GAS-PHASE REACTIONS OF FULLERENE IONS WITH OZONE

Christopher L. Holliman and Stephen W. McElvany, Chemistry Division / Code 6113, Naval Research Laboratory, Washington, D.C. 20375

The oxidation behavior of fullerenes has been extensively studied. Specifically, the interaction of ozone with fullerenes in solution yields a wide variety of oxides, e.g. $C_{60}O_n$ with $n = 1-5$. Here a series of $C_{60}O_n^-$ ions ($n=1-16$) are generated by reaction of C_{60} anion with ozone in a Fourier-transform mass spectrometer.

Ozone is generated by passing pure oxygen (>99%) at 140 mL/min over an electric discharge. The ozone is concentrated from the unreacted oxygen by passing the gas stream through a silica gel trap that is immersed in a isopropanol/dry ice bath (~195 K). Fullerene soot is pressed into a pellet and mounted on the end of a direct insertion probe tip. The frequency-doubled output (508 nm) of a Nd:YAG laser is attenuated and focussed to obtain the threshold conditions required for desorption and ionization. The total ozone pressure in the cell during these reactions was approximately 8.5×10^{-8} torr. The mole fraction of ozone that reached the ion cell was approximately 0.25 as measured by electron ionization of the neutrals. Fullerene oxide product anions are mass selected and subsequently fragmented by low-energy collision induced dissociation with argon.

Reaction of Fullerene Ions with Ozone

The products formed from a ten minute reaction of C_{60} anion with ozone is shown in Figure 1. The distribution of products is striking when compared to the product distribution that is observed from fullerene/ozone reactions in solution. Typically no oxides ($C_{60}O_n$) with $n > 5$ are observed from ozonated solutions of fullerenes whereas in the gas-phase n values as high as 16 are observed. Kinetic data indicates that the oxygens add stepwise and $n=16$ may not represent the maximum number of oxygens that can be added to the sphere. Similar product distributions are observed for C_{70} anions with the maximum value of $n=10$ for a 3 minute reaction time. The measured reaction rates for the anions of C58, C68, and C72 are significantly slower than the rates of C60 and C70. The slower measured rates most likely reflect the relative stability of these fullerenes. Interestingly all fullerene cations investigated were relatively unreactive towards ozone. This result indicates that the additional electron density on the fullerene anions plays an important role in at least the initiation of the gas-phase reaction.

Collisionally Induced Dissociation of Fullerene Oxides

The CAD spectra of the fullerene oxides are consistent with those obtained from bulk fullerene oxides produced by ozone reactions in solution. $C_{60}O^-$ fragments by loss of O to yield C_{60}^- . CID of the higher oxides ($n = 2-11$) always yields multiple or combinations of CO and CO_2 losses resulting in the disruption of the cage. This indicates that for all of the oxides investigated here by CID, the oxygens have covalently bonded to the fullerene anion. Only in the CID spectra of $C_{60}O^-$ has the loss of oxygen been observed.

Collisionally Induced Dissociation of $C_{59}O_n$ Anions

One would expect that structural isomers must form during the reaction of ozone with fullerenes. Unfortunately the low-energy fragmentation channels that are accessed by FTMS are not structurally informative. In this study a given fullerene oxide is formed by a single route; consecutive additions of oxygen to the fullerene anion. When multiple losses are observed in the CID spectra (such as losses of CO and CO_2) it cannot be determined whether this indicates the existence of structural isomers or is merely different fragmentation routes of the same ion. In contrast, an ion such as $C_{59}O_n^-$ can be formed by several routes utilizing CID-induced losses of CO and CO_2 and reactions with ozone. For example, the ion $C_{59}O^-$ can be formed by 3 routes:

The CID spectra for $C_{59}O_2^-$ (m/z 740) formed by the three different reaction routes is shown in Figure 2. Although all three ions lose CO and CO_2 , the relative abundances of the losses are significantly different and indicate that structural isomers exist. How these spectra pertain to the relative positions of the oxygens on the parent ions is unknown. Current efforts are focussed on using the above strategy with the higher oxides to establish trends in CID fragmentation. It is hoped that these trends will lend insight into the bonding topology of the fullerene oxides produced by reactions with ozone.

GAS PHASE COORDINATION CHEMISTRY: HOW IS IT RELEVANT TO CONDENSED PHASE COORDINATION CHEMISTRY?

Keith Fisher,* Ian Dance, Brett Williams and Gary Willett.

School of Chemistry, University of New South Wales, Sydney 2052

The ion trap is a very useful test tube in which to carry out chemical reactions. The only problem is to get metal ions or complex metal ions into the gas phase. That proves not to be a problem with a suitable laser, ablating metals or metal compounds. We have used laser ablation and the ion trapping facility of the FTICR/MS to study some inorganic coordination chemistry. Along with the mass spectrometry we have used density functional theory to predict minimum energy structures for some of the ions observed.

In inorganic coordination chemistry we are concerned with the attachment of donor ligands to metals. The donation of a pair of electrons from the donor atom of a molecule to the metal atom or metal ion increases the electron density on the electropositive metal. The coordination number is the number of donor atoms surrounding the metal. In solution, coordination numbers of 4, 5 and 6 are common but 0 is never found and 1, 2 and 3 are rare. In the gas phase the reverse is true.

The two most important factors influencing coordination chemistry in the condensed phase (not present in the gas phase) are the solvent and crystal packing forces. The stabilities of oxidation states, solubilities, coordination of the solvent, the crystalline product formation and determination are all at the mercy of these powerful extraneous forces. They do not exist in the pristine conditions of the gas phase and so what you see is what you should get! The reactions of metal ions in the gas phase with conventional condensed phase coordination ligands is possible.

Laser ablation produces the M^+ ion which is not common in solution. The best examples of M^+ are Na^+ , K^+ , Tl^+ and Ag^+ . Ag^+ provides some good examples of comparative coordination chemistry in the condensed phases and the gas phase.

The reaction of silver ions (Ag^+) with pyridine has been studied in solution and in the gas phase.

In solution $Ag^+(solv) + py(solv) \rightarrow [Ag(py)_4]^+(solv)$

Gas phase $Ag^+(g) + py(g) \rightarrow [Ag(py)]^+(g) \rightarrow [Ag(py)_2]^+(g)$

In the gas phase the under-coordinated Ag^+ (initially zero coordinate) undergoes addition of two pyridine molecules by donation of two electrons from the nitrogen atoms. Density functional calculations on the $[Ag(py)]^+$ ion indicate that the Ag is raised out of the plane of the pyridine ring. This suggests that the Ag ion is bound to the pyridine ring by both p-donation from the nitrogen and a π -interaction of the aromatic system.

Ag_3^+ reacts with pyridine and the final product is the $[Ag_3(py)_3]^+$ ion, density functional calculations indicate that the whole system is planar. There is no condensed phase equivalent ion.

$[Ag_2(CN)]^+$ is known in liquid ammonia and with limited pyridine dissolved in the ammonia it will form $[Ag(CN)(py)_2]^+$. A similar ion has been observed in the gas phase.

$[Ag_2(CN)_2(py)_2]^+$

Ag^+ reacts with benzene in the gas phase to produce the ion $[Ag(C_6H_6)]^+$ which has also been observed in the condensed phase¹ in the compound $[Ag(C_6H_6)]AlCl_4$. Interestingly the density functional calculations on this ion indicates that the Ag^+ sits above a carbon-carbon bond and not in the centre of the C_6H_6 ring. This is also found in the crystal structure.

Ag^+ reacts with S_8 in the gas phase² to produce an ion $[AgS_{16}]^+$, this ion has been observed in the condensed phase³ in the compound $[Ag(S_8)_2]AsF_6$.

Triphenylphosphine (PPh_3) is a very common ligand in coordination and organometallic chemistry but in the gas phase it suffers a problem when reacting with M^+ ions; it has a low ionization energy (7.36 eV). Thus with Ag^+ it is a reducing agent, (undergoes charge transfer) but it can act as a ligand to ions having low ionization energies, in such complex ions as $[NaPPh_3]^+$, $[Ca(PPh_3)_2]^+$ and $[Eu(PPh_3)_2]^+$.

Simple coordination chemistry can be similar in the condensed phase and the gas phase as long as the solvent does not play an important role, such as a strong ligand or aiding proton abstraction.⁴ In the more dense environment of the condensed phase, higher coordination numbers may be expected.

Investigations of Ion Formation, Fragmentation, and Collisions Using DC and Pulsed Ion Extraction

Randy J. Arnold and James P. Reilly
Department of Chemistry, Indiana University, Bloomington, IN 47405

The application of delayed ion extraction in MALDI/TOF mass spectrometry experiments has led to significant improvements in resolution compared to that obtainable using DC electric fields¹⁻⁴. These improvements arise because the delayed application of an ion accelerating field enables focussing of the broad velocity distribution that characterizes the desorbed molecules. While resolution improvements have been of primary interest to most practitioners, delayed ion extraction can impact MALDI mass spectra in other ways. For example, matrix adducts are commonly observed in MALDI mass experiments. We found that the relative quantity of intact adduct ions appears to decrease as a function of time after the desorption event. Using delayed ion extraction, it is possible to study the spontaneous decay of matrix adducts in the source region of the time-of-flight instrument. Figure 1 displays MALDI/TOF mass spectra of lysozyme in ferulic acid at three different ion extraction delay times: 3.49 μsec , 6.8 μsec , and 8.9 μsec . The loss of adduct structure with increasing time reflects the spontaneous fragmentation of these adduct complexes. Adduct formation and fragmentation are highly dependent on the matrix in use. Figure 2 displays lysozyme mass spectra recorded in (A) ferulic acid, (B) α -cyano 4 hydroxycinnamic acid, (C) 2,5 dihydroxybenzoic acid and (D) sinapinic acid. Spectrum B displays the fewest matrix adducts and even provides evidence of parent ion fragmentation in the source region of the mass spectrometer. This is consistent with the common observation that α -cyano 4 hydroxycinnamic acid is the most explosive of the popular matrix compounds⁵.

Since the degree of ion fragmentation and adduct formation in MALDI experiments depends strongly on the matrix in use, it may be possible to learn about the origins of these variations by looking for other experimental observables that vary from one matrix to the next. For this reason, we chose to study the velocity distributions of ions produced using popular protein matrices. While matrix velocity distributions have been measured in a number of previous studies, direct comparisons of different matrices recorded under essentially identical experimental conditions have not been previously reported. Data for ferulic acid and α -cyano 4 hydroxycinnamic acid are displayed in Figure 3. We find that the two distributions peak between 1200 and 1400 m/sec. While α -cyano 4 hydroxycinnamic acid ions are somewhat faster, differences in the velocity distributions are less dramatic than are differences in the Figure 2 lysozyme mass spectra. We therefore conclude that the matrix velocity distributions and the degree of adduct formation and parent ion fragmentation are weakly correlated parameters.

Gas-phase Reactions of Biopolymers in a MALDI QUISTOR TOF-MS

Markus Stoeckli, Peter Kofel, Urs P. Schlunegger
Institute of Organic Chemistry, University of Berne, Switzerland

The combination of a QUISTOR with a TOF analyzer results in an instrument well suited for exploring ion molecule reactions. Ions created by MALDI directly in the QUISTOR are trapped and cooled by a helium gas pulse. During the following storage time of several seconds the primary ions react with neutrals to new ions. The ionic products of these reactions are extracted into the flight tube by a short voltage pulse. This method allows to detect all the product ions of each cycle.

Melittin is a highly hydrophobic peptide composed of 26 amino acids. The sequence reveals a strong basicity with its 5 Lys and Arg amino acid residues. For this reason the addition of small organic acids to this molecule can be studied. Often used matrices such as sinapic acid and 2,5-dihydroxybenzoic acid desorb from the probe tip during the ion storage and can make interactions with the stored ions. Some of these matrix addition reactions were also studied.

The addition reaction of melittin with matrix molecules was quantitatively measured. Up to 5 DHB molecules add to one melittin ion. These addition reactions occur during the time period of several seconds after the ionization. Sinapic acid matrix molecules were also found to make additions to melittin. Products with up to 3 sinapic acid molecules added on one melittin ion were measured.

Several peptides consisting of parts of the melittin sequence with fewer basic groups were also studied. These less basic molecules gave as expected products with fewer DHB molecules.

Trifluoroacetic acid that was let into the QUISTOR in a small concentration (2E-8 mbar) results in addition products of 4 to 6 TFA molecules with one melittin ion (figure 1). Products with less TFA molecules added could not be observed (figure 2).

The addition of acids to basic peptides is only one of the possible reactions that can be performed with a QUISTOR-TOF mass spectrometer. Future studies will go into the direction of specific gas-phase reactions that will allow an identification of specific functional groups. This identification has the advantage that it can easily be performed and that it gives additional information on the interesting molecule in a short time.

Differentiation of Carbohydrate Stereochemical Features via MS/MS of FAB- and ESI-Generated Ni(N-Glycoside) Complexes

Glenn Smith and Julie A. Leary*
Chemistry Dept., University of California, Berkeley, CA 94720

In a recent communication (1), the dissociation mechanisms of nickel-coordinated monosaccharides (in the form of N-glycoside ligands) were dependent upon stereochemical features of the complexed monosaccharides. Specifically, kinetic energy releases (KER) and product ion abundances associated with the metastable dissociation of FAB-generated $[\text{Ni}(\text{diaminopropane}/\text{monosacc.})-\text{H}]^+$ complexes (m/z 293) were sensitive to the axial/equatorial configuration of the C-2 hydroxyl substituent of the monosaccharide. These studies have been extended to investigate the ability of this methodology to differentiate configurations of substituents at other carbon centers in D-aldoheptoses.

The tricoordinate m/z 293 ions were allowed to undergo unimolecular dissociation and mass-analyzed ion kinetic energy spectra (MIKES) of the resulting product ions were obtained. Metastable dissociation of the m/z 293 precursor ion leads to the efficient formation of the m/z 233 product ion (neutral loss of $\text{C}_2\text{H}_4\text{O}_2$) only for complexes possessing cis C-2 and C-3 substituents (Table 1). KER values associated with this metastable dissociation can differentiate axial and equatorial C-2 substituents in complexes possessing equatorial C-3 substituents. Similar trends in KER are not present for complexes possessing axial C-3 substituents. KER values and product ion intensities are not dependent upon the orientation of the C-4 substituent.

Tricoordinate Ni(N-glycoside) complexes were also generated for four monosaccharides via ESI at concentrations that are 1000 times lower than those utilized with FAB. Formation of m/z 203 and 173 product ions (neutral losses of $\text{C}_3\text{H}_6\text{O}_3$ and $\text{C}_4\text{H}_8\text{O}_4$, respectively) following CID of the m/z 293 precursor ion was more efficient relative to metastable-MIKES for all monosaccharide complexes. However, formation of the m/z 201 product ion (neutral loss of $\text{C}_3\text{H}_6\text{O}_3 + \text{H}_2$) is observed only for complexes possessing a monosaccharide with an equatorial substituent at C-2.

Finally, experiments involving the metastable dissociations of deoxy-glucose and isotopically labeled glucose complexes are used to elucidate the mechanisms leading to product ion formation. ^{13}C -Labeled monosaccharides (glucose-2- ^{13}C and glucose-6- ^{13}C) indicate the presence of two dissociation pathways for the tricoordinate complex leading to the loss of the $\text{C}_2\text{H}_4\text{O}_2$ neutral fragment (Figure 1). These losses most likely involve either C-5 and C-6, or C-3 and C-4, while C-2 is always retained by the product ion. The nickel/6-deoxy-glucose complex also indicates that the tricoordinate complex may dissociate by losing either C-5 and C-6, or C-3 and C-4. The absence of an m/z 233 product following metastable dissociation of the tricoordinate Ni/3-deoxy-glucose complex suggests that loss of C-3 and C-4 may result from a stepwise loss of each carbon.

ION-MOLECULE COMPLEX LABILITY IN THE GAS PHASE FOR ALKALI METAL ION - CROWN ETHER SYSTEMS

Jeremy Nicoll, Chadin Dejsupa, Marshall Pope, and David V. Dearden

Department of Chemistry and Biochemistry, Brigham Young University, Provo, UT 84602

INTRODUCTION

The examination of molecular recognition in the gas phase, in the absence of the complicating effects which arise due to solvation and / or the presence of counterions, is receiving increasing attention both within and beyond the ion-molecule chemistry community. Previous experiments have examined the rates of alkali cation transfer between crowns with different size cavities and different cation affinities, and between substituted crowns with similar size cavities but different cation affinities.^{1,2} The patterns in the rate constants as the metals are varied suggest the size relationship between the crown cavities and the metal cation may be important in determining the transfer rates, but this conclusion is ambiguous because the differences in ligand cavity size and / or cation affinities can mask the subtle effects expected from size relationships alone. One way to eliminate such complicating effects is to examine rates for *thermoneutral* exchange between ligands with *identical* cavity sizes. Experimentally, this is done by isotopically labeling a complex ion and then measuring rates of exchange to unlabeled (but otherwise identical) neutrals. Fourier transform ion cyclotron resonance mass spectrometry offers a convenient means of labeling ions and performing these measurements. Herein, we present the results of such experiments, which do indeed show patterns which correlate with the size relationship between the ligand cavity and the radii of the metal ions.

METHODS

All experiments used a Fourier transform ion cyclotron resonance mass spectrometer (FTICR/MS) (model Apex 47e, Bruker Instruments) with a 4.7 tesla superconducting magnet. Neutral crowns were introduced by way of a solid sample probe. Solutions were prepared from metal salts and crown ethers (Parish Chemical Company, Orem, Utah) dissolved in 50:50 methanol:water. The solutions were electrosprayed using an Analytica / Bruker electrospray source modified for microelectrospray. All alkali metal ions for both 18-crown-6 and 21-crown-7 experiments were run together. In the 18-crown-6 experiments, protonated 15C5 was sprayed and the proton transfer to the 18C6 background monitored before and after each kinetics experiment. 21-crown-7 self-exchange involved the series of alkali metals. 18-crown-6 self-exchange included the alkali metals as well as thallium (I), silver (I), and hydrogen ion transfer.

Since the reaction involves a self-exchange, the reactants had to be labeled to distinguish them from the products. This was done by natural abundance isotope labeling (NAIL). NAIL involves isolation of the M+1 peak arising from the presence of naturally-occurring ¹³C among the atoms of the ligand. For a molecule such as 18-crown-6, which contains 12 carbon atoms, the M+1 peak is relatively intense (13.2% of the all-¹²C peak), facilitating easy isolation. The M+1 (¹³C) peak was isolated using a home-built implementation of stored waveform inverse Fourier transform (SWIFT) to ensure that the complex was not translationally heated during isolation.

The reappearance of the M (all ¹²C) peak was monitored over time. The rates of self-exchange were extracted from the data using an in-house kinetics fitting routine. The rates for the 18-crown-6 self-exchange were then normalized to the 15C5 proton transfer to 18-crown-6 rate to yield relative rate constants and estimates of absolute rate constants.

RESULTS AND CONCLUSIONS

Figures 1 and 2 show the relative rates vs. ionic radius.³ For 18C6, the slowest rate constant is the self-exchange of silver (I) ion, with potassium ion in the same range. The ionic radii of these two ions match

closely with the cavity radius of 18C6, as shown in Figure 1. Larger and smaller cations self-exchanged more quickly.

The results for 21-crown-7 self-exchange are less clear-cut, mostly because of the large error bars. The only statistically significant difference is that between lithium ion and cesium ion. The error bars associated with the 21-crown-7 self-exchange are large due primarily to the fluctuation of pressure between kinetics runs. The relative average error of fit within a given run is much lower than the relative standard deviations of the average rate values. In every run, the trend was Li⁺ self-exchange fastest, and Cs⁺ self-exchange slowest. The cavity radius for 21-crown-7, as shown in Figure 2, matches closest to the ion radius of cesium. Again, the results correlate with size match between the host ligand and the guest cation, with rates being slowest in the case of good size match.

Assuming 15C5 proton transfer to 18C6 is 100% efficient, the absolute self-exchange rates for 18C6H⁺ are estimated to be between 1×10^{-9} and 6×10^{-10} cm³ molecule⁻¹ s⁻¹. (LGS theory predicts rates on the average 43% less than experimental values⁴. The range above is 100% LGS and 57% LGS respectively.)

Ligand Exchange of Ionophoric Ca^{2+} Complexes by Microspray/FTICR

Nanzhu Shen, Marshall Pope, Jeremy Nicoll, Spence Carter, and David V. Dearden

Department of Chemistry & Biochemistry, Brigham Young University, Provo, Utah

The important role of calcium ions as a signal or messenger in a wide variety of cellular processes makes the chemistry of calcium ionophores very interesting. The architectures of natural calcium binding domains have similar features in a diverse range of enzymes. We presume that these similarities are not coincidental, and we have made an effort to understand the factors that influence Ca^{2+} recognition in natural systems by studying intrinsic recognition events in well-ordered synthetic ionophores such as crown ethers and glymes. We have measured absolute rate constants for gas-phase displacement of 12-crown-4 (C4) or triethylene glycol dimethyl ether (triglyme, TG) by 18-crown-6 (C6) in the following complexes; the symmetrical "sandwiches" $(\text{C4})_2\text{Ca}^{2+}$ (1) and $(\text{TG})_2\text{Ca}^{2+}$ (3) and the "mixed-sandwich" $(\text{TG})(\text{C4})\text{Ca}^{2+}$ (2). The rate constants acquired by FTICR mass spectrometry are consistent with an exchange reaction which occurs on a double-minimum potential surface.

