision cross section.

$$\Phi(z, t) = \frac{sae^{-\alpha}}{4\sqrt{\pi D_z t}} \left(v_d + \frac{z}{t} \right) \left[1 - e^{-\delta^2/4 D_z} \right] e^{-(z - v_d t)^2/4 D_z t} \quad (5)$$

Studies of Terpyridine-Based Polyether dendrimers and their Iron(II) metallocomplexes by LSIMS- and ESI-FTICR

Rebecca L. C. Lau and T. -W. Dominic Chan*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, N. T., Hong Kong

INTRODUCTION A series of low mass ($MW < 3500$) terpyridine-based polyether dendritic ligands (Gn) and their iron(II) metallocomplexes $[\text{Fe}^{\text{II}}(\text{Gn})_2][\text{PF}_6]_2$ are characterized using liquid secondary ion mass spectrometry (LSIMS) and the high mass ones ($MW > 3500$) are studied by electrospray ionization mass spectrometry (ESI-MS). Structures of the zeroth generation dendrimer G0 and its corresponding metallo dendrimers $[\text{Fe}^{\text{II}}(\text{G0})_2][\text{PF}_6]_2$ are shown in Figure 1.

EXPERIMENTAL Positive-ion mass spectra were recorded on a Bruker APEX 47e FTMS mass spectrometer (Bruker Instrument, Billerica, MA). In LSIMS, a 15 kV cesium ion guns was used to produce ions and 3-nitrobenzyl alcohol was used as the matrix. ESI experiments were carried out by spraying the dendrimer samples from a 97.3 (% volume) acetone acetic acid solution. For metallo dendrimers, pure acetone was used instead. All the samples were a gift from Dr. H. -F. Chow.

RESULTS AND DISCUSSION LSIMS mass spectra of terpyridine-based polyether dendrimers and their iron(II) complexes show fragmentation pattern well related to their structure. Terpyridine moiety of the free dendrimers show a tendency to lose multiple electrons which corresponds to the formation of multiply charged ions $[\text{Gn}+\text{H}]^{(n+1)+}$ (where $n = 1-4$) in free dendrimers, $[\text{Fe}^{\text{II}}(\text{Gn})_2]^{6+}$ and $[\text{Fe}^{\text{II}}(\text{Gn})_2]^{10+}$ ions in metallocomplexes. The comparatively more intense $[\text{Gn}+\text{H}]^{3+}$ and $[\text{Gn}+\text{H}]^{5+}$ ions and the observation of $[\text{Fe}^{\text{II}}(\text{Gn})_2]^{6+}$ and $[\text{Fe}^{\text{II}}(\text{Gn})_2]^{10+}$ ions support the notion that loss of even number of electrons from the terpyridine moiety are more favorable. Under LSIMS conditions, the iron(II) metal center is shown to undergo redox reactions leading to the formation of both iron(I) and iron(III) complexes. Scheme 1 and 2 summarizes the fragmentation pathways for the low mass dendrimers and metallo dendrimers under LSIMS conditions. The limitation of LSIMS in measuring higher mass dendrimers ($MW > 3500$) is compensated by the application of ESI. The softness of this ionization technique enables measurement of intact molecular ions of both dendrimers and metallo dendrimers with little fragmentation.

ELECTRICAL ION GUIDES

Jochen Franzen, Bruker-Franzen Analytik GmbH, Fahrenheitstr. 4, D-28359 Bremen, Germany

There are two types of electrical ion guides, guiding ions from a location near a to a location near b :

(1) **electrodynamic ion guides** with repellent inhomogeneous rf fields at surfaces forming electric pseudo-potential walls which can be modeled to build a tube from a to b , usable preferentially in bad vacuum up to roughly 1 millimeter free mean path length. - A well-known example for this type is the Paul quadrupole filter consisting of four long rods, and the extension towards hexapole and octopole rod systems. These ions guides, however, are only very specific forms of a more general principle of reflecting walls for ions consisting of inhomogeneous rf fields in front of surfaces.

(2) **electrostatic ion guides** with attracting forces round a thin wire stretching from a to b , usable only in good vacuum environments with low number of collisions. - An examples for this type of ion guide is the famous tube-and-wire arrangement, less known ist the branching guide which can switch ion currents to arrive at different locations.

Effect of inhomogeneous rf fields

An rf field around the tip of a wire drops in field strength proportional to $1/r^2$, the rf field of a long, thin wire drops with $1/r$, where r is the distance to the wire tip, or to the wire axis. Both fields reflect - at the same time - positively as well as negatively charged particles.

The particle oscillates in the alternating field. Independent of its polarity, it encounters its largest repelling force exactly at the time when it is located in its position nearest to the wire, that is the point of strongest field strength during the oscillation. It encounters its strongest attracting force exactly in its location farrest to the wire, i. e., in the point of lowest field strength during its oscillation. Integrated over time, a repelling force results. This integrated repelling force field often is called „pseudo force field“, described by a „pseudo potential distribution“. The pseudo potential is proportional to the square of the rf field strength: it drops with $1/r^4$ in case of the tip, and with $1/r^2$ in case of the long wire, but is, in addition, inversely proportional to both the particle mass m and the square ω^2 of the rf frequency ω .

Thus any finely structured surface-filling periodic pattern of electrodes, connected alternatively to different phases of rf voltage, reflects ions below a kinetic energy threshold and above a cut-off mass-to-charge ratio.

Point Grid

Mesh-and-Point Grid

Line Grid

Point grids, mesh-and-point grids, or line grids can be bent to form the inner surface of cylinders or cones, resulting in cylindrical or conical ion guides.

Most interesting are line grids rolled up to cylinders:

- (1) If the lines are parallel to the cylinder axis, we get the well-known multipole rod systems.
- (2) If the cylinder is rolled up along the lines, we get a system of rings, forming a multitude of tiny ion traps with shallow pseudo-potential wells along the axis.
- (3) If the cylinder is rolled up under an angle, we get an ion guide with a helical structure.

Pentapole

An example for an unusual rod system is the pentapole. Five rods are connected to a 5-phase rf voltage. The pentapole is the lowest odd rod system with stable ion storage capabilities.

Ion guides as ring systems

The rf ring system forms a sequence of tiny ion traps with shallow pseudo-potential wells. The ring system is not the best ion guide because it holds back puddles of ions inside the shallow wells.

Helical wire ion guides

Helical wire ion guides can be build as double helixes, quadruple helixes, and so on. All helical wire ion guides have smooth pseudo-potentials along their axis. Rigid devices can easily be built by using double-pitch screws and isolating holders, glued to the wires. The depth of the pseudo-potential well can be controlled by the pitch.

Helical wire ion guides can also be formed as cones or flat spirals.

Electrostatic ion guides

In an electrostatic ion guide, ions tumble around the wire without touching it. A two-way ion guide can switch ion currents to different locations. E.g., two wire halves, isolated by a glass pearl in the center, can switch ions from a quadrupole mass filter towards one of two multipliers.

Conclusions

In contrast to the more fixed design of electrostatic tube-and-wire ion guides, there exists a wide variety of realizations for ion guides and ion stores using the repelling pseudo-forces. Most interesting is the double helix arrangement because it can be tailored to a wanted depth profile of the pseudo-potential well.

All ion guides can be used as ion stores, if closed at both ends by ion reflecting means, e. g., by a double spiral wall, or simply by an aperture.

Double Cylindrical Electrode Electrostatic Ion-guide for API-MS

Yasuaki Takada, Takayuki Nabeshima, Minoru Sakairi and
Hideaki Koizumi

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo 185, Japan

In atmospheric pressure ionization (API) for liquid chromatography/mass spectrometry (LC/MS), a solution is sprayed by a nebulizer and sample molecules in the solution are ionized at atmospheric pressure. The ions are introduced into a vacuum region in which a quadrupole mass spectrometer is located. In this API method, however, large droplets are also produced by the spray and flow into the vacuum region. When these droplets travel through the mass spectrometer, they are a major source of random noise. Therefore, to improve the sensitivity by eliminating the droplets through diffusion, the mass spectrometer is located far from the ion sampling aperture that introduces the ions and the droplets into the vacuum region, and an ion transport system is constructed between the aperture and the mass spectrometer. To provide easier transport of the ions, we have developed a novel electrostatic ion-guide (EIG) that consists of two cylindrical electrodes positioned coaxially with each other.^{1,2}

Figure 1 shows an image of the EIG. Rectangular openings are formed in the inner electrode, and their angular position alternates by 90° with respect to the preceding opening in the axial direction. The outer electrode also has openings to evacuate the interior of the inner electrode. When a potential difference is applied between the inner and the outer electrode, an electric field penetrates into the interior of the inner electrode through the openings. Therefore, the EIG is expected to have almost the same characteristics as a series of Einzel lens but only uses the two electrodes. Our preliminary results show that an EIG (20-cm-long, 15-mm-i.d.) provides ion transport efficiency of 97%.²

A more effective way to prevent the droplets from reaching the mass spectrometer, though, is to position the center axes of the sampling aperture and the ion entrance opening of the mass spectrometer so that they are offset from each other. In this case, the EIG is used to deflect the ions toward the entrance. This ion-optics configuration is called an "Offset-EIG" (Fig. 2). When the offset distance between the axes was set to 4 mm, the S/N ratio was improved by a factor of ten when using a 10-cm-long, 20-mm-i.d. EIG.

The use of an EIG is a promising technique because the sensitivity of the API-MS can be improved by using only two electrodes, allowing the simple construction of a highly sensitive LC/MS for wider application to biological and environmental analysis.

Acknowledgments We are grateful to Mr. Yoichi Ose and Ms. Kiyomi Yoshinari for their helpful discussions concerning the ion trajectory.

AN IMPROVED ION GUIDE INTERFACE FOR ELECTROSPRAY LC/MS

Alex Mordehai and S. E. Buttrill, Jr.
 Varian Associates, Ginzton Research Center
 3075 Hansen Way
 Palo Alto, California 94304

The sensitivity of electrospray LC/MS is determined by many factors, but one of the most important is the efficiency of transporting ions from atmospheric pressure into the vacuum of the mass spectrometer. The separation of ions from gas at high pressure with electrostatic fields is difficult because of aerodynamic drag. Under viscous flow conditions, the ions are swept along with the gas, but the viscous forces on the ions are strongly pressure dependent.

The conventional API interface is axially aligned, providing a direct path for the neutral jet from atmospheric pressure into the mass analyzer vacuum chamber. It is possible for microdroplets to pass through the differential pumping regions of the interface into the high vacuum. As a result, the performance of the mass analyzer can be effected by the high pressure and become dependent on the electrospray conditions and sample flow rate.

We have constructed a new interface for our ion trap time-of-flight mass spectrometer described last year [1]. In the new design, the ions are separated from the neutral jet as soon as possible. The jet from the capillary is directed into an rf hexapole at an angle so that the gas beam can pass through the rods and the rf field can deflect and confine the ions. Compression of the ion beam toward the center of the hexapole is achieved through collisions with gas molecules in the hexapole chamber. The fact that the ion phase space is compressed along with the physical size of the ion beam allows more of the ion beam to be transmitted into the ion trap compared to what would be possible with electrostatic ion optics.

Figure 1. Schematic diagram of the new API interface.

Figure 1 shows a schematic diagram of the new interface. The rf hexapole has a characteristic radius of 2 mm and operates at 1 MHz and about 200 volts. The rf ion guide also serves in place of a skimmer as a differential pumping restrictor between the interface and the ion trap vacuum chamber.

The first version of the interface was built with the axis of the heated capillary axially aligned with the axis of the hexapole. The upper trace in Figure 2 shows the dependence of the pressure in the TOF chamber on the liquid sample flow rate into the electrospray ionizer. After modification of the interface to send the gas jet from the heated capillary into the hexapole at an angle, the pressure in the TOF chamber was decoupled from the sample flow rate, as shown by the data in the lower trace of Figure 2. The axially aligned design apparently allows a portion of the high pressure gas jet to pass through the first three chambers into the TOF chamber. This jet may include particles and liquid droplets as well as evaporated solvent. The new design is successful in eliminating the effect of solvent flow on TOF vacuum chamber pressure.

Sensitivity with the new interface is about 10 times better than previously [1], although because of other unavoidable changes to the mass spectrometer, we were unable to make a direct comparison. Figure 3 shows the result of a flow injection sensitivity test using 1 pg of reserpine (MW=608) in injected into a flow of 200 microliters per minute of 50:50 methanol:water containing 1% acetic acid. The signal to noise is about 5. In this experimental system, the baseline is composed of both electrical and chemical noise.

Figure 2. Vacuum performance.

Figure 3. Flow injection 1 pg reserpine.

Neither is subtracted from the data in Figure 3.

The new interface has better vacuum performance and better sensitivity compared to earlier designs.

The formation of the ion beam is an important process in any gas-dynamic interface. It is possible to improve the beam quality by passing it through an RF multipole operating at relatively high pressure [1,2]. Last year we reported the first results obtained with a small RF quadrupole installed in the gas-dynamic interface of our ESI-TOF mass spectrometer [3]: both sensitivity and resolution were improved, and mass discrimination was minimized [4]. Here we describe the results of recent theoretical and experimental studies of ion motion in the RF-quadrupole ion guide.

A theoretical model of the RF-only collisional multipole ion guide can be based on the calculation of frictional and random thermal interactions of ions with the buffer gas. We have shown on the basis of a hard sphere model that a formalism describing Brownian motion in the RF electric field is applicable within the energy and mass range of interest. Analytical formulae have been derived describing the time and space characteristics of the ion energy dissipation, the time dependent space distribution of thermalized ions and the asymptotic radial distribution of the ion beam [5].

A corresponding computer program (IBM PC) has also been developed for numerical calculations. The program allows investigation of the ion motion in the collisional quadrupole ion guide for various parameters of the system: ion mass, charge, initial energy and position, RF frequency and amplitude, dimensions of the ion guide and, finally, the buffer gas parameters: pressure, temperature, molecular mass and flow speed. All the parameters can be changed interactively to allow fast estimation of the various modes of ion guide operation. Fig.1 illustrates the results (trajectories) obtained with the program for ions of mass 5000 Da and charge 4 entering the quadrupole at angles 10°, 20°, 30°, 40° and 50° with energy 20 eV. The energy dissipation path is in this case <1 cm, which is less than the length of our quadrupole (3.5 cm). However, this is not the case for larger and more compact ions which require a longer path for either energy dissipation or focusing.

The main unknown parameter in the program at the time it was developed was the force driving ions along the axis of the quadrupole; ions were assumed to drift together with the gas at a constant velocity of ~50 m/s. To estimate the real average velocity of the ions and to investigate factors determining this velocity, the distributions of time delays for different ions passing through the ion guide were measured experimentally. A focusing ring electrode installed ~3 mm upstream from the first skimmer was used for gating ions: a short positive pulse was applied to the electrode with the frequency 100 Hz to let ions in, while between the pulses ions were repelled by a negative potential. Spectra were recorded at a frequency of 3333 Hz, so 33 spectra per gate pulse contributed to the measured delay distributions. The average time measured for several peptide and protein ions with masses from 1347 to 66,500 Da turned out to be nearly the same: 1.1±0.1 ms. However, this time increased substantially when the 'pulling' voltage at either end of the quadrupole was decreased to zero (Fig.2), indicating that the axial ion motion is provided by penetration of the DC electric fields into the quadrupole. Note that this penetration is possible due to a small length of our quadrupole.

A longer residence time of ions in the quadrupole may result in undesirable chemical reactions: formation of adducts and/or charge transfer. Both types of processes have been observed in our instrument when the buffer gas contained impurities; with a pure gas they can be also observed when the residence time is artificially increased by decelerating ions at the exit of the quadrupole (see Fig.3).

The Mass Spectrometry Internet Site - Experiences of the First Year

Bostwick, David E.; Shealy, Sarah J.; Busch, Kenneth L.
School of Chemistry and Biochemistry
Georgia Institute of Technology
Atlanta, GA 30332-0400

The Usenet newsgroup sci.techniques.mass-spec was created in June 1995. The purpose of the newsgroup is to provide a forum for the discussion of topics related to mass spectrometry, and especially to allow mass spectrometrists to receive prompt assistance with questions or problems. Topics of discussion have included advice on instrument purchases, requests for information on hardware and software, and suggestions of procedures to accomplish a task.

Figure 1 shows the geographic distribution of the origin of the postings to the newsgroup. Of the postings from the United States, approximately 50% came from academic institutions, 40% were from companies, and 10% were from government laboratories.

The topics discussed are shown in Figure 2. The majority of topics discussed were requests for help with hardware or software problems, instrument comparisons, meeting announcements, suggestions of procedures, and help with spectral interpretation.

The value of the newsgroup as an information resource is illustrated in Figure 3. Of the messages requesting information, 62% received at least one response in the newsgroup, and many received several. Some also received responses by electronic mail. Most responses were received within a day or two. An answer to a question might come from someone halfway around the world, demonstrating the world-wide impact of the newsgroup. Even if a user has no access to Usenet newsgroups directly, the addition of a listserver allows anyone with an e-mail address to take part in the discussions, both sending and receiving postings. An archive of past postings is available at Georgia Tech and at several other sites.

A newsreader program is required to access the newsgroup directly. If the group is not already active, use the "go" or "search" features to locate sci.techniques.mass-spec, and subscribe to the newsgroup when it is found. A Web browser may also be used, but will probably need a newsreader as a helper application. Point the browser to <news:sci.techniques.mass-spec>.

For those who do not have direct access to the newsgroup, articles may be submitted for posting by e-mail. The submission address is <mass.spec@gatech.edu>. To provide postings by e-mail, a listserver is maintained by John Bartmess of the University of Tennessee at Knoxville. Approximately twice each week, a file containing all new postings is mailed to subscribers. To subscribe to the listserver, send a message to <maiser@novell.chemistry.utk.edu>, with no subject, and "subscribe stmslist" in the body.

The Web page for sci.techniques.mass-spec is at <<http://www.chemistry.gatech.edu/stms/>>. This page contains links to the FTP archive of past postings, as well as links to the newsgroup's mailing addresses and to the listserver. The Web page will be updated regularly with additional links.

An Internet Accessible, On-line Ion trap Mass Spectrometer for Collaborative Research¹

John M. Price², Michael V. Gorshkov³, Jefferey A. Mack and Bruce Rex
Pacific Northwest National Laboratory, P.O. 999, Richland, WA 99352

The next generation of collaborative research instruments will integrate software for remote instrument monitoring and control across wide area networks (WANs) with tools for sharing data and working effectively with remote collaborators. This technology promises to help scientific research efforts in a number of ways: providing better access to one-of-a-kind or specialized instrumentation, the capability to work with instruments in hazardous or inaccessible locations and giving researchers unprecedented access to experimental data and local expertise. Building instruments of this type requires that technical challenges in many areas be overcome including: instrument and local operator safety, data and instrument security and human factors central to working together effectively without being in the same location.

Figure 1. On-line Instrument System Architecture analysis system.

¹ This work was supported by the Laboratory Directed Research and Development program at Pacific Northwest National Laboratory (PNNL) and by the Division of Chemical Sciences, Office of Basic Energy Sciences, U. S. Department of Energy. Pacific Northwest National Laboratory is operated for the U.S. Department of Energy by Battelle under Contract DE-AC06-76RLO 1830.

We present a working prototype for this future class of instrument in the form of an on-line RF trap mass spectrometer designed to be run from across the Internet. The on-line RF trap mass spectrometer is one focal point in Pacific Northwest National Laboratory's "Collaboratory" (collaborative-laboratory) project and integrates tools for video conferencing, network data storage and retrieval, a World Wide Web (WWW) based electronic notebook system and other network group ware with a remote data acquisition and

Figure 1, shows the overall system architecture in schematic form. Instrument control is mediated by a server process on a local laboratory computer. This system is responsible for handling data acquisition, evaluating user settings of instrument parameters, and transmitting information back to the remote instrument client application across the network. Scientists making use of the instrument communicate with the server via the client application interface which can be located virtually anywhere. Through the client, the researcher may acquire data, change instrument settings and manipulate a remote controlled laboratory camera system used with video conferencing software to interact with scientists at the laboratory site. Once data has been acquired from the instrument, the remote client can automatically save a copy of the data and metadata about the experiment to the EMSL network data archive system. This information including system settings, operator comments and data acquisition parameters is stored in a flexible object oriented database for later searching and retrieval.

Coupled to the database is a library of routines for communication with the system using a World Wide Web based interface. Figure 2 shows the prototype electronic "notebook" system developed for the project which allows the user to search through

experiments stored in the database and view web pages generated dynamically in response to the queries. Because the database is integrated with the client data acquisition software, data taken by the instrument is immediately available on the Web for viewing / download by collaborators.

Future work will extend the web-based approach used in this study to provide a Java based interface to the instrument server as well as to the data archive system. This will have the advantage of cross platform compatibility as well as enhanced security for the instrument and data.

Extension of the TICfilt Data Treatment Algorithm to Separation/MS Techniques

A. Carrier, D. Zidarov and M.J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montréal, Montréal, Canada, H3C 3J7

The development of hyphenated systems including mass spectrometry with techniques such as gas chromatography (GC), liquid chromatography (LC), supercritical fluid chromatography (SFC) and capillary electrophoresis (CE) has considerably increased the range of compounds that can be analyzed by mass spectrometry. These combinations retain the selectivity, specificity, universality and sensitivity associated with each technique while offering additional advantages. However, a problem encountered in these techniques, that affect compound identification, is the contribution to the total ion chromatogram (TIC) and mass spectra from background sources in the mass spectrometer, the column and mobile phase. The presence of background signal can lead to problems in the analysis of unknown samples. Recently, a computer algorithm, TICfilt, has been developed in order to eliminate the often overwhelming background signal generated in LC/MS [1-3]. This background treatment allows the detection of weak elution peaks in the TIC and provides analyte mass spectra free of background ions, often making compound detection and identification straight-forward. In order to broaden the scope of application of TICfilt for data treatment, the algorithm has been applied to different separation/MS data sets such as those obtained in SFC/MS and GC/MS.

Most of the SFC/MS introduction systems allow the eluent to enter partly or totally into the ion source. Therefore the eluent (CO_2) and organic modifiers present in the mobile phase can be ionized. Thus, SFC/MS data, share a common feature with the LC/MS data sets which is the presence of high levels of background signal than can create difficulties in the interpretation of the results. Figure 1, which corresponds to an injection of caffeine analyzed by SFC/MS illustrates the high level of noise associated with SFC/MS data. As shown in the original MS (Fig 1A) the peak of caffeine at m/z 195 is accompanied by heavy background associated to the mobile phase (CO_2/MeOH) and also acetone which was used as the injection solvent. As for the treated spectrum (Fig 1B) the background peaks have been eliminated and a major ion corresponding to the protonated caffeine is easily observed at m/z 195. As for GC/MS, the background intensity is less than SFC or LC but many more interfering ions are present. As a consequence of that interference, the noise produced in GC/MS is mainly due to the inherent noise associated with the ion multiplier quality and also spectrum quality can be degraded as a result of changes in chromatographic conditions, such as carrier flow rate and column bleed during an analysis. Mass spectra of detectable or undetectable analyte peak in the TIC can often be dominated by chemical noise which results in difficulties in analyte detection and identification. For example, Figure 2, corresponds to the EI mass spectrum of phenanthrene analyzed by GC/MS. In the original data (Fig 2a) the peak of phenanthrene at m/z 178 is accompanied by many background peaks. A comparison of the original data with a library spectrum [4] (Fig. 2c) shows the presence of heavy background that can lead to

the misinterpretation of the spectrum. However, the treated data, shown in Fig. 2b), clearly reveals the presence of phenanthrene at m/z 178. Furthermore, the treated spectrum is directly comparable to the library spectrum. The background treatment performed by the algorithm, TICfilt, has been shown to be a powerful and essential tool in the elucidation of separation data. Through examples presented involving SFC/MS and GC/MS analysis, TICfilt has shown the ability to reveal weak elution peaks lost in the background in the original data and an applicability to the identification of unknown compounds.

Data-Controlled Modification of the Chromatographic Time Frame Using Feedback Flow Modulation

Douglas C. Stahl, Michael T. Davis, and Terry D. Lee
Beckman Research Institute of the City of Hope, Duarte, CA 91010

Introduction and Purpose

We have previously described the development of a low flow HPLC solvent delivery system controlled by a mass spectrometer data system [1], and an expert system that uses incoming mass spectral data to set and modify acquisition parameters in real-time [2]. Additionally, we recently reported the development of a microscale electrospray interface for on-line LC/MS/MS analyses [3]. A unique feature of this interface is the ability to maintain signal intensity and acceptable chromatographic separation while rapidly reducing HPLC effluent flowrate as eluting components are detected by a mass spectrometer [4]. This "peak parking" phenomenon significantly extends the time that eluting components are available for mass spectral analysis. The goal of this work was to integrate automatic "peak parking" into the rule base of our expert system to further reduce sample consumption and increase the information obtained in each LC/MS/MS analysis.

Materials and Methods

All mass spectrometry was performed on a Finnigan MAT (San Jose, CA) TSQ 700 triple quadrupole mass spectrometer equipped with a Finnigan MAT electrospray ion source modified for microelectrospray as previously described [4]. The electrospray source was coupled to a gradient capillary HPLC system built by the authors [1]. Both the mass spectrometer and HPLC system were controlled by a Digital Equipment Corp. (Merrimack, NH) DECStation 5000/240 computer running Finnigan ICIS data system software version 7.2. Programs for data acquisition and instrument control were developed by the authors using Finnigan Instrument Control Language (ICL) version 7.27. The analog output line (UO1) on the TSQ 700 was connected to an ISCO (Lincoln, NE) high pressure syringe pump operating in a voltage-controlled mode. Feedback flow modulation was achieved by programming the mass spectrometer data system to adjust this voltage in response to real-time changes in spectral information. Precursor ions were automatically selected for collision induced decomposition (CID) analysis by the computer based on previously described criteria [2].

Results

Integration of feedback flow modulation with our existing expert system has provided a variety of benefits. A data-controlled LC/MS/MS analysis was performed on 500 fmol. of a standard digest mixture. The data system was programmed to "park" on each eluting component. Once parked, a maximum of 8 CID spectra were collected at the standard collision energy of -17eV. If the signal remained stable, additional CID spectra were collected while increasing the collision energy 0.25 volts per scan. An example was shown where the mass spectrometer "parked" on a peptide, and collected 50 CID spectra while gradually increasing the collision energy from -17eV to -28.5eV. The collision energy gradient serves two purposes. Different regions of the CID spectra were enhanced at different collision energies. Additionally, the spectral instability resulting from eventual over-fragmentation of the peptide was used as a signal to terminate the CID analysis and return to Q1MS precursor ion scanning.

In another experiment, 500 fmol. of the standard digest mixture was analyzed by automated LC/MS/MS using feedback flow modulation. A representative segment of the HPLC pressure profile and reconstructed ion chromatogram are shown in **figure 1** on the following page. The 12 numbered events in the HPLC pressure profile are explained as follows:

Figure 1
HPLC Delivery Pressure (psi)

In response to a precursor ion detected at (1), the system "parked" and collected 9 CID spectra on a doubly charged peptide. While the HPLC system was still "parked", a single precursor scan detected another peak at (2), and collected 10 CID spectra for the singly charged species of the same peptide. The system then performed two additional precursor scans to search for additional components (3). When none were found, two additional precursor scans were performed at 50% of normal HPLC delivery pressure (4). No new peaks were observed in the interface. Consequently, the normal HPLC running pressure was restored (5) until the next peak was observed (6). Events (7) through (12) describe the automatic acquisition of MS/MS information for multiple charge states of a different peptide in the same digest mixture.

Automatic feedback flow modulation (peak parking), combined with other automated procedures, can be used to prolong the analysis of user-defined subsets of components observed during tandem microspray LC/MS/MS analyses without seriously affecting signal intensity or chromatographic separation.

Study on Polychlorinated Terphenyls Using GC-coupled Methods and Multivariate Analysis

A Nikiforov¹⁾, G Remberg (jr)¹⁾, P Sandra²⁾ W Nyiry³⁾ and N. Winker³⁾

¹⁾ Inst Org Chem, Univ Vienna, Währingerstr 38, A-1090 Vienna, Austria,

²⁾ Research Institute for Chromatography, Kennedy Park 20, B-8500 Kortrijk, Belgium,

³⁾ Allgem Unfall- Versicherungsanstalt (AUVA), Adalbert Stifterstr. 65, A-1200 Vienna, Austria

Today, the analysis of polychlorinated biphenyls (PCB) has become an established method in many countries, and the problems associated have extensively been investigated. By contrast, the determination of polychlorinated terphenyls (PCT) is still an unsolved problem. This study therefore investigates the analytical potential of coupled methods GC/(+EI-LR and HR)MS, GC/FTIR GC/MS/MS) and of multivariate evaluation of the resulting data for the selective detection of PCTs.

PCT: Distribution of isomers

Fig.1. Calculated distribution of 8557 PCT isomers

At first, the overall number and the distribution of possible PCT- isomers were calculated and the resulting structures were imported via .SDF file in ISIS/BASE to check independently for isomorph structures. The total possible 8557 PCT isomers separate in three classes of 3239 ortho-, 3279 meta- and 2039 para-terphenyl derivatives and constitute therefore even as a family of their own a non-soluble problem for any analytical separation. The next task at hand was therefore to prove, if at least the partial separation of PCB and PCT compounds, or of PCTs according to their degree of chlorination is possible. Using 14 commercially available single PCT standards, the retention times were determined on four GC-phases. However, neither the capillary columns (HP-Ultra-1, HP-5MS, RSL-300 and Polycarbonate), nor the LC aminopropyl silane column used enabled the desired partial separation of the components of commercial PCB (Aroclor 1260) and PCT (Aroclor 5432 and 5460) mixtures. Moreover co-elution of PCBs and PCTs was always the rule. In the following the GC-coupled spectroscopic data of PCT standards were evaluated in terms of classical ion profiles and selected wavelength chromatograms. However using data of complex mixtures, like Aroclor in oil matrix, the limits of this classical procedure soon became obvious

As an alternative approach, the multivariate cluster analysis of the GC/(LR)-MS, GC/FTIR and GC/MS/MS data of PCT standards was carried out and showed the principal possibility of the separation of the (LR)- (EI)-MS data of PCTs into four to six structural types and the less pronounced separation of IR data into approx. five different types. In no case, however, full separation of PCB and PCT components was achieved.

Comparison of ion profiles for different chlorination degrees (Cl-5 -Cl-8) of PCT in a PCB/PCT mixture

Fig.2: Comparison of PCT ion profiles

Though the GC/MS-MS data proved to provide more specific information, its use can not be recommended because of the variety of experimental settings to be defined. The best results, however, were obtained using multivariate correlations of full scan high resolution EI-GC-MS data. **EXPERIMENTAL.** The GC/MS/FTIR data were registered in a serial arrangement of IR and MS (HP-5965 IRD and 5970C MSD), GC-MS(LR) and GC-MS/MS using a Varian Saturn 3 Ion Trap and GC-MS(HR) (R= 7000, cyclus time 0.5 sec, 50-700u) with a Finnigan MAT 95S mass spectrometer. The recorded data was converted into own data arrays for subsequent data processing. Isomers computation: structure generator MOLGEN V 3.0 plus (Chemical Concepts, Weinheim, BRD) in combination with MDL Information Systems ISIS BASE V. 2.0. All calculations were made as desktop applications using VOBIS Highscreen P133 Pentium PC. For multivariate correlation of second and third order data sets own programs were used.

Fragrance creations analysis using semiautomatic spectra(MS,IR) interpretation and olfactive data

A.Nikiforov¹⁾, Marion Reich¹⁾, L.Jirovets²⁾, G.Buchbauer²⁾ and S.Körnig³⁾

- 1) Inst.Org.Chem., Univ. Vienna, Währingerstr 38, 1090-Vienna, Austria,
- 2) Inst.Pharmac.Chem., Univ. Vienna, Althanstr.14, 1090-Vienna, Austria,
- 3) ChemicalConcepts GmbH, Boschstr 12, D-69469 Germany

In perfume creation a complex system of components exhibiting distinguished olfactory properties is involved, however the resulting scent impression can be a priori hardly predicted. The components used in turn may constitute either low price synthetic products (e.g. monoterpene compounds like limonene or linalool) or again consist of high value complex natural systems (e.g. essential oils). In this respect the aim of presented study was to find out if there is a possible prediction or correlation of resulting perfume attributes on the basis of instrumental analysis data alone, and if a comparison of complex full GC-MS data sets carried out via semiautomatic procedures is possible.

In the first part of this work as starting material a primary basic set consisting of 30 commercially available odor compositions (as basic materials for fragrance creations) was selected and analyzed with respect to components involved by means of GC-coupled methods (GC/MS/FTIR) and with respect to the most important olfactorically active components using the „GC-sniffing-technique“. The spectra interpretation was performed using substructure based MS-spectra libraries (NIST/EPA/NIH), PBM Bench Top spectra library, own spectra collection and semiautomatic preselection of spectral data recorded. In this way a list of approx. 50 odor intense components together with more than fifty further compounds with restricted olfactory activity was compiled.

All systems investigated were evaluated by a total of six professional perfumers or fragrance chemists (3+3) in order to determine the sample specific odor attributes. Already at this stage of this study a surprising (?) result was a high percentage of so-called „high prize“ samples investigated consisting of low prize (especially synthetic) odor components and solvating agents mainly.

Fig.1. Clustering of 30 perfume samples on the basis of projection of full GC-MS data matrices in a plane.

Subsequently with the help of the principal component analysis (PCA) and multivariate evaluation of both the components and the odor attributes, a cross correlation of resulting data was carried out. The results showed, in terms of components involved, the presence of less than ten basic compositions only.

In the next step of this work an extended set of fragrance creations consisting of approx. 100 further samples (partly also components of basic set stored at differing conditions) was investigated using arithmetic operations in comparison of chromatograms (multiplications of intensity and of time scales by a factor to achieve a compatible chromatograms, building the difference of „synchronised“ chromatograms). Also these results confirmed the tendency of the use of low priced constituents accompanied by moderate alteration only.

In the last section of this work a multivariate correlation of full extend GC-MS data sets of 30 commercial perfume samples (3rd order data set) was carried out (every full GC-MS data set was projected as point in a plane) and the resulting clusters were correlated with the clustering

Fig.2: Displacement of perfume samples on the basis of PCA of 30 odor attributes profiles.

of the corresponding olfactory profiles (on the basis of 30 attributes and PCA). The results show that prediction of dominating olfactory attributes of the group, balsamic, oriental and musty on the one hand, and of the group, floral, citrus-like and fresh on the other hand is possible in approx. 60% of the samples with high significance, and in further 30-40 % of the samples with lower significance, even when solely full GC-MS data sets are evaluated by multivariate analysis

EXPERIMENTAL. The GC/MS/FTIR data were registered in a serial arrangement of IR and MS (HP-5965 IRD and 5970C MSD). The recorded data was converted into own data arrays for subsequent data processing. All calculations were made as desktop applications using VOBIS Highscreen P133 Pentium PC. For multivariate correlation of second and third order data sets own programs were used.

Finding Target Analytes in Complex GC-MS Data Files from Screening of Textiles for Azo-Dyes

Peter Kesners and Manfred Mayer
ecb-ONLINE Analysentechnik GmbH
Hagenower Str 73, 19061 Schwenn, Germany

Peter Sander
Bruker-Franzen Analytik GmbH
Fahrenheitstr 4, 28359 Bremen, Germany

Introduction

Software packages for computerized peak detection in GC-MS data often fail in the case of minor peaks or superimposed matrix compounds that are present at high concentration. While some software is able to discuss the purity of a peak component related mass spectra are not produced. Here the operator is merely given an indication to improve his sample preparation.

The normal approach to resolve such problems generally aims at creating higher concentrated samples with time consuming additional extract clean-up and extract preconcentration by solvent evaporation.

Methods

A new semi-automated approach to detect arylamine target analytes obtained from the screening analysis of textiles assures laboratory quality and facilitates the evaluation of GC-MS data in three steps.

Step 1 processing step is performed with an extremely low peak detection threshold. This way a lot more peaks are found and thus more mass spectra are compared with the spectral library. To reduce the amount of hits a custom user database containing only the mass spectra of the target analytes is used. A report is generated which shows the compounds that produce a peak in TIC.

Step 2 is fully automated data processing with a new fuzzy logic data evaluation tool described previously (1,2). Part of this step is the automatic report generation. The automated evaluation approach has been customized to detect semi-volatile arylamine target analytes obtained from the screening analysis of textiles. A fuzzy logic spectral separation algorithm is used to analyse the GC-MS data for individual constituents. This algorithm is based on the determination and evaluation of the time correlated appearance of masses belonging to a mass spectrum. The resulting component related mass spectra are background subtracted and do not contain masses from superimposed substances. In the process of automated deciding on the existence of a substance in a sample such clean mass spectra are superior to spectra which are simply background subtracted. Improved match scores are obtained in library searches so that computerized automated reporting is facilitated.