The rate constants shown in Scheme 1 suggest the rate of passage along the reaction coordinate is not directly controlled by the thermodynamic limits but rather by an intermediate barrier. The most direct evidence is the comparison of k_1 and k_4 . Because of the flexible configuration of donor atoms, TG has a higher binding affinity for Ca^{2+} than C4. Corroboration comes from semi-empirical calculations performed in this laboratory and experimental work of Taft and coworkers on the corresponding potassium complexes [1]. It might be expected that exchange of C4 from (1) would proceed faster than the corresponding exchange of TG from (3). However, experiment shows that the latter is 50% faster. We note also that, when comparing the exchange rate *per ligand*, C4 displacement from the mixed-sandwich (2) is 35% faster than the equivalent substitution on (1). No such acceleration is observed for triglyme. Another paradox is encountered in the secondary reaction where the rate *enhancement* for either exchange is nearly identical.

EDTA exchange on calcium complexes in solution occurs via an "unzipping mechanism" in which the reaction coordinate is "metered" by a sequential series of thermoneutral (oxygen-for-oxygen) substitutions. However, the low gas-phase exchange rate for C4 compared with TG suggests an activation barrier which is relatively higher in the C4 complex than the TG complex. This is consistent with an exchange mechanism in which the rate limiting step involves replacement (or weakening) of two or more C4 oxygens by those of C6 while, the rate-limiting step for TG substitution involves a lesser number of oxygens. We suggest that a double minimum well, simpler than the periodic multi-minimum well envisioned by the "unzipping" analogy, can be used to account for each of the perplexing trends in rate constants.

The rate constants k_2 and k_3 show that TG and C4 are displaced from (2) at the same rate, but k_4 for exchange of TG from (3), is 1.5 times faster than k_1 , substitution of C4 from (1). We need not presume that the Ca^{2+} affinity of either C4 or TG is dependent on the co-ligand if the activation barrier to formation of a tight complex, in which half of the C6 donor atoms are within the first shell of Ca^{2+} , is an early one that resembles the rate-limiting step of TG displacement from (3).

[1] Taft, R.W. Anvia, F. Gal, J.F. Walsh, S. Capon, M. Holmes et al., *Pure & Appl. Chem.*, 1990, 62, 17-23.

The fact that rate enhancement is similar for k_5 and k_6 (when compared to $\frac{1}{2} k_4$ and $\frac{1}{2} k_1$ respectively) may be explained by a recession of Ca^{2+} into the C6 cavity. The cavity radius of C4 (0.64 Å) is too small to accommodate Ca^{2+} (0.99 Å). However, the alkaline earth is "size matched" to the pocket of C6. The capture of Ca^{2+} restricts the steric angle accessible to the smaller ligand (either TG or C4) and may weaken coordination. Hence, the rate increase in the second exchange of C6 for the remaining TG or C4 chelate is similar.

Ion-Molecule Reactions in FAB Do They Really Contribute to the Ions Observed ?

John Allison, Gabriella Szekely, Guy Smith and Kathleen Noon
Department of Chemistry
Michigan State University
East Lansing, Michigan 48824

A variety of chemical processes occur for the species present in a fast atom bombardment target. Presumably, these processes vary with the nature of the analyte. In this study we have been evaluating mechanisms through which singly charged ions are formed from species that are present in solution as multiply charged species as well as mechanisms for the formation of matrix-related ions, protonated molecules, proton-bound clusters and fragment ions.

Some analytes exist in solution at high pH as multiply charged species. For example, Tartaric acid, H₂Tar, is mostly in the form of Tar²⁻ above pH = 5. The ions detected in the FAB mass spectrum of tartaric acid analyte at this pH are HTar⁻ and NaTar⁻. The relative abundances of these two types of ions depend on the desorption environment. The sodium adduct ions are probably formed in fast +/- ion/ion recombination processes that are taking place in the interfacial region linking the condensed and gas phases of the experiment. Additional ion-molecule reactions can occur in the gas phase in the selvedge region. To investigate the contribution of these ion-molecule reactions to the ions formed, the time dependence of the mass spectra has been studied in the case of the glycerol matrix. As the sample is depleted dramatic changes in the ion currents occur (Figure 1). These may indicate the depletion of the selvedge region thereby showing that the probability of ion-molecule reactions is decreased. When the pressure in the selvedge region is so small that no additional chemistry occurs, the ions formed upon bombardment can pass through to the mass analyzer unchanged. We propose, that the small ion currents detected at this time are due to the primary reactant ions of particle bombardment of glycerol (Table 1). According to thermochemical calculations most of the primary cations of glycerol protonate gas phase glycerol in an exothermic process. This model suggests that it is not only the proton affinity of glycerol that determines whether an analyte will be protonated in the gas phase but also the structures of primary reactant ions. In the time dependent FAB spectra of Digoxin as the analyte, the relative intensities of the pseudomolecular ion and fragment ions change throughout the experiment. Fragment ions are still observed when the protonated molecule is no longer detected. We also present results of ICR studies of the gas phase ion chemistry of glycerol, which suggests that in case of analytes strongly interacting with H-bonding solvents/matrices, MH⁺ as well as proton-bound clusters of glycerol could be formed directly upon bombardment.

Figure 1. Positive Ion FAB Mass Spectra of 1 µl Glycerol. The glycerol sample was bombarded continuously for one hour, with one mass spectrum acquired each minute.

Chiral Selectivity in Gas-Phase Proton Transfer Reactions of Multiply-Protonated Cytochrome *c* Ions

Elvira J. O. Camara, M. Kirk Green, Sharron G. Penn and Carlito B. Lebrilla

Proton transfer reactions of cytochrome *c* with R- and S-*sec*-butylamine, as well as *n*-propyl and *t*-butylamine, were studied in an external source Fourier transform mass spectrometer.¹ Multiply charged cytochrome *c* ions were introduced into the reaction/detection cell by electrospray ionization (ESI).^{2,3} Rate constants were determined for the isolated +7, 8 and 9 charge states of cytochrome *c*, as well as the +7 and +8 ions produced by proton loss of more highly charged states. All charge states showed a strong preference for the R(-)-*sec*-butylamine over the S-(+) enantiomer, suggesting that the intermediate for proton transfer has surprisingly high structural specificity, i.e. displays chiral behavior.

The proton transfer rate constants listed in Table 1 indicate that the R isomer is generally more reactive than the S, but the two show similar trends in reactivity with respect to the three charge states. The decay of the +9 charge state as a function of time is best described by a single rate constant, while both the isolated +8 and +7 charge states exhibit double exponential behavior. For the R(-)-*sec*-Butylamine, the isolated +9 rate constant is similar to the fast rates of the +8 and +7 charge states. This suggests a possible single reactive site for the three charge states. The S isomer shows slightly decreasing reactivity with decreasing charge state, as anticipated from purely electrostatic considerations.

The two rate constants found for each of the +7 and +8 charge states are consistent with published results of gas-phase cytochrome *c* that suggest different conformers for various charge states. Clemmer *et al.* proposed at least three conformers for the +7 and two for the +8 charge states to explain ion mobility experiments⁴. Furthermore, they suggested that the relative abundances strongly depend on the ionization conditions. Similar results were observed with these experiments in that when the electrospray source conditions were varied, reactivity was diminished. Different reacting species are not observed in the reactions of cytochrome *c* with *n*-propylamine or *t*-butylamine. The rate constants for both the initially isolated and reactively-produced ions were determined and compared. The rates of the slow-reacting species of the initially isolated +8 and +7 charge states are similar to those of the reactively-produced +8 and +7 ions for both isomers. This suggests that the latter ions may be missing the highly reactive sites found on the former charge states, therefore, they would display similar behavior to the remaining fraction of the corresponding isolated states containing the reactive sites.

For comparison, *n*-propylamine and *t*-butylamine were reacted with the same three charge states. *t*-Butylamine, the most basic of the three amines, is also the least reactive, undoubtedly because of its steric bulk. Its reactivity follows the trend expected from a structurally non-selective

deprotonation reaction due to electrostatic forces. *n*-Propylamine, which is 1.7 kcal/mol less basic and less hindered than the R and S isomers,⁵ is as reactive as the S-*sec*-butylamine, suggesting a rise in the reaction barrier for the S isomer equivalent to a 1.7 kcal/mol increase in the endothermicity of the reaction due to its steric effect. The R(-) enantiomer, on the other hand, is about seven times faster than *n*-propylamine, roughly what would be expected from its higher gas-phase basicity, implying that the protonated species discriminates against the *sec*-butylamine of the unfavorable configuration.

This study suggests that deprotonation reactions of multiply charged gas-phase ions with neutral amines involve intermediates with highly specific structures sensitive to steric effects. Chiral probes of gas-phase protein structure may provide insight to the three dimensional structure of gas-phase proteins.

Table: Rate Constants of Deprotonation Reactions Involving Amines and the 9⁺, 8⁺, and 7⁺ Charge States of Cytochrome *c* (Dissolved in 50:50 H₂O:MeOH) Produced by Electrospray. Units for rate constants are molecule/cm³/s.

Solvation Effects on the Stability and Reactivity of Multiply Charged Gas-Phase Ions

Deborah S. Gross, Paul D. Schnier, Yuexing Zhao and Evan R. Williams
Department of Chemistry, University of California, Berkeley, CA 94720

The interactions of multiply charged ions with solvent molecules during and after electrospray ionization (ESI) affects many aspects of gas-phase ion conformation and stability, and plays a critical role in the maximum extent of charging in the electrospray process. In solution, solvent not only can shield intramolecular electrostatic interactions ($\epsilon_r = 78$ for H_2O), but can also stabilize intermediate conformations through hydrogen bonding and hydrophobic interactions. By studying molecules in the absence of solvent, information about their intrinsic properties can be obtained. By increasing the amount of solvation we can begin to understand how many solvent molecules are required to reproduce the properties of a fully solvated molecule. Kebarle and coworkers¹ have recently investigated the relationship between gas-phase ion conformation and hydration equilibria. They showed that intramolecular cyclization, which stabilizes protonation sites, dramatically decreases the ΔG° for hydration of the charge site, and showed that measurement of the hydration equilibria can provide information about the extent of intramolecular interactions.

Solvation: We investigated the solvation of 1,7-diaminoalkane ions in an FTMS; by decreasing the temperature and voltage of the heated stainless steel capillary in the electrospray source these ions can be trapped in an FTMS cell with various numbers of solvent molecules attached. The singly protonated forms of these ions cyclize, and both nitrogens interact with the proton.² In contrast to results obtained by Kebarle and coworkers¹ who detected only 1 solvent molecule attached to the singly protonated, and 6 solvent molecules attached to the doubly protonated ions, we observe the same extent of solvation for both the singly and doubly protonated diaminoalkane ions. Attachment of up to 6 methanol molecules is observed when diaminoalkane is electrosprayed from a methanol/acetic acid solution. We have observed up to 7 water molecules clustered to the singly protonated diaminoheptane electrosprayed from water/acetic acid. We also observe up to 7 water molecules attached to the diaminoheptane proton-bound dimer (Figure 1).

Attempts to trap the peptides leucine enkephalin, leucine enkephalin-Lys, and gramicidin S with attached solvent molecules were unsuccessful. In addition, attempts to generate solvated peptides by electrospraying into a high pressure of water vapor (~10 Torr introduced into the first stage of the electrospray source) were unsuccessful. Kebarle has shown that the net free energy gain for attaching three water molecules to a primary amine is ~20 kcal/mol.⁴ The net free energy gain for intramolecular solvation of such a group, *i.e.* the side chain of a lysine or ornithine residue, within a peptide is the difference in gas-phase basicity (GB) of the free residue and that of the residue in a peptide. This value ranges from ~17 to 21 kcal/mol, for the linear peptide YGGFLK³ and the cyclic peptide gramicidin S⁴, respectively. These values underestimate the stabilization provided by intramolecular solvation since the amine group in the free amino acid cyclizes and interacts with the N-terminus. These results indicate that solvation of the charge sites in linear peptides should be marginally stable. However, when these ions are thermalized and trapped in an FTMS cell, the solvent can rapidly boil off.

Maximum Charge States: The relationship between molecular structure and the maximum extent of charging possible with ESI has not been well characterized. Several mechanisms for the formation of ions with ESI have been proposed, but these do not quantitatively account for the maximum extent of charging. We have found that calculations of the gas-phase proton transfer reactivity of multiply protonated ions can accurately account for the maximum charge states of a variety of commonly electrosprayed proteins to within 6% of the experimentally measured value.⁵ These calculations are based on a model in which protons are assigned to specific sites in the molecule based on estimates of the intrinsic gas-phase basicity of the sites of protonation ($GB_{intrinsic}$)³ and point charge Coulomb interactions, such that the free energy of the ion is minimized (equation 1),

$$GB^{app} = GB_{intrinsic,i} - \sum_{j=1}^n \frac{q^2}{(4\pi\epsilon_0)\epsilon_r r_{ij}} \quad (1)$$

where ϵ_r includes all effects not explicitly treated in this model, including the ion-molecule potential, the effective shielding between charges, and ion conformation.

Using the same parameters described previously,⁵ we are able to explain the maximum charge states of a series of arginine rich peptides recently investigated by Downard and Biemann.⁶ A strong linear correlation between our calculated maximum charge states and the experimental values is observed, which is improved if the terminal arginine residues are allowed to extend 4 Å beyond the end of the peptide backbone.

We have extended this model to account for the maximum extent of sodium attachment possible for poly(ethylene glycol) (PEG) ions ranging in molecular weight from a few hundred up to 1 million Da, experimentally measured by Fenn and coworkers.⁷ This model differs from that proposed by Fenn in that 1) the maximum charge state is determined by the *relative* apparent binding affinity of the ion to that of the solvent, 2) we include an effective shielding constant, and 3) we do not evenly distribute charges along the polymer chain, but rather space them to *minimize* the total Coulomb energy. For the intrinsic affinity of the charge carriers, we use the value for the Na^+ binding energy to dimethoxy-ethane (46 kcal/mol). We calculate an "apparent" Na^+ affinity and compare this with the Na^+ affinity of methanol (26.6 kcal/mol). $\epsilon_r = 1.5$ is used, which is from the experimentally determined value for poly(propylene glycol)_n bis(2-aminopropyl ether) ($n = 2 - 7$),⁸ a polymer structurally similar to PEG. An excellent correlation is found between our calculated maximum charge states and those experimentally observed (Figure 2) for molecular weights up to 1 MDa. In contrast to what has been previously assumed,^{7,9} the lowest energy charge configurations do not have charges evenly spaced along the polymer, but have a greater charge density near the ends of the molecule than in the middle (Figure 3). These three combined factors improve the accuracy of these calculations, and the results obtained from this model indicate that the same ion formation mechanism applies for all ions up to 1 MDa in size.

Transition Metal Transfer Between Crown Ethers

Yongjiang Liang, Chadin Dejsupa, R. Marshall Pope and David V. Dearden

Department of Chemistry and Biochemistry, Brigham Young University, Provo, UT 84602

Introduction Studies of transition metal-containing ions reacting with crown ethers have been reported (1). These studies suggested that δ -bonds between the metal ions and the donor atoms of the crown ether are formed. Reaction of Fe^+ with 12-Crown-4 (12C4) forms nine products, while Cr^+ forms four products, this manifests the rich chemistry of transition metal ions reacting with crown ethers (4). Collision induced dissociation experiments on transition metal ion-crown ether complexes have been interpreted in terms of Cu^+ covalently bound to the oxygen atoms of the crown and/or possible insertion of Cu^+ into the C-C or C-O bonds of the crowns (2). To shed further light on these systems, we have studied the kinetics of transition metal transfer between crown ethers.

Results Experiments were done on a Bruker Apex 47e FT-ICR mass spectrometer. Micro-electrospray was used to generate crown ether-metal ion complexes. Ligand exchange reactions were studied. These can be expressed as: $(\text{Crown})\text{MNO}_3^+ + 18\text{C6} \rightarrow 18\text{C6MNO}_3^+ + \text{Crown}$. Rate constants for this reaction are listed in Table 1. Some data pertaining to electronic structure and radius for the metal ions are listed in Tables 2 and 3, respectively. Transfers of MNO_3^+ from 12-C-4 and 15-C-5 to 18-C-6 were readily observed. Sandwiched complexes of 12-C-4 with doubly charged metal ions, Co^{2+} , Ni^{2+} , Cu^{2+} and Zn^{2+} , were also observed. However, no Co^{2+} , Ni^{2+} and Cu^{2+} were observed to transfer from the sandwiched complexes to 18-C-6. In a self-exchange study of $(12\text{-C-4})_2\text{Cu}^{2+}$, no transfer of Cu^{2+} was observed either. Tl^+ transfer appears to occur via a dissociative mechanism, since free Tl^+ was observed in the transfer reactions from 12-C-4 and 15-C-5 to 18-C-6.

Discussion Electrospray is a versatile ionization source for producing a variety of metal-ligand complexes, including those with multiply charged metal centers or containing counter-anions. The experiments are quite straightforward, but the results are much more difficult to explain than those for alkali metals, which can be explained on the basis of size-match and are known to involve primarily electrostatic bonding. The fact that the transfer reaction is facile suggests that the interaction of transition metal ions (or MNO_3^+) with crown ethers is simply electrostatic. But our other experimental results do not support the interpretation. First, the measured rates for transition metal complexes reacting with 18-C-6 do not correlate with cation size the way the alkali rates do, but it is difficult to make the comparison considering that the radius of the transition metal cations are not clearly defined. Second, similar size cations react at very different rates. It is well known that d electrons participate in many reactions of transition metal ions with organic molecules. Thus, the electronic structure of the transition metal cations must play a role in our transition metal transfer experiment. For 12C4 complexes, the reactivity roughly correlates with the number of d electrons: with increasing number of d electrons, the cations transfer faster. However, no obvious correlation has been observed for 15C5 complexes. The lack of size-based reactivity for the $(\text{Crown})\text{MNO}_3^+$ complexes, and the inertness of the $(\text{Crown})_2\text{M}^{2+}$ toward ligand substitution, both suggest that these are not simple electrostatic complexes, but involve some covalent character, especially when the metals possess empty d-orbitals.

Proton Transfer Reactions of Doubly Protonated Diamines Containing Polarizable Groups

Sandra E. Rodriguez-Cruz and Evan R. Williams
Department of Chemistry, University of California, Berkeley, CA 94720

Electrostatic interactions play an important role in the conformation and function of biomolecules in solution. Using electrospray ionization, multiply protonated gas-phase ions can be produced, which makes possible the investigation of intramolecular electrostatic interactions in the absence of solvent. Rates of proton transfer between multiply protonated protein ions and neutral bases increase with increasing charge state. From this increase in reactivity, information about the intramolecular electrostatic interactions can be obtained.

We have proposed a point charge Coulomb model to account for the reactivity of multiply protonated ions, as given in equation 1,

$$GB^{app} \approx GB_{intrinsic} - \sum_{i=1}^n \frac{q^2}{(4\pi\epsilon_0)\epsilon_r r} \quad (1)$$

where GB^{app} and $GB_{intrinsic}$ are the "apparent" and intrinsic gas-phase basicities of the multiply protonated ion and the neutral molecule, respectively, q is the charge, ϵ_0 is the vacuum dielectric permittivity, r is the distance between charges and ϵ_r is the effective dielectric polarizability which includes all effects not explicitly included in the model, like effects of the reaction potential, ion conformation, etc. (1). Results for doubly protonated 1, n -diaminoalkanes ($n=7-10, 12$) (2) showed that the proton transfer reactivity could be modeled with an $\epsilon_r = 1.01 \pm 0.07$. This indicates that these gas-phase ions are in a linear conformation and that the $-CH_2-$ groups between the charges provide negligible shielding in the gas-phase.

In order to understand the role of polarizable groups on charge-charge interactions, the proton transfer reactivity of doubly protonated poly(propylene glycol) $_n$ bis(2-aminopropyl ether) (PGAE) (Figure 1a), with $n=2-9$, was measured.

(a)

(b)

Figure 1

Both bracketing and where possible, the kinetic method, were used to obtain GB^{app} . The GB^{app} of an ion is assigned to be halfway between the most basic neutral with which the protonated species does not undergo proton transfer and the least basic neutral with which the proton transfer reaction is fast. A clear difference in reactivity is observed for these ions. This is illustrated in Figure 2, which shows kinetic curves for the reaction of PGAE ($n=6$) with 2-fluoropyridine ($GB=203.9$ kcal/mol) and 3-fluoropyridine ($GB=208.6$ kcal/mol), respectively. The GB^{app} of PGAE ($n=6$) is assigned between these two bases, corresponding to a value of 206.2 kcal/mol. From similar experiments, gas-phase basicities were obtained for $n=2$ to 9. The GB of DL-2-amino-1-propanol (Figure 1b) was determined and used as a model for the intrinsic reactivity of the protonation site. Proton transfer results are shown in Table 1. Molecular modeling was used to obtain the distance between charges in the doubly protonated species. Using a point charge model and the difference between $GB^{app}(MH^+)$ and $GB_{intrinsic}$, ϵ_r can be determined for each one of the doubly protonated ions. Results are shown in Table 2.