Step 3 the final step employs dedicated macros to search for the ion traces of the target analytes. Here the report from step 2 is verified by the gc-ms operator. Written in the HP macro language, dedicated user defined macros allow a quick cross-checking of the fully automated data evaluation performed in step 2. Each analyte is assigned one window containing the retention time interval and three characteristic ion traces. The window is annotated with the name of the target compound. By invoking the macro, the windows for four target analytes are displayed together. Verifying a processed data file evaluation for 20 targets thus is simply a matter of invoking 5 macros.

Application

From the analytical routine operation of a laboratory for textile testing a typical example is given below. The gc-ms data are collected from a leather extract solution. The purpose of the test is to find arylamine fragments from azo-dyestuffs. Here the automated step 2 has dissected an arylamine target compound from a superimposed matrix of hydrocarbons.

Fig. 1: GC-MS of greasy leather extract

Conclusion

The evaluation of GC-MS data can be a time-consuming and error prone task. To decide on the presence of an analyte in a sample a new threefold approach is shown. While the tedious report compilation is automated with "state of the art" software an operator is given powerful tools to verify the correct reporting of gc-ms analyses.

This approach has proven to be an efficient way to evaluate large numbers of gc-ms data files.

Mass Spectral Identification Using Substructure Information Generated from Library Searches

O. David Sparkman

O. David Sparkman & Associates, 4045 Eagle Ridge Drive, Antioch CA 94509

Soon after the development of the first mass spectral data system, databases of electron ionization (EI) mass spectra for the identification of compounds whose spectra are contained in these databases came into use [1]. Because "mass spectrometry deals with the mass of the molecule and the mass of the pieces of the molecule" [2], numerous attempts have been made at either predicting mass spectra of organic molecules or interpreting mass spectra with rule-based computer systems [3]. In a recent publication by Stein at NIST [4], an optimized algorithm for use with the NIST Mass Spectral Search Program for Microsoft® Windows™ and the NIST/EPA/NIH Mass Spectral Library was reported. This study involves the use of that algorithm with a series of compounds whose spectra are known not to be in the Library.

As used in this study, a substructure is any of a number of features of a molecule that includes:

- ♦ presence of certain heteroatoms
- ♦ saturated ring systems such as those found in steroids
- ♦ aromatic structures with and without attachments
- ♦ carbonyls, ketos, esters, ethers, etc.
- ♦ presence of terminal methyls and methylene groups
- ♦ sites of aliphatic unsaturation
- ♦ presence of silicon groups within the molecule
- ♦ estimation of the number of rings-plus-double bonds

These are just a few; the current implementation includes 540 different substructure features.

A unique feature of the Stein algorithm is the inclusion of the probability of the presence of substructures along with the probability of the absences of specific substructures. Just as the obvious absence of X+2 (except for oxygen) in an isotopic cluster of peaks aids in the determination of an elemental composition of an ion from these data, the absence of certain substructures can aid in the identification of a compound that produced a mass spectrum.

As implemented in the Structure Information utility of the NIST MS Search Program, Version 1.5, the Stein Substructure Identification algorithm is enhanced with two other features: chlorine/bromine (Cl/Br) and molecular weight (MolW) estimators. These three features are used in conjunction with one another to gain insight into the nature of the molecule that produced the mass spectrum to be interpreted.

The substructure information is obtained through an evaluation of the hit list produced by a search of the NIST/EPA/NIH Mass Spectral Library. The MolW and Cl/Br estimations result from examination of the unknown mass spectrum.

The mass spectra used in this study were obtained by using a Hewlett-Packard 5970 GC-MS interfaced with the HP-IRD. Pure analyte, in solution, was injected onto the GC column in amounts to ensure that quality mass and infrared spectra could be obtained without spectral skewing. These spectra were acquired for inclusion in future versions of the NIST Infrared Database and the NIST/EPA/NIH Mass Spectral Library.

The unknown spectra were compared with the NIST/EPA/NIH Mass Spectral Library by using the Program's Identity Search routine [5].

Valuable information, which might not be obvious from just an examination of the hit lists that resulted from an Identity Search, was obtained for all the spectra by using the Substructure Information utility of the NIST Mass Spectral Search Program. In some cases, high-confidence identification of compound structures was possible. Other cases would require additional information that may not be obtainable even with an exhaustive interpretation of the spectrum.

Automated Determination of the Consistency of Mass Spectra and Chemical Structure
Robert Mistrik and Stephen E. Stein
National Institute of Standards and Technology, Gaithersburg, Maryland

The goal of this work was to develop a computer-based system that predicts possible reaction pathways from chemical structure for molecules ionized by electron impact. The inability to predict energies and barriers in ionized molecules prevents the prediction of mass spectra. However, a comprehensive set of known reaction mechanisms allows prediction of possible fragmentation and rearrangement reactions. The predicted ions and their m/z -values can be used for checking the consistency of a chemical structure with its mass spectrum. Such consistency checking can be of value in establishing the identity of a compound from a measured mass spectrum.

This system (see figure) attempts to find plausible unimolecular ion reactions on the basis of general fragmentation rules and rearrangement reactions. Using these constraints, the system generates all available elementary reaction steps for given molecular structure. For each product ion, available reaction channels may be displayed in complete structural detail. After generation of possible ion reactions, plausible product ions ("explained" peaks) in the input spectrum are displayed in the original mass spectrum. Selecting an explained peak reveals all pathways leading to it. Inspection of the mechanism can be used to judge its reasonableness in view of the observed intensity. An unexplained peak can be an indicator for inconsistency of given spectrum with proposed structure. In some cases (for instance H-rearrangement) this system can generate too many reactions because there are a lot of formal possible solutions especially for "bigger" structures. To avoid a combinatorial explosion in similar cases, the individual fragmentation and rearrangement types contain a flexible set of reaction restrictions. Results of applying these methods to an input chemical structure are shown graphically, allowing the display of reaction pathways. For this purpose algorithms have been developed that solve problems of linear mechanism topology and methods to depict ion-radical reactions. The presented system provides a useful tool for evaluating mass spectral data. This software may be also viewed as a novel contribution to computer based methods of spectra elucidation. For any problem involving mass spectral interpretation, the system can assist by identifying the

most easily explained fragments and pathways and focusing attention of the less common pathways. It may also find application for educational purposes for illustrating structure-spectral relationships in graphical detail.

This software is still under development. We are primarily engaged in extending its application to increasingly diverse classes of chemical structures.

Software for automated generation of rearrangement and fragmentation reactions

Effective/Efficient Searching of Multiple EI Libraries on Hewlett-Packard Data Systems

J. L. Little
Eastman Chemical Company
Kingsport, TN 37662

Stanton Loh and Doug Stauffer
Palisade Corporation
Newfield, NY 14867

Introduction: Eastman Chemical Company routinely employs 28 Hewlett-Packard GC/MS's to identify unknowns in mixtures. These instruments employ a variety of electron impact mass spectral libraries including the NIST (75K spectra, 60K structures), the Wiley6 (230K spectra), and our proprietary (30K entries, 17K structures) data bases. Neither the HP DOS/Windows or HP UNIX data systems effectively or efficiently search multiple data bases. This severe limitation is overcome by combining the mass spectral libraries to be searched. This is demonstrated by creating a combined mass spectral library of 334K entries from the NIST, Wiley6, and the Eastman Chemical Company data bases. Both the Hewlett-Packard UNIX and DOS/Windows software packages do a very good job of searching this large data base. Searching with the HP DOS/Windows data system yields both spectra and structures with the search results. The HP UNIX system yields only spectral matches with the results. The method for producing combined data bases and incorporating user structures in structural data bases is shared in this poster session.

Creation of HP JCAMP (HPJ) Files. Our data base is maintained on a VG OPUS data system with structures in SMILES format. The VG specbase program is used to export the files over the network in netCDF format to a PC. The files are then converted to HPJ format (Hewlett-Packard Company's ASCII format) using MassTransit software. The VG data format has many user text fields (chemist, location, date, laboratory, etc.) which are not found in the HPJ format. These fields are merged into the ##SAMPLE DESCRIPTION field in the HPJ file using C programs written at Eastman Chemical Company.

In order to get our structural information displayed with the HP search results, "pseudo-CAS" numbers are assigned to all our entries. The SMILES structures for our entries cannot be entered directly into the HPJ data file. No "real-CAS" number is less than 50-00-0 or 50000. Therefore, our entries were given a unique "pseudo-CAS" number starting with 1, but not greater than 49999. These "pseudo-CAS" numbers are used to cross-reference and display our structures with the library search results. Our structures in SMILE's format or converted/transferred to a file in MOL format for use with the Hewlett-Packard DOS/Windows data systems (see later section on Structural Database).

Creating Combined Libraries: The HPJ files containing user information and "pseudo-CAS" numbers must be converted to HP binary files. These binary files can then be used to perform data base (library) searches on both the HP UNIX and HP DOS/Windows systems. They are identical on both systems with only minor differences in file names.

Three different approaches were used to convert the HPJ files to HP binary files. They included adding the HPJ files: 1) with the HP DOS/Windows software, 2) with the HP UNIX software, and 3) with the Palisade MassTransit software. Only the latter approach was viable for converting large HPJ ASCII files. The MassTransit software (newest Release, Jan. 1996) contains software for converting HPJ ASCII files to HP binary files. Also, the MassTransit software can convert HP binary files such as the Wiley and NIST data bases to HPJ ASCII files. The DOS editor can be used to combine any number of HPJ ASCII files into one large HPJ ASCII file. This combined file is then converted with MassTransit software to a HP binary file that is searchable with the HP software.

The HP binary files created with the MassTransit software can then be used to perform data base (library) searches on both the HP UNIX and HP DOS/Windows systems. They are identical on both systems with only minor differences in file names. The full spectrum file is not required (full.d on DOS/Windows, FULL.d on UNIX) on either system for searching the data base. On older UNIX systems with small disk drives, the FULL.d file was not included. The FULL.d on UNIX and the full.d file on DOS/Windows is only displayed after the search is performed for a visual comparison by the user. It is desirable to include the full.d or FULL.d if disk space is available.

Structural Database: Our structures were initially created in the SMILES format. They had to be converted to MOL format to be used in the HP DOS/Windows software. The HP software first does the library search to identify the library match. If the library match has a CAS number and a structure is associated with the CAS number, the structure is displayed with the library result. The structures are located in the database directory in files with extensions .ind and .sdb. These files, ecc.sdb and ecc.ind, must be created from our SMILES entries. The creation of our structural data base employed C programs written at Eastman Chemical Company and a macro written for the Hewlett-Packard DOS/Windows software, and ConSystant program (Exographics Company). The molstruc.sdb and molstruc.ind are available with the HP system and contain structures for the NIST library. These structures are also displayed with the Wiley Library since the latter library also contains CAS numbers.

Summary: The approach described permits the sharing of our Corporate Data Base of approximately 30,000 entries and 17,000 structures with all our Hewlett-Packard DOS/Windows users. It also permit effective and efficient searching of multiple data bases. The sharing of this data greatly facilitates the identification of unknowns by minimizing redundant work and sharing mass spectral expertise accumulated over the years. A complete description of the process and C programs written at Eastman Chemical Company is available.

ALIS: A New LCMS Pharmaceutical and Agrochemical Data Report Writer

I. D. Tabani,
Innovative Automation, Sacramento, CA 95823

J.W. Cornacchia,
R.A. Bethem,
Alta Analytical Laboratory, El Dorado Hills, CA 95762

The use of high speed automated analytical procedures such as LC/MS/MS in support of FDA/EPA data submissions has markedly increased over the past five years. Instrument through-put can easily exceed several hundred result records per analytical run creating the need for software capable of performing real-time post-acquisition data processing and report generation. LCMS based pharmacokinetic reports and field dissipation reports are typically method or protocol specific requiring a high degree of flexibility in the design of the report writer software. *ALIS*, a windows based LCMS report writer, allows the creation of study specific sample log-in screens, electronic benchsheets, and report forms customizable through an extensive set of user utilities. The *ALIS* report writer currently supports automated data transfer from two instrument platforms: the Finnigan XSQ 700/7000 and the Sciex API 3/300.

ALIS employs two template builders to facilitate the collection and processing of data based on study specific requirements. Method templates are created that dictate sample preparation and instrument operation parameters. Post-acquisition quantitation options are also assigned to the method template including the type of calibration curve fitting, sample response types and any result correction factors that will be applied to the data. The use of method templates greatly reduces laboratory errors due to method deviations and promotes the generation of a uniform study database.

To accommodate as many study types as possible, the *ALIS* user interface allows the alteration of the underlying sample descriptor database structure by the user. Allowing the user to create study specific sample log-in templates has enabled a high degree of flexibility in the back-end grouping and sorting of analytical results. Post processed data can be stored in MS Access, Oracle or any RDBMS capable of supporting ODBC. In the case of MS Office based *ALIS*, results data sets can be queried from Access using SQL, stored query definitions or through the interactive use of the MS Access Query Builder. Sample descriptors are used as query parameters or criteria to group the data according to the required final report table formats. Data tables can be created directly from the queries and/or by importing the data sets into Excel, Word or Crystal Reports for final processing. Electronic deliverables can be created in most popular file formats using the file export capabilities within the above third party report writers.

ALGORITHMS OF AUTOMATED PEPTIDE SEQUENCING USING PARTIAL ACID HYDROLYSIS

M. Klint, R. Zubarev, P. Håkansson and B.U.R. Sundqvist
Division of Ion Physics, Department of Radiation Sciences,
Uppsala University, Box 535, S-751 21 Uppsala, Sweden

Two different approaches can be implemented in mass spectrometry for sequencing of peptides. The first one uses fragmentation of molecular ions in a mass spectrometer, while the other one involves chemical degradation of the sample molecules prior to mass spectrometric analysis. The simplest wet-chemistry technique to fragment a peptide is partial acid hydrolysis. In a combination with novel mass spectrometric methods it is proved to be a powerful technique for sequencing small amounts of small- and average-size peptides [1].

The mass spectra of hydrolysates often show remarkable ladder-like patterns allowing one to establish directly at least a partial sequence. More efficient, however, is to employ a computer processing of the data. Direct permutation of all possible sequence combinations leads to a combinatorial explosion of the number of such combinations, making analysis unacceptably time-consuming for peptides longer than 10-12 residues. For example, to the molecular mass 1076.57 ± 0.10 Da, there are $\approx 1.6 \cdot 10^{10}$ various sequences of linear peptides containing only the 20 most abundant amino acids.

On the other hand, limiting the area of search can cause an omission of the correct sequence. The contradiction can be overcome by an algorithm that restricts the search area in a safe manner, i.e. without the risk to omit the correct answer (algorithm 1). The other approach is to check first more plausible combinations, gradually progressing towards less plausible ones until the user is satisfied with the best solution found at the moment (algorithm 2). The algorithm 2 should be capable, if necessary, of performing the total permutation ensuring the complete search. The task is, therefore, to construct the criteria for the progression of such an algorithm.

The input for both algorithms is a list containing the monoisotopic masses of molecular ions of hydrolysis fragments, and the corresponding relative intensities. The masses are measured with 10-50 ppm accuracy by high resolution TOF mass spectrometry. It should be noted, that the list might

contain "false" masses arising from sample contamination or fragmentation of the molecular ions after desorption. Even "correct" molecular ions may be of different types: MH^+ , MNa^+ or MK^+ . The first step in both algorithms is therefore to check the mass difference between the peaks and, with the help of the operator, to exclude other types of molecular ions than MH^+ .

The algorithm 1 limits the searching field by finding, among fragment masses, a pair of masses M_i and M_j that satisfy the following equation:

$$M_i + M_j - MH_2O = M_0 \pm 2dM,$$

where MH_2O is the mass of the water molecule and M_0 is the molecular mass of the intact peptide, and dM is the accuracy of mass determination [1]. It is assumed that the masses M_i and M_j correspond to two complementary hydrolysis fragments. Then all *amino acid compositions* corresponding to the masses M_i and M_j are searched and permuted. Since the number of sequences increases as factorial with the mass, reducing the permutation to two lower masses limits the search area greatly. Besides, there may be more than 1 pair of the complementary fragments which speeds up the search additionally. In the case of bradykinin, where 3 complementary pairs were found, the total search took less than 1 s on a Power PC™ computer. The success of this algorithm depends upon the validity of the complementary pairs found; the speed - upon the number of such pairs and the mass accuracy dM .

The algorithm 2 derives from the molecular masses of the fragments their amino acid compositions, and then permutes them. For every set of compositions, it checks whether it is possible to compose a peptide with a mass corresponding to that of the parent peptide. The preferable situation here is when there are many low mass fragments with overlapping sequences. On the other hand, false masses, missing fragments and repeating sequence may cause problems for this algorithm.

Both algorithms were programmed and tested on a series of peptides. The results suggest that the two algorithms are complementary to each other, and should be used in parallel. The final stage - evaluation of the validity of the results and determination of the order sequence - is still done manually. This will be a subject for future automation.

Verification of Oligonucleotide Synthesis by ESI-MS/MS Utilising a Novel Sequencing Algorithm

D.Stranz, Micromass, Inc., Modesto, CA 95350 USA

E.Kapp, J.Langridge and T.McKenna, Micromass UK Ltd., Altrincham, WA14 5RZ, UK

T.Brown and J.Langley, Dept. of Chemistry, University of Southampton, Southampton, UK.

Introduction

Recent work has shown that nucleic acids fragment in reproducible patterns by collisionally induced dissociation in a triple stage quadrupole instrument, consistent with previously reported tandem MS results [1-3]. Negative ion electrospray produces a series of multiply-charged product ions and enough fragmentation data to afford at least partial, and often complete, sequence information. The present study explores the use of ESI-MS/MS and demonstrates a novel sequencing algorithm for sequencing complete unknowns or verifying the structures of synthetic oligonucleotides.

Sequencing Algorithm

An oligonucleotide sequence can be derived principally from two ion series, **w** from the 3'-end, and **a-B** from the 5'-end [1]. The starting point for the **w** series is assignment of **w₁**, identified as the most abundant of the four possible mononucleotide ions. The starting point for the **a-B** series is assignment of **a₂-B₂** which represents the first 5' nucleotide (because of loss of **B₂**). The next in the series is identified by iterative addition of residue masses and testing for correspondence with an ion in the spectrum. Priority in deduction is assigned as follows, in decreasing order of importance:

- i) number of different charge states observed for a given ion-type;
- ii) low apparent mass error; and
- iii) greater relative abundance.

Predicted sequence ions are displayed in list format with their matched peaks, and a labelled spectrum is produced. Required input to the algorithm is the molecular weight of the oligonucleotide, its type (DNA or RNA), linkage (phosphate or phosphorothioate), termini (hydroxyl or phosphate), and charge state of the precursor ion. The m/z tolerance and threshold used for matching expected ions to spectral features can be specified to minimise coincidental matches to minor ions.

ESI-MS/MS

Synthetic oligonucleotides were analysed on a Micromass Quattro II triple quadrupole mass spectrometer equipped with an API ion source operating in negative ion mode. Samples were diluted to a concentration of 20 pmol/μl in isopropanol + 1% aqueous tripropylamine. MS/MS data were acquired by transmitting the optimised multiply-charged precursor through MS1 to the collision cell. Argon collision gas was used in the collision cell at a gas pressure of 4.7×10^{-3} mbar with a collision energy of 19eV. MS2 was set to unit mass resolution and scanned over the appropriate range.

Figure 1. ESI-MS/MS spectrum of the synthetic oligonucleotide GCGCTTAAGCGC

Rank: 1	Calculated MW 3646.42	Difference: 0.00 (matches MW)
Scores	Consensus sequence	charge 31 intensity 35509976
	a-B series	charge 16 intensity 14953992
	w series	charge 19 intensity 24156608

M = matches monomer M/Z, P = Pre-assigned residue

	M
a-B series	G C G C T T C A G A T X
	I I I I I I I I
Consensus	G C G C T T A A G C G C
	I I I I I I I I
w series	X C A C T T A A G C G C
	M

Figure 2. Sequence prediction details for GCGCTTAAGCGC

Results and Discussion

Figure 1 shows the spectrum labelled with proposed **w** and **a-B** ions up to and including the precursor ion charge and figure 2 details the scores and consensus sequence for the highest scoring sequence. ESI-MS/MS on triple quadrupole instruments can produce series ions with sufficient intensity up to 10 to 12 residues in from either the 3' or 5' ends under favourable circumstances. The practical limit on total oligonucleotide length is thus about 20 to 25 residues.

Spectral Simplification of Peptide Sequencing Data by Massive Inference

A.G.Ferrige*, B.N.Green** J.Skilling* & X.K.Zhang***

*MaxEnt Solutions Limited, Isleham, Cambs., U.K. CB7 5RX

**Micromass Limited, Altrincham, Cheshire, U.K. WA14 5RZ

***NHLBI, Bethesda, MD 20892 U.S.A.

Low resolution ESMS has become one of the standard techniques for elucidating the structure and sequence of peptides. One procedure is to select the doubly-charged molecular ion and fragment it to produce a mixture of singly- and doubly-charged fragments. The mass spectrometrists then has the painstaking and time-consuming task of interpreting extremely complex data in terms of the various a, b, c, i, w, x, y & z series so that the sequence can be determined.

The complexity of the interpretation is partly due to mass defects and the varying isotope patterns, so that as m/z increases, the observed m/z does not equate with integer masses. In addition, for poorly resolved or overlapping ions, it is often not possible to determine whether they are singly- or doubly-charged, and evidence from other parts of the data must be used to infer charge states. What is required is to simplify data so that interpretation is rather more straightforward. To this end, Massive Inference™ (MassInf) - a new probabilistic program and successor to the maximum entropy technique (MaxEnt) - has been used to deconvolve out the mass defects and the isotope patterns and to automatically disentangle the charge states and reconstruct two zero-charge spectra, respectively derived from singly- and doubly-charged ions. The mass spectrometrists is then free to use integer masses and does not have to consider mass defects, isotope patterns or charge state.

The symbolic structure of the peptide used for testing MassInf is shown below:

E-G-V-N-D-N-E-E-G-F-F-S-A-R

The top figure shows part of the data containing both singly- and doubly-charged ions (*centre trace*). The MassInf result shows an absence of species derived from doubly-charged ions in this region (*top trace*). The singly-charged species at m/z approximately 684, 723, 740, and 813 all appear in the respective zero-charge spectrum as single peaks at integer masses approximately one less than the parent m/z masses (*lower trace*). The remaining major signals at m/z approximately 759, 758, 777 and 786 are less well resolved and arise from doubly-charged ions. Their zero-charge masses will therefore appear at higher mass in the zero-charge spectrum reconstructed from the doubly-charged ions.

To illustrate the ability of MassInf to cleanly deconvolve out the isotope patterns, the central figure shows the results for ions spread around m/z 180 and m/z 1100. Although the intensity ratio in the isotope patterns is very different, MassInf reconstructs the correct zero-charge integer masses.

The bottom figure shows the complete zero-charge reconstruction (the sum of the two zero-charge results) along with the data. The expected gain in resolution from MassInf processing is apparent. Space and size do not allow the interpretation to be shown. Full details available on request to the first author.

In conclusion, MassInf has successfully removed mass defects, removed the isotope patterns, disentangled the charge states, reconstructed the zero-charge spectra on an integer mass scale and provided enhanced resolution.

Quantified ICP-MS Elemental Analysis by Massive Inference and the Identification of New Interferences

A.G.Ferrige*, D.Gregson** & J.Skilling*

*MaxEnt Solutions Limited, Isleham, Cambs., U.K. CB7 5RX

**VG Elemental, Winsford, Cheshire, U.K. CW7 3BX

Traditionally, ICP-MS analysis uses only those isotopes unique to each element, whether they be of high or low abundance. Where a total analysis is required, interferences are only resolved at high resolution. However, Massive Inference™ (MassInf) - the successor to the maximum entropy technique (MaxEnt) - uses all the data and almost all interferences are resolved at low resolution. Probabilistic errors are assigned to each species and the probability of its presence or absence is also determined. This unique treatment also allows previously unsuspected species to be identified and quantified.

In this example, the rare earths are explored in the presence of a large excess of Ba, which gives rise to a serious BaO interference. The acquired data are reduced to single intensity values at each mass, as shown in the figure below. Intensities are displayed as their *square root* to visualise weak responses. Through specifically designed firmware, Y and Y² are stored for each mass and a noise model is not required.

The known isotope pattern for each element and known molecular interference is stored in an on-line library. The relevant patterns may then be automatically called to produce a "Species Menu" for the analysis according to the acquired mass range or a specific menu may be chosen. The mixture analysed contained 20ppb each of Nd, Sm, Eu and Gd plus 5000ppb of Ba. A menu containing all species present will give errors of 2 standard deviations or less. The misfit using a menu containing the plausible elements Ce, Nd, Sm, Eu & Gd is shown at the left of the figure below. The large under-fit at 154 & 155 arises from one or more species not been included in the menu. Adding BaO improves the misfit (2nd from left) but there is still a serious under-fit at 155. Including BaOH reduces the misfit to +1.6 to -5.8 s.d. This is still excessive and adding NdO, SmO, EuO & GdO, the reduces misfit to ± 1.6 s.d.

The presence of these species and the effect of one element on another is not apparent from the misfit but MassInf answers this. The full analysis is shown in the table. "Cert" column is the certainty of an element being present and "Counts" is the found intensity, along with the probabilistic error.

Species	Cert	Counts	Correlation matrix										
			Ce	Nd	Sm	Eu	Gd	BaO	BaOH	NdO	SmO	EuO	GdO
Ce	10%	2± 6		1	1	1	-1			2	-	-7	
Nd	100%	16017±208	1		12	1		2	-1	1	-	-1	-1
Sm	100%	18024±279	1	12		3	2	36	12	1		-	-1
Eu	100%	18084±264	1	1	3		1	22	12		-	1	
Gd	100%	17693±215	-1		2	1		4	14	10	-1	1	-1
BaO	100%	4430±331		2	36	22	4		21	1			1
BaOH	100%	6955±305	-	-1	12	12	14	21		1	-1	-2	-1
NdO	100%	324± 36	2	1	1		10	1	1		12	1	-1
SmO	100%	99± 15	-	-		-	-1		-1	12		1	4
EuO	46%	8± 9	-7	-1	-	1	1		-2	1	1		
GdO	100%	182± 18		-1	-1		-1	1	-1	-1	4		

From the quantified analysis it can be concluded that Ce is absent and that EuO is unlikely to be present and these species could be omitted from the Species Menu. From the correlation matrix BaO is seen, as expected, to interfere with Sm & Eu and accounts for their increased errors. Similarly, BaO interferes with BaOH. This is more severe and the errors are therefore higher. Importantly, BaOH is a previously unconsidered interference that has only become apparent through this type of data analysis.

In conclusion, MassInf has resolved the molecular interferences on low resolution data, allowed the identification a previously unconsidered interference, provided quantitative results and errors on all species, given the certainty of a species being present and shown the extent to which species interfere with one another.

The Use of Modular Excel Macros for Quantitation in a GLP Environment

Michael J. Hayes, Steve F. Carlsen, Ciba Pharmaceuticals, Research Department, 556 Morris Ave, Summit NJ 07901

A set of two Ultrix C shell scripts and two Excel 5 macros have been developed to facilitate calculation of quantitation results from MS analysis. The system generates peak areas using the Finnigan ICIS software provided with the TSQ-700 mass spectrometer and performs all other calculations on a PC using two Excel 5 macros. The first macro transfers peak area data into an Excel spreadsheet, the second generates calibration curves and calculates final sample concentrations. Sample types are coded using a simple system that allows the macros to tabulate standards, quality controls and unknowns into separate sheets for processing.

The programs on the Finnigan data station are Ultrix C shell scripts. This is the standard script language used by Finnigan and provides control of the ICIS II post-acquisition application programs. The two scripts are 1) QUANT which controls the generation of peak areas and creates an ASCII file to be exported to the PC and 2) QUANTP which prints the integrated chromatograms for documenting the analysis. The Unix and Windows PC must be networked to allow automatic data transfer. This is best accomplished using NFS mounting of the Unix drive on the PC.

Visual Basic for Applications (VBA) within Microsoft Excel was used for all programming on the PC side. Excel provides a wide range of built-in data processing functionality for calculating, organizing and presenting data. This reduces the amount of programming needed to produce a useful system. The VBA language provides a structured programming environment with features such as explicit variable declaration, an interactive debugger, semi-automatic code formatting, modular programming capability, and rapid development of Windows user interfaces.

The UNIXDAT.XLT macro that imports the peak areas sorts the samples into different sheets for standards, QC's and unknowns. It has a number of features that facilitate rapid data analysis. The first is a plot of the absolute internal standard areas vs. the injection number in the series. This is useful for detecting unusual changes in instrument performance or errors in peak detection and integration. The second is a plot of the peak area ratios of

both the standards and QC samples vs. concentration. This also provides a rough check for peak detection errors and an indication as to how well the analysis is progressing. If errors or problems are found, results from manual reintegration are automatically incorporated into the tables and reinjections are appended to allow comparison of results.

The REGRESS.XLT regression macro is invoked from the toolbar of the data sheet generated by UNIXDAT.XLT. It automatically imports all data from the UNIXDAT sheet, provides linear and weighted linear regression, calculates the quality control sample concentrations and the corresponding accuracy and precision values and generates final sample concentrations. This macro is implemented separately because it is also used as a general purpose regression tool within the department.

The data reduction system described above provides an environment in which data from routine analyses can be quickly and reliably processed. It also allows a flexible environment for method development work where the analyst can see the effects of a variety of changes in the way in which a data set is analyzed.

The various data sheets that are created provide a complete record of what was done. This set of programs does not provide rigorous audit trail security, as in a closed LIMS system. However, by archiving the raw data files along with the Excel sheets, it is easy to document the processing that was done. This results in a data record that can be readily followed for GLP compliance.

This system is intended as an interim solution to enhance productivity and GLP compliance while a more sophisticated LIMS solution is developed. It also serves as a prototype for the kinds of data processing that should be incorporated in the LIMS system. Excel 5 was chosen because it includes a variety of readily available and reliable calculation and plotting functions. This allows the rapid construction of a working system that enhances productivity. All the functions of Excel are available for manual use by the analyst from the start. The resulting program code is fairly easy to document and debug thereby reducing the possibility of programming errors. It can be readily expanded to provide additional functionality as needed.

Multi-Dimensional Visualization of Ion Trap MSⁿ Spectra

Peter Sander, Bruker-Franzen Analytik GmbH,
Postfach 33 01 26, 28331 Bremen, Germany

Ion Trap instruments enable to perform MS/MS of several generations (MSⁿ). Until now, there is a clear lack in the visualization of such set of mass spectral data.

The visualization of MSⁿ spectra, e.g., of different daughters of the same parent (siblings) or consecutive parent/daughter of several MS/MS steps, is crucial when drawing up suitable parent and daughter sequences for MSⁿ analytical tasks. This becomes even more important with emerging MS/MS capabilities of 2, 3, or even more daughter generations. Some of these possibilities may have never been applied, simply because of the lack of survey in such setups.

Experimental:

The measurements presented here were carried out on the Bruker ESQUIRE mass spectrometer. The ESQUIRE mass spectrometer is an ion trap instrument with non-linear quistor technology. Simple software-controlled ion selection is used to isolate ions for MS/MS and MSⁿ experiments. Ion accumulation is automatically adjusted for each scan in the trap using ion charge control so that a high sensitivity is achieved without compromising resolution by overloading the trap. The instrument is equipped with an Analytica electrospray source for soft ionization of a wide variety of molecules at high sensitivity.

The sample analyzed here is a solution of 0.1 mg/ml Leucine-Enkephalin (amino acid sequence: Y-G-G-F-L) in a water/methanol/acetic acid mixture.

Example:

Figure 1 shows a series of consecutive parent/daughter spectra up to MS⁶ = MS/MS/MS/MS/MS/MS. The first parent spectrum (consisting mainly of M+H = 556.28u, clipped peak) is depicted at the top right corner. The first daughter is depicted perpendicular to its parent at the isolation mass of 556u close to the top left corner. The most prominent peak is at mass 397.2 u (a₄) which is used for the next MS/MS step.

Spectra of higher order are depicted each on the opposite side of its respective parent at the mass of the isolated fragment ion. — Even order spectra are depicted from bottom left to top right; odd order spectra are depicted from bottom right to top left. The annotations outside the scales give the number of MS/MS steps and the isolated fragment ion for each MS/MS step of each spectrum.

Every MS/MS step involves isolation of a single ion with unit mass resolution and subsequent fragmentation. To obtain a MS⁶ spectrum, therefore, 11 ion trap operating steps have to be performed: 5 isolations alternating with 5 fragmentations and a final mass scan.

Conclusion:

This kind of visualization MSⁿ measurements gives new options of displaying, organizing, comparing, and/or presenting data. There is a promising aspects of its usefulness and practicability which has to be confirmed on coming up applications of MSⁿ.

Fig. 1 A series of 6 consecutive parent/daughter spectra – MS⁶ = MS/MS/MS/MS/MS/MS – of Leucine-Enkephalin (Y-G-G-F-L).

Development of a GUI Based Data Reduction Program for FTICR and TOF Mass Spectrometry

Clifford H. Watson, Kevin L. Goodner, and John R. Eyler
Department of Chemistry, P.O. Box 117200, University of Florida,
Gainesville, FL 32611-7200

Introduction

Many commercial mass spectrometers utilize relatively expensive Unix based workstations as a "front-end" for data acquisition and post-processing. This is largely true for Fourier transform ion cyclotron resonance (FTICR) mass spectrometers which require considerable data reduction. To maximize productivity/throughput users may opt for some means of off-line data reduction which may require an additional (and often expensive) workstation and site-license for the commercial/proprietary software. In order to improve productivity in our laboratory, an off-line data reduction program, WinICR, which utilizes the Microsoft Windows™ environment, was developed to help process data from several types of commercial FTICR and TOF mass spectrometers. This program was developed to allow users to process simple 1-dimensional data files off-line on relatively inexpensive computer platforms.

Equipment Required for WinICR

- Windows™ compatible PC, 486 or higher recommended

FFT size†	Typical FFT processing speeds:	
	Pentium P133	80486DX2 80
4k	0.2s	0.7s
16k	0.9s	3.3s
64k	3.9s	15.3s

- VGA or higher resolution display
- Windows 3.x, Windows 95, or OS/2 (2.1 or higher)
- 8 Mbytes or more of RAM (will run with 4 Mbyte)

Memory size (Mbytes)	Maximum data size (Kbytes)†
4	128
8	256
16	512
32	1028

†Double precision floating point representations are used for all data arrays.

Features

1. Graphical and command line interface: Commands accessed via pull down menus, popup menus (program and user definable) and a command line interface for ease of use
2. Several data formats currently supported including: Bruker FTICR and TOF Xmass, Bruker Aspect, IonSpec Omega, and ASCII (additional formats are being added).

3. Multiple apodization functions: Blackman-Harris (3 and 4 term), Hamming, Hanning (3 and 4 term), Kaiser-Bessel, Exponential, Gaussian, Sine-Bell, ect.
4. Various peak picking methods. highest point, 3-point fit, polynomial fit, and centroid.
5. Automated data reduction. Includes automation routines (script files) in addition to chaining multiple commands together on command line or in user definable popup menus.
6. Several types of calibration equations supported.
7. Theoretical transient generation. Control of all relevant parameters via a setup file.
8. Signal-to-noise and LOD determination
9. Tabular data extraction via clipboard and peak reports via ASCII data files.
10. Graphics hardcopy to any Windows™ supported device or exported via HPGL format.
11. Deconvolution of multiply charged peaks for both high and low resolution spectra.

Conclusions/Future Work

We find the current version of WinICR to be versatile and powerful for off-line data analysis. However, there is always room for improvement and extra functionality is continually being added. Two additional TOF and FTICR data file formats are currently being implemented and will be included soon. Additional formats will be included based on user demand. The graphical interface, while adequate is also currently being reworked to provide more of a WYSIWYG format. An improved Windows™ help-file is being implemented and will be included with the future versions.

The WinICR (and associated programs) are available to the FT/MS and TOF community as freeware. Customization of the program and addition of new features based on user's request will be considered on a case-by-case basis.