Table 2

For $n=2$ to 7, the reactivity of the doubly protonated ions can be modeled using a Coulomb potential with an $\epsilon_r = 1.5 \pm 0.2$, and a completely elongated ion conformation. This $1/r$ relationship indicates that a point-charge Coulomb model is applicable to this system, that these ions are largely extended, and that the polarizable oxygens provide some shielding between the charges. A value of $\epsilon_r = 3.0$ is obtained for $n=8$ and a dielectric value cannot be determined for $n=9$, since $GB^{app}(MH^+) > GB(M)_{intrinsic}$. This higher GB^{app} for the larger ions indicates that solvation of the charge occurs, effectively increasing the $GB_{intrinsic}$ of the charge site. This solvation is also indicated by molecular modeling. To extend this method to these larger ions, a model for their $GB_{intrinsic}$ must be found. In order to distinguish the extents of solvation in this series of ions, hydrogen/deuterium (H/D) exchange experiments were done using ND₃. However, no significant differences are observed in the rates of exchange for these ions.

Gas Phase Solvation Effect on Proton Transfer

Yong Huang and David H. Russell*
Department of Chemistry
LABORATORY FOR BIOLOGICAL MASS SPECTROMETRY
Texas A&M University
College Station, TX 77843

As a part of our fundamental studies of MALDI, we have developed a cluster beam apparatus to probe photochemistry/photophysics of substituted aromatic molecules. The apparatus and preliminary experimental data were presented at ASMS 95.¹ Here we report experiments on solvent assisted proton transfer from a MALDI matrix to amino acids and correlations between the extent of proton transfer and matrix acidity.

The experiments were performed using a home-built time-of-flight apparatus presented last year.¹ Figure 1(a) contains the mass spectrum obtained from 355 nm irradiation of an Ar/NH₃ cluster beam seeded with proline/ferulic acid (3-methoxy-4-hydroxy-cinnamic acid, labeled as MH). The Ar/NH₃ beam is seeded with proline/ferulic acid by 337 nm laser desorption of the proline/ferulic acid crystal lattice. The peak area of [Pro+H]⁺ is 34 times greater than that in Figure 1(b) which contains a spectrum of the same experiment except the carrier gas is pure Ar. The same abundance change is observed for a few other amino acids. For example, the peak area of [Ile+H]⁺ is 53 times greater when the carrier gas is Ar/NH₃ than when it is Ar only.

Figure 1 Upper trace (a). Proline (mw = 115) + ferulic acid (mw = 194) in 38 psi Ar / 8 psi NH₃. Lower trace (b): Proline + ferulic acid in Ar (No NH₃). Ordinate: signal intensity in volt; abscissa: time in μs.

To explain this change in protonated analyte abundance, we carried out PM3 semiempirical molecular orbital calculations using software MOPAC (CACHÉ Scientific). The enthalpy change thus calculated for proton transfer from ferulic acid to proline is 117.67 kcal/mol. We also used COSMO (Conductor Screen Model)² to simulate NH₃ dielectric continuum solvation. Supposing the above proton transfer reaction occurs in NH₃ continuum, which mimics the NH₃ clusters around the reactants and products, the enthalpy change is 9.80 kcal/mol, favored in energy by 107.87 kcal/mol. The same calculation done for the excited state (assuming optimized ground state geometry) shows that the reaction is favored in NH₃ by 102.74 kcal/mol. In actuality the energy difference will be smaller since the number of NH₃ molecules surrounding reactants and products is not infinite as the COSMO assumes.

Pure matrix experiments are also performed and the peak area of the protonated NH₃ clusters and radical cations of the matrix bound by different number of NH₃'s is measured. MOPAC calculation is done for matrix acidity. Figure 2 contains a plot of $\Sigma H^+(NH_3)_n / I(\text{total})$ versus $\Delta H_{\text{acid}}(\text{gr})$, the former reflecting the extent of proton transfer and the latter being the ground state acidity of the matrix. (total cluster ion abundance $I(\text{total}) \equiv \Sigma H^+(NH_3)_n + \Sigma MH^+(NH_3)_n$). To our surprise, there are two fitting lines in the plot, which are understandably upgoing (Figure 2). Good reproducibility of this experiment leads us to think that the two categories of these matrices might correspond to two different kinetic processes. The same two lines are also found for the calculated excited state acidity and for the same experiment using 266 nm ionization laser beam (not shown). Since sinapic acid and 4-hydroxycinnamic acid are on the same line while ferulic acid on the other, an explanation of why there are two lines based on steric hindrance for proton transfer is not justifiable. On the other hand, structural similarity of these molecules rules out the effect of different entropy as a correction added to enthalpy. Further work is under way to probe the kinetics of these proton transfer reactions.

Ligand Effects in C-H and C-C Bond Activation by Gas-Phase Transition Metal-Ligand Complexes

Brenda L. Tjelta and P. B. Armentrout*

Department of Chemistry, University of Utah, Salt Lake City, Utah 84112

The activation of C-H and C-C bonds of alkanes by gas-phase atomic transition metal ions has been studied intensely over the past decade. Fewer studies examining how the reactivity of the metal center varies with ligation have been performed, although it has been demonstrated that the addition of a single ligand to the metal center can dramatically alter the reactivity. In the present study, we examine how ancillary ligands (those not actively involved in the reaction) can affect C-H and C-C bond activation. Using guided ion-beam mass spectrometry, we are able to quantitatively assess both the kinetic and thermodynamic differences in the reactions.

We examine C-H and C-C bond activation in the simplest alkanes, methane and ethane at an ionic iron center. We have previously characterized the state-specific chemistry of these molecules with Fe^+ in its $^4\text{D}(4s^13d^6)$ ground electronic state and $^4\text{F}(3d^7)$ first excited state, 0.23 eV higher in energy.¹ The present work examines the effects on this chemistry induced by ligation of Fe^+ with CO and H_2O . Our collision-induced dissociation (CID) studies² have determined that the bond dissociation energies (BDEs) relative to the $\text{Fe}^+(\text{D})$ asymptote for the two complexes are essentially equal, and theory finds that the ground state of $\text{Fe}(\text{CO})^+$ is $^4\Sigma^+$, while that of $\text{Fe}(\text{H}_2\text{O})^+$ is $^6\text{A}_1$.³ Thus, the reactivities of these two complexes are expected to be different based on electronic, but not on thermodynamic considerations.

The guided ion beam apparatus used in these studies and our data reduction procedures have been described in detail previously. FeL^+ ($\text{L} = \text{H}_2\text{O}$ and CO) ions are produced in a meter-long flow tube ion source as described elsewhere.⁴ The ions undergo $\sim 10^5$ collisions with the buffer gas before exiting the flow tube, and therefore are expected to have equilibrated to a temperature of 300 K with respect to all internal states. The FeL^+ ions are mass and energy selected and then interact with CH_4 and C_2H_6 under single collision conditions inside an octopole ion trap. Reactant and product ions are mass analyzed and detected, and their intensities are converted to absolute cross sections.

Carbon-hydrogen and carbon-carbon bond activation is observed in the interaction of FeL^+ with methane and ethane, and there is no evidence for direct interaction of either ligand in the chemistry. Thresholds for these processes are measured and converted to the LFe^+-CH_3 0 K bond dissociation energies listed in Table 1. Comparison of these values to the previously determined $D_0(\text{Fe}^+-\text{CH}_3)$ and to $D_0(\text{LFe}^+-\text{D})$ bond energies permits a quantitative assessment of the effects of ligation of σ -bond activation by metal complexes.

Results obtained here indicate that the CO ligand greatly diminishes the Fe^+-R ($\text{R} = \text{H}$, D, or CH_3) BDEs compared to the unligated metal ion, while the H_2O ligand has a much smaller effect on these BDEs. This difference can be understood by examining the electronic configuration of the metal ligand complexes. $\text{Fe}(\text{H}_2\text{O})^+$ has an electron in a $4s-4p$ orbital that is polarized away from

the H_2O ligand and can form a strong covalent bond with the R groups. $\text{Fe}(\text{CO})^+$ does not have a $4s$ electron, and formation of $(\text{CO})\text{FeR}^+$ must involve binding R to the $3d\sigma$ molecular orbital.

Also note that the bond strength of $(\text{H}_2\text{O})\text{Fe}^+-\text{CH}_3$ is 0.29 eV smaller than $(\text{H}_2\text{O})\text{Fe}^+-\text{D}$, whereas $D_0[(\text{CO})\text{Fe}^+-\text{CH}_3] \approx D_0[(\text{CO})\text{Fe}^+-\text{D}]$ and $D_0(\text{Fe}^+-\text{CH}_3)$ is 0.21 eV larger than $D_0(\text{Fe}^+-\text{D})$. For $\text{Fe}(\text{H}_2\text{O})^+$, the H_2O ligand destabilizes the Fe^+-CH_3 interaction because both ligands are π -donors.

Table 1: Thermodynamic Information.

L =	Fe^+-L	$(\text{H}_2\text{O})\text{Fe}^+-\text{L}$	$(\text{CO})\text{Fe}^+-\text{L}$
H	2.12 ± 0.06	2.23 ± 0.15	1.24 ± 0.24
CH_3	2.37 ± 0.05	1.97 ± 0.10	1.31 ± 0.05
	Fe^+-L	HFe^+-L	$\text{CH}_3\text{Fe}^+-\text{L}$
H_2O	1.32 ± 0.05	1.42 ± 0.14	0.93 ± 0.13
CO	1.36 ± 0.08	0.55 ± 0.13	0.30 ± 0.11

Changing the ligation of the metal affects not only the reactivity of the metal center but also its selectivity. In the reactions of FeL^+ with ethane, we observe that although the probability of reaction is essentially the same at high energies for both $\text{L} = \text{CO}$ and H_2O , there is a strong preference for C-H bond activation over C-C bond activation in the case of $\text{Fe}(\text{H}_2\text{O})^+$. Another indication of this strong preference is that dehydrogenation reactions are observed only in the H_2O system. $\text{Fe}^+(\text{D})$, however, shows a strong preference for C-C bond activation, and the Fe^+ and $\text{Fe}(\text{CO})^+$ quartet states have a C-H/C-C branching ratio near unity.

In work in progress, we have extended these studies to the reactions of FeL^+ with propane. Similar results to those described here are obtained at high energy in the propane system, but at thermal energy the selectivity changes dramatically (by over an order of magnitude) and inverts ($\text{Fe}(\text{H}_2\text{O})^+$ prefers C-C bond activation and $\text{Fe}(\text{CO})^+$ prefers C-H bond activation).

SIFT/CID STUDIES OF THE LIGATION OF Fe^+ AND $(\text{c-C}_5\text{H}_5)\text{Fe}^+$ WITH HYDROCARBONS

V. Baranov,¹ H. Becker,² H. Schwarz³ and D.K. Bohme¹

¹Department of Chemistry, York University, North York, Ontario, Canada M3J 1P3

²Brandenburgische Technische Universität, Karl-Marx-Str. 17, D-03044, Cottbus, Germany

³Inst. für Org. Chemie, TU Berlin, Str. des 17 Juni 135, D-10623 Berlin, Germany

As part of a larger study of the gas-phase coordination chemistry of Fe^+ using the SIFT/CID technique, we report here results for the ligation of the ground states of Fe^+ and $(\text{c-C}_5\text{H}_5)\text{Fe}^+$ with a variety of hydrocarbons. The ions were produced from ferrocene or iron pentacarbonyl by electron impact and allowed to thermalize by collisions with helium atoms before entering the SIFT reaction region.⁴ Rate coefficients were measured for all observed ligation steps and bond connectivities in the fully co-ordinated ions were probed with multi-collision CID.⁵ The hydrocarbons investigated include methane, ethane, propane, butane, ethylene, propene, allene, 1,3-butadiene, acetylene, diacetylene, methylacetylene, cyclopentadiene, benzene and toluene. Some representative data are shown in Figures 1 to 3.

The rates of ligation with alkanes, alkenes and alkynes were found to depend on the nature and size (3N-6 degrees of freedom) of the hydrocarbon (see Fig. 4). $\text{c-C}_5\text{H}_5$ ligation of Fe^+ was found to enhance the rate of ligation.

The extent of ligation with alkanes, alkenes and alkynes was found to depend on the nature of the hydrocarbon, but not markedly on its size (see Figures 5 and 6). In most cases $\text{c-C}_5\text{H}_5$ ligation of Fe^+ reduces the extent of efficient ligation by one.

The observed ligation is consistent with expected electronic structures and the 18-electron rule. The Fe^+ and $(\text{c-C}_5\text{H}_5)\text{Fe}^+$ ions require 11 and 6 electrons, respectively, to complete their electronic shells. They are able to form complexes with up to 5 (for Fe^+) and up to 3 (for $(\text{c-C}_5\text{H}_5)\text{Fe}^+$) ligands with two π -electron donors (eg. ethylene, acetylene, etc.) and four π -electron donors (eg. 1,3-butadiene and cyclopentadiene).

For a number of ligands evidence was found for the occurrence of intramolecular ligand/ligand reactions mediated by Fe^+ . For example, the addition of two molecules of cyclopentadiene to Fe^+ leads to the elimination of H_2 (Fig. 1, left) and formation of ionized ferrocene, according to the match in the CID spectrum of $\text{Fe}(\text{C}_{10}\text{H}_{10})^+$ produced from cyclopentadiene and $(\text{c-C}_5\text{H}_5)\text{Fe}^+$ produced from ferrocene (Fig. 1, right). CID leads to the same sequential dissociation, viz. $\text{Fe}(\text{C}_{10}\text{H}_{10})^+ \rightarrow \text{Fe}(\text{C}_5\text{H}_5)^+ \rightarrow \text{Fe}^+$, with similar onsets. In comparison, $(\text{c-C}_5\text{H}_5)\text{Fe}^+$ adds only one molecule of cyclopentadiene (Fig. 2). Another example involves the known oligomerization of 3 acetylene molecules to benzene.⁶ Fig. 3 shows the observed sequential addition of acetylene to Fe^+ . CID of the third adduct $\text{Fe}(\text{C}_2\text{H}_2)_3^+$ leads directly to the formation of Fe^+ and to the elimination of C_6H_6 . In this case a match is observed with the CID spectrum of $(\text{C}_6\text{H}_6)\text{Fe}^+$ produced directly from Fe^+ and benzene (see Fig.3, right).

Ligated complexes of iron comparison through their ion/molecule reactivity

L. Capron, H. Mestdagh, C. Rolando
Laboratoire de chimie, Ecole Normale Supérieure
24, rue Lhomond 75006 PARIS, France

The reactivity of naked metallic cations has been largely studied¹ providing a large variety of new mono- or poly-ligated organometallic complexes. On the contrary, the reactivity of ligated species has been investigated more recently² and few works described the role and the influence of the ligands³.

We were interested in characterizing different $\text{Fe}(\text{CX})^+$ complexes ($\text{X} = \text{O}, \text{N}, \text{S}, \text{Cl}_2, \text{F}_2$) through their reactivity with oxygen and allyl chloride. Distinct behaviors were expected from these reactions; indeed allyl chloride has been observed to give different types of coupling reactions with poly-ligated complexes $\text{Fe}(\text{CO})_n^+$ ⁴ and $\text{Fe}(\text{CN})(\text{ICN})_n^+$ ⁵ whereas oxygen was known to give oxidation products and/or ligand exchange reactions⁶.

Using our pentaquadrupole instrument, we have investigated by ion/molecule experiments the reactivity of the $\text{Fe}(\text{CO})_n^+/\text{ICN}$ system combined to CAD in the second collision cell. Several complexes $\text{Fe}(\text{L})\text{CN}^+$, $\text{Fe}(\text{L})\text{I}^+$ ($\text{L} = \text{ICN}, \text{CO}$) and $\text{Fe}(\text{ICN})_n^+$ were characterized.

On the other hand, we were able to generate other complexes such as $\text{Fe}(\text{CS})^+$, $\text{Fe}(\text{CCL}_2)^+$ or $\text{Fe}(\text{CF}_2)^+$, from iron pentacarbonyl and a reagent gas, inside the ion source,

Then it was very interesting to compare their reactivity as a function of iron ligands. Ion/molecule reactions were also a tool for structure determination of the complexes which are not accessible by low energy CAD experiments only. The reactive gases chosen for this comparison were allyl chloride, which was observed to give coupling products with $\text{Fe}(\text{L})\text{CN}^+$, and oxygen, successfully used for FeNCH^+ and FeCNH^+ isomer distinction by Schwarz *et al.*

⁵ Capron, L.; Mestdagh, H.; Rolando, C. Submitted for publication.

⁶ Schröder, D.; Schwarz, H. *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1420-1422.

With allyl chloride as reagent gas, some interesting products were detected especially with $\text{Fe}(\text{CS})^+$ complexes leading for example to $\text{C}_3\text{H}_5\text{CS}^+$ as a sizeable product (10%).

The reaction of FeCO^+ complex with $\text{C}_3\text{H}_5\text{Cl}$ precendently studied in our group, lead to the insertion complexe $\text{Cl-Fe}^+-\text{C}_3\text{H}_5$. The reactivities of other complexes $\text{Fe}(\text{CN})^+$, $\text{Fe}(\text{CF}_2)^+$ and $\text{Fe}(\text{CCL}_2)^+$ are very similar to bare Fe^+ reactivity, reflecting a strong binding energy of these ligands with Fe^+ .

The reactivity with oxygen gave some evidence for structure assignation of the complexes. A FeSC^+ structure is likely in opposition to the FeCO^+ structure.

A very small cross section had been determined for the reaction between bare Fe^+ ions and oxygen leading to the single product FeO^+ . In the presence of a ligand new pathways were detected :

ELECTRONIC EFFECTS IN THE GAS PHASE REACTIONS OF Ta⁺, Pt⁺ AND Au⁺ WITH SMALL ALKENES

Introduction

The gas phase chemistry of bare metal ions has been the subject of a great deal of interest for more than a decade. The focus of much of this work has been directed toward reactions involving hydrocarbons, in which oxidative addition to both C-H and C-C bonds has been observed. The behavior of first-row metal ions in these reactions has been studied extensively using a variety of techniques.¹ By comparison, fewer studies have focused on the chemistry of the third-row transition metal ions. However, it has been shown that these heavier ions exhibit considerably greater reactivity than their first- and second-row homologues as a result of stronger metal-ligand interactions arising from the similar sizes of the 5*d* and 6*s* orbitals. In this work, we have examined the reactions of the two late third-row ions Pt⁺ and Au⁺ with C₂H₄, C₃H₆, 1-C₄H₈, *c*-2-C₄H₈ and *t*-2-C₄H₈. In addition, we also have carried out the reaction of Ta⁺ (an early transition metal) with C₃H₆. The association of the metal with the alkene double bond often results in regioselective activation of σ -bonds. Also, the alkenes have the capability to form π -complexes with transition metals, resulting in competitive adduct formation in some cases. Comparisons of the reactions of the three metal ions have been made in order to explore the effects of 5*d* orbital filling on all these possible product channels.

Experimental

The reactions outlined above were examined using a drift cell and a selected ion flowtube (SIFT). Both instruments are equipped with externally-mounted glow discharge ion sources. In the drift cell experiments, metal ions formed in the discharge were directed into the drift cell containing 1 torr of a He/alkene mixture. An electric field drew the ions through the gas mixture where reaction occurred. Drift cell parameters were set such that $E/N \approx 5$ Td. The extent of reaction was controlled by varying the alkene mole fraction from 10⁻⁴ to 10⁻³. Reactant and product ions were mass-analyzed with a quadrupole mass spectrometer. In the SIFT experiments, ions formed in the discharge were injected into a flowing He buffer at a pressure of approximately 0.5 torr. The ions were carried by the He through a thermalization zone, and the reactant alkene was subsequently injected. The reaction was allowed to proceed for a time defined by the buffer gas velocity and the length of the reaction zone. The extent of reaction was controlled in the same manner as in the drift cell. The reaction mixture was sampled with a quadrupole mass spectrometer.

The metal ions used in this work were examined for the presence of excited states using electronic state chromatography (ESC).² A 5 μ s pulse of ions was injected into the drift cell which contained 2 torr of He. Different configurations were temporally separated in the drift cell by virtue of differences in their mobilities. The quadrupole is tuned to transmit only the mass of interest, and the signal is collected as an arrival time distribution (ATD) using an MCS triggered by the injection pulse. ATD's for all three metal ions studied here showed evidence of the presence of one or more excited states; however, no state-specific product channels were identified.

Results and Discussion

The outcomes of the reactions examined here are detailed in Table I. Pt⁺ and Ta⁺ display a variety of bimolecular product channels in which H₂ elimination predominates. Notably, Pt⁺ activates C-H bonds

only in primary steps, with subsequent reactions limited to adduct formation. Ta⁺ exhibits much greater reactivity, as evidenced by multiple dehydrogenations occurring in primary, secondary, and tertiary steps. Minor product channels consistent with C-C bond activation are also observed in the SIFT with Pt⁺, in addition to products indicative of hydride abstraction. Au⁺ forms adducts in primary steps with both C₂H₄ and C₃H₆, and exhibits hydride abstraction with C₃H₆ and the C₄H₈ isomers.