A Novel Algorithm to Enhance Signal to Noise Ratios in CE-MS and LC-MS

Baoming M. Huang, David C. Muddiman, Gordon A. Anderson, Qinyuan Wu, Mary S. Weir-Lipton, Alan L. Rockwood, and Richard D. Smith*
Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory
Richland, WA 99352

Andrew Proctor
Department of Chemistry, Vanderbilt University, Nashville, TN 37235

One key step in the analysis of CE-MS or LC-MS data is the effective reconstruction of electropherograms (EGs) or chromatograms (CGs) from the sequence of mass spectra. Generation of large data files (>500 spectra) in CE-MS and LC-MS is not uncommon, which precludes routine examination of each mass spectrum, and often restricts conventional methods for user intervention to eliminate noise and/or reset the background. Poor S/N in an EG or CG may prevent identification of unknown components, even though their mass spectra may be usable if effectively located in the EG or CG.

The conventional method for reconstruction of an EG or CG is accomplished by integrating the total ion current of each mass spectrum. However, background noise and large ion currents due to buffers may not result in discernable peaks in the EG or CG due to poor S/N. To address this problem, we have recently developed a novel reconstruction algorithm which utilizes the similarity between sequential mass spectra. In this method, named sequential paired covariance (SPC), the minimum y-value is first subtracted from each mass spectrum and then a virtual geometrically signal-averaged mass spectrum is created. Each data point in the virtual mass spectrum represents the dot product of the corresponding data points in two adjacent spectra. The EG or CG is obtained by plotting the integral of ion current in the virtual mass spectra vs. time (or number of scans). This reconstruction method increases the analyte signal while simultaneously suppressing the random noise.

The CE-ESI-MS was performed with a home-built TOF instrument based on the inverted perflectron principle. A Crystal 310 CE system was interfaced to a Finnigan ESI source via a sheathless interface. The ESI source was interfaced to the ESI-TOF system through a heated capillary. The ions are detected by a 20 cm X 8 cm multichannel plate in a chevron geometry. LC-MS data was obtained using a Finnigan TSQ 7000. The separation was performed with a micro-LC system from Microtech Scientific Inc. using a 1 mm X 250 mm C18 column from Phenomenex. Data analysis was conducted using either GOOGLY software or programs developed at PNNL.

While the SPC approach has increased the S/N over an order of magnitude in the reconstructed electropherograms in the CE-ESI-TOF experiments¹, it was speculated, but not demonstrated, that the SPC approach should also enhance the apparent resolution in both EGs and CGs. This is important because LC is commonly utilized for separation of complex mixtures and mass spectrometry for subsequent analysis. In this presentation, to demonstrate the enhancement in resolution SPC provides, LC-MS data of an enzyme digest of Histone H2B protein isolated from chicken erythrocyte cells is used. Due to the large number of peptides generated in the digestion step, the "co-elution" of several peptides is often observed in chromatograms reconstructed with the conventional total ion current method. The SPC algorithm inherently enhances similar features in adjacent mass spectra while suppressing minor components, resulting in an enhancement of resolution, which is demonstrated in Figure 1.

The general applicability of the SPC algorithm for the effective reconstruction of electropherograms or chromatograms has been demonstrated with several types of instruments and different data formats, such as CE-ESI-TOF on a home-built instrument, LC-ESI-Quadrupole on a Finnigan TSQ 7000, and CE-ESI-FTICR on an FTMS instrument. Further development of the algorithm, such as utilization of higher order of covariance to extract broad, low intensity peaks, and to reduce correlated noise, has also been demonstrated.

Reference Muddiman et al. Application of Sequential Paired Covariance to CE-ESI-TOF MS, *Anal.Chem.* 1995, 67, 4371-4375.

Acknowledgment We thank the U.S. Department of Energy, Office of Health and Environmental Research, for support of this research. Pacific Northwest National Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy through contract No. DE-AC06-76RLO 1830.

Figure 1. Chromatograms reconstructed from LC-ESI-Triple Quadrupole MS data set of an enzyme digest of Histone H2B isolated from chicken erythrocyte cells using (A) total ion current (TIC), and (B) sequential paired covariance (SPC), and (C) 3rd order SPC (utilizing the similarity among three sequential spectra). The peptides seem to co-elute in (A), while Chromatogram (B), reconstructed with SPC, clearly shows different peptide components with different number of acetylation and phosphorylation. The higher order sequential covariance method (C) further enhances the S/N and resolution.

ElectroSpray Spectrum Analyser: A New Tool to Deconvolute Multiply Charged Spectra.

P. Proulx, D. Zidarov and M. J. Bertrand,

Regional Center for Mass Spectrometry, Department of Chemistry,
University of Montreal, Montreal, Canada, H3C 3J7

Electrospray (ES) ionisation is a useful method for the analysis of large biopolymers. The interpretation of small proteins spectra is fairly easy due to the few charge states being generated. An increase in size of the protein will result in more charge states being generated, thus complicating the spectrum. Enzymatic digests are usually the first step in large protein sequencing. It results in mixture of proteins and peptides. The computer-assisted interpretation of ES spectra of such mixtures still proves to be a challenge. Another approach that is useful for the interpretation of ES spectra of mixtures is presented. This method does not use ion abundance profiles nor does it makes any assumption on trial spectra to generated a zero-charge spectrum

Human hemoglobin was purified at MSD/Hemosol by Dr Dianna Pliura. HPLC-MS of the tryptic digest (500pmol) were made at PE-Sciex (Toronto) by Dr Takeo Sakuma using a 1×300 Aquapore OD-300 column with a gradient of 30→60% ACN containing 0.1%TFA over 30min at 40μL/min coupled to an API3-Plus equipped with an ionspray source (Sciex, Thornhill, Canada). No attempt were made to sequenced tryptic peptides. The mass spectrometer was scanned from 600 to 1800Da at interval of 0.2Da. A synthetic data file of the mixture was prepared by combining the spectra of the individual components. The algorithm was coded in Borland C++ 4.0. Calculations were done on a Pentium-90 PC equipped with 8Meg RAM, running Windows 3.11. Average execution times were approximately 4 min for a 5000 data points spectrum.

A flowchart of ESSA is depicted in Figure 1. The first step in the treatment of the spectrum is a sensitive filtering. Unlike arbitrary baseline-subtraction, the background noise is removed with an algorithm which as "chemical justification". It is an Electrospray-optimized version of a FAB signal treatment algorithm "FILTER". The filtering process is particular by the fact that the signal removal process self-adapts to the noise content of each spectrum region. Figure 2 shows the specificity of the filtering of a spectrum.

- Computing time ~1-2min
- Usually removes 80-95% of data points
- Self-adapting to noise content of each spectrum region
- Limits further background contributions and computing time

The filtered spectrum is first submitted to a charge-optimizer function. This step will yield the most probable charge for every data point. From these charges, a zero-charged spectrum is calculated in which the major component is extracted. Its multiply charged ions are then removed from the original spectrum.

The iterations are repeated until removal of all components (TIC<5%) Table 1 shows that the accuracy of the algorithm is very good for this test-mixture with component ranging from 5-17kDa. The accuracy was limited by the 0.2Da sampling of the data files, and one would gain from using a 0.1Da sampling.

- Iterative process
- Charge optimisation eliminates mass harmonic (Mann)

- High accuracy in mass determination (worst case < 0.01%)
- Computing time <1min per component
- Filtered spectrum necessary for speed (n² process)
- Not based on ion abundance profiles

The interpretation of Electrospray spectra of protein mixtures is still a non-trivial task. The software **ESSA** (ElectroSpray Spectrum Analyser) was design to provide an automatic assistance in the treatment of such spectra. The software is divided in two parts. The first part is a powerful filtering algorithm that removes most of the non-significant data points from the spectrum. The second part is the deconvolution algorithm. It is based on an iterative process which begins with a charge optimisation of the data points and the subsequent removal of the major component found. This approach allowed us to characterise protein mixtures with component ranging from 5-20kDa.

Application of Wavelet Transforms to Electrospray Spectra: Denoising, Smoothing, and Dataset Compression

V. J. Barclay, R. F. Bonner, *PE SCIEX, 71 Four Valley Drive, Concord, Ont. Canada, L4K 4V8*

I. P. Hamilton, *Department of Chemistry, Wilfrid Laurier University, Waterloo, Ont. Canada N2L 3C5*

The interpretation of experimental spectra is often complicated by noise. By definition, noise is instantaneously irreproducible although often, on average, it is characterizable. Many methods exist for smoothing and denoising data.¹ Here, we make a distinction between smoothing and denoising. An observed intensity $y(x)$ defined in the x -domain (which is our general designation for the m/z or time axes) is the sum of the true signal $s(x)$ and noise $n(x)$. Smoothing is defined as an activity which operates on $\{s(x) + n(x)\}$ to remove jaggedness by minimizing $\sum \partial y(x)/\partial x$. Denoising, on the other hand, is defined as an activity that has as its direct goal the removal of $n(x)$, regardless of its apparent effect on the jaggedness. Note that smoothing requirements can be fulfilled even with a large contribution from $n(x)$, i.e., it is possible to have a smooth but noisy spectrum.

We show methods of smoothing and denoising which depend on the recently-developed discrete wavelet (DW) transform technique.² The wavelet transform may be thought of as analogous to the Fourier transform, except that the basis functions are dually localized in both the x - and f -domains.

In the context of a spectrum that is transformed from the x -domain to the f -domain, the distinction between denoising and smoothing becomes clearer. Whereas noise is distributed across the f -domain, the signal is usually localized to parts of the f -domain. Smoothing removes components of the transformed signal occurring in the high end of the f -domain regardless of amplitude. Denoising removes small-amplitude components occurring in the f -domain regardless of position. In practice, denoising and smoothing may give similar results, since noise is often insignificant at the low end of the f -domain, where the signal typically has high amplitude.

The DW smoothing and denoising methods are filtering techniques³ which are applied to the transformed dataset, prior to back-transforming it to the x -domain (m/z or time units). We compared these DW techniques with other common methods of smoothing (Savitzky-Golay, SG⁴) and denoising (Fourier transform filtering, FT⁵). We examine synthetic datasets (ideal functions to which a known amount of noise has been added) and also real LC-MS datasets.

For the synthetic datasets, we concluded that denoising, and in particular, DW denoising, gives superior results when peak widths vary widely. Neither smoothing method worked well when the peakwidth varied dramatically in a dataset, because both methods tended to remove too much intensity from the narrowest peaks. However, the SG method is arithmetically simplest and requires less memory than the

computationally-intensive transform-based methods. Design of filters for FT or DW methods requires systematic investigation with typical datasets. Compared to the FT method, the DW filters are more straightforward, and will also lead to overall dataset compression.

There are some drawbacks to the DW methods, but these are less serious than the drawbacks to the FT method. Both FT and DW algorithms require a dataset of size 2^j , which may be prohibitive for very large datasets. Some judgment about padding the dataset is required. Lastly, we note that the choice of cut-off may vary depending on type of dataset, but there is no need to model the signal and noise functions in the f -domain, as the FT method requires.

The optimum application of these techniques for typical LC-MS data is shown in Figure 1. We observed that chromatographic data, which are characteristically smooth, could be compressed by denoising. We also observed that a typical mass spectrum could have much of its high-frequency noise component removed, for at least 4:1 compression. In Figure 1 (a) the chromatogram is denoised (upper trace) by removing all elements with a transformed intensity less than 0.5% of the maximum transformed coefficient. This led to nearly 3/4 of all points being discarded in the transformed vector. In Figure 1 (b) the mass spectrum is smoothed (upper trace) by a 4:1 compression.

Improved Software Tools for the Analysis of MALDI Time-of-Flight Mass Spectrometry Data

Kevin G. Owens, Department of Chemistry, Drexel University
Scott D. Hanton, Air Products and Chemicals, Inc.

Introduction

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI TOFMS) methods have been developed to determine the chemical structure of a wide variety of industrial polymers. These methods produce data allowing us to determine the masses of end groups, the oligomer repeat units, and the polymer molecular weight distribution. The increased use of the technique for more complicated samples has prompted our development of improved software tools to analyze MALDI TOFMS data.

The commercial software currently available largely determines the amount and quality of information that can be easily extracted from a MALDI TOFMS spectrum. Four key steps need to be accomplished to fully analyze MALDI TOFMS data:

- Mass Calibration
- Baseline Correction
- Peak Identification
- Average Molecular Weight Calculation.

Results

The WAVACQ (WAVEform ACQUISITION) program¹ described here was modified in-house for the analysis of MALDI data. Mass calibration is determined from instrument parameters, known ion peaks, known mass differences², or a calibration file. For known ion peaks, either masses or molecular formulas can be entered. The software will calculate the correct mass from a formula using an isotope look up table. To facilitate mass calibration, we have created an initial external calibration file derived from the average calibration equations for oligomeric samples of polyethylene glycol, polystyrene, polymethylmethacrylate, and polydimethylsiloxane.³ After mass calibration the spectrum can be analyzed and plotted on either a linear time or linear mass scale.

The baseline used to quantitate a MALDI TOFMS spectrum has a significant effect on the calculated average molecular weights. To obtain the most accurate quantitation, the baseline is corrected by subtracting a function that is fit to the expected baseline. This function is approximated by a first to fourth order polynomial fit of one to sixteen points.

Peak identification within a mass spectrum is aided by the use of programmable tags and a dual cursor. Mass tags are calculated for individual species or for a series of oligomer peaks. The isotope look-up table is used to calculate the tag position for each species. For polymers, additional functions are present to

calculate tags for a possible copolymer series composed of two different monomer units, two different end groups, and a cation. The program calculates the tags and displays them superimposed on the spectrum. The dual cursor is useful for the identification of two related peaks. The cursors can be spaced by a fixed number of channels, time, mass, mass multiple, or mass fraction.

To calculate the molecular weight distribution, it has been recognized that the average molecular weights correspond to the statistical moments of the distribution of ion peaks⁴. The n th order statistical moment about the origin of a distribution (given as signal intensity versus mass) is given by

$$M^n = \sum h_i \cdot m_i^n$$

where m_i is the mass and h_i is the intensity of the i th point in the mass spectrum. The number average (M_N) and weight average (M_W) molecular weights of a polymer distribution are related to the statistical moments via the equations:

$$M_N = M^1/M^0$$

$$M_W = M^2/M^1$$

The polydispersity (PD) of the distribution is simply

$$PD = M_W/M_N$$

The program calculates the moments only within the region specified by the "moment mask". The mask can have an unlimited number of peaks within it. The use of selective moment masks helps to exclude matrix or contaminant ions from the distribution calculations. This allows for the independent calculation of different species within a single spectrum, for example, calculating the average molecular weights for both Na and K cationized oligomer peaks.

Conclusion

Data analysis, whether accomplished manually or automatically, must be carefully undertaken if meaningful information is to be extracted from a MALDI TOFMS mass spectrum. We have developed improved software tools to aid these analyses. The mass calibration, baseline correction, peak identification, and average molecular weight calculation tools have greatly increased the accuracy and speed with which we analyze our spectra.

A Modular System for Tailored Waveform Generation in FTICR/MS Based on VXI Instrumentation and LabVIEW Software

Chadin Dejsupa and David V. Dearden

Dept. of Chemistry and Biochemistry, Brigham Young Univ., Provo, UT 84602

Tailored waveform excitation methods in FTICR/MS (such as stored waveform inverse Fourier transform excitation^{1,2}) are especially powerful means of performing ion isolations or ejections with high mass resolution and with precise control of energy deposition as a function of mass. In this paper we demonstrate a home-built implementation of tailored waveform excitation, which could easily be applied to most available data systems. Our equipment makes use of VXI, an open standard industrial platform for data acquisition and analysis. VXI is especially useful for this application because it has a very high throughput rate (up to 40 MB/s), and it is modular, making it very easy to modify, upgrade, or repair. It also allows precision timing and synchronization between individual instrument modules. This standard modularity frees the designer from dependence on a single vendor, as it allows the use of modules from any vendor in compliance with the standard.

Our waveform excitation setup was tested for natural abundance isotopic labeling experiments. Specifically a high-resolution single notched ejection was applied to isolate the carbon-13 peaks of doubly protonated gramicidin S ions. A second experiment involved a single-pulse high resolution isolation of the M+1 carbon-13 peaks of the complexes of 18-crown-6 with lithium, sodium, potassium, rubidium, and cesium ions spanning a mass range from 200 to 400 m/z. The third experiment involved a single notch isolation of dimer ions of diethylether. Electrospray ions were generated using a home-made microspray source, consisting of 50 μ m i.d. glass capillary tubing and a 50 μ m i.d. temperature-controlled stainless steel desolvating tube, guided into a commercial electrospray ion lens, and subsequently into the "Infinity" trapping cell by a series of electrostatic lens voltages. Neutral 18-crown-6 was introduced into the cell through a solid probe, and maintained at 1.1E-8 mbar. Solutions used were 0.2 mg/ml of gramicidin S dissolved in H₂O:CH₃OH:acetic acid in a ratio of 48.5:48.5:3 for the first experiment, 100 mM of 18-Crown-6 and 200 mM of alkali metal chloride in a ratio of 12:4:1:1.5:1.5 respectively, dissolved in H₂O:CH₃OH in a ratio of 1:1 for the second set. The third experiment was an external chemical ionization of diethyl ether using methane as a reagent gas. The hardware we used includes a Hewlett-Packard model E1401A VXI chassis, a Hewlett-Packard model E1445A arbitrary waveform generator with 256k of waveform memory and 32k of sequence memory, and a National Instruments model VXI-SB2020 computer interface kit including a MXI cable for connection to a SPARCstation 10 computer (Sun Microsystems). A Nicolet model 450e digital oscilloscope with dual channels, 8 bit resolution, and a digitizing rate of 200 MS/s was used to monitor the waveforms. The software we used includes NI-VXI software to control the VXI system and a National Instruments application, LabVIEW version 3.0.1, which has a built-in instrument driver for the HP E1445A. LabVIEW is a user-friendly graphical programming language and its code is cross-platform compatible. Figure 1 shows a schematic diagram of the tailored waveform generation setup.

The implementation was applied successfully. Figure 2 shows spectra obtained from the first two experiments. Figure 3 depicts the achievement of the desired isolation while leaving the ions internally and translationally colder than could be easily done with frequency-sweep isolation of the dimer ions of diethylether. The total cost for the system (excluding the computer) was about \$18,000. This figure seems high but is still much less than the commercial workstation cost. Also once the major components, such as the mainframe, the slot 0 (interface card), the computer, the software and the arbitrary waveform generator have been purchased, the additional cost is much lower. The only change is adding more VXI devices to the existing

system as needed for complex isolation and/or excitation processes. The current system has great flexibility in terms of tailoring waveforms and sequencing of the data acquisition events. In addition, GPIB devices (such as our digital oscilloscope) can be integrated into the system. We expect that prices will go down and the availability of good products will go up due to market competition.

The Application of SIMION 6.0 to Problems in Time-of-Flight Mass Spectrometry.

Steven M. Colby and John J. Manura, Scientific Instrument Services, Inc. Ringoes, NJ 08551

A full version of this abstract is available at <http://www.sisweb.com>

Introduction: This poster examines the use of SIMION 3D v.6.0 in Time-of-Flight Mass Spectrometry. SIMION is a ion optics software program originally developed by David Dahl at the Idaho National Laboratory.¹ The latest version allows for greatly expanded simulation capabilities. These include larger array size (10 million points) and three dimensional modeling. Dynamic parameter variation and time varying potentials are now also possible. We show how the software can be used to analyze the effects of non-ideal grids.

Simulation of the Effects of In-homogeneous Grids: Fine mesh or grids are commonly used to establish and divide acceleration regions in TOFMS. When different electric fields are placed on each side of a grid a small electrostatic lens is produced at each opening. The effects of these lenses on the ion throughput and time resolution of instruments has been a point of controversy. Two published papers have indicated that the grids have little or no impact on the performance of the instrument^{2,3}. Two others suggest that grids can have a considerable effect and in some cases may even be the limiting factor in instrument resolution^{4,5}. We have used SIMION 3D v.6.0 to simulate the flight of ions through individual grid holes.

The grid material most commonly used is produced by Buckbee Meers of St. Paul, MN. Their products include a wide variety of wire densities and transmission. The most popular meshes have wire densities of 70, 117.6, 333, and 1000 lines per inch.

Simulation Conditions: Our SIMION 3D simulation is illustrated in Figure 1. It included nine grid holes and the volume within a distance of 1.5 grid holes on either side of the grid. At that distance the electric field was assumed to be uniform and a pair of solid electrodes were used to establish the fields in either direction. (One of these electrodes has been removed in Figure 1 to view the grid more clearly.) The potentials at over 20 million grid points were used to calculate ion trajectories. This was accomplished by specifying 5.1 million points and then employing two axis of symmetry. The grid and one electrode were held at ground while the other electrode was held at high potential in order to establish an electric field.

Ion Trajectories: Ions were flown using 70, 117.6, and 333 line per inch grids as well as electric fields of 2000 and 10,000 V/cm. Ions were also flown in both directions; e.g. from high field to field free region and visa versa. When ions originated in the field free region they were assumed to start with 200 eV of energy. When flown in the opposite direction ions were assumed to have been accelerated through 1.0 cm to either 2000 or 10,000 eV of energy when they reach the grid. All trajectories started along the Z axis perpendicular to the surface of the grid.

Results: The profile of angular deflections due to passage through a grid opening is shown in Figure 2. The X and Y axis are in distances relative to the center of the grid opening. This shape is typical of the results obtained. The area plotted represents one quadrant of the grid hole opening. The data displayed is for an ion traveling from a field free region into a 10,000V/cm field. *The angle is measured relative to the Z axis at distance of only 0.55 mm after the grid.* If the region was only 0.55 mm long this would be the angle at which the ion reaches the next region. However, if the ion is accelerated further, i.e. from the current 744 eV to 10.2 KeV (1 cm travel) the deflection angle will be reduce dramatically because all of the additional velocity is in the Z direction. After this acceleration the average (absolute) deflection angle will be reduced from 3.62 to 0.98 degrees. Calculated results for a number of standard grid sizes are shown in Table 1. These results are independent of ion mass. The values for "average deflection angle" refer to the average absolute value in a given quadrant.

Ramifications in Real Instruments: The angles listed in Table 1 are quite small but we must consider their impact on real time-of-flight instruments. We observed the effects of ion lensing by simulating the trajectories of ions from the source to the detector of a reflectron. When ions are given angles of plus and minus 0.153 degrees at the exit of the source the ions hit the detector 4 mm from the center of the ion beam. In addition the flight time difference between the three ions is 25 ns! This is because the reflectron has regions of deceleration. In these areas the velocity component due to deflection is unaffected so it becomes a greater fraction of the overall velocity. In the reflectron this can quickly become the dominant component of velocity.

Conclusions: SIMION 3D has been a useful tool for analyzing the problems of grid in-homogeneity in TOFMS. We have found that grids can indeed have a significant impact on the performance of time-of-flight instruments.

Table 1: Deflection angles

Starting Region	Grid Size (lines/inch)	Field Strength	Deflection Angle.* ^a	Perpendicular Velocity ** ^a	Deflection Angle.* ^b	Perpendicular Velocity ** ^b
Field Free	70	2000 (V/cm)	2.33 (deg.)	4.0 (%)	0.91 (deg.)	1.6 (%)
	117.6	2000	1.12	2.0	0.40	0.70
	333	2000	0.351	0.61	0.11	0.20
	70	10,000	3.62	6.3	0.99	1.7
	117.6	10,000	2.67	4.6	0.61	1.1
	333	10,000	2.58	4.5	0.45	0.80
High Field	70	any	0.153	0.27	0.153	0.27
	117.6	any	0.091	0.16	0.091	0.16
	333	any	0.033	0.058	0.033	0.058

Automating Mass Spectrometry—Sample Dependent Data Processing

R.F. Bonner, L.L. Burton and T.R. Covey, PE Sciex, 71 Four Valley Drive, Concord, Ontario, Canada L4K 4V8

M. McLean, PE Sciex, 850 Lincoln Centre Drive, Foster City, CA 94404

Although automated mass spectrometry is not new, it is only recently that the concept of "walk up" mass spectrometers has become popular. Such instruments are intended to allow those with minimal MS training to obtain meaningful results. Generally such systems are configured so that samples are analysed by flow injection analysis (FIA), data is acquired in either the positive or negative mode and the post-acquisition processing is pre-defined.

We describe a program, called *MSExpress*, that retains ease of use but is sufficiently flexible that it can be configured for other techniques such as LC/MS. This flexibility is achieved because the data processing program can be controlled by AppleScripts and the end user can select both the acquisition method and the processing script. AppleScript is a high-level scripting language, developed by Apple Computer, which allows messages to be sent to a program from a script or from another program.

The system is maintained by an administrator who configures the window seen by end users—this can range from very simple (user and sample name only) to customised versions that require specific information. Figure 1 shows a window which has been configured with a custom mass field into which users can optionally enter the expected molecular weight of their compound. In this case the administrator has also made several acquisition methods and processing scripts available.

Please enter the sample information:

User Name:

Sample Name:

Acquisition method:

Processing script:

MH mass:

Figure 1. *MSExpress* sample entry window, configured to allow users the ability to select both the acquisition method and processing script. A custom mass field has also been defined.

A particularly important feature of this system is the technique we have termed "sample dependent processing"—the processing operations are the same for every sample, but the actual values used vary from sample to sample. These values are supplied when the user submits the sample using a custom field, as shown in Figure 1. These values are stored in the data file so that they are available for future reference and use. For example a script can be written to generate the mass chromatogram of the expected molecular weight of the sample.

The "Find Metabolites" script automates an operation that is common in the identification of drug metabolites, namely plotting the mass chromatograms of expected masses based on the mass of the parent drug and the relative masses of likely metabolites. Figure 2 shows a portion of the output of this script applied to a plasma sample following administration of Omeprazole.

In addition to presenting an overview of the system and a brief description of AppleScripting, we illustrate the data processing capabilities with several examples. We describe the "Find Metabolites" example mentioned above, a semi-quantitation script and a peptide mapping script based on the expected sequence of a protein.

Figure 2. A portion of the output of the "Find Metabolites" processing script.

Comparison of Halocarbon - PAH Ion Molecule Reactions in an Ion-Trap and a Quadrupole Source

Andrew A. Mosi, William R. Cullen and Guenter K. Eigendorf*
University of British Columbia, Department of Chemistry, Vancouver, B.C.,
Canada, V6T 1Z1

Experimental work recently carried out in our laboratory on ion molecule reactions between halocarbon cations $[RX]^+$ and polycyclic aromatic hydrocarbons (PAHs) in an ion trap (Varian Saturn 4D) and a quadrupole chemical ionization ion source (Delsi-Nermag R10-10C) has been useful for differentiating between some PAH structural isomers¹. The isomeric differentiation is achieved due to differences in the formation of $[M + RX]^+$ and $[M + RX - HX]^+$ adducts between the PAH and the halocarbon cation RX^+ . In the ion trap only small amounts of the direct addition product $[M + RX]^+$ have been observed, while in the chemical ionization ion source the direct adduct $[M + RX]^+$ can be observed in significant amounts if the pressure of the reagent gas is high enough (0.1-0.5 Torr). The work presented here gives a comparison of the differences in $[M + RX]^+$ and $[M + RX - HX]^+$ adduct formation using $CDCl_3$ and CH_3CHF_2 as reagent gases and anthracene and phenanthrene as substrates (M).

The formation of $[M + RX]^+$ is much greater in the quadrupole ion source for both gases. The mass spectra for the adducts $[M + CDCl_2]$ and $[M + CDCl_2 - HCl]$ are shown in Figure 1. Collision induced dissociation in an ion-trap demonstrate differences in the nature of the $[M + CDCl_2]$ adduct for phenanthrene and anthracene. The $[M + CDCl_2]$ adduct of anthracene yields ions at $m/z=226$ ($M + CDCl_2 - HCl$) and $m/z=178$ (M), while for phenanthrene only the $m/z=226$ is observed.

Although the sensitivity of the ion trap used for these experiments was much greater than our quadrupole instrument, with improved sensitivity of the quadrupole CI source the latter may offer an analytical advantage due to the formation of large amounts of both $[M + RX]^+$ and $[M + RX - HX]^+$ adducts.

Ion-Molecule Reactions with Hydrogen Cyanide in an Ion Trap Mass Spectrometer

S. König, P. Köfel and U.P. Schlunegger

Institute of Organic Chemistry, University of Bern, Freiestr. 3, CH-3012 Bern, Switzerland

Ion-molecule reactions involving hydrogen cyanide are of considerable interest concerning the building up of larger organonitrogen molecules as the purines are. Since in recent times the research of new planets and interstellar environments has become more and more sophisticated, the existence of HCN was proofed on many interstellar object. Therefore reactions including hydrogen cyanide are of particluar interest.

The quadrupole, quistor, quadrupole tandem mass spectrometer provides a good opportunity to perform and study such ion-molecule reactions, since many requirements, like a great pressure range in the quistor from 1.0E-8 mbar up to 1.0E-2 mbar and selective ion injection into the quistor, are given by the construction of the instrument. Ions were generated in an external and differentially pumped ion source under CI-conditions, mass selected by the first quadrupole and injected into the quistor. After a variable reaction period with neutral gas the product ions were analyzed by a second quadrupole mass filter.

Experimental parameters were: ionisation/injection time 10 ms; nominal injection energy 1.2eV, helium pressure 1.0E-3 mbar; reagent pressure 4.0E-6 4.4E-4 mbar; reaction time 1..200 ms.

Two different reactions were measured and their reaction kinetics studied.

- 1) An addition reaction between protonated cyanamide and HCN was measured.
- 2) HCN reacts with $(\text{CH}_3)_2\text{COH}^+$ in two different ways:
 - proton transfer reaction to form HCNH^+
 - formation of an intermediate adduct ion and and a following water cleavage

Protonated cyanamide (H_2NCNH^+ , m/z 43) was generated under CI-conditions in the ion source and formed with HCN a adduct ion of m/z 70. Hydrogen cyanide was let into the quistor in a concentration between 1.2E-6 mbar and 4.4E-4 mbar. Reaction time was varied from 10 ms to 200 ms.

A reaction rate constant of $6.0\text{E-}13 \text{ cm}^3\text{molecule}^{-1}\text{s}^{-1}$ was determined.

Spectrum 1

Spectrum 1 shows the reaction after 20 ms storage time at a reagent gas pressure of 2.4E-4 mbar HCN.

Between protonated acetone (m/z 59) and HCN the following two reaction channels were found:

- 1) $(\text{CH}_3)_2\text{COH}^+ + \text{HCN} \longrightarrow \text{HCNH}^+ + (\text{CH}_3)_2\text{CO}$
- 2) $(\text{CH}_3)_2\text{COH}^+ + \text{HCN} \longrightarrow (\text{CH}_3)_2\text{CCN}^+ + \text{H}_2\text{O}$

Spectrum 2

Spectrum 2 shows the reaction of $(\text{CH}_3)_2\text{COH}^+ + \text{HCN}$ after 150 ms storage time at a reagent gas pressure of 1.4E-5 mbar HCN.

Figure 1

Figure 1 shows the reaction kinetic of $(\text{CH}_3)_2\text{COH}^+ + \text{HCN}$.

A reaction rate constant of $4.0\text{E-}13 \text{ cm}^3\text{molecule}^{-1}\text{s}^{-1}$ was calculated.

Ion-Molecule reactions of the epimeric 4'-hydroxyl-4'-methyl cyclohexyl benzoates in a Quadrupole Ion Trap Mass Spectrometer.

Rathahao E., Liere P., Perlat M.C., Fournier F., Tabet J.C.*

Laboratoire de Chimie Structurale Organique et Biologique, EP103 CNRS, UPMC, 4 place Jussieu, 75252 Paris Cedex 05, FRANCE.

Ion-molecule reactions play an important role in the ion chemistry. They can provide information about intrinsic reactivity of organic species. Several studies of stereochemical effects on ion-molecule reactions in chemical ionization have been developed in order to elucidate gas phase ion-molecule mechanisms and for distinguishing epimers (1).

Such studies were performed in ion-cyclotron-resonance spectrometers, as well as in flowing afterglow instruments and tandem instruments. The ability to store ions for long period (msec) in the ion trap shows that it is a suitable device for studies of ion-molecule reactions. Furthermore, chemical ionization mode was already performed (2) in ion trap. Thus, in the present study, ion-molecule reactions performed with the epimeric 4'-hydroxyl-4'-methyl cyclohexyl benzoates (**1c** and **1t**) (Mw 234) have been examined under CI-NH₃ conditions in an ion trap mass spectrometer. Behavior of similar substrates toward ammonia has been, ten years ago, investigated with reversed geometry sector instrument (3). Herein, in the ion trap, instrument parameters which affect the CI spectra (reaction time, temperature, reactant pressure, CI-RF level) have been shown characteristic (2, 4). The CI-NH₃ mass spectra of the epimers exhibit strong differences (Table 1) than those observed in a triple quadrupole instrument where the adduct ions appear less reactive.

Table 1. Ions displayed in CI/NH₃ mass spectra of **1c** and **1t**.

m/z		252	235	234	217	130	113	112	95
% relative abundance	1c	60	-	45	100	-	-	10	12
	1t	100	2	-	7	30	29	9	15

Indeed, both the nucleophilic sites yield the SN reaction which take place at the hydroxyl site from the *cis* epimer (i.e. formation of [MNH₄-H₂O]⁺, m/z 234) and at the benzoate site from the *trans* epimer (i.e. formation of [MNH₄-PhCOOH]⁺, m/z 130). Furthermore, the *cis* epimer exhibits abundant fragment [MH-H₂O]⁺ ion (m/z 217) while (i) only a weak abundance characterizes [MH]⁺ (m/z 235) and (ii) [MH-PhCOOH]⁺ (m/z 113) ion is not detected. But the *trans* isomer undergoes both the H₂O and PhCOOH eliminations, leading to [MH-H₂O]⁺ (m/z 217) and [MH-PhCOOH]⁺ (m/z 113), respectively. This behavior indicates that the ammonium solvation takes place competitively at -OH and -OOCPh sites. The NH₄⁺ solvation at the benzoate site is shown to be more reactive than it is at the hydroxyl site. The observed stereochemical effects can be explained by possible proton transfer (5) in the *cis* epimer between two functional groups in the transient MH⁺ (or MNH₄⁺) ions, resulting in the H₂O elimination (group having the lower PA). On the other hand, the loss of benzoic acid is stereospecific from the *trans* isomer and it is favored by anchimeric assistance of the hydroxyl group (Figure 1).

Figure 1. Anchimeric assistance yielding the water and benzoic acid losses consistent to the ammonia elimination from the *trans* MNH₄⁺ epimer.

The energy-resolved breakdown curves of the selected MNH₄⁺ ions confirm the stereochemical effects observed from CI-NH₃ mass spectra (Figure 2.). Furthermore, abundance of the substituted ions (m/z 234 and m/z 130) which increases with the magnitude of the resonant excitation voltage indicates that the SN process mainly occurs via S_Ni pathway rather than the S_N2 mechanism. Finally, non-resonant mode was not used because consecutive decompositions are enhanced which hinders observation of stereochemical effects.

Figure 3. NH₃ PCI-CID energy-resolved breakdown curves of the selected [M+NH₄]⁺ ion.

Reaction of Hydantoin and Succinimide Anticonvulsants with Dimethyl Ether Ions in a QIT

*Jim Shen; Jennifer Brodbelt, Department of Chemistry and Biochemistry,
University of Texas at Austin, Austin, TX 78712

Introduction

In this study, reactions of seven anticonvulsant compounds with dimethyl ether(DME) ions were evaluated in a quadrupole ion trap. The product ions formed from the reactions with dimethyl ether ions were isolated and their structures further studied using the method of CAD. Fragmentation pathways are verified using techniques such as deuterium labeling and MS³.

Experimental

All experiments were carried out in a Finnigan MAT quadrupole ion trap mass spectrometer(ITMS). The nominal sample pressure was between 0.8-3.0 $\times 10^{-6}$ torr. CAD was accomplished by applying an ac tinkle voltage between 350-700 mVp-p across the end-caps for duration of 4-10ms. Gas phase basicities of molecules are measured using the ligand exchange method.

Results/Discussion

I. Gas-phase basicities

The gas-phase basicities range from less than 190 kcal/mole for hydantoin to above 203 kcal/mole for ($\pm$)-aminoglutethimide(Table 1). Hydantoin has a basicity lower than that of the simple cyclic ketone, cyclopentanone. With the addition of the electron-releasing phenyl substituents, the gas-phase basicity increases, although overall the basicities are still lower than pyrrole.

II. Ion-molecule reactions with dimethyl ether ions

DME ions were allowed to reaction with each anticonvulsant for 100ms, and the relative percentages of products are summarized in Table 2. Neither simple hydantoin nor ethosuximide react with CH₃OCH₂⁺ ions to form any substantial abundance of stable products. When one or more phenyl substituents are added to the hydantoin or succinimide structure, then the formation of (M+45)⁺ and (M+13)⁺ products is significantly enhanced.