TABLE I: SUMMARY OF REACTIONS

REACTION	PRIM. PRODS.	SEC. PRODS.	TERT. PRODS.	METHOD
Ta ⁺ + C ₃ H ₆	TaC ₃ H ₄ ⁺ TaC ₃ H ₂ ⁺	TaC ₆ H ₈ ⁺ TaC ₆ H ₆ ⁺	TaC ₉ H ₁₂ ⁺ TaC ₉ H ₁₄ ⁺	Drift Cell
Pt ⁺ + C ₂ H ₄	PtC ₂ H ₂ ⁺	PtC ₄ H ₆ ⁺	PtC ₆ H ₁₀ ⁺	Drift Cell, SIFT
Pt ⁺ + C ₃ H ₆	PtC ₃ H ₄ ⁺ PtC ₂ H ₂ ⁺	PtC ₆ H ₁₀ ⁺	PtC ₉ H ₁₈ ⁺	Drift Cell, SIFT
Pt ⁺ + 1-C ₄ H ₈	PtC ₄ H ₆ ⁺ PtC ₃ H ₄ ⁺ PtC ₂ H ₂ ⁺ C ₄ H ₇ ⁺	PtC ₈ H ₁₄ ⁺	PtC ₁₂ H ₂₂ ⁺	Drift Cell, SIFT
Pt ⁺ + <i>c</i> -2-C ₄ H ₈	PtC ₄ H ₆ ⁺	PtC ₈ H ₁₄ ⁺	PtC ₁₂ H ₂₂ ⁺	Drift Cell
Pt ⁺ + <i>t</i> -2-C ₄ H ₈	PtC ₄ H ₆ ⁺	PtC ₈ H ₁₄ ⁺	PtC ₁₂ H ₂₂ ⁺	Drift Cell
Au ⁺ + C ₂ H ₄	AuC ₂ H ₄ ⁺	AuC ₄ H ₈ ⁺	AuC ₆ H ₁₂ ⁺	Drift Cell, SIFT
Au ⁺ + C ₃ H ₆	AuC ₃ H ₆ ⁺ C ₃ H ₅ ⁺	AuC ₆ H ₁₂ ⁺ C ₄ H ₇ ⁺ C ₆ H ₁₁ ⁺	C ₇ H ₁₃ ⁺	Drift Cell, SIFT
Au ⁺ + butenes	C ₄ H ₇ ⁺	C ₅ H ₉ ⁺ C ₈ H ₁₅ ⁺	C ₉ H ₁₇ ⁺	Drift Cell, SIFT

The results of the Pt⁺/butene reactions suggest that H₂ elimination is most likely proceeding via activation of allylic C-H bonds. The equivalent behavior of all three C₄H₈ isomers indicate that the reactions proceed via a common allylic intermediate which results in the formation of a Pt-butadiene structure. Dehydrogenation of propene by Pt⁺ results in a species containing either an allene or a propyne structure. Pt⁺-induced elimination of H₂ from C₂H₄ likely results in the formation of a platinum-acetylene species. Differences in the behavior of all three metals suggest that C-H bond activation is enhanced in systems where the 5*d* subshell is sparsely occupied. This is supported by the ligand effect observed here in which the presence of a π -donor ligand deactivates Pt⁺ with respect to subsequent C-H activations.

Reactivities of Metallo-Carbohedrenes: Nb₈C₁₂⁺

Y. G. Byun, S. A. Lee, S. Z. Kan, and Ben S. Freiser, H. C. Brown Laboratory of Chemistry,
Purdue University, West Lafayette, Indiana 47907

Since the report of their discovery by Castleman and coworkers in early 1992, metallo-carbohedrenes, M₈C₁₂ (M = Ti, V, Zr, Hf, Cr, Mo, and Fe) have been studied intensely. A pentagonal dodecahedron cage structure with T_h symmetry was originally proposed by Castleman and coworkers, and several additional structures have been proposed to account for the special stability of these species. Most theoretical studies have indicated that distorted structures are substantially more stable than the originally proposed pentagonal dodecahedron cage structure with T_h symmetry. Rohmer et al., for example, estimated that the T_d and D_{2d} structures of Ti₈C₁₂⁺ are more stable than the T_h structure by 190 kcal/mol and 154 kcal/mol, respectively.

Castleman and coworkers have found that Ti₈C₁₂⁺ sequentially associates with up to 8 polar molecules such as water, ammonia, methanol, and 2-butanol and up to 4 π -bonding molecules such as C₆H₆, CH₃CN, C₂H₄, and pyridine. They explained that the polar molecules attach to 8 similar metal sites, and the π -ligands each bond to the two titanium atoms in one pentagonal surface, by a d- π interaction, in accordance with the T_h structure.

We recently reported the reactions of V₈C₁₂⁺ with water, ammonia, alcohols, CH₃CN, benzene, and CH₃X (X = Cl, Br, I). For polar molecules, four "fast" sequential attachment reactions occurred leading to the initial truncation product V₈C₁₂L₄⁺, followed in all cases except water by additional much slower association reactions. These results were proposed to be consistent with the theoretically calculated more stable T_d or D_{2d} symmetry with two sets of 4 equivalent metal sites, as opposed to the T_h symmetry.

The previous studies on Ti₈C₁₂⁺ and V₈C₁₂⁺ indicate that the two met-cars might have different structures. It is certainly not necessarily the case that all met-cars should have the same structure and, therefore, it is important to study the structures of other met-cars and by a variety of techniques. Thus, in this paper, the reactions of Nb₈C₁₂⁺ with water, ammonia, alcohols, acetonitrile, benzene, and methyl halide are reported. Nb₈C₁₂⁺ reacts with water and alcohols via sequential attachments and dehydrogenations leading to the initial truncation products Nb₈C₁₂(OR)₄⁺ (R = H, CH₃, C₂H₅, C₄H₉). Also, Nb₈C₁₂⁺ reacts with NH₃ via sequential attachments to produce the initial truncation product Nb₈C₁₂(NH₃)₄⁺. Nb₈C₁₂L₅₋₈⁺ peaks for ammonia and alcohols are also observed, but they grow in slowly. A measurement of the relative rate constants for the sequential addition reactions of NH₃ confirms that addition of the fifth NH₃ is at least an order of magnitude slower than the first 4 attachments. In reactions with acetonitrile and benzene, a maximum of 4 attachments of these ligands is observed. Sequential halide abstractions with CH₃X yield Nb₈C₁₂X_n⁺ truncating at n = 4 for X = Cl and n = 5 for X = Br and I. The "titration" results and the relative rate constants for the sequential addition reactions of NH₃ provide supporting evidence that the geometric structure of Nb₈C₁₂⁺ is the theoretically more stable T_d or D_{2d} symmetry having two sets of 4 equivalent metal sites, as opposed to the T_h symmetry with all 8 equivalent metals.

One significant difference in the experiments performed in this work compared to that of Castleman and coworkers is that considerably lower pressures are utilized in the FT-ICR spectrometer, 3 or more orders of magnitude lower. Under these conditions, association complexes must be relatively long-lived in order to be radiatively or collisionally stabilized, such that they are observed. Thus, strong binding sites may readily be distinguished from weak binding sites on a

cluster, if the latter leads to association complexes which do not survive long enough to be observed. In contrast, at the higher pressures employed in Castleman's experiments, even though the metal sites may not be equivalent, all eight can bind ligands with sufficient strength to be efficiently stabilized by collisions. Therefore, the low pressure FT-ICR experiments should be better at discriminating more subtle differences in binding site energies, which appears to be the case for these met-cars.

Interestingly, for the π -ligands CH₃CN and benzene, a clear truncation at M₈C₁₂L₄⁺ has been observed for all 3 met-cars studied to date, M = Ti, V, and Nb. This observation has been explained for Ti₈C₁₂⁺, based on a T_h structure, as each π -ligand bonded to 2 metals in a pentagonal face. In our studies, however, we believe that each π -ligand bonds to only one of 4 "active" metal centers on the distorted structure. There is precedence for both types of bonding in the organometallic and surface literature.^{50,51}

Finally, while V₈C₁₂⁺ and Nb₈C₁₂⁺ react in nearly the same fashion, we note one striking difference. The initial truncation product for V₈C₁₂⁺ with water and alcohols is V₈C₁₂(OR)₂(ROH)₂⁺ while for Nb₈C₁₂⁺ it is Nb₈C₁₂(OR)₄⁺, R = H, alkyl. Thus, a second dehydrogenation is observed for Nb₈C₁₂⁺ and not V₈C₁₂⁺. In looking at the dehydrogenation reactions of these and other metal-carbon clusters, there is a trend that emerges that the number of dehydrogenations goes up with the number of accessible unpaired electrons, as determined by the reactions with CH₃I. For example, for M₈C₁₂⁺ (M = Ti, V, Nb), the number of accessible electrons are determined to be 1, 4, and 5, respectively, and the number of dehydrogenations are 0, 1, and 2, respectively. This might suggest that a mechanism, such as oxidative addition which requires at least 2 electrons, is involved. Additional data and theoretical studies are underway on other systems to test this trend.

Table 1. Relative rate constants for the sequential addition reactions of Nb₈C₁₂⁺ with NH₃.

Species	Relative Reactivity
Nb ₈ C ₁₂ ⁺	1
Nb ₈ C ₁₂ L ⁺	0.59
Nb ₈ C ₁₂ L ₂ ⁺	0.41
Nb ₈ C ₁₂ L ₃ ⁺	0.29
Nb ₈ C ₁₂ L ₄ ⁺	0.03

Organolanthanide Complexes from Reactions of Laser Ablated Lanthanide Ions with Cyclic Hydrocarbons*

John K. Gibson, Chemical and Analytical Sciences Division
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

Gas-phase reactions between metal ions, M^+ , and neutral organics (R) probe organometallic bonding and mechanistic, often elucidating condensed-phase processes such as catalysis. In the present work, products of reactions of nascent laser-ablated lanthanide ions (Ln^+) with cyclic- C_6 hydrocarbons were monitored by TOF-MS (Fig. 1); this is a variation of the laser ablation molecular beam (LAMB) method¹

The principal processes were dehydrogenation/complexations according to the following generic reaction: $Ln^+ + C_6H_{6+2r} \rightarrow Ln^+ \cdot [C_6H_{6+2p}] + (r+p)H_2$ ($r=0-3$; $p=0-1$). The dominant product ions were the benzene ($p=0$) and benzyne ($p=1$) complexes, $Ln^+ \cdot (C_6H_6)$ and $Ln^+ \cdot (C_6H_4)$. The following order of Ln^+ reactivities is comparable to results of earlier FTICR-MS studies^{2,3}: $Ce^+ \geq Tb^+ \geq Gd^+ \approx Pr^+ \geq Ho^+ \geq Dy^+ \geq Lu^+ > Tm^+, Sm^+, Eu^+, Yb^+$. These reactivities are consistent with the following two-step mechanism (exemplified for benzyne adduct formation from benzene): i. **Insertion:** $Ln^+ + C_6H_6 \rightarrow H-Ln^+-C_6H_5$; ii. **β -H Abstraction:** $H-Ln^+-C_6H_5 \rightarrow Ln^+ \cdot [\eta^2-C_6H_4] + H_2$. The relative Ln^+ reactivities are consistent with the requirement of two non-f valence electrons for the formation of the insertion intermediate² and accordingly reflect the [4f/6s]-5d promotion energy (PE)³. The correspondence between the LAMB and FTICR results suggests that most ablated Ln^+ were in or near the ground electronic state, allowing metal ion chemistries to be coherently differentiated using nascent laser-ablated ions¹. From Fig. 2, for example, it is apparent that Gd^+ (PE = 0) was most reactive, Lu^+ (PE = 1.47 eV) less reactive and Tm^+ (PE = 2.06 eV) unreactive. Comparative reactivities were independent of the reactant (e.g., C_6H_6 or C_6H_{12}) or product (i.e., $Ln^+ \cdot (C_6H_6)$ or $Ln^+ \cdot (C_6H_4)$), consistent with a universal rate-controlling insertion step.

The reaction efficiency and product composition—particularly the amount of benzene vs benzyne adduct—varied consistently with the degree of hydrogen-saturation of the neutral reactant (Fig. 3). Single- and double-dehydrogenation of C_6H_8 and C_6H_{10} were typically the most efficient processes. Faster, high-energy Ln^+ induced a greater degree of dehydrogenation in the process of forming a cohesive adduct, indicating a “cooling” effect of H_2 -loss. The following relative yields from reaction of Ce^+ with C_6H_6 and C_6D_6 indicate the role of ligand vibrations in assimilating internal energy of nascent adducts: $Ce^+ \cdot [C_6H_6] / Ce^+ \cdot [C_6H_4] < Ce^+ \cdot [C_6D_6] / Ce^+ \cdot [C_6D_4]$.

The coherent elucidation of metal ion electronic structures and interactions with organic molecules by the techniques demonstrated here should extend to gas-phase organoactinide chemistry, where scarcity and radioactivity hinder the study of the conventional condensed phase chemistry. Recent FTICR studies of hydrocarbon activation by U^+ suggested greater chemical activity of 5f (vs 4f) electrons⁴. We intend to clarify this effect by comparing reactivities of transuranic actinide ions (An^+), where the 5f orbitals become increasingly contracted and chemically inactive. Variations in An^+ 5f-6d promotion energies across the series (e.g., ~0.2 eV for Np^+ vs ~2.6 eV for Am^+) should be readily apparent in dehydrogenation activities

Radiative Association Rates and Bond Strengths of Metal Ion Complexes

Yen-Peng Ho and Robert C. Dunbar
Department of Chemistry, Case Western Reserve University, Cleveland, OH 44106

INTRODUCTION

The measurements of binding energy of metal ion-ligand complexes have been an interesting topic for decades. Recently, kinetic analysis of association reactions of metal ions with organic neutrals has become a new approach to measuring binding energies for association complexes. In the low pressure region where collisional stabilization of the association complex is not important, the stabilization mechanism is predominantly radiative and a radiative association rate constant can be assigned to this association process. The radiative association rate is normally determined by the competition between infrared radiative stabilization and back dissociation of the activated complex. Since the redissociation rate is a strong function of binding energy of the complex, measuring the low-pressure association rate gives an accurate method to evaluate the binding energy.

EXPERIMENTAL

The association reactions of Ag^+ with acetone and acetaldehyde were studied at the National High Magnetic Field Lab in Tallahassee. Data were acquired with an Extrel FTMS-2000 Fourier-transform ion cyclotron resonance mass spectrometer equipped with a 3 Tesla superconducting magnet and an Odyssey data system. The silver ions were produced by focusing the laser light pulse from the doubled output of a Continuum Nd:YAG laser on a silver plate which was mounted on the automatic insertion probe.

The experiments for the associations of Au^+ with C_6HF_5 and Au^+ with C_6F_6 were carried out in the Fourier-transform ion cyclotron resonance mass spectrometer in our laboratory, equipped with an IonSpec data system. The ions were trapped in a one inch cubical cell with a magnetic field of approximately 1.4 Tesla. The metal ions were produced by focusing the 532 nm light pulse (generated by a Nd:YAG laser) onto a metal plate attached to a sample holder near the cell.

Only monomer complex was observed for the reactions $\text{Au}^+ + \text{C}_6\text{HF}_5$ and $\text{Au}^+ + \text{C}_6\text{F}_6$. The association of Ag^+ with acetone gave both monomer complex and dimer complex. For the association of Ag^+ with acetaldehyde, a series of products from monomer to hexamer complexes were observed. The abundance of metal ion and ion complex were monitored as a function of reaction time to derive the association rate constant. Fig. 1 shows spectra for the reaction of Au^+ with C_6F_6 after a series of reaction times. Figs. 2 and 3 illustrate the time-plots for the reaction of Ag^+ with acetaldehyde and the reaction of Au^+ with C_6F_6 .

KINETIC ANALYSIS AND RESULTS

The apparent bimolecular association rate constant k_2 for the association of M^+ with N is defined by $d\text{M}^+/\text{dt} = k_2[\text{M}^+][\text{N}]$. A general formalism in terms of four microscopic rate constants, complex formation rate constant, redissociation rate constant, collisional stabilization rate constant and IR radiative rate constant, may be employed to predict the association rate constant by varying the assumed binding energy for the complex.

Two methods were used to calculate the radiative rate constant k_r required in the calculation of k_2 :

- (1) Quantum chemical calculations. By collaborating with Klippenstein's group, IR frequencies and intensities were calculated employing the Gaussian 92 software package to derive k_r .
- (2) Pressure dependence experiments. A linear pressure-dependent equation for k_2 can be derived: $k_2 = k_{\infty} + k_3[\text{N}]$. k_3 is the termolecular rate constant. k_{∞} is the radiative association rate constant and is independent of neutral density. McMahon suggested that the radiative rate constant k_r can be written as $k_r = k_{\infty} k_c/k_3$. Once the intercept and the slope are derived from a plot of k_2 vs pressure, k_r can be determined.

Fig. 4 illustrates a plot of k_2 vs pressure for the association of Au^+ with C_6F_6 . The radiative association rate constant as a function of binding energy was calculated with $[\text{N}]$ set to zero. The computer code used in the calculations was provided by Klippenstein. Fitting the experimental results to the theoretical values gives the corresponding binding energies. Fig. 5 shows a plot of the predicted k_{∞} vs binding energy for the reaction of Ag^+ with acetaldehyde. The binding energies derived from theoretical modeling of the experimental association rate constants for the reactions studied are listed in Table 1.

CONCLUSIONS

E_0 assignments for $\text{Ag}^+(\text{acetaldehyde})$, $\text{Ag}^+(\text{acetone})$, $\text{Au}^+(\text{C}_6\text{HF}_5)$ and $\text{Au}^+(\text{C}_6\text{F}_6)$ are 1.92, 1.65, 1.36 and 1.08 eV respectively. The sensitive dependence of radiative association rate on the binding energy offers another approach to determining metal ion-ligand bond strengths. Future work will include (1) the determination of bond energies for larger complexes than monomer complexes for the association reactions studied in the present work and (2) the further investigation of association process of gold ions with other organic neutral molecules.

Radiative Association Reactions of Chromium Ion with Benzene and Benzene Derivatives

Lin, Chuan-Yuan and Dunbar, Robert C.*

Department of Chemistry, Case Western Reserve University, Cleveland OH 44120

Introduction A new independent approach with great promise for measuring ligand/metal-ion bond energies for gas-phase metal complex ions is through the kinetic modeling of ion-molecule radiative association reactions. This method is based on the fact that the rate of producing stabilized complex ions is an extremely strong function of the ligand/metal-ion bond energy. Recent advances in understanding the kinetics of this process lead to a completely theoretical prediction of the bond energy implemented by *ab initio* calculations.¹ Several recent reports show success in determining bond energies through kinetic analysis of radiative association.² Here, the ion-molecular reactions of chromium ion with benzene and its derivatives (toluene, p-xylene, and mesitylene) were studied in a FT-ICR mass spectrometer. The ligand/metal-ion bond energies were derived from kinetic modeling of the experimental results.

Experiments The precursor ion, Cr⁺, was generated from the vapor of Cr(CO)₆ by electron impact. After that, the filament was turned off and allowed to cool for the rest of the trapping time. The neutral reactant was introduced into the ICR cell through a leak valve. The working pressures were kept in the range of (1-5) × 10⁻⁸ Torr. Under these experimental conditions, the associated complex ion was stabilized by emitting IR photons and also by collisional cooling. Then the complex and precursor ion abundances were monitored as a function of time. Temperature measurements were done with a copper-constantan thermocouple mounted next to one trapping plate. Since the derivation of absolute bimolecular rate constants greatly depends on neutral pressures, pressure measurements were calibrated by the kinetic analysis of the proton-transfer reaction between C₆H₁₂ and CH₃OH₂⁺.

Results Fig. 1 displays the reaction of Cr⁺ with C₆H₆ at different reaction times. Two reaction products were found, Cr⁺(C₆H₆) and Cr⁺(C₆H₆)₂. A general reaction scheme for the present work can be expressed as

where L = C₆H₆, C₇H₈, C₈H₁₀, or C₉H₁₂. Fig. 2 illustrates two time-resolved plots for Cr⁺ with C₆H₆ and C₇H₈. The solid lines are the best fits according to Eq. 1 and 2. Fig. 3 illustrates the pressure dependence of the bimolecular rate constants of association reactions of Cr⁺ with C₆H₆ and C₇H₈. In the pressure regime of the present study, the radiative stabilization process dominates with negligible three-body collisional stabilization processes.

Kinetic modeling of radiative association reactions has been established in several publications by Dunbar and McMahon.^{2,3} Recently, a high level variational transition state theory (VTST) modeling of radiative association reactions was developed by Klippenstein and Dunbar¹ and successfully applied to several ionic systems. For a thermal ensemble of reactants, the effective bimolecular rate constant can be obtained by integrating the efficiency of complex stabilization from a thermal distribution of reactants over all possible E and J values, as shown in Eq. 3

$$k_{\text{eff}} = \int dE dJ k_f(E, J) P_{\text{reactants}}(E, J) \Phi(E, J) \quad (3)$$

where $\Phi(E, J)$ is the efficiency of complex stabilization

$$\Phi(E, J) = \frac{k_f(E, J) + k_b(E, J)[M]}{k_b(E, J) + k_f(E, J) + k_c(E, J)[M]} \quad (4)$$

$P_{\text{reactants}}(E, J)$ describes the probability of a thermal distribution of reactants with particular E and J values. $k_c(E, J)$ is the collisional rate constant, for which the Langevin model was used. $k_b(E, J)$ is the radiative rate constant (Eq. 5)

$$k_r(s^{-1}) = \sum_{l=1}^{\infty} \sum_{n=0}^{\infty} 1.25 \times 10^{-7} n P_l(n) I_l (\text{km/mole}) v_l^2 (\text{cm}^{-1}) \quad (5)$$

$k_f(E, J)$ and $k_b(E, J)$ are the complex formation and back-dissociation rate constants, respectively. Both rate constants were calculated from the VTST approximation in this modeling.

ab initio The vibrational frequencies and IR intensities of reactants and complex ions were obtained from *ab initio* calculations (GAUSSIAN 92 program suite at the HF/LANL2DZ level of theory) for the benzene and toluene systems. For Cr⁺(C₆H₁₀), Cr⁺(C₆H₁₂), and all Cr⁺(L)₂ systems, the vibrational frequencies and IR intensities were estimated from Cr⁺(C₆H₆) and Cr⁺(C₇H₈) with some adjustments. The bond energy, E_b , is the only remaining unknown parameter, which is treated as an adjustable parameter to bring the modeled kinetics into agreement with the experimental results. Table I is a summary of the bond energies studied here.