III. CAD of protonated compounds

Each of the protonated anticonvulsants was collisionally activated. Two trends of dissociation pathways are observed depending on whether the compound is a succinimide derivative or a hydantoin derivation. The most important fragmentation pathways of 5-substituted hydantoin is elimination of carbon monoxide followed by cleavage of NH=C=O for losses of 28 u, 43 u, and 71 u. For succinimide derivatives, two common fragmentation pathways are observed. The first one involves consecutive loss of 42 u and 28 u to give net loss of 70 u. The second one involves consecutive cleavages of carbon monoxide and ammonia. The mechanisms are most easily rationalized by initial localization of proton at a amide nitrogen or a carbonyl oxygen with facile migration of the proton during collisional activation.

IV. CAD of (M+13)⁺ ions

The (M+13)⁺ ions dissociate by neutral losses that are in many cases identical to those observed for the corresponding protonated molecules. Extensive results from deuterium labeling and MS³ experiments point to a mechanism shown in scheme 1, in which the methylene substitution reaction occurs on the phenyl ring. Thus, the site of protonation vs. methylene addition differ, and both types of ions give structurally diagnostic information.

ELECTROSPRAY ION TRAP MSⁿ MAPPING OF SURFACTANTS

Robert J. Strife & Marcia M. Ketcha, The Procter & Gamble Co.,
P.O. Box 538707, Cincinnati, OH 45253-8707

Sequential product ion analyses (so-called "MSⁿ") from protonated molecules are facilitated by the electrospray ion trap, now embodied in the commercial "LCQ" instrument. Re-excitation / refragmentation beyond MS/MS is advantageous for many reasons including: 1) cumulative internal energy depositions lead to more substructural information, and 2) ion relationships are revealed that better define ion product ion genesis.

Mapping the MSⁿ data for surfactants is being done to establish a base of data from which "reverse" interpretation of data on unknowns can be done, providing another structure elucidation tool. As we have already shown (1), a structure can be derived "from scratch" on surfactants present even in complex mixtures.

The structure to the right is a commercial surfactant with a quaternary center. The parent ion exists preformed in solution and produces M⁺ at m/z 430. The MS/MS spectrum from the TSQ shows m/z 371, 327, 298, 254, and 118 at E_{cm} less than 2.0 eV, but all of the ions can be derived from m/z 430 by multiple collisions. Higher E_{cm}'s drive the fragmentation toward m/z 254 (base peak) and weak fragments (<5% relative intensity) below m/z 100.

MS⁵ Map -- In the ion trap, m/z 430 may be cleanly isolated from higher and lower masses, particularly the [¹³C] isotope peak, with over 95% efficiency. The isolation is accomplished by application of a "notched" excitation waveform across the trap endcaps, which includes the range of z-axial frequencies of ions in the trap. The MS⁵ map is summarized below. Notice that 5 MS³ experiments are possible and performing just four of them yields 11 possible MS⁴ experiments. There can be an almost exponential explosion of information, and the mapping process is ripe for automated software to select the experiments and generate the maps.

Some salient features of the map are: 1) MS⁴ was possible on even a very weak ion at m/z 298, by increasing the ion injection time by a factor of 40. The fragmentation pattern was the only branch of the map giving m/z 88 and 70 and led to the hypothesis that a small amount of isomeric "quat" was present in the sample (see scheme); 2) m/z 371 fragments mainly to m/z 254 and 118. Its lack of a relationship to the other ions can not be derived from the MS/MS product ion spectrum from the TSQ; 3) A totally unique series of ions (67, 81, 95...) dominates the MS⁴ and MS⁵ spectra of m/z 254. We have seen these ions in other surfactants and in another place (see these proceedings) we report on our hypothesis that they are highly unsaturated C_nH(2n-3) type ions derived

from the alkyl chain. They are absent in the TSQ spectrum at lower E_{cm} and very weak (<5%) at higher collision energies.

MSⁿ Analysis of Quaternary Surfactant

Other Fragmentations -- In this case, the entire map was readily interpreted and included even-electron fragmentations only. The formation of m/z 118, for instance, is hypothesized to involve H-abstraction at the alpha position to the amide nitrogen, after elimination of the quat terminus as trimethylamine. This path produces HO-CH₂CH₂N(H)-CH₂CHOHCH₂ + a primary carbonium ion, probably stabilized in cyclic forms with the various heteroatoms. This ion is interesting because water loss gives two isomeric ions of m/z 100. However, only one of the isomers is proposed to fragment by loss of 28, via retro-Diels Alder elimination of ethylene from a cyclic form (MS⁵).

QUAT ISOMER

ELECTROSPRAY MSⁿ OF SURFACTANTS - VERY UNSATURATED IONS FROM SATURATED AMIDES

Robert J. Strife & Marcia M. Ketcha, The Procter & Gamble Co.,
P.O. Box 538707, Cincinnati, OH 45253-8707

In one of our first electrospray MSⁿ (sequential product ions) analyses of an "unknown" surfactant in a shampoo extract, an unusual series of product ions was detected at m/z 67, 81, 95, 109, and 123 as the principal product ions at the MS³ stage. Also, the transitions of $95^+ \rightarrow 67^+$, $109^+ \rightarrow 81^+$ and $109^+ \rightarrow 67^+$ were observed in MS⁴ experiments. Other spectral evidence had led us to hypothesize the unknown was a substituted N-(2-aminoethyl) fatty amide. Confirmation of the final structure by obtaining an authentic sample of the proposed material (lauryl amphomono-acetate, LAMA, $MH^+ 345$) led to our next step -- determination of the origin of the unusual, methylene-related, ion series. Several amides were examined, but two in particular fragmented in a similar fashion to LAMA, lauryl diethanolamide (LDEA, $MH^+ 288$) and laurylamido- β -propyl betaine (LAPB, $MH^+ 343$).

MS/MS of Surfactants on a TSQ -- LDEA fragmented by loss of 61 to the only significant ion (m/z 227) above the unusual series. This observation is attributed to the following gas-phase

"Mimicked MS³" -- The carbonium ions of m/z 227 (LDEA), 226 (LAMA) and 240 (LAPB) were generated collisionally in the electrospray expansion region of the TSQ instrument.

They were subject to CID in the second quadrupole and were found to produce relatively intense ions at m/z 67, 81, 95, 109, 123.. consistent with the result on the electrospray ion trap. Their respective breakdown curves were plotted as absolute intensity vs. center-of-mass collision energy. The ion of m/z 95 was the most intense for all three compounds, followed next by m/z 109. The maxima of the curves occurred between 2-3 eV but were significantly different for each compound. The results suggested they fragment to common ions through different intermediates.

Composition of Ions of m/z 67, 81, 95... -- Since the ions are generated from species containing only one nitrogen, there are only two possibilities: 1) they are nitrogen-bearing, odd radical cations or 2) they are zero-nitrogen, $C_nH_{(2n-3)}$ or $C_nH_{(2n-5)}O$ even-electron types. The first proposal is unlikely for two reasons -- it cannot apply if the genesis of m/z 227 as suggested is correct (zero nitrogen) and further, production of odd radical cations from even-electron precursors by CID is unlikely in the case of electrospray ionization. The exceptions we have seen to this general principal always involve radicals stabilized in highly conjugated aromatic systems. These *unsaturated* compositions are unusual because the methylene spacing of the ions points to the *saturated* alkyl chain as their origin.

Generation of m/z 67, 81, 95... in a Nitrogen-Free System -- A retrosynthetic analysis of the structure of the ion of m/z 227 suggested that the ethylene glycol ketal of 2-tridecanone, when subject to electron ionization, should fragment to the same even-electron ion.

The synthesis was followed by capillary GC/MS and the mass spectrum of the product produced the expected ion at m/z 227 (30% relative intensity). GC/MS/MS yielded a product ion spectrum with m/z 95 (base peak), and m/z 67, 81, 109 between 45-50% relative intensity supporting the suggestions made concerning LDEA. Using 1,1,2,2-[²H]₄-ethylene glycol in the reaction (parent ion m/z 231) produced no mass shifts in the product ion spectrum.

Mechanism of Product Ion Formation -- We currently believe that the ions are likely $(C_nH_{2n-3})^+$ types, though an experiment with [¹⁸O]-labeled ethylene glycol would definitely rule out the even more unsaturated oxygen-containing formulas. We suspect the non-cyclized form of the ion shown (primary carbonium ion) abstracts hydride from the alkyl chain. The carbonyl group is suggested to be retained in an enol form, and with rearrangement may stabilize the carbonium ion as an allyl-type. Further H-rearrangement and loss of water from the original enol could generate the second necessary unsaturation. Further experiments with labeled substrates are under consideration.

Reactions of Nicotine Analogs: Functional Group Selectivity of Electrophiles

John J. Isbell and Jennifer S. Brodbelt

Department of Chemistry, University of Texas at Austin, Austin, TX 78712-1167

Jeffrey I. Seeman

Philip Morris Research Center, Richmond, VA 23261

The site of cation attachment in chemical ionization, or other ionization processes is one of the most important pieces of information for understanding product stabilities, predicting fragmentation pathways, and for rationalizing many thermochemical parameters of ions. Gas-phase basicity is one thermochemical parameter that is often used in the evaluation and prediction of sites of cation attachment for other types of reactions, such as metal cation attachment or methyl cation addition. Sites of ionization are probed¹ by application of tandem mass spectrometry, including collisional activated dissociation and isotopic labeling.

A detailed study was done to determine the site of methylation of nicotine analogs in the gas phase. Since the primary objective focuses on determining the site of methylation of nicotine, a strategy for indirect elucidation of the sites is needed. Isomer distinction in mass spectrometry is often done by comparing the collisionally-activated dissociation (CAD) spectrum of the isomer of unknown structure with one or more ion reference standards, i.e., ions of known structure.² Table 1 summarizes the CAD spectra and methylation ratio for the series of nicotine analogs. Both isotopic labelling and collision activated dissociation were used to elucidate the structure of ions and sites of reaction. Based on many comparisons and correlations, we show that methylation of nornicotine occurs predominantly on the pyridine nitrogen, in contrast to the solution results. (Gas-phase results are shown in Table 1. Solution-phase methylation results were previously reported.³ The N'/N ratios were found to be 2.6, > 100, and > 100 for nicotine, 2-isonicotine, and N,N-dimethyl-3-aminomethylpyridine, respectively.)

Methylation of nicotine and nicotine analogs with trimethyl oxonium yields products resulting predominantly from kinetic control, resulting in preferential alkylation at the pyridine nitrogen, in direct contrast to the site of methylation in solution. The only exceptions found in this work were for very slow ion-molecule reactions between trimethyl oxonium and 2-isonornicotine and 2-isonicotine. This change in the preferred alkylation site was attributed to steric inhibition in the rate of reaction, and, in accordance with the Hammond Postulate,⁴ resulted in more product-like transition states, and, therefore, the thermodynamically-preferred products were formed in greater abundance. This work also clearly demonstrates that the site of initial cation attachment need not be on the thermodynamically-preferred site.

^d The poor signal-to-noise of this spectrum made quantitation of m/z 134 difficult.

^e The (M + CD₃)⁺ CAD spectrum yielded: m/z 111, 100% (N); m/z 97, 3% (N); m/z 94, 2% (N')

THE USE OF TRIMETHYL BORATE AS A CI REAGENT FOR THE ANALYSIS OF BIOLOGICALLY ACTIVE MOLECULES

Esther C. Kempen; Jennifer S. Brodbelt; University of Texas at Austin, Austin, TX, 78712

Introduction

The use of tandem mass spectrometry coupled with chemical ionization has grown tremendously over the past decade. The use of ion-molecule reactions to selectively derivatize molecules in the gas phase has proved to be a particularly useful structurally-specific tool. While transition metal ions may overcome these problems, they often require special apparatus for their generation. Dimethoxy borinium ion, however, is easily generated by electron ionization of trimethyl borate. A positively charged borinium ion such as dimethoxy borinium ion contains two empty p-orbitals, allowing it to undergo multiple binding interactions with electron-rich functional groups. Trimethyl borate has proven successful as a chemical ionization reagent previously for the ionization of saccharides,¹ diols,² amides,³ and barbiturates.⁴ In this work, we explore the use of dimethoxy borinium ion as a CI reagent for biologically active organic molecules containing sites of Lewis basicity. The goal of this project is to evaluate the efficiency of borinium adduct formation and the degree of structural information from the CAD spectra of the adducts.

Ion-Molecule Reaction with Borinium Ions:

Several factors are important when evaluating a reagent for chemical ionization and characterization of analytes. These include the ion-molecule reaction efficiency, selectivity, and the degree of new information obtained from the dissociation of products. Upon reactions with $B(OCH_3)_2$ ions, most organic substrates form $(M + B(OCH_3)_2)^+$ adducts at $(M+73)^+$ and/or $(M + B(OCH_3)_2 - CH_3OH)$ products at $(M + 41)^+$. The substrates that form $(M + 41)^+$ ions all possess an acidic hydrogen that can be removed by a lone pair from an oxygen of the methoxy groups from the borinium ion.

CAD for Structural Elucidation

CAD patterns for nine biologically active compounds containing both protic and nonprotic sites of Lewis basicity were recorded. These compounds included; β -valerolactam, pimozone, nifenazone, *N*-methyl ephedrine, nitrazepam, eburnamonine, nifedipine, isoxicam, and tenoxicam. These patterns were compared with the CAD patterns obtained from the protonated analytes and methoxy methylene adducts because we have studied these alternative ionization processes extensively. In the cases of nifenazone, isoxicam, *N*-methyl ephedrine, nitrazepam, and nifedipine, the borinium ion adducts showed more diverse fragmentation on CAD than did either the protonated species or the methoxy methylene adducts. The most common losses observed from CAD of $[M+73]^+$ ion were 32u and 58u. Loss of 32 u corresponds to a loss of methanol from the $[M+73]^+$ ion. The loss of 58 u corresponds to a loss of $O=BOMe$ from the $[M+41]^+$ ion.

Site of Borinium Ion Attachment

To probe the favored site of borinium ion attachment, ligand exchange experiments were undertaken to evaluate the borinium ion binding affinities of model compounds. Four models were chosen to mimic the functional groups found in the biologically active analytes: acetophenone, *N,N*-dimethylaniline, pyridine, and *N,N*-diethyl toluamide. All of the nitrogen-containing compounds have greater borinium ion affinities than the oxygen containing model, acetophenone. The *N,N*-disubstituted aniline likely has a reduced borinium ion affinity due to steric constraints on the nitrogen, thus the aromatic amide has the greatest borinium ion affinity. These model studies suggest that in compounds containing both a sterically hindered amine functionality and an amide functionality, that the borinium ion may preferentially bind to the amide. This is supported by the observed losses of 58 u from the $[M+41]^+$ of those compounds containing both functionalities, since this loss may only occur when a relatively labile oxygen binds the borinium ion. It should also be noted that both the oxygen-boron and nitrogen-boron bonds are stronger than the oxygen-hydrogen, nitrogen-hydrogen counterparts. Because of this fact, and steric considerations, the borinium cation

should be much less labile than a proton and one would not expect it to migrate or change positions easily.

Conclusion

Dimethoxy borinium ion shows some promise as a chemical ionization reagent for analysis of biologically active organic molecules containing functional groups of Lewis basicity. CAD of dimethoxy borinium ion complexes with these types of molecules often yield large numbers of products. Although these products do not necessarily occur in high yields, they serve as highly effective fingerprints which are useful for compound identification. The losses such as CH_3OH and $O=BOMe$ occur predominantly for the $[M+(CH_3O)_2B]^+$ adducts and give insight into the functional groups which are interacting with the borinium ion.

Temperature and Size Dependence of Radiative Association Rates

Victor Ryzhov, Stephen J. Klippenstein* and Robert C. Dunbar*

Department of Chemistry, Case Western Reserve University, Cleveland, OH 44106

Introduction

Radiative association is the sticking together of an ion and a neutral molecule in gas phase with stabilization of the collision complex by photon emission. This process represents an emerging tool for quantitative estimations of binding energy of complexes as well as an important part of the interstellar chemistry. In this work we continue our efforts to rationalize what governs the association kinetics.

A high level VTST modeling of radiative association kinetics was developed recently¹ and successfully applied to describe the temperature dependence of NO⁺ associating with 3-pentanone. For a wider application of this theory to the temperature dependence of radiative association rates we extended our study to two other systems, (CH₃)₂COH⁺ / (CH₃)₂CO and (CD₃)₂COD⁺ / (CD₃)₂CO. These systems are attractive because some high quality kinetic data are available^{2,3} which can be combined with our experimental data. There are also reliable values of their binding energies.

While this high level theory gives reliable predictions for the temperature and binding energy dependence within a particular system, it is not easy to use it for comparison among several different systems. From this point of view the simple generic "standard hydrocarbon" model⁴ is much more convenient. A new, refined version of this model has just appeared⁵. To test the model we studied the size effect along the series of aliphatic ketones looking at the association with NO⁺ as well as the formation of the ketone protonated dimers. These systems keep the structural changes minimal and the binding energy does not vary much. This enables us to separate the size effect from all other factors affecting the association kinetics.

Methods

Rates of radiative association were measured in the temperature regime from 245K to 400K. The pressure of the neutrals varied from 5x10⁻⁹ to 5x10⁻⁶ torr. The ion gauge pressure readings were calibrated to match the known proton transfer rate constant between acetyl cation and acetone³.

Experiments were performed on a FT-ICR spectrometer with a 2.54 cm cubical cell. NO was pulsed into the cell and ionized by EI (electron energy 15 eV). The protonated ketone ions were formed by self-CI. After a thermalization period (at least 5 collisions) the desired ions were isolated by series of ejection pulses and allowed to react for a time which ranged from 200 ms to 20 s and the extent of association was measured as a function of the reaction time.

The reaction chamber was heated by heating tapes or cooled by dry ice. A copper-constantan thermocouple was located inside the chamber on the trapping plate. To avoid extra heating by the filament, an idle time up to 20 s was provided in each working cycle.

Comparison with theory

The bimolecular rate constant for radiative association at zero pressure limit is given by

$$k_2 = k_{ra} = k_f k_r / (k_b + k_r), \quad (1)$$

where k_f is the bimolecular rate constant for the collisional complex formation, k_b is the unimolecular redissociation rate constant, k_r is the unimolecular rate constant for IR photon emission from the energized complex.