Conclusions Looking at Table I, the increase of ligand/metal-ion bond energies from Cr⁺-(C₆H₆) to Cr⁺-(C₉H₁₂) is rationalized as reflecting the increase of the polarizability of the corresponding neutral ligand (10.4 to 15.9 Å³ from C₆H₆ to C₉H₁₂). The third column of Table I is the bond energies of Cr⁺-(C₆H₆) and (C₆H₆)Cr⁺-(C₆H₆) reported by Armentrout *et al.*⁴ The excellent agreement between these two quite different approaches demonstrates the kinetic analysis of radiative association reactions to be a valuable and alternative method for determining ligand/metal-ion bond energies in gas phase. *Uncertainty arising from kinetic shifts is a constant problem in determining bond energies of ionic species by dissociation methods.* This problem is entirely avoided in the present method using kinetic analysis of radiative association reactions.

Table I: Summary of Bond Energies (eV).

The Role of Radiative Relaxation in the Fe⁺-Catalyzed Polymerization of Chlorobenzene.

Asgeir Bjarnason

Science Institute, University of Iceland.

D. P. Ridge

Department of Chemistry and Biochemistry, University of Delaware.

More than a decade ago Dietz, Chatellier and Ridge¹ reported on the reactions of Fe⁺ with the phenyl halides in the gas phase as studied by ion cyclotron resonance spectroscopy. Instrumental advances, in particular the development of Fourier transform mass spectrometers (FTMS), have opened doors to more detailed analysis of ion-molecule reactions in the gas phase. In a recent paper, an FTMS study of the reactions of Fe⁺ with the phenyl halides in the gas phase was reported² and later the reactions of all the other first-row transition metal ions were studied.³ In addition, Huang and Freiser have reported on the reactions of Fe⁺ with chlorobenzene using similar techniques.⁴ Among the interesting reactions observed in the studies mentioned above, was the iron-catalyzed formation of oligomers of phenylene of the form (C₆H₄)_n⁺, with n = 2-5 from iron complex ions of the form Fe(C₆H₄)_n⁺, which in turn were produced in successive dehydrohalogenation reactions.

We describe here a study of an interesting pressure dependence in the relative rate constants for reactions 1 and 2, when n = 3, the significance of which escaped attention in previous studies. In particular, at low pressures (<10⁻⁷ Torr) reaction 1 dominates while at high pressures (> 10⁻⁶ Torr) reaction 2 dominates. The branching ratio changes 12-fold between the high and low pressure regimes. Because reaction 2 terminates the chain, the formation of larger oligomers is favored at low pressure.

The loss of Fe⁺ from Fe(C₆H₄)₃⁺ (1) to form (C₆H₄)₃⁺ (2) in reaction 2 (n = 3) is a bimolecular process as is the formation of Fe(C₆H₄)₄⁺ (3) in reaction 1. We postulate that the reaction forming 1 is exothermic so that 1 is formed with considerable internal energy and we designate it as 1*. 1* reacts with chlorobenzene according to reactions 1 and 2 with rate constants k₁^{*} and k₂^{*}, respectively, where k₁^{*}

< k₂^{*}. 1* can also relax, either radiatively⁵ with rate constant k_r or collisionally as the result of collisions with a non-reactive gas such as Ar or C₆F₆. The rate constants for collisional relaxation are designated as k_{Ar} or k_{C₆F₆}. Upon relaxation 1* becomes 1, which reacts with chlorobenzene according to reactions 1 and 2 with rate constants k₁ and k₂, respectively, where k₁ > k₂. At low pressures of chlorobenzene ((k₁^{*} + k₂^{*})[C₆H₅Cl] < k_r), 1* relaxes radiatively more rapidly than the reaction occurs, therefore the products of reaction 1 dominate because k₁ > k₂. At high pressures of non-reactive collision gas (k_{Ar}[Ar] > (k₁^{*} + k₂^{*})[C₆H₅Cl]) 1* relaxes collisionally to 1 before reacting and again the products of reaction 1 dominate because k₁ > k₂.

The reaction of Fe(C₆H₄)₃⁺ with chlorobenzene is fast and efficient and produces two primary products. The ratio of the two products depends on the pressure of the chlorobenzene. This change in product branching ratio is a chemical effect of a radiative process. The reactant ion is formed in an exothermic process, which leaves the ion with excess internal energy. At low pressures, radiative relaxation is faster than the bimolecular reaction. The branching ratio at low pressures is, thus, characteristic of a reactant ion without excess internal energy. At high pressures the excited ion reacts before radiative relaxation is possible. Collisional relaxation of the ion in the presence of unreactive buffer gases similarly changes the branching ratio, confirming the role of excess internal energy. The effect is large. While the total rate constant was found to be virtually unchanged as the reactant pressure changes by an order of magnitude, the branching ratio changes by over an order of magnitude.

The data obtained are consistent with a kinetic model that includes the radiative process. Comparison of the data and the model gives a value for the radiative cooling rate constant (1.7 s⁻¹) comparable with cooling constants in the literature⁵ for photoexcited aromatic ions. The results demonstrate the power of Fourier transform ion cyclotron resonance techniques to probe slow unimolecular processes, such as radiative relaxation, as this behavior is likely to be common in the kinetic environment of the ICR trap.

A new platinum cluster $Pt_4(PF_3)_8$ has recently been synthesized.[1] The chemical composition was established by FT-ICR MS. The volatility of the parent compound is such that a small amount of the compound may be placed in a capillary vial on a solids insertion probe, generating a constant background pressure of 2.0×10^{-7} torr and 1.0×10^{-9} torr (source and analyzer side of the dual trap) without probe heating. At this pressure, standard electron ionization performed on the source side of the dual trap (<70 eV electron energy) produces predominantly abundant molecular ions. Collisionally activated dissociation (CAD) of the parent ion causes sequential loss of PF_3 groups, finally forming the Pt_4^+ metal cluster core. CAD of the Pt_4^+ metal cluster core yields abundant fragments corresponding to Pt^+ , Pt_2^+ , and Pt_3^+ . We have recently developed a simpler method of forming the naked metal cluster ions $(Pt_n)^+$ by standard electron ionization (electron energy <20 eV) of the neutral parent cluster at ultra-high vacuum ($<1.0 \times 10^{-8}$ torr). Each of the naked metal cluster ions may then be isolated by SWIFT excitation, for further reaction with a variety of neutral compounds.

Naked metal clusters have been proposed to be highly selective and efficient catalysts. The study of metal clusters is especially interesting because they can help elucidate heterogeneously catalyzed reactions by probing the reactivity as a function of cluster size. Cluster size is very important since the surface of a bulk solid can be considered an assembly of clusters of various sizes and isomers.[2] The reactivity of platinum clusters is of particular interest since a bare platinum ion has recently been used to catalyze the reaction of methane with oxygen to produce methanol.[3] Here, we react small platinum cluster ions with a variety of acyclic, cyclic, and aromatic hydrocarbons. Specifically, reactivity is probed as a function of dehydrogenation. Trends in the reactivity of the small platinum clusters may be observed.

Figure 2 shows the gas-phase catalytic activity of Pt^+ on neutral cyclohexane. Cyclohexane dehydrogenates, forming the $(Pt+C_6H_6)^+$ complex (Figure 2, middle). Single-frequency sustained off-resonance irradiation (SORI) CAD on the complex at 1.0×10^{-5} torr recovers the bare Pt^+ catalyst (Figure 2, bottom), ready for another catalytic cycle. Work supported by the National Science Foundation (CHE 93-22824), and the National High Magnetic Field Laboratory at Florida State University.

The reactivity of transition metal complexes in the gas phase is very dependent on the nature and number of ligands; the case of solvation of metal cations by water molecules is specially attracting in connexion with solution chemistry. For a better understanding of the role of solvation, it is interesting to study the variation of the reactivity of a given metal cation with the number of solvent molecules.

In order to collect complementary information on a large range of cluster size, two different experimental devices were used :

(i) MS/MS/MS multiquadrupole mass spectrometer. This device allowed preparation of small $\text{Fe}(\text{H}_2\text{O})_n^+$ complexes ($n = 0-2$) by ligand exchange reaction of $\text{Fe}(\text{CO})_n^+$ with H_2O , interaction of mass-selected $\text{Fe}(\text{H}_2\text{O})_n^+$ with a reagent gas, and mass analysis of the reaction products.

(ii) Laser evaporation ion source, associated with collision cell and TOF mass spectrometer. Used with helium as carrier gas, water as seeding gas, and metallic iron as laser target, the source efficiently generated a distribution of larger $\text{Fe}(\text{H}_2\text{O})_n^+$ clusters ($n = 0-20$, mainly $n = 4-10$). These ions were collided with a reagent gas prior to mass analysis of the products.

We focussed this study on simple reactions : fragmentation, ligand exchange and ligand addition. These three competing channels were actually the only processes observed in the reaction of $\text{Fe}(\text{H}_2\text{O})_n^+$ with low reactivity ligands such as D_2O , MeOH or O_2 . With Ar or N_2 only fragmentation occurred.

In the case of small clusters, pressure dependence of product relative abundances allowed to estimate relative substitution rates.

Relative substitution rates

Reaction of $\text{Fe}(\text{D}_2\text{O})_n^+$ with H_2O :

Reaction of $\text{Fe}(\text{D}_2\text{O})_n^+$ with MeOH :

While $\text{Fe}(\text{D}_2\text{O})_2^+$ reacts with H_2O slower than $\text{Fe}(\text{D}_2\text{O})^+$, it reacts faster than $\text{Fe}(\text{D}_2\text{O})^+$ with MeOH , and the second methanol molecule binds faster than the first one.

For large clusters, the effective cross sections for scattering of each cluster ion by Ar, O_2 , N_2 , MeOH were determined. Collision models for these cross sections show fully inelastic collision with Ar, indicating penetration of Ar atoms into the cluster, while scattering by molecules O_2 , N_2 , MeOH is best modelised assuming elastic collisions. Addition or substitution reactions are detected with MeOH only. Determination of substitution cross sections in the case of MeOH indicates that for large clusters the relative substitution efficiency increases only slightly with cluster size.

Clustering Reactions of Metal Ions in Excited Electronic States

College Station, TX 77843

INTRODUCTION

The gas phase chemistry of metal carbonyls have been used as selective ionizing agents and structural probes for complex molecules. Because of low-lying d orbitals, long lived excited state ions are formed upon ionization, contributing to a wide array of reaction products. To understand the ion-molecule reaction mechanisms, it is important to understand the role that internal energy of the metal ion plays in governing product distribution, through charge transfer and clustering reactions. Being able to manipulate the energy of the precursor ion, allows for limiting the reaction channels accessed by the reaction complex that occur. By using metal carbonyls, modelling of the energy transfer process can be accomplished.

We previously described an ICR based method for investigating the ion-molecule chemistry of long lived excited metastable states of gas phase metal ions through charge transfer reactions [1]. A large percentage of these excited states are produced via electron impact ionization (EI) (65%), as well as laser desorption ionization (LDI) (83%), which react with neutrals forming a distribution of product clusters all based on the precursor ion's energy. We are currently using this method to probe the effects of excited state metal ions (M^+), and ground state metal ions (M^+), on the product distribution and further reactivity of ionic cluster fragments.

EXPERIMENTAL

A two-section cell was used to study the effects of internal energy on ion-molecule reactions. The benefits of using this approach enables us to mass select a particular ion for study in one cell, partition it to the other which contains a buffer gas (argon), used as an energy sink to cool the ion to ground state (Fe^+), then partitioned back to the source for ion-molecule reactions with neutral

$Fe(CO)_5$. By varying the quenching time in the second cell, the internal energy can be varied, thus effecting the distribution of products.

CONCLUSIONS

Studies were made of the products formed as a function of the precursor ion's internal energy. By isolating a particular ion, secondary ion formation can be determined. The products formed by charge transfer and cluster formation and from ion-molecule reactions were compared with excited state and ground state ions. Since each initial ion was produced by the same ionization

source, the distribution of excited states were determined to be similar, and by varying the collisional cooling time, a larger population of ground state (M^+) products were detected. Comparisons made between the products from the excited and ground states showed a preference to low energy product ion formation.

Laser Ablation Mass Spectrometry of Tin Sulfide

Gary D. Willett, Phillip Jackson, Ian G. Dance and Keith J. Fisher,

School of Chemistry, The University of New South Wales, Sydney, NSW 2052, Australia.

Gerhard E. Gadd, Australian Nuclear Science and Technology Organisation, Private Mail Bag 1, Menai, NSW 2234, Australia.

Introduction: The chemistry of nanostructured materials is an important technological area of research where the properties of such materials are determined by interaction between the building blocks and their associated interfaces. One route for the synthesis of such materials or their composites is by gas phase condensation. In this method the substrate materials are evaporated in an inert atmosphere and then condensed to form micro-clusters. Consequently, an important criterion for the study of the laser induced gas phase ion chemistry of such materials is that it can provide a guide to the synthetic stability of selected micro-clusters as well as provide thermochemical results. Such science provides for a better understanding of the condensed phase/vapor equilibrium associated with these materials.

Our recent laser ablation FT-mass spectrometry experiments have revealed that a large number of remarkable polynuclear clusters can be generated by laser ablation [1-4]. We have previously examined the anion metal chalcogenide clusters with the general composition $[M_xE_y]^-$, $E = S, Se, Te$. Besides their production, a trenchant result is that there is a continuous series of ions for each combination of M and E , and that the maps of x, y for each element pair are clearly dependent on M , and largely independent of the precursor solid. Furthermore, our experiments show that these clusters are formed in the laser plume from the assembly of components generated by the laser pulse on the solid precursor, and that these clusters represent stable combinations of the elements which are expected to have high electron affinities (eg., $ReO > 3.5$ eV). In our experiments the positive and negative charged clusters were trapped in an ICR cell and their reactivities studied under conditions like those employed in thin film manufacture.

Methodology

- The laser ablation of tin sulfide to establish which ions can be generated and trapped in an FT-mass spectrometer.
- The CID of photoablated ions with argon to probe their geometrical structures.
- Ion-molecule reactions of the clusters with selected organic and inorganic gas phase molecules to probe cluster reactivities and determine IE's and EA's.
- Density Functional Theory computations on the neutral and ionic clusters to determine their electronic and geometrical structures as a probe of their reactivities.

Results and Discussion: Fig. 1 shows the positive- and negative-ion laser ablation FT-mass spectra of tin sulfide at a laser power of 200 MW/cm². At all laser powers (~200–1000 MW/cm²) the only positive-ion observed was Sn^+ . In the anion spectra at these laser powers only a limited range of $Sn_xS_y^-$ ($x=0-6, y=1-6$) clusters were observed. At increased laser powers Fig. 2 (at 450 MW/cm²) shows that the $Sn_3S_3^-$ cluster appears to react with sulfur to form $Sn_3S_4^-$. This presumably arises through the increased pressure of sulfur as evidenced by the base peak assigned to S_3^- in Fig. 2. Fig. 3 shows the laser ablation, isolation and collision-induced-dissociation mass spectra of $Sn_3S_3^-$ with argon. In this experiment $Sn_3S_3^-$ had ~190 eV centre-of-mass translational kinetic energy and is calculated to undergo ~2-3 collisions with argon in a 50 ms collision period after isolation. The CID of this ion results in the loss of SnS and Sn_2S_2 . Continuous ejection of $Sn_2S_2^-$ during the CID experiment did not affect the intensity of the SnS^- indicating that the two channels are parallel reactions. Density functional theory with functionals derived from the von Bath-Hedin/Hedin-Lundqvist functional combination, as in the DMol package, was used to optimise the neutral and anionic structures of SnS , Sn_2S_2 , Sn_2S_3 , Sn_3S_3 , and Sn_3S_4 . Fig. 4 shows the minimised neutral structure for Sn_3S_3 . The adiabatic EA of Sn_3S_3 is calculated to be 2.17 eV. It is noteworthy that the addition of an Sn atom to what is basically the Sn_2S_3 structure weakens the SnS bonds of one of the bridging S atoms in the formation of a new strong SnS bond. CID of $Sn_3S_3^-$ (Fig. 3.) might be expected then to readily break off an SnS fragment. Ion/molecule reactions of $Sn_3S_3^-$ showed no reaction with H_2O , H_2S , C_2H_6 and $EtOH$ but reaction with N_2O , O_2 and C_2F_3Cl . The latter reagent resulted in the production of SnS_2Cl^- and $SnSF^-$.

Charge transfer has been found to occur during collisions (at keV laboratory energies) between certain inert gases and certain gaseous protein and peptide ions. Peptide and protein ions were generated by matrix-assisted laser desorption/ionisation (MALDI) and analysed by time-of-flight mass spectrometry.

The analyte ions investigated were: bombesin (1619.9 Da), insulin chain B (3495.6 Da), bovine insulin (5733.5) and β -lactoglobulin (18300 Da). Xenon (12.1 eV), argon (15.8 eV), helium (24.6 eV) and nitric oxide (9.25 eV) were the collision gases studied. The values in brackets are the lowest ionisation energies (IE) of the gases.

Three (TOF) spectra of β -lactoglobulin with NBA matrix are shown in Fig. 1. One was measured without collision gas, the second with argon as collision gas and the third with xenon as the collision gas. As can be seen from the spectra the presence of xenon in the collision cell affected the intensity of the analyte peak, $(M+H)^+$, whereas the presence of argon did not. The matrix ion peak ($NBAH^+$) was slightly reduced in intensity when xenon was the collision gas compared to the peaks in absence of gas or with argon. It was generally found that the matrix ion peaks were not affected on introduction of collision gases. The results obtained are summarised in Table 1.

To present succinctly the effects of collision gases on analyte peak intensities under different conditions, ratios of matrix-to-analyte peak intensities are considered at various incident ion energies and centre-of-mass collision energies. The ratios of the matrix-to-analyte peak intensities at different collision energies for β -lactoglobulin with argon, nitric oxide and xenon as the collision gases are shown in Fig. 2. The two sets of points in the figure represent the ratios without ($\square$) and with ($\diamond$) collision gas. Similar plots (not shown) have been prepared for bovine insulin, insulin chain B and bombesin.¹

The conclusions drawn from this work are based upon the presence or absence of differences between matrix-to-analyte ratios with and without collision gas at given incident ion energies in a qualitative sense.

The reductions in analyte signals observed (Table 1) are explained by charge transfer, as in equation 1.

A represents the collision gas and M the protein or peptide.

If the "neutral" on the product side of equation 1 was M and the radical was H^+ , the energy of the reaction, ΔE , could be expressed as: $\Delta E = PA(M) - IE(H^+) + IE(A)$

PA is the proton affinity and IE is the ionisation energy.

Suppose that the proton affinity of a protein is about 10 eV.² Given that the ionisation energy of H^+ is 13.6 eV, charge transfer according to equation 1 will be endoergic by an amount dependent on the ionisation energy of the inert gas.

Comparing the centre-of-mass energies with the ionisation energies, it is found that there is a correlation with the reduction, or otherwise, of analyte peak intensities on introducing collision gas. The centre-of-mass collision energies exceeded the ionisation energy of the collision gas at all ion energies in the following cases: β -lactoglobulin/Xe, bovine insulin/Ar, bovine insulin/NO, insulin chain B/Ar, bombesin/Xe and bombesin/Ar. In all of these cases, a reduction in the analyte peak signal

was observed when collision gas was introduced (Table 1). When nitric oxide was the collision gas and β -lactoglobulin the analyte ion, the centre-of-mass collision energy exceeded the ionisation energy for ion energies higher than 6 keV. Experimentally, a reduction in the β -lactoglobulin signal was definitely observed only at the higher ion energies (Fig. 2). In the cases where no changes were observed in the analyte peak intensity on introducing collision gas (Table 1), the centre-of-mass collision energies are either less than or comparable to the ionisation energies of the inert gases.

Table 1 Obtained Results

	Helium	Argon	Xenon	Nitric Oxide
Bombesin	no effect ^{a)}	decrease ^{d)}	decrease	-
Insulin Chain B	no effect	decrease	-	-
Bovine Insulin	no effect ^{b)}	decrease	-	decrease
β -lactoglobulin	-	no effect	decrease	decrease ^{d)}

- a) No change in the analyte peak intensity on introducing the collision gas.
b) No measurements performed.
c) A decrease in the analyte peak intensity was observed when the collision gas was introduced.
d) When nitric oxide was the collision gas, a decrease in the β -lactoglobulin signal seemed to be observed at the high energy end of the range of collision gases but not at the low end.

MS/MS of N and C-terminal Derivatized Peptides on a Quadrupole Ion Trap

Tong Lin and Gary L. Glush

Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290

INTRODUCTION

Derivatization of peptides has been used to facilitate sequencing and characterization of peptides because a charge can be fixed on either the N- or C-terminus of a peptide to enhance ionization and direct fragmentation when doing CID. It has been demonstrated^[1-2] that a peptide which is derivatized at the N-terminus generates exclusively N-terminal fragment ions. Similarly, when a peptide is derivatized at the C-terminus, it generates exclusively C-terminal fragment ions. A complete ion series may be obtained with derivatized peptides, and the MS/MS spectrum is much simpler than that for protonated species.

Most work with derivatized peptides has involved sector instruments and high collision energy (keV) CID. Our interest is to understand the CID process involving peptides in a quadrupole ion trap. We present here results for ethyl-TPP derivatized peptides on a quadrupole ion trap, and compare these with the results from high energy CID on a sector instrument. To effect CID more efficiently in the quadrupole ion trap, we also used heavy gases, such as argon, to increase the energy deposition per collision. The ethyl-TPP derivatization method was chosen because it is well studied, and the derivatization group can be attached to either the N- or the C-terminus of a peptide.

EXPERIMENTAL

A modified Finnigan ion trap and Rev.B ITMS or ICMS-FL software were used for the experiments. Electrospray ionization was used as the ionization technique. The flow rate was set at 1-2 $\mu\text{l}/\text{min}$. Helium was used as the bath gas and to effect collision-induced dissociation at a typical pressure of 1×10^{-3} torr. Argon was pulsed in through a pulse valve (General Valve Co. IOTA ONE, Fairfield, NJ) to effect CID together with helium when doing heavy gas studies.

A Finnigan MAT 900 was used for the study of high energy CID process. FAB was used as the ionization technique. MS/MS spectra were obtained with helium as the collision gas at a pressure to attenuate parent ion beam by 50%.

Peptides were purchased from Sigma. All derivatization reagents were used as obtained from Aldrich or Sigma without further purification. Peptide derivatization was accomplished following the protocol developed by Watson's group^[1-2].

RESULTS AND DISCUSSION

Several peptides were used in this study, including leucine enkephalin, VGVAPG, des-Arg¹-bradykinin and des-Arg²-bradykinin. As an example of the data obtained, MS/MS of the singly charged N-terminal ethyl-TPP derivatized peptides provides essentially no sequence information which is in contrast to high energy CID results. Instead, only the ethyl-TPP group is observed as a product ion from the derivatized peptide ion (Fig. 1). Conversely, the C-terminal ethyl-TPP derivatized peptides can form doubly charged ions upon electrospray and dissociate to provide some structural information (Fig. 2). The MSⁿ capabilities of the quadrupole ion trap can then be used to obtain more structural information on the peptide product ion. However, more research needs to be carried out to determine the general applicability of this approach.

Hydrogen/Deuterium Exchange Reveal Hydrogen Transfer During Fragmentation of Peptide b_2 Ions

Klaus Eckart and Joachim Spiess, Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann Rein Str. 3, D-37075 Goettingen, Germany

INTRODUCTION

The structure of b ions (1) and more specifically of heteromeric b_2 ions (2) was recently investigated on the basis of mass spectrometric experiments and theoretical calculations (1,2). In contrast to the general assumption that an acylium ion structure was characteristic for b ions (3), the protonated oxazolone and the immonium ion structure were found to represent b_2 ions (4). No stable minimum could be located for the acylium ion by the geometry optimization of the quantum chemical calculations (2). On the basis of experimental results, the formation of the isomeric protonated diketopiperazine was excluded (5). In the present paper hydrogen/deuterium exchange in combination with collisionally activated dissociations (CAD) was used to obtain detailed information about the structure of various heteromeric b_2 ions.

METHODS

Mass spectral data was obtained on a Micromass AutoSpec-T tandem mass spectrometer equipped with a 3°-focal plane detector. Data were recorded and performed with the OPUS data system. Samples were delivered in a mixture of 49.5 % water, 49.5 % methanol, and 1 % acetic acid into the micromass electrospray interface containing the skimmer lens and hexapole lens for increased ion transmission. The sampling cone voltage offset was set to 50 V. The spray chamber was held at 30°C. For H/D exchange, samples (100 μ g each) were dissolved in 100 μ l of a mixture of 49.5 % deuterium oxide, 49.5 % methanol d_1 , and 1 % acetic acid d_1 . The samples were dried, redissolved twice, and delivered in the deuterated solvent. CAD mass spectra were recorded on the array detector adjusted to a 15° angle which resulted in a 1:1.1 mass ratio. The gas cell was floated to 50% of the ion energy potential and the ion beam was attenuated to 30 % with 2×10^{-6} mbar helium.

RESULTS

Fig. 1: CAD mass spectra of deuterated and non-deuterated Ala-Gly (upper) and Gly-Ala (lower) b_2 ions

The Ala-Gly and Gly-Ala b_2 ions were obtained by cone skimmer CAD in the ES interface from the peptides H-Ala-Gly-Gly-OH and H-Gly-Ala-Gly-OH, respectively. The CAD mass spectra of the Ala-Gly b_2 ion revealed abundant signals for the CO loss (m/z 101) and the Ala immonium ion (m/z 44, Fig. 1a). In contrast, the Gly immonium ion (m/z 30) became additionally abundant in the CAD mass spectrum of the Gly-Ala b_2 ion (Fig. 1b). According to quantum chemical calculations the occurrence of the immonium ion fragment of the N-terminal amino acid residue was associated with an immonium ion structure of the b_2 ion, whereas the immonium ion of the C-terminal amino acid residue was linked to the protonated oxazolone structure (4).

H/D exchange of the acidic protons in the precursor peptides yielded specifically labelled b_2 ions carrying three deuterium atoms instead of the amide and amine hydrogen atoms (6). The b_2 ions did not show scrambling between the hydrogen and deuterium atoms in the CAD mass spectra. This was obvious for the N-terminal amino acid residue, but the C-terminal residue in the protonated oxazolone structure carried one deuterium atom before fragmentation and two deuterium atoms after fragmentation. The transfer of the second deuterium atom occurred in the rate determining step (RDS), because a primary kinetic isotope effect was observed. The ratio of the reaction rates of 2.8 was calculated from the enhancement of the Gly immonium ion relative to the competing immonium ion of Ala following H/D exchange (Fig. 1b). The same effect was observed in the Gly-Pro (2.4) and Gly-Sar (4.4) b_2 ions. No change of the immonium ion abundances was found for the corresponding a_2 ions. This made clear that the protonated oxazolone type b_2 ions did not fragment via a_2 ions as intermediates.

DISCUSSION

On the basis of these observations a mechanism for the formation of the C-terminal amino acid immonium ion fragment from protonated oxazolones is proposed. Initially one amine hydrogen is transferred from the N-terminal residue to the amide nitrogen of the C-terminal amino acid residue in the rate determining step. The second step may be easily described as a concerted cleavage of the five membered oxazolone ring.

CONCLUSION

H/D exchange in various b_2 ions revealed the highly specific transfer of acidic hydrogen atoms in oxazolone type b_2 ions and of non-acidic hydrogen atoms in immonium ion type b_2 ions. The primary kinetic isotope effect observed in oxazolone type b_2 ions demonstrated that a_2 ions did not play a role as intermediates in the C-terminal amino acid immonium fragment ion formation.

Stereochemical Effects in MS of Pentapeptides with One N-alkyl Amino Acid

Tomas Vaisar, Jan Urban, and Hiroshi Nakanishi
Molecumetics Ltd., 2023 120th Ave NE, Bellevue, WA 98005

Mass spectrometry is known not to be very sensitive to stereochemistry of organic molecules. Number of diastereoisomeric systems have been studied by MS (1), however, peptide diastereoisomers have been studied only rarely on systems containing a protecting groups, where losses of these groups were found to reflect stereochemical differences(2). Also, different efficiencies of losses of small neutral molecules (water, ammonia) were observed to reflect stereochemistry on selected peptides (3).

Recently, N-alkylated amino acid residues were found to have strong effect on stability of peptides both in solution and in the gas phase (4,5). N-alkylation greatly enhances fragmentation of a protonated peptide and directs it to the C-terminal amide bond of the N-alkylated residue with formation of a *b* ion.

As diastereoisomers differ only by mutual orientation of parts of the molecule, for such flexible compounds as peptides the actual conformation is an important factor. Generally, peptides with an N-alkylated amino acid residue (including Pro) are known to assume a conformation of various β -turn motifs as result of N-alkyl amino acid incorporation. An X-ray study of simple model peptides found that all-L diastereoisomers form predominantly β II-turn while those with a D-N-alkyl amino acid prefer β VI-turn conformation (6). These structural differences can in turn be reflected in mass spectrometric behavior.

Collision induced dissociation and mechanistic considerations

Protonated diastereoisomers with L- isomers of NMeAla and Pip show abundant formation of *b*₁ ion compared to their D- isomer peptides and the rest of peptides under study (Table 1). This is single major result of structural differences between the two diastereoisomers. Pro peptide does not follow NMeAla and Pip due to unfavorable structure of the product ion and/or the transition state with [3.3.0] bicyclic oxazolone-like structure. It can be hypothesized that if the fragmentation proceeds in a similar fashion to the mechanism proposed by Arnott et al. (7), the crucial step is protonation of the carbonyl oxygen of the N-alkylated residue be proton transfer from originally protonated N-terminus. Thus, this transfer can be enhanced in the protonated peptides with L-NMeAla and L-Pip, which results in abundant formation of the *b*₁ ion (as there is no proton present to complete double proton transfer required for formation of the *y*₂ ion).

Molecular mechanics Monte Carlo conformational search

A Monte Carlo conformational search finds different conformations for global minimum structure of protonated peptides with D- and L- N-alkylated residue. Thus for protonated Ala diastereoisomeric peptides both D- and L- isomers are found with *trans* amide bond, while for NMeAla, Pip and Pro the L- isomer prefers *cis*- and D- *trans*- N-alkylated amide bond. Furthermore, conformations where protonated N-terminus is hydrogen-bound to N-alkyl residue's carbonyl oxygen are found much closer to the global minimum for diastereoisomers with the L-N-alkyl residue than for the D- analog (Figure 1).

Conclusions

Protonated diastereoisomeric peptides H-Ala-Val-L/D-Xaa-Leu-Gly-OH (Xaa = NMeAla, Pip) are found to exhibit distinct CID fragmentation. Protonated peptides with L- isomer produce mainly *b*₁ ions as a result of enhanced hydrogen bonding from the protonated N-terminus to the carbonyl oxygen of N-alkylated residue. This is corroborated by molecular mechanics Monte Carlo conformational search, which finds for these isomers a conformation of corresponding structure much closer to the global minimum structure than in the case of D- isomers.

Stereochemical effects were also found in dissociations of proton bound heterodimers ($M_D \cdot H^+ \cdot M_L$) of all studied peptides resulting from higher proton affinity of the diastereoisomers with D- isomer of the central amino acid residue.(8)

To distinguish between PSD- and CID-fragment ions of peptides in a MALDI-RETOF-MS

Köster, Claus

Bruker-Franzen Analytik GmbH, 28359 Bremen, Germany

Introduction

In recent years matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI TOF MS) [1] has grown rapidly in its importance in the analysis of biomolecules. As an additional tool, post source decay (PSD) as well as collision induced dissociation (CID) measurements with reflectron time-of-flight mass spectrometers (RETOF) has become an established technique for obtaining structural information from picomol amounts of small peptides [2]. PSD-ions are fragments created by metastable decay of the parent ion after the ion source but before the reflector, the metastability of the parent ion can be induced e.g. by multiple low energy collisions during acceleration or photon absorption, however the decay happens in the microsecond time scale. CID-ions are created in TOF-MS by high energy collisions with decay-rates less than nanoseconds. The one by one configuration of an ion source, a collision cell and an einzel lens can distinguish between immediate and metastable decay.

Methods

The measurements were performed on a BRUKER REFLEX instrument assorted with a collision cell between the ion source and an einzel lens. By varying the einzel lens potential ions in a certain kinetic energy range can be focussed and appear amplified in the mass spectrum. By binding the einzel lens potential to the reflector potential CID-fragment ions can be distinguished from PSD-fragment ions where a "normal" PSD-spectrum is taken at a fixed einzel lens potential to give most intense parent ion signal. The collision cell was vented with air at a pressure of approx. 10^{-5} mbar. 10 pmol of analyte were mixed with a 5000 fold of α -cyano-4-hydroxy-cinnamic acid as matrix. Data were acquired using a 125 MHz digitizing rate. The detector response of low-mass matrix ions was minimized by the application of a deflection voltage pulse. The total PSD-spectra were pasted from a set of 21 PSD-spectra where each spectrum represents the sum of 100 consecutive laser shots.

Results

In figure 1 is shown a comparison of PSD- and CID-measurements of Substance P. Where the PSD-spectrum (top) shows intense a- and a-17-fragments, is the CID-spectrum (bottom) dominated by d-fragment ions which is especially due to the amplification effect of the bound einzel lens. The mass difference of 113 amu of fragment ion a_{10-17} and a_{9-17} inside the PSD-spectrum as well as the mass difference of 42 amu of the a_{10} and d_{10} ion in the PSD- and CID-spectrum makes sure that the amino acid # 10 in Substance P is Leu and not Ile.

Conclusion

By adding an electrical lens directly behind any fragmentation device (e.g. a collision cell) in a RETOF-MS or any other type of MS (except trap-MS) can be distinguished between fragment ions which are created by metastable or immediate decay of the parent ion. The amplified appearance of the immediate arising fragment ions can be used for example to distinguish between isobaric amino acids in a peptide sequence.

THERMALLY INDUCED DESOLVATION AND DISSOCIATION OF IONS IN A NEW ESI TOF MASS SPECTROMETER

P.V. Bondarenko, S. Song and R.D. Macfarlane

Department of Chemistry, Texas A&M University, College Station, Texas 77843

In addition to the collisional activation in the nozzle-skimmer region, thermal heating has been employed by several authors [1-3] to aid the desolvation-dissociation of electrospray ions. We have recently designed an ESI TOF mass spectrometer, consisting of a heated electrospray ion source, a linear TOF mass analyzer with orthogonal ion acceleration and an electrostatic ion guide as the interface between them [4]. This electrospray ion source employs heat as the only means of ion desolvation and dissociation and has a relatively simple design. The heated ion source has two differentially pumped regions used to transport ions between the atmospheric pressure electrospray chamber and the high vacuum region of the instrument, while pumping away the residual gas. This source consists of a flat nozzle and two skimmers (all at ground potential) positioned coaxially inside a stainless steel housing (see insets in Figure 1). The housing temperature is elevated to 300° C by a heating tape, which is wrapped around the housing.

Electrospray droplets from the atmospheric chamber are entrained in the nitrogen stream and are accelerated to sonic velocity when they pass through the orifice. Free jet isentropic expansion from the orifice results in a beam of charged droplets with high axial velocity and low radial velocity. Ions thermally evaporated from these charged droplets retain most of the features of the velocity profile of the parent droplets and are efficiently transported through the skimmers. Figures 1a and 1b show two spectra of cytochrome C recorded at different pressures inside the heated ion source. When pressure inside the ion source is low (Figure 1a), the droplets evaporation rate is slow. The droplets pass through the heated source in the regime of low surface-charge density. There is a relatively large contribution of ions in low-charge states to the total population, even though such ions desorb slowly. Cytochrome C molecular ions are produced with charges ranging from 1+ to 12+ and with low signal intensity. It appears that the majority of sample ions do not desorb effectively from the droplets. Rather, they penetrate the ion source as a component of the droplets, then enter the high vacuum region and become lost. When a higher source pressure is maintained inside the ion source (Figure 1b), numerous collisions with molecules of residual gas in the hot interior of the ion source cause rapid and complete evaporation of the droplets. The ions desorb intensively from the small and highly charged droplets and, as a result, have increased intensity and charge states. Total ion intensity of the cytochrome C molecular ions in the twelve peaks (from 5+ to 16+) is ~ 5.5x10⁵ counts. While acquiring the spectrum for 2 minutes with an electrospray rate of 1 µl/min and sample concentration of 5x10⁻⁵ M, a total ~ 6x10¹³ cytochrome C molecules were consumed. Therefore, one out of ~ 1 x 10⁸ sample molecules was transmitted from the solution state to the detector. Addition of methanol to the water solution and decrease of analyte concentration and electrospray rate can increase the total transmission efficiency by an order of magnitude or even more for several other proteins.

Figure 2 shows dissociation products of angiotensin II. The y and b- mode fragment ions dominate in the fragmentation spectrum. This fragmentation pattern is typical for collisional activation of the electrospray ions.

EXPERIMENTAL EVIDENCE THAT NEUTRAL GLYCINE HAS THE STRUCTURE $\text{H}_2\text{N-CH}_2\text{-COOH}$ IN THE GAS PHASE

Michael J. Polce and Chrys Wesdemiotis
Chemistry Department, The University of Akron, Akron, OH 44325

Glycine is known to adopt a zwitterionic, $^+\text{H}_3\text{N-CH}_2\text{-COO}^-$, arrangement in its crystalline form and in aqueous solution near its isoelectronic point. Only in the isolated gas phase, is the Gly molecule believed to take on the $\text{H}_2\text{N-CH}_2\text{-COOH}$ structure. Earlier EI studies have shown that the molecular ion of Gly, differs from the m/z 75 ions obtained from dissociative ionization of isoleucine^[1] and homophenylalanine,^[2] which were assigned the structure of the isomeric enol ion $\text{H}_2\text{N-CH=C(OH)}_2^+$. This work presents new experimental results which characterize the molecular ion obtained from EI of Gly, along with its enol isomer and investigates their neutral and anionic forms.

All experiments were performed with a modified VG AutoSpec instrument of E_1BE_2 geometry previously described.^[3] The source temperature was 180-200 °C, the electron energy 70 eV, and the accelerating voltage 8 kV. The m/z 75 ions were mass-selected by E_1B and their metastable ion (MI), collisionally activated dissociation (CAD), neutralization-reionization (NR), neutral-fragment reionization (N₂R), and charge inversion spectra acquired in (FFR-3) by scanning E_2 . O_2 was used for CAD and reionization and trimethylamine (TMA) for neutralization and charge inversion. TMA was replaced with He for N₂R experiments.

Our MI results on the m/z 75 from homophenylalanine and ionized glycine agree with those of Depke et al.^[2] However, we find the MI spectra from the two enol ion precursors to differ, with the m/z 75 ion from Ile losing only H_2O to give ionized aminoketene (m/z 57). While the additional H_2 and H^+ losses, previously reported^[2] for the m/z 75 from homophenylalanine, and also observed by us, are apparently due to coproduction of isobaric C_6H_5^+ .

The CAD spectra are dominated by the same product ions as seen for metastable dissociation, i.e., $\text{H}_2\text{N}^+=\text{CH}_2$ (m/z 30) for ionized Gly and $[\text{H}_2\text{N-CH=C=O}]^+$ (m/z 57) for the enol ion from Ile. Peaks at m/z 73 and 74 (due, respectively, to H_2 and H losses from C_6H_5^+ contamination) are again evident for the m/z 75 from homophenylalanine. Other, less abundant, fragment ions are obtained upon CAD that can be used to differentiate ionized Gly from its enol isomer, which produces more $^+\text{C(OH)}_2$ (m/z 46), $\text{HC}^+=\text{C=O}$ (m/z 41), H_3O^+ (m/z 19), and a distinguishing charge stripping product, 75^{++} . The CAD spectrum of ionized Gly-d5 reveals that doubly charged immonium ions (34^{++}) can also be formed.

NR data (Fig. 1) show the C_6H_5^+ impurity, more clearly, due to the large NR cross-sections of highly conjugated hydrocarbon ions. The enol ion generated from Ile yields a sizable survivor (recovery) ion signal, illustrating that the $\text{H}_2\text{N-CH=C(OH)}_2$ neutral enol is a stable species in the gas phase. The NR spectrum of ionized glycine (Fig. 1c) also produces a detectable recovery peak which, based on the m/z 75:57 ratio, is not due to the enol isomer. Deconvolution of its N₂R spectrum (Fig. 1d) from the NR spectrum results in a fragmentation pattern consistent with the structure $\text{H}_2\text{N-CH}_2\text{-COOH}$, not $^+\text{H}_3\text{N-CH}_2\text{-COO}^-$.

Charge inversion experiments (Fig. 2) reveal that charge reversal of the m/z 75 enol cation formed from Ile produces a stable $\text{H}_2\text{N-CH=C(OH)}_2^-$ molecular radical anion, while none is detected for ionized Gly. The stability of the enolic radical anion, an open-shell species, suggests that addition of an electron to the neutral enolic tautomer is exothermic. Almost all of

the fragments observed correspond to even-electron (closed-shell) anions. Several unique peaks are observed for the enol ion, e.g., HNCH^- (m/z 28), HCCO^- (m/z 41), and HNCHCO^- (m/z 56) that are absent from the spectrum of ionized Gly which shows mainly COOH^- (m/z 45).

This study shows that several MS/MS MIKES techniques can be used to distinguish ionized glycine from its enol isomer, $\text{H}_2\text{N-CH=C(OH)}_2^+$, which is cleanly produced from dissociative ionization of isoleucine. Moreover, we find that $\text{H}_2\text{N-CH=C(OH)}_2^+$ generated from homophenylalanine is contaminated with isobaric C_6H_5^+ . We also present first experimental evidence for the existence of the neutral enol, $\text{H}_2\text{N-CH=C(OH)}_2$, and the radical anion $\text{H}_2\text{N-CH=C(OH)}_2^-$. Finally, our results reveal that the $\text{H}_2\text{N-CH}_2\text{-COOH}$ structure, is produced upon reduction of ionized glycine, verifying it is indeed a stable species in the gas phase.