Only k_r can be readily estimated, using the dipole corrected Langevin equation. k_f and k_b are not easily estimated and demand the resources of fairly good theoretical approaches.

A high level VTST approach to radiative association reactions developed recently^{1,6} was used to describe the temperature dependence. The geometries of the association adducts were calculated *ab initio* along with their vibrational frequencies and IR intensities at the MP2 level. This led to a calculation of the photon emission rate k_r . Subsequent canonical VTST treatment of Eq. 1 at different temperatures gave excellent agreement with the experimental values (see Fig. 1).

One of the adjustable parameters in this modeling is the binding energy. Characteristically, the best-fit binding energies agree with the experimental values within 1 kcal/mol.

Unfortunately, *ab initio* calculations do not give reliable results for big systems (more than 20 atoms). To use this theory for such systems one needs an alternative source to estimate the vibrational frequencies and IR intensities of the complex.

The simple "standard hydrocarbon" model that was found useful in describing the size dependence of radiative association previously⁷ was applied in its refined form. A major change compared to the old version is the use of phase space theory to treat Eq. 1 canonically rather than a simple calculation of k_b by RRKM theory.

The main uncertainty of this model is the estimate of the photon emission rate k_r :

$$k_r (s^{-1}) = 73 (E_0(eV))^{1.5} (N)^{-0.5} \quad (2)$$

The equation does not take into account any chemical specificity of the complex. This sometimes leads to wrong predictions of the photon emission rates. For example, for the acetone protonated dimer Eq. 2 gives $k_r = 13 s^{-1}$, while the reliable experimental value is 102⁸. On the other hand, for the NO⁺ / 3-pentanone complex the model predicts $k_r = 27 s^{-1}$, in good agreement with the VTST value of 34⁹. Consequently, the absolute numbers predicted by this model for the latter system agree well with the experiment (Fig. 2). For the ketone protonated dimers (Fig. 3) we had to scale the modeling predictions to match the experimental value for acetone. The model predicts a straight line for quantity $R = k_r / k_b$ used in Fig. 2 and 3 plotted against the square root of the number of degrees of freedom N in semilogarithmic coordinates when the binding energy E_0 is constant.

What is important, however, that in both cases this simple model succeeds in prediction of the trends (see Fig. 2 and 3), when we go from acetone along the series of ketones.

Conclusions

- The high level VTST approach applied here shows excellent agreement with the observed experimental temperature dependence for different systems over a wide range of temperatures.
- The capabilities of this theory are somewhat restricted due to the limited availability of IR frequencies and intensities of the collisional complex.
- The simple "standard hydrocarbon" model gives a very easy and accurate estimate of the size dependence.
- While one should accept the absolute numbers predicted by this model with caution, "standard hydrocarbon" is very convenient for making comparisons among several different systems.

Infrared Photodissociation of Gaseous Ions in a Fourier Transform Ion Cyclotron Resonance Spectrometer

D. Scott Tonner and Terrance B. McMahon
University of Waterloo, Waterloo, Ontario

Previous studies have shown that ambient infrared black body radiation induces unimolecular dissociation in weakly bound ionic clusters under the conditions of Fourier Transform Ion Cyclotron Resonance (FTICR) Spectrometry. This technique has been named ZTRID for zero-pressure, thermal, radiative induced dissociation. The long trapping times (>2000 s) and low pressures ($<10^{-9}$ torr) of FTICR allow photodissociation by relatively weak infrared sources. This technique can be extended to include photodissociation of ionic clusters with low power, (0.1 - 3.0 W) CO_2 laser radiation. Since the ions can be generated in an external high pressure ion source, the background neutral pressure in the FTICR cell is low and we are able to examine photodissociation events under essentially collisionless conditions. This also rules out excitation of neutral species and subsequent collisional energy transfer to the ions.

Both positive and negative ions have been studied in our laboratory. Various proton bound dimers as well as protonated water clusters have been dissociated using both ZTRID and CO_2 laser photodissociation techniques. High Pressure Mass Spectrometry (HPMS) has been used to determine the energetics of cluster formation under equilibrium conditions. The laser power dependence of the photodissociation rate constants has been investigated for several of these species and correlations to binding energetics are being investigated. Future work will attempt to relate the laser power dependence to the temperature dependence of ZTRID rates.

The intermediate $\text{S}_{\text{N}}2$ complexes $\text{Cl}^-(\text{RBr})$, $\text{Br}^-(\text{RCl})$ ($\text{R}=\text{C}_2\text{H}_5$, $\text{i-C}_3\text{H}_7$) have also been studied in the FTICR. A bimolecular reaction with background water transfers a halide ion to the water molecule. In all cases, the ion transferred corresponds to the entrance channel complex. Thus, the structure of these reaction intermediates is unambiguously determined. The kinetics of black body induced dissociation of $\text{Cl}^-(\text{C}_2\text{H}_5\text{Br})$ are shown in Figure 1. It is evident that the $\text{Cl}^-(\text{H}_2\text{O})$ cluster is formed along with chloride and bromide ions but no $\text{Br}^-(\text{H}_2\text{O})$ is observed. HPMS provides the stationary points of the $\text{Cl}^- + \text{RBR} \rightleftharpoons \text{Br}^- + \text{RCl}^-$ potential energy surface (PES) and the resultant PES is shown in Figure 2. Photodissociation of the $\text{Cl}^-(\text{C}_2\text{H}_5\text{Br})$ species produces more bromide than chloride as expected from the PES. The branching ratio (Br^-/Cl^-) increases with increasing laser power. The overall rate of dissociation of $\text{Cl}^-(\text{CH}_3\text{CH}_2\text{Br})$ via black body radiation is 1.8 times faster than that of $\text{Br}^-(\text{CH}_3\text{CH}_2\text{Cl})$ despite being 2.4 kcal/mole more strongly bound. However, the rate of Cl^- production from $\text{Cl}^-(\text{CH}_3\text{CH}_2\text{Br})$ is on the order of 1/2 the rate of Br^- production from $\text{Br}^-(\text{CH}_3\text{CH}_2\text{Cl})$. Thus, for the $\text{Cl}^-(\text{CH}_3\text{CH}_2\text{Br})$ complex, the pathway to Br^- product is the more efficient. Both results are possibly due to poor coupling of the intramolecular vibrational modes of $\text{CH}_3\text{CH}_2\text{Br}$ to the low frequency Cl^- dissociation modes. This agrees with theoretical predictions by Hase for other $\text{S}_{\text{N}}2$ reactions in which excitation of specific vibrational modes leads to increasing reaction rates.

Future experiments will continue to explore the photodissociation dynamics of protonated species and $\text{S}_{\text{N}}2$ reaction complexes. In addition, the effects of translational energy and vibrational excitation on the bimolecular $\text{S}_{\text{N}}2$ reaction rate will be studied. Finally, a broadband infrared source combined with a circularly variable filter (CVF) will be used to obtain low resolution infrared spectra of weakly bound ions.

Figure 1: ZTRID kinetics for $\text{Cl}^-(\text{CH}_3\text{CH}_2\text{Br})$ at 22°C .

Figure 2: Potential energy surface of the $\text{Cl}^- + \text{C}_2\text{H}_5\text{Br} \rightleftharpoons \text{Br}^- + \text{C}_2\text{H}_5\text{Cl}$ reaction determined by HPMS.

FT ICR STUDY OF CHIRALITY EFFECTS IN THE FORMATION OF PROTONATED AND AMMONIUMATED DIMERS AND TRIMERS

M.I.Nikolaeva, E.N. Nikolaev

Institute of Energy Problems of Chemical Physics Russian Academy of Sciences, Moscow, 117334 Russia

J.H. Futrell, D.P. Ridge

Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

Previously (see poster ThPL 283 for references) we found a strong chirality effect in the kinetics of the formation and dissociation of tartrate protonated dimers. This showed the tartrates to be a convenient model system for chiral molecule and chiral matrix interactions. We report here a study of modifying the chiral matrix by changing the core ion and adding more molecules. We also report the results of extending our study to chiral molecules of particular biological importance: amino acids.

METHODS

FTICR mass spectrometry (FTMS 2000 instrument (Finnigan FTMS Madison, W1) with homemade external ion source) was used in this study. The following ionization techniques were used: self chemical ionization in FTICR cell, metal ion laser desorption in FTICR cell and chemical ionization in high pressure external ion source followed by injection of the ions into the FTICR cell.

RESULTS

Influence of core ion type on chirality effects for tartrates.

The processes of tartrates association complex formation were studied for the following core ions: H^+ , Li^+ , Na^+ , K^+ , H^+NH_3 , $H^+C_2H_5NH_2$, H^+H_2O . All the experiments were carried out with the enantiomer-labeled racemic mixture of dimethyltartrate (DMT). The antipodes of DMT were distinguished by 2H -labeling of the methyl groups of one antipode to give the pairs of $L\text{-}^2H_6\text{-DMT}$ and $D\text{-DMT}$. Li^+ , Na^+ , K^+ ions were produced by laser desorption from a stainless steel foil covered by salts of the appropriate metal.

The results of all the experiments are represented in the table.

Protonated amino acids dimers and trimers.

Studies of protonated amino acids dimer and trimer formation was carried out using a direct inlet probe to introduce sample into the FTICR cell region. Ionization was by EI followed by self-CI. The direct inlet probe temperature was chosen to maximize ion complex formation. The following amino acids and their derivatives were used: L-alanine, $L\text{-}^2H$ -labeled alanine, D-alanine, D-serine, L-serinamide, D-tyrosine, L-tyrosinamide, L-glutamine, D-glutamine. Peaks corresponding to dimers and trimers with different numbers of L and D molecules were distinguished either by molecular weight (D-serine and L-serinamide) or by isotopic labeling of one of the enantiomeric forms ($L\text{-}^2H$ -alanine and D-alanine).

Dimers of ($H^+ + 2M$) type were found for alanine, glutamine, serinamide and tyrosinamide. Those dimers were also present in the corresponding amino acids mixtures. Trimers of ($H^+ + 3M$) type were found only for alanine. No higher association complexes were found in the amino acid spectra. No pronounced chirality effect on dimer and trimer formation kinetics was found for any of studied amino acids systems over wide range of temperatures and pressures. Diastereomeric products showed the binomial abundance distribution 1:2:1 and 1:3:3:1 for dimers and trimers, respectively.

Table
Chiral Effects in Tartrate Complexes

Core Ion Type	Dimers	Trimers	Tetramers
H^+	homochiral dominates	heterochiral dominates	homochiral weakly preferred
Li^+ Na^+ K^+	No effect No effect No effect	- - -	- - -
$H^+ + NH_3$	No effect	homochiral dominates	-
$H^+ + C_2H_5NH_2$	No effect	homochiral dominates	-
$H^+ + H_2O$	heterochiral dominates	homochiral dominates	-

CONCLUSIONS

Chiral discrimination in tartrate complexes is caused by hydrogen bonds formation. If the core ion strongly coordinates tartrates there is no effect for dimers; there is an effect for trimers, with the homochiral component dominant. Weak coordination with core ions (H^+ and H^+H_2O) leads to a strong chirality effect for both dimers and trimers. The character of the effect changes when water molecules are added.

CI spectra of alanine, serine, glutamine, tyrosine, serinamide and tyrosinamide were measured over a wide range of temperatures and pressures and no pronounced chirality effect was found in their protonated dimers and trimers.

MEASUREMENTS OF FORMATION AND DECOMPOSITION RATE CONSTANTS OF HOMO- AND HETEROCHIRAL PROTONATED DIMETHYL TARTRATE DIMERS IN SELF CHEMICAL IONIZATION CONDITIONS BY FT ICR MASS SPECTROMETRY.

E.N. Nikolaev* and E.V. Denisov

Institute of Energy Problems of Chemical Physics Russian Academy of Sciences, Moscow, 117334 Russia

Previously tartrate dimer formation and decomposition processes were investigated using the self chemical ionization technique [1,2], FT ICR with high pressure ion source and high pressure mass spectrometry [3], it was shown that homo and heterochiral protonated dimers of these substances differ in stability. Kinetic measurements were made in conditions of vacuum isolation of protonated dimers, when they can be activated only by absorption of black body radiation from the vacuum system walls. The goal of this work is to investigate the influence of chirality on the rate of dimethyltartrate protonated dimer formation and the rate of dimer decomposition in self-chemical ionization conditions. The experiments were carried out using an ion cyclotron resonance spectrometer CMS-47 (Bruker Spectrospin) equipped with a 4.7 Tesla superconducting magnet. The cell and vacuum chamber temperature in the cell region was changed by heating the whole vacuum system using system bake-out heaters. To obtain temperatures below room temperature liquid nitrogen vapors were used, blown through the gap between magnet cryostat tube and the vacuum chamber tube. A carbon fiber field emitter electron source was used for ionization of tartrate vapors to avoid heating of the ICR cell. DMT left-hand form was labeled by replacement of two methyl groups by CD_3 to separate peaks belonging to different chiral forms in mass spectra. To separate reagent chirality influence to elementary processes of dimer formation and decomposition, we carried out measurements of relative rate constants for homo and hetero chiral dimer formation processes and their monomolecular decomposition processes also. Fig. 1 presents the mass spectra of dimers that were produced in ion-molecule association reactions from initially isolated protonated monomers and DMT molecules of different chirality. It can be seen that the ratio of homo- and heterochiral dimers (sum of the left and right peak to the middle peak) is growing with reaction time. The extrapolation of heterochiral dimer peak intensity to a sum of homochiral dimer peak intensities ratio to zero reaction time of dimer formation reaction gives approximately 1. It means that the reaction rate constant k_1 for protonated dimer formation in the case of DMT does not depend upon monomer chirality. We can conclude from this fact that DMT molecule is not large enough to influence capturing process by hydrogen bond formation during ion molecular association reaction and this process is governed only by ion-averaged dipole and -induced dipole interactions. From expression of equilibrium constant via backward and forward reaction rate constants $K = k_- / k_+$, it follows that only decomposition rate constant k_- depends upon chirality of monomers from which dimer is produced. We measured decomposition kinetic curves for initially isolated protonated homochiral $k_1 = 0.16(\pm 0.02) s^{-1}$. k_1 does not depend upon the pressure in region from 10^{-7} to 5×10^{-8} Torr. It means, that the dimer decomposition time is greater than the time between the dimer-molecule collisions. In standard classification of association reaction our experimental conditions correspond to the high pressure regime. Fitting the dependence of k_1 on T by $k = A \cdot \exp(-E/RT)$ we get for parameters A and E : $A = 10^{14} s^{-1}$ and $E = 21 (\pm 0.5) kcal/mol$. The frequency factor A is close to typical values for unimolecular

dissociation, and activation energy E is equal to the enthalpy of proton bound DMT dimer formation from protonated monomers, at $T > 50^\circ C$ [3]. The coincidence of E with high-temperature value of the enthalpy of dimer formation permits us to conclude that the decomposing dimers have activated state conformation corresponding to the temperatures higher than $50^\circ C$. For heterochiral dimer decomposition constant we got $k_2 = 1.19(\pm 0.02) s^{-1}$. This value is approximately one order of magnitude higher than k_1 . If we compare the results obtained with the results of measuring homo- and hetero dimer decomposition constants obtained by Nikolaev and McMahon [3] for vacuum isolated dimer at room temperature:

$k_1 = 0.027(\pm 0.002) s^{-1}$, $k_2 = 0.22(\pm 0.02) s^{-1}$, we find, that dimer collisions with monomer effectively thermalise dimers and keep them in equilibrium with monomers, increase decomposition rate constant for both homo- and hetero dimers by nearly an order of magnitude. According to McMahon and Dunbar [4,5] activation of vacuum isolated dimer decomposition is realized through absorption by dimers blackbody radiation of vacuum chamber walls. From our results we can conclude that time of equilibrium establishing between blackbody radiation and dimers are much higher than dimer decomposition time in experiments of Nikolaev and McMahon and dimer in these experiments are underactivated and their internal temperature was less than the temperature of the walls. We find out that the effective dimer decomposition rate constant in the case of a mixture of an enantiomers is strongly connected with their concentration at fixed temperature. It means that by measuring the effective decomposition rate constant of protonated DMT dimer we can determine the concentration of L and D forms in the mixture of unlabeled DMT molecules. It seems to us that this result is of analytical importance.

Determination of the Gas-Phase Acidities of Uracil and 5-Fluorouracil by FT-ICR Mass Spectrometry

Wei gun Li*, Ivan Santos, Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab, Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

* Department of Chemistry, Florida State University

5-Fluorouracil (5FU) is a commonly prescribed anti-tumor agent and can also replace normal uracil (U) in RNA. The disruption of normal RNA base-pairing as well as the normal biosynthetic pathways involving uracil have been partly attributed to the greater acidity of the 5FU compared to uracil. Because the interior of an RNA helix in which the base pairs are located is hydrophobic, the gas-phase acidities (GA) of 5FU and U may be a better indication of hydrogen-bond strength in A:U (or A:5FU) base pairs inside an RNA helix than the corresponding solution acidities.

Gas-phase acidity (GA) is defined as the Gibbs free energy change for the following reaction: $AH = A^- + H^+$ [1]. A smaller (positive) GA value corresponds to a more acidic compound. Gas-phase acidity is an intrinsic molecular property without the complication of solvation, and is well-suited for fundamental analysis of structure-energy relationships. Here, we report the relative gas-phase acidities of uracil (U) and 5-fluorouracil (5FU) by Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry by use of the kinetic method (2). Consider the reaction:

If the two competing dissociation reactions have similar entropy changes, then

$$\ln(k_1/k_2) = \delta \Delta G^0_{\text{acid}}/RT_{\text{eff}}$$

in which k_1/k_2 may be approximated as the relative ion abundance ratio of B^- to A^- .

Table 1. GA's of several compounds used in these experiments. We determined the GA's of uracil and 5FU by the kinetic method. Other GA's are from the literature [3].

Compound	$\Delta G^0_{\text{acid}}(\text{kcal/mol})$
Uracil	328.9 ± 0.3
4-Chlorobenzoic acid	327.2
3-Cyanobenzoic acid	321.5
5-Fluorouracil	321.3 ± 0.2
4-Nitrobenzoic acid	320.0

$\Delta G_{\text{acid}}(\text{U}) - \Delta G_{\text{acid}}(\text{5FU}) = 1.8 \text{ kcal/mol}$, or $K_a(\text{5FU})/K_a(\text{U}) = 20$. **5-Fluorouracil is 20,000 times more acidic than uracil in the gas phase compared to solution.**