The Relationship Between the Structure of Highly Branched Oligosaccharide Ions and their Relative Collision Induced Dissociation Thresholds, studied by MALDI FTMS.

Sharron G. Penn^a, Mark T. Cancilla^a, Jerry L. Hedrick^b and Carlito B. Lebrilla^a.

(a) Dept. of Chemistry (b) Section of Molecular and Cellular Biology, University of California, Davis, CA 95616.

Collisionally induced dissociation (CID) is used in an external source Fourier transform mass spectrometer (FTMS) equipped with matrix assisted laser desorption/ionization (MALDI) to study a number of complex, branched oligosaccharides. Figure 1 shows the MALDI MS of difucosyllacto-N-hexaose (I) (Structure shown). The fragment at m/z 1241.4 is the loss of a fucose. The fucose glycosidic bond is very labile, contributing to nearly all the observed fragments. Figure 2 shows the MS/MS spectrum. Extensive structural information is obtained. The CID amplitude was 25 V_{b-p} for 0.25 ms to maximize fragmentation, this calculates to a center-of-mass frame energy (E_{COM}) of 7.22 eV. MS/MS/MS has also been carried out on a number of oligosaccharides, to increase further the amount of structural information.

For I the lowest CID amplitude at which any fragment is observed is 16.6 V_{b-p} . This is the $Y_{3X''}$ cleavage (loss of a fucose) again showing it is very labile. This threshold was calculated to occur at an $E_{COM} = 3.18 \pm 0.2$ eV. This is the first time such values have been calculated for large, highly branched, oligosaccharide ions. The CID amplitude at which all the major fragments of the isomer of II, difuco-para-lacto-N-hexaose (II) appear were also determined. As expected, different fragments had different E_{COM} values.

For the two isomers I and II, the loss of the fucose sugar is always the lowest energy fragment observed, and occurs at the same energy in both isomers ($E_{COM} = 3.18$ eV), when the sugar is sodiated (Table). Alkali metals can influence the fragmentation of oligosaccharides in MALDI FTMS. The addition of Cs⁺ has been shown to decrease the fragmentation of oligosaccharides. To quantify this effect I was doped with CsCl and the dissociation threshold determined. When I is complexed to Cs the energy threshold for the removal of the fucose moiety increases to 3.78 eV E_{COM} , indicating that the Cs is involved in a coordination complex which stabilizes the sugar. Molecular modelling calculations indicate that the cesium is complexed to at least 5 monosaccharide units in I, as compared to only 2 for the sodium adducted species.

Table : Thresholds for the loss of fucose in oligosaccharide isomers

Oligosaccharide	Coordination metal	Loss of fucose	E_{COM}
Difucosyllacto-N-hexaose (I)	Na	$Y_{3X''}$	3.18
Difucosyllacto-N-hexaose (I)	Cs	$Y_{3X''}$	3.78
Difucosyl-para-lacto-N-hexaose (II)	Na	$Y_{3\beta}$ or $Y_{5\alpha''}$	3.18

(2) MS/MS of Difucosyllacto-N-hexaose, at $E_{COM} = 7.22$ eV

Low Energy CID of Doubly Charged Metal(II)-Oligosaccharide and Acetonitrile Complexes

Martin Kohler and Julie A. Leary*, College of Chemistry
University of California, Berkeley, CA 94720-1460

Electrospray ionization grants easy access to multiply charged gas phase metal complexes, which are interesting targets for theoretical (mechanistic aspects) and practical studies (structure elucidation) [1]. Low energy collision induced dissociation pathways of doubly charged metal(II) complexes of oligosaccharides and various small organic ligands such as acetonitrile, pyridine and methanol were investigated. The dissociation pathways were correlated to the differences in the ionization potentials between metal, ligands and collision gas.

The low energy CID spectrum of $[M + \text{Co(II)}]^{2+}$ (M representing the conserved trimannosyl core pentasaccharide, MW: 910 Da) is shown in Figure 1. Fragmentation of the doubly charged precursor occurs through two pathways. Loss of a neutral dehydromannose fragment (Z, 162 Da) leads to a doubly charged ion at m/z 403.5. Simultaneously, a dehydroxymannose cation (Y, 163 Da) is lost by heterolytic bond cleavage, forming a singly charged complementary ion at m/z 806. If Co(II) is replaced by Ca(II), the heterolytic bond cleavage process is not observed and no complementary ion pair is found.

In order to learn more about these pathways, experiments with small organic molecules coordinated to metal(II) ions were undertaken. Figure 2 shows a low energy CID spectrum of $[\text{Co(II)} + (\text{CH}_3\text{CN})_2]^{2+}$ using Xe as the collision gas. In this case, heterolytic bond cleavage is seen as before, confirmed by the ions $[\text{CH}_3]^+$ and $[\text{Co(II)} + \text{CN}]^+$ at m/z 15 and 85, respectively. Neutral loss from the doubly charged precursor was observed as well, demonstrated by an abundant signal for $[\text{Co(II)} + \text{CH}_3\text{CN}]^{2+}$ at m/z 50. However, for the metal(II)-acetonitrile system, a series of additional pathways is observed, most notable among them reduction of Co(II) to Co(I) by electron transfer from the collision gas to the metal. This is demonstrated by the $[\text{Co(I)}]^+$ and $[\text{Xe}]^+$ species, detected at m/z 59 and 128-136. In addition to the collision gas, the other source of electrons is the acetonitrile ligand, shown by the signals for the reduced $[\text{Co(I)} + \text{CH}_3\text{CN}]^+$ species and the oxidized acetonitrile ligand $[\text{CH}_3\text{CN}]^{+•}$ at m/z 100 and 41, respectively. In addition to this electron transfer process, proton transfer between the acetonitrile ligands was found, shown by the product ions $[\text{CH}_3\text{CN} + \text{H}]^+$ and $[\text{Co(II)} + \text{CH}_3\text{CN} - \text{H}]^+$ at m/z 42 and 99, respectively. If Co(II) is replaced by Ca(II), the low energy CID spectrum looks much different. The only processes found in this case are consecutive losses of neutral ligands down to the bare $[\text{Ca(II)}]^{2+}$ species. No reduction and no ligand cleavage processes are observed. These observations can be explained by the fact that the second ionization potential of Ca (11.9 eV) is lower than the ionization potential of the electron sources available, which are the collision gas (Xe, 12.1 eV) and the ligand (acetonitrile, 12.2 eV). This can be further confirmed by replacing acetonitrile with pyridine, a ligand having a very low ionization potential (9.3 eV). In this case, Ca(II) is also reduced, demonstrated by the signals for $[\text{Ca(I)}]^+$ and $[\text{pyridine}]^+$ at m/z 40 and 79, respectively (see Figure 3).

Tandem mass spectrometry is a powerful tool for ion structural analyses and its application to carbohydrates has been an area of great interest. One extensively applied methodology has been to convert hydroxy groups into methyl ethers (permethylation) and to dissociate ions formed by adduction with alkali metals. This allows for the identification of multiple glycosidic cleavages (internal fragments) and provides linkage specific fragments. In this poster the

dissociation spectra of Na adducted, permethylated maltoheptaose is evaluated by a number of different methods. Infrared photon induced dissociation (IR PID) in a 7 Tesla FT ICR and off resonance dipolar excitation (SORI) with argon gas collision in a 9.4 Tesla FT ICR spectrometer is compared with the collision induced dissociation spectra from high and low energy collisions with tandem beam instruments (a 10 kV JEOL HX110 with He collisions and a TSQ 700 triple quadrupole). Preliminary results with PSD on a MALDI TOF are also discussed.

Energy-Resolved Collision-Induced Dissociation of Deprotonated Mononucleotides

*Ho, Yeunghaw; Kebarle, Paul
Department of Chemistry, University of Alberta, Edmonton
Alberta, Canada T6G 2G2

The mechanisms involved in the CID of deprotonated dinucleotides have been studied by several groups¹⁻⁴. These mechanisms might provide models for the decomposition of polynucleotides which have important application in the sequencing of nucleic acids. Energy resolved CID of dinucleotides with a FTMS have been reported by Beauchamp et al.¹ McLuckey et al.² who used an Ion Trap. In the present work we reported energy resolved CID studies of deprotonated mononucleotides. The ions, generated by Electrospray (ES) were thermalized in a chamber maintained at 10 torr, before they enter a triple quadrupole mass spectrometer. CID was obtained with Xe under single collision conditions. The threshold curves were fitted with the Armentrout CRUNCH program⁵, however no correction for the internal energies of the precursor ions and for the kinetic shift were made. The results for the mononucleotides provide some important insights also for the mechanism of the dinucleotides.

The formation of the B⁻ and [M-H-BH]⁻ ion products in the CID of deprotonated dinucleotides has been rationalized by Beauchamp et al.¹ on the basis of an E2 mechanism which leads to the B⁻ ion. The B⁻ ion forms a ion-dipole complex with the neutral fragment. The complex may lead either to formation of a free B⁻ or the B⁻ ion can deprotonate the phosphate group and generate the [M-H-BH]⁻ ion.

The present results (Figures 1 and 2) show that the E2 mechanism can not be applied to the fragmentation of mononucleotides while the S_N2 mechanism proposed by Gross, M.L. et al.³ provides an adequate model for the formation of the B⁻ ion. The formation of the [M-H-BH]⁻ ion can be rationalized on the basis of an ion-dipole complex followed by deprotonation of the phosphate group by the B⁻ ion. These conclusions follow the results shown in (Figures 1 and 2).

CID of the adenosine 2':3'-cyclic monophosphate leads to B⁻ as the major product (Figure 1). This ion can not be formed by E2 elimination because the only available hydrogen on the C2' atom is in the anti position. Only the S_N2 type attack on the C1' is possible. Because there is no available hydrogen on the phosphate, the [M-H-BH]⁻ ion can not be formed, in agreement with the results (Figure 1).

CID of adenosine 3'-monophosphate (Figure 2) leads to both B⁻ and [M-H-BH]⁻ ions. Also in this case no suitable hydrogen is available on the C2' atom and no E2 mechanism can be expected. The [M-H-BH]⁻ ion can be formed in this case because hydrogens at phosphate group are available and this ion is actually observed.

The shapes of the appearance curves of the B⁻ and [M-H-BH]⁻ (Figure 2) are consistent with the proposed ion-dipole mechanism. The [M-H-BH]⁻ ion is dominant at low energies, however, the yield of B⁻ ion increases much faster with collision energy and becomes dominant at high energies. At high energies, direct departure of B⁻ ion from the dipole complex is expected to be favored over the phosphate group deprotonation, which requires the formation of a proton bound complex.

McLuckey et al.¹ have obtained energy resolved CID results for 2'-deoxymononucleotides 3'-phosphate. The [M-H-BH]⁻ ion was the by far dominant fragment and only very low abundance of the B⁻, H₂PO₄⁻ and PO₃⁻ ions were observed over the whole energy range.

We have obtained under single collision conditions quite different results for the very same precursor ions (Figure 3). All four products [M-H-BH]⁻, B⁻, H₂PO₄⁻ and PO₃⁻ are observed with substantial intensities. It is interesting that the [M-H-BH]⁻ ion which has the lowest energy threshold is the only ion observed at high intensities in the ion trap experiments. This indicates relatively low energies at the ion trap conditions.

Another important difference can be present under the multiple collision conditions. Product ions produced at low energy thresholds, which themselves decompose with low energy threshold may not be observed in high abundance in the continuous heating conditions, because they will decompose rapidly.

The threshold energies observed under simple collision conditions are very much better defined (Figure 3) than the thresholds obtained with the ion trap.¹

Structural Characterization of Porphyrins by high-energy FAB CID-MS/MS

School of Science and Engineering, Waseda University, Tokyo
The Institute of Physical and Chemical Research (RIKEN), Wako-shi, Japan

Toshimichi Shibue, Hisashi Kambe, Hiroyuki Nishide, Satoko Akashi, Naoshi Dohmae, Koji Takio, Yoko Ohashi.

Recently, we reported on the EI CID-MS/MS of 5,10,15-tris(*o*-pivalamidophenyl)20-(*o*-aminophenyl)porphyrinatocobalt and 5,10,15,20-tetrakis(*o*-pivalamidophenyl)porphyrinatocopper. Their fragmentations were studied by B/E-constant and B(1-E)/E-constant linked-scan techniques using a JMS-SX102A. The spectral data clearly showed the number of pivaloyl substituents contained in the porphyrin derivative, proving that the EI CID-MS/MS technique is useful for the characterization of porphyrin substituent groups.

These porphyrins are volatile compounds, whereas 2-[8-(*o*-methylimidazol-1-yl)octanoyloxymethyl]-5,10,15,20-tetrakis(*o*-pivalamidophenyl)porphyrinatoiron (a) is not (Fig.1). FABMS revealed the molecular weight of this non-volatile porphyrin. However, fragment ions diagnostic of the structure usually appear in the low-mass region, often being smeared by the matrix ions. On the other hand, tandem mass spectrometry selectively showed the sample-originated ions even in the low-mass regions.

Described here first is the structural characterization of compound (a) by high-energy FAB CID-MS/MS. These fragmentation behaviors, particularly regarding the way in which elimination of the imidazole radical occurs at the pyrrole-2-position, is discussed.

Based on linked scan spectrometry, we propose that the imidazole is eliminated as a neutral species from the pyrrole-2-position, following

Fig.1

which four pivaloyl groups are cleaved off in series from the rest of the molecule. Next, we extended our study to the matrix effect on the porphyrin ring system reduction during FAB mass spectrometry. Matrices tried were 3-NBA, glycerol and thioglycerol. Natural isotope abundance of M+1, M+2 and M+3 were calculated for the observed ion height of M, then they were compared with the apparent ion intensities at these m/z values. It was found that when the matrix was 3-NBA, the values of the measured ion intensities of M, M+1, M+2 and M+3 almost agree with the calculated natural isotope abundances. However when the matrix is glycerol or thioglycerol, the observed ratios of M+1, M+2 and M+3 were markedly higher than the values calculated as natural isotopes of M. Thus, it is suggested that, in addition to the expected protonated molecular, even reduced molecular species are produced in the ion source.

Our last study concerned the tandem mass spectrometry performed using a JMS-HX110/HX110 with an array detector, which clearly showed the charge-remote fragmentation representing the precise structure of the pendant chain of the imidazole in addition to the structural information obtainable by the linked scan (Fig.2). B/E-constant linked scanning using a JMS-SX102A showed charge-remote fragmentation much less clearly. Thus high energy FAB CID-MS/MS with an array detector is currently the most useful analytical means for the structural studies of porphyrins.

Relative Reaction Cross-Sections and Dynamics of Collisional Dissociation of the Fullerene Ions

Toshihide Nishimura

Pharmacia-Upjohn Inc., 23-Wadai Tsukuba-city Ibaraki 300-42 Japan

Objectives There have been numerous experimental and theoretical studies on ionic dissociation of fullerene ion together with various ionization techniques including electron ionization (EI), photo-dissociation (PD) method, and collision-induced dissociation (CID) with noble gases. Scheier et al. (1994) suggested that the even-numbered fullerene ions are produced via the successive evaporation of nC_2 ($n = 1, 2, 3, \dots$) in EI since energy differences of their appearance energies were quite similar each other. However, Wesdemiotis et al. (1995) recently indicated in terms of their reionization experiments for neutral species produced from collision-induced dissociation of fullerene positive ions that the even-numbered fullerene fragment ions are most probably formed via the direct elimination of C_{2n} ($n=1,2,3,\dots$). This question of fragmentation mechanism still remains unresolved. Moreover, although Smalley et. al (1988) first gave a question on the formation mechanism of small carbon cluster ions ($< C_{32}^+$), its dynamics has not been fully understood yet. Namely, "Can we interpret dynamics of collision-induced dissociation of fullerene ions with the same theoretical frames as fragmentation of other organic ions?" Here, we have investigated collision-induced dissociation of fullerene ions, C_{60}^+ and C_{70}^+ , by measuring their relative cross-sections as function of CM collision energy, appearance energies of major fragment ions, and their branching ratios (see Fig. 1).

Methods Instrument: Finnigan MAT-90 (BE-type) mass Spectrometer and JEOL HX-110/HX-110 tandem mass spectrometer. The primary beam of fullerene parent ions, C_{60}^+ , was produced by 200-eV electron ionization with a direct probe heated to 270 C. (ion source temperature was ca. 300 C.), and was selected with a magnet sector (B). This beam was introduced into a collision cell located at 2FFR and its mass-analyzed ion kinetic energy (MIKE) spectra of fragment ions produced via collision-induced dissociation was measured by an electric static analyzer. Collision energy was varied with changing acceleration energy of the parent fullerene ion, E_{LAB} . The maximum collision energy E_{CM} which is available for excitation of the parent fullerene ion can be given as

$$E_{CM} = E_{LAB} \times m_{He} / (M + m_{He}). \quad (1)$$

The energy resolutions of the primary beam were as follows: $E/\Delta E$: ca. 3000 ΔE : ca. 1.5eV ($E_{LAB} = 4720eV$) and $E/\Delta E$: ca. 500 ΔE : ca. 0.5eV ($E_{LAB} = 230eV$)

Attenuation rate of the primary beam was set to be ca. 50-% so that a single collision condition holds for all experiments. There, the number of collision in a collision cell was less than 0.8. The source of C_{60}^+ and C_{70}^+ was commercially attained as FULLERITE (C_{60} $C_{70} = 90\%:10\%$) from SIGMA CHEMICAL CO. The relative CID cross-section $\sigma(mi)/\sigma_T$ can be expressed using the beam intensities of the primary beam prior to and after gas introduction I_0 and I_0' , and those of specific fragment ions m_i , I_{mi} :

$$\sigma(mi)/\sigma_T = I_{mi}/I_0 \ln(I_0/I_0') \quad (2)$$

Herein, σ_T is the total collision cross-section. Appearance energy of an ion (mi) was evaluated from an extrapolation to $\sigma(mi)/\sigma_T = 0$ in a plot of $\sigma(mi)/\sigma_T$ against $1/E_{CM}$. Branching ratios were obtained as

$$B(mi) = I_{mi} / \sum I_{mi} \quad (3)$$

Results and Discussion

In low CM collision energies the even-numbered fullerene fragment ions seem to be formed mainly via the direct elimination of C_{2n} ($n=1,2,3,\dots$) although there seems to be also a contribution of the successive losses of C_2 . Moreover, CID-MIKE spectra indicated that their formation may occur via a *fast anisotropic dissociation* accompanying a large kinetic energy release since an expected *Derric shift* in He-CID processes for the fullerene ions, C_{60}^+ and C_{70}^+ , is small compared to experiment. This observation may be interpreted by dissociation of a "distorted" fullerene parent ion which is formed via *collisional deformation prior to fragmentation*. The even-numbered fullerene ions were formed in CM collision energies restricted narrowly within 3 - 4 eV for C_{60}^+ and of 4 - 6 eV for C_{70}^+ . The total carbon cluster ions ($\sum C_y^+$; $y < 32$) were produced with their appearance energies of 6.1 eV and 5.9 eV respectively from C_{60}^+ and C_{70}^+ , which are almost identical. The appearance energy of C_{60}^{+2} produced by a charge-stripping process from C_{60}^+ was found to be around 10 eV and this value was consistent with those reported in the previous literature. In higher energies branching ratios of fragment ions were found to converge on the equivalent values and the small carbon cluster ions ($\sum C_y^+$; $y < 32$) are formed competitively with the even-numbered fullerene ions.

These breakdown curves or branching ratios of both C_{60}^+ and C_{70}^+ seem to suggest that in CM collision energies higher than ca. 10 eV dissociation occurs concurrently from a non-structural fullerene parent ion, which better be expressed as a "bubble"-state fullerene ion, while in lower CM collision energies fragmentation takes place from a "distorted" fullerene parent ion, which still holds its specific binding structure. Our observation may support the suggestion on existence of a "liquid"-state fullerene ion and its explosive fragmentation given by Campbell et al. Furthermore, the coincident appearance energies of He-capture (Campbell et al in 1992) and the small carbon cluster ions ($\sum C_y^+$; $y < 32$) (this study) may suggest that a phase change in binding structure resulting in the concurrent fragmentation of a fullerene parent ion is led by a multiple collision between a helium atom and an inner wall of the fullerene cage.

Fig. 1. The partial He-CID breakdown diagram of the fullerene parent ion, C_{60}^+

Target Capture of Noble Gas Atoms by Fullerene Radical Cations.

Jackie A Mosely, Richard T Gallagher and Peter J Derrick.

Institute of Mass Spectrometry, University of Warwick, Coventry, CV4 7AL, UK.

Introduction The notion of target capture in keV-collisions of massive ions was put forward by Neumann *et al.*⁽¹⁾ who suggested that under the appropriate collision conditions an impacting ion and a target gas would not separate following their collision. With molecules such as fullerenes there lies the possibility that the target gas could be trapped inside the cage. Evidence published shows that a target gas can be incorporated into C_{60}^+ and C_{70}^+ in high energy collisions by trapping helium⁽²⁾ neon⁽³⁾ and argon⁽⁴⁾.

Experimental A Kratos Analytical IHH four-sector tandem mass spectrometer with scanning array detection was used for these experiments. Fullerene radical cations were produced by electron impact ionisation and accelerated with a potential (V_{acc}) of 7.9 kV. Ions were mass-analysed through the first double-focussing mass spectrometer and then focused into a collision cell. The collision cell was floated at a value above earth (V_{cell}) such that the desired laboratory-frame collision energy (E_{lab}) was obtained. The β -slit situated after E2 was used to control translational energy resolution of E2. Target gas pressure was sufficient to reduce the parent ion to 50% of its original intensity. The second electric (E2) was fixed at a selected potential and the second magnet (B2) was scanned.

Target Capture of Krypton by C_{60}^+ . Figure 1 ($E_{lab} = 440$ eV) has been obtained by reducing the potential on E2 by a value equal to the centre-of-mass collision energy. For collisions between krypton and C_{60}^+ a peak corresponding in mass to the most abundant isotope of krypton (^{84}Kr) was observed. Two groups of five peaks were also evident. The relative intensities among the peaks in each cluster were consistent with the relative abundances of the five most abundant isotopes of krypton. The cluster of peaks around $m/z = 780$ is assigned as $C_{58}^+Kr^+$ and the cluster of ions about $m/z = 756$ is assigned as $C_{56}^+Kr^+$ ($x = 80, 82, 83, 84$ and 86).

Figure 2 ($E_{lab} = 500$ eV) shows the spectrum obtained with the potential on E2 reduced by an amount, $E_{def} = 92$ eV, calculated for the loss of six carbon atoms from $C_{60}^+Kr^+$. Under these conditions the full $C_{60}^+Kr^+$ adduct would not be observed, although fragments from $C_{58}^+Kr^+$ to $C_{50}^+Kr^+$ were observed at E_{def} 's appropriate for their formation from $C_{60}^+Kr^+$. The observation of $C_{54}^+Kr^+$ suggests that the full adduct $C_{60}^+Kr^+$ exists in a transient state at this energy. The observation of fragment ions $C_{56}^+Kr^+$, $C_{52}^+Kr^+$ (and possibly $C_{50}^+Kr^+$) containing krypton suggests that the full adduct is an endohedral complex $Kr@C_{60}^+$.

Discussion From results obtained in this research with He, Ne, Ar, Kr and Xe, exemplified here using krypton as the target gas, it is suggested that the complete target gas/fullerene collision complex is an endohedral structure. It is deemed unlikely that an adduct with the noble gas atom associated with the outside of the fullerene cage would survive decomposition intact. The question must then be asked, how does the inert gas atom become trapped inside the fullerene cage? Impulsive collision transfer (ICT) theory⁽⁵⁾ envisages an atom interacting with a highly localised area of the ion. The target gas is proposed to pass

through the front wall of the fullerene cage but not to penetrate the backwall. Entrapment would occur as the cage "anneals" behind the target gas atom.

Conclusion All of the noble gas atoms He, Ne, Ar, Kr and Xe have been trapped by C_{60}^+ and C_{70}^+ and are deemed to be endohedral structures.

Fragmentation of a Per(onio) Substituted Benzene. How many charges can fit on the head of a pin?

X. Kate Zhang* and Henry M. Fales*

National Heart, Lung, and Blood Institute, NIH, Bethesda, MD.

The degree to which accumulation of charge on peptides and proteins contributes to their subsequent fragmentation on collisional activation has been the subject of much recent study (e.g., D.S. Gross *et al.* J. Phys. Chem. 1995, 99, 4034; K.M. Downard and K. Biemann, J. Am. Soc. Mass Spec. 1994, 5, 966, etc.). An extreme example of accumulation of charge is provided by a recent synthesis of the hexatriplate salt of hexakis(4-dimethylaminopyridyl)benzene (Weiss *et al.*, Angew. Chem., 1995, 34, 1319-1321) (structure on next page). This compound involved an interesting reaction between hexafluorobenzene and 4-dimethylaminopyridine (DMAP) in the presence of trimethylsilyltrifluoromethanesulfonate, the latter serving to remove the fluoride ions from the reaction by their conversion to gaseous trimethylsilylfluoride. The compound proved difficult to characterize since its only unique feature compared to DMAP is the ^{13}C NMR of its benzene ring at $\delta 140.99$ but this is obscured at 200 MHz by the C_2C_6 of DMAP at $\delta 140.99$. Fortunately, the single crystal x-ray dimensions (Dr. J. Silverton) were found to be identical with the reported values. The recrystallized salt was dissolved in a water-methanol solution and subjected to electrospray analysis in the Finnigan TSQ-700. However, due to the accumulation of positive charge the benzene ring undergoes easy nucleophilic attack by both solvents, forming a monophenol and its methyl ether by displacement of one of the dimethylaminopyridine substituents. When dry acetonitrile was used, these complications were minimized and the spectrum shown on the next page was obtained. Ions were observed containing the polycationed benzene ring with from 2-5 trifluoromethanesulfonate anions yielding total charges from +4 to +1 were observed. As in the case of the iron complex of acetic acid reported last year (ASMS paper #238, May 1995) the maximally charged species with two counterions is in numeric agreement with the x-ray structure where these two counterions are located perpendicular above and below the benzene ring with their three sulfonate oxygens pointed toward the positively charged ring.

Compound 1 therefore produces 4 peaks at m/z 1549, 700, 417, and 275.5 for the complexes $(\text{C}:5\text{T})^{+1}$, $(\text{C}:4\text{T})^{+2}$, $(\text{C}:3\text{T})^{+3}$, and $(\text{C}:2\text{T})^{+4}$ where C = cation⁶ and T = CF_3SO_3^- . The monophenol (P) formed by hydrolysis of 1 is present as the anion and internally reduces the overall charge by 2 so that the 4 peaks observed are at m/z 1145, 498, 282.3, and 174.5 for $(\text{P}:3\text{T})^{+1}$, $(\text{P}:2\text{T})^{+2}$, $(\text{P}:1\text{T})^{+3}$, and $(\text{P}:0\text{T})^{+4}$. It is interesting that in both the monophenol and the original cation the maximum charge state is +4. $(\text{P}:0\text{T})^{+4}$ at m/z 174.5 is very weak but was identified both by its isotope pattern and by subsequent MS/MS where it decomposed even at 11V to yield DMAPH⁺. By contrast, the more heavily solvated monophenol ions require 20-30V and the least solvated singly charged ion, 50V. In the case of the symmetrical cation C, decomposition of the singly charged $(5\text{CF}_3\text{SO}_3^-)$ ion cannot be decomposed even at the maximum voltage of 83V. The other ions in the C series decompose at ~22V, again with more decomposition at higher charge states.

The types of decomposition produced by MS/MS are shown below.

REACTIONS PROVEN BY MS/MS

Fragmentation induced by ion-atom reactions

Leymarie, N.; Mestdag, H.; Poisson, L.; *Rolando, C.; Sablier, M.
École Normale Supérieure, Département de Chimie, URA 1679 du C.N.R.S., Processus
d'Activation Moléculaire, 24 rue Lhomond, 75231 Paris Cedex 05, France

Tandem mass spectrometry (MS/MS) has become one of the most powerful techniques for the structural analysis of organic molecules and collisionally-activated dissociation (CAD) is the most frequently used experiment in MS/MS. However, with high mass ions, the CAD efficiency tends to fall off due to the limitations in energy transfer imposed by collision dynamics and an increased number of degrees of freedom.

The mechanism by which the energy is transferred into a precursor ion can significantly affect the CAD spectrum and the answer to the mechanistic question, *Can chemistry occur during the activation process?*, is certainly yes owing to the reported results of reactive endothermic ion-molecule reactions (1).

The alternative that we present here allows *chemistry* to dissociate ions. Using ion-atom reactions, hydrogen atoms playing the role of target gas, the experiments have consisted in the formation of an hydrogen atom-bounded complex which subsequently dissociates into one or several fragment ions. The formation of this complex depends on the heat of the reaction with atomic hydrogen. The important aspect of these ion-atom reactions is that the relative heat of reaction is completely utilized in the formation of this complex and subsequent dissociation pathways are opened up by this mean. Exothermic hydrogen bond formation is then converted into internal energy deposited in the hydrogen atom-bounded complex inducing vibrational repartition of this energy.

We have investigated the increase of fragment yields in the total ionic current for several organic precursors chosen for their functionalities. These organic cations were produced by electron impact at 70 eV, mass selected by the first analyzer of our MS/MS/MS instrument and guided to the second collision cell where they were allowed to collide the atomic hydrogen (2).

Results for fragmentation experiments with different precursor cations, discharge off and on are presented Table 1.

From these preliminary results, we can draw some conclusions on the reactivity of the investigated compounds. According to their reactivity towards atomic hydrogen, several classes of compounds can be proposed :

(i) those which have conducted to the formation of $[M+1]^+$ cations by the following process :

for the acetone (in some extent) and benzene, in correlation with the presence of a double bond C=C in the neutral precursor.

(ii) those which have lead to the formation of an $[M-1]^+$ cation by elimination of a molecular

hydrogen molecule :

with the following order of reactivity $CH_3OCH_3 > (CH_3)_3N > CH_3SCH_3$ (acetaldehyde showed a reactivity extent similar to that of the trimethylamine).

(iii) those which have not reacted with atomic hydrogen : $(CH_3)_4Si$ and CH_3SOCH_3 .

(iv) finally, those which have principally conducted to a noticeable increase of their fragmentation ratio : CH_3COX (X= H, CH_3 , OCH_3 , $N(CH_3)_2$).

It must be kept in mind that the effective dissociation of molecular hydrogen is rather low (ca. 2%), which means that owing to the order of fragmentation increase, the observed induced fragmentation reactions can be considered as appearing in a quasi steady-state yield.

Some promising results have been obtained with the carbonyl and amide precursors that allows to perform similar efficient dissociation on peptides. We would expect that such reactions may be extended to much larger molecules with the same efficiency and, indeed, our efforts are currently aimed in that direction.

Crossed-beam Study of Collisional Excitation of CS_2^+ and CO_2^+

Ronald E. Tosh, Anil K. Shukla and Jean H. Futrell
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716

Usually in studies of molecular excitation, spectroscopic investigations carried out with tunable radiation guide the analysis of collision experiments because the former offers the most direct information about the energy spectrum of an isolated molecule. Of course, this is the case because we can easily deposit a specific amount of energy into a molecule with a photon; whereas, our inability to control impact parameter and steric orientation of colliding reactants results in products with a distribution of internal and translational energies. However, the application of spectroscopic studies to collision phenomena is not straightforward in most cases because the energy levels of the molecule in question are often strongly perturbed by the other particle, and the precise dependence on angular momentum and steric orientation is not known. So, when in spite of all these difficulties a collision experiment reveals a particularly simple pattern of energy deposition, we have a rare opportunity to disclose a precise mechanism for energy transfer, establish a surer link to spectroscopic investigations, and thereby lay the groundwork for theoretical studies, which are desirable if we should ever expect to attain the level of control over reactive collision dynamics that is possible with optical excitation spectroscopy.

The experiments reported here, utilizing the Delaware "crossed-beam" instrument, exhibited strikingly simple yet distinct patterns for energy deposition into CS_2^+ and CO_2^+ when these molecules collide with Ar atoms. The crossed-beam technique, which permits simultaneous angle and energy measurements of reactants and products, is ideally suited to resolving state-to-state transitions when the relevant energy levels are sufficiently well separated, as happens with these two ions. All of our measurements clearly show that transfer of energy from translation into internal modes occurs differently in the two species, and the angular scattering patterns suggest that this is related to the existence of distinct underlying mechanisms for momentum transfer: one involving a simple two-body collision between the target neutral and parent ion, while the other involves an impulsive scattering event in which only part of the parent ion participates in the collision (the other part is a collision spectator).

As we reported last year at the 43rd ASMS, the recoil-velocity spectra for CS_2^+ in 8.9 and 17.8 eV (CM) collisions with Ar are surprisingly simple, exhibiting almost exclusively elastic scattering with a small percentage of inelastic scattering, visible mostly in the backward hemisphere. Interestingly, the angular distributions are entirely consistent with two-body, hard-sphere scattering where, in the inelastic events, sufficient energy is removed from relative translation to populate the electronic A and B states of CS_2^+ .

An entirely different picture emerges from the recoil data of CO_2^+ collisions with Ar at all energies investigated: 5.7, 11.9 and 23.8 eV (CM). By contrast to the CS_2^+ data, the majority of all scattering is inelastic. Moreover, vibrational excitation is evident and may constitute the primary excitation channel. The latter is certainly true for the 5.7 eV collisions, in which the angular distribution shows a negligible contribution for reaction inelasticity (energy deposition into CO_2^+) sufficient to populate any electronic states of the parent ion. Instead, vibrational excitation increases with scattering angle, consistent with a line-of-centers argument in which larger scattering angles are correlated with smaller impact parameters. A closer inspection of the velocity-contour plot reveals a ridge of intensity

with distinctive symmetry about a particular point on the relative velocity axis which, as we have argued elsewhere, implicates a "knockout" mechanism whereby momentum transfer to the parent ion occurs through an impulse delivered to one of its components, in this case CO (the remaining O is then a collision spectator).¹

We find additional support for this interpretation in the velocity contour plots obtained at the higher collision energies, both of which show a similar ridge at lower scattering angles. In both cases, this ridge is intersected by another ridge that dominates the scattering at higher angles. The latter exhibits a symmetry about the reactant CM, suggesting a two-body excitation mechanism similar to that observed in the inelastic scattering of CS_2^+ . The corresponding inelasticity is about 3.9 ± 0.3 eV in both cases, which is sufficient energy to populate the A state and perhaps the B state of CO_2^+ . By contrast to the CS_2^+ data, separate features corresponding to A and B state excitation are not discernible in the contour plots, so we are unable to say whether one or both of these states are populated.

At present, we are not able to explain why the kinematics for these collisions is so simple or why two similar species behave so differently in collisions with Ar atoms. Answers to these questions may emerge as we investigate the spectroscopic literature for information on excited states and carry out *ab initio* studies of some of the potential surfaces. Finally, we would like to underscore an important distinction between the knockout mechanism proposed here and that articulated in our previous work.¹ There, we invoked a nonadiabatic transition in the approach trajectory as a precursor to CID, here, of course, no such transition is involved because the excitation is purely vibrational. Therefore, these data may constitute the first observation of vibrational local modes being excited in a molecule by means of a collision, an example of bond-selective chemistry which has hitherto been studied most actively by optical methods.

Unimolecular and Collision-induced Dissociation of CS_2^{2+} with Ar at High Collision Energy

X. D. Zhou, A. K. Shukla, R. E. Tosh, and J. H. Futrell

Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716, USA

Introduction: Collision-induced dissociation (CID) of multiply charged ions in tandem mass spectrometers has recently assumed great importance as an analytical technique for characterizing quasi-molecular ions of high molecular weight compounds generated by electrospray ionization. In this "soft" ionization technique there is very little fragmentation of molecular ions and CID is commonly used to fragment these ions to generate desired structural information. Although dissociation mechanisms are similar (e. g., formation of characteristic sequence ions from peptides), a strong Coulomb barrier strongly affects the energetics and CID dynamics of multiply charged ions. Since almost no CID dynamics information exists for multiply charged ions, we have initiated an experimental study of these phenomena. CS_2^{2+} was chosen as a starting point, with the expectation that it would be possible both to establish detailed mechanisms for CID of such a simple ion and deduce principles which would apply to larger ions generated by electrospray ionization.

Experimental: All results were obtained on a reversed-geometry, double ZAB-2F mass spectrometer, using the technique of mass-analyzed ion kinetic energy spectroscopy (MIKES). CS_2^{2+} ions were generated using 70eV electron impact ionization and accelerated to 6 keV ion energy for mass selection by the magnet. Reactant ions were focused into a 20mm long collision cell, where Ar gas was introduced for collisional activation. The collision gas was maintained at low pressure (corresponding to ~20% attenuation of the primary ion signal intensity) to ensure that CID occurred under single collision conditions. The collision cell was floated electrically to distinguish collision-induced reactions occurring within the cell from those occurring in the field-free region (metastable and background gas CID).

Results and Discussion Figure 1 shows a MIKES scan for the unimolecular dissociation of 6116 keV CS_2^{2+} ions to CS^+ ions. The two side peaks marked a and c are the forward and backward scattered CS^+ ions from the charge-separation dissociation (CSD) reaction with no gas introduced into the collision cell. As anticipated, this Coulomb explosion reaction gives strongly forward and backward scattered peaks. The center peak b is an electron-capture induced dissociation ECID reaction product from collisions with background gases even though the measured base pressure in the flight tube is 8×10^{-9} mbar. This is supported by their pressure dependence and shift in peak position when the collision cell is floated.

Figure 2 shows the zero degree MIKES spectrum for S^+ ions generated by colliding 6 keV CS_2^{2+} ions with Ar. Three distinguishable processes - two collision-induced charge-separation dissociation (CICSD) reactions and one ECID reaction are shown in this spectrum. The second pair of side peaks, characterized by higher kinetic energy release and absent in Fig. 1 represents a new CID reaction channel previously unreported for this system.

Translational energy lost by CS_2^{2+} ions collisions which form S^+ ions in the ECID process is 1.0 eV while the endothermicity this reaction is 3.3 eV. This suggests that the dissociation of CS_2^{2+} to S^+ involves parent ions in their ground electronic state which are vibrationally excited just below the potential barrier for dissociation. The energy lost by CS_2^{2+} fragmenting to CS^+ ions in ECID process is measured to be ~1.0 eV, however, thermochemically this process is endothermic by 4.3 eV. Kinetic energy gains by colliding CS_2^{2+} demonstrates they already have sufficient internal energy for dissociation which is only triggered by the collision event. Consequently the dissociation of CS_2^{2+} to CS^+ proceeds from highly excited CS_2^{2+} . The minimum internal energy these ions

must have for this CID process is then 5.3 ± 0.5 eV, which corresponds to the $^3\Sigma_g^-$ state of CS_2^{2+} . It may also represent the dissociation of vibrationally excited $^1\Delta'$ CS_2^{2+} (see below).

The energy release for the two CICSD processes were measured to be 3.4 eV and 4.1 eV with nearly zero energy transfer translation into internal modes. This large kinetic energy release is due to the coulomb barrier for dissociation. To understand and explain this phenomenon, we have carried out ab initio calculations for the CS_2^{2+} potential energy surface using Gaussian 94 program. Fig. 3 shows the ab initio calculations results for CS_2^{2+} dissociating from the ground state by two different mechanisms. In one example, we fix the CS distance at its equilibrium value, for the other we relax this distance to the lowest energy value as the other C-S bond is extended. The fixed ground state surface gives the kinetic energy release of 4.1eV which coincides with one of our experimental result. The relaxed ground state surface gives 3.7eV, compared with our 3.4 eV experimental result. These surfaces describe the adiabatic and prompt-or-vertical- dissociation mechanism for CICSD. The first excited $^1\Delta'$ is also shown in the figure.

Conclusions: The two collision induced dissociation processes - charge separation and electron capture-induced dissociation - proceed via different mechanisms of energy transfer and dissociation. There are two energetically distinct mechanisms for the dissociation via charge separation, both involving ground state ions. ECID to S^+ fragment ions involves ground state ions while CS^+ fragment ions are formed from excited CS_2^{2+} ions.

ROLE OF ISOMERIC STRUCTURES IN MECHANISM AND ENERGETICS OF FRAGMENTATION, THE CASE OF BENZENE MOLECULAR ION.

Rahul Chawla, Anil Shukla and Jean Futrell, Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware.

INTRODUCTION

Angle and energy resolved CID provides valuable information about energy transfer, reaction mechanisms and role of excited states in activation and dissociation steps. Recent studies from our laboratory have demonstrated that electronic excitation is a prominent mechanism in low and moderate energy CID of certain ions (acetone, nitromethane) but others (enol acetone, methane, propane, methyl nitrite) dissociate predominantly on the ground state hypersurface.

A current focus of our research is angle and energy resolved CID studies of polyatomic ions. Polyatomic ions are thought to follow RRKM/QET delayed dissociation mechanisms. Presence of an isolated electronic state, noncommunicating isomeric structures or an alternate fragmentation pathway are reasons why an ion may not follow statistical theories of dissociation. CID of Benzene molecular ion has been extensively studied in the past and the mechanism of dissociation remains unresolved. We have therefore extended our dynamics studies to this ion.

EXPERIMENTAL

The hybrid tandem mass spectrometer used by us in these studies has several features which make it ideal for studying angle-and-energy resolved CID of ions. A series of tube and rectangular lenses capable of slowing a beam of several kV energy to a variable range between 1 eV to a few hundred eV while maintaining a well defined ion beam. A supersonic neutral beam which overlaps the slit image of the ion beam. This provides us with higher gas densities and narrower velocity distribution than collision chamber experiments. A hemispherical energy analyzer to provide high energy resolution and high ion transmission. A rotating detector assembly consisting of hemispherical energy analyzer, quadrupole mass filter and detector.

DATA COLLECTION AND ANALYSIS

Experimental data are obtained in terms of an energy and intensity distribution of lab scattering angles. These energy distributions are converted into velocity distributions. All data are collected in the Laboratory frame of reference. However, analysis is simplified in the center of mass frame of reference. In this frame of reference, the origin, the CM of the collision pair, is unchanged in the collision. Motion of the two particles can be reduced to a single particle of reduced mass μ .

Expressing data in this form, provides a direct means of deducing kinetic energy transformation into internal energy of the ion. Data are finally presented as a Cartesian velocity probability contour diagram, which displays relative product ions to be scattered at a particular CM angle and velocity. Points of equal intensity in the transformed velocity distributions are joined together as contour lines to define peaks and valleys in the scattering diagram.

RESULTS AND DISCUSSION

Dissociation of benzene molecular ion to $C_3H_3^+$ and $C_4H_4^+$ at various center of mass collision energies.

$C_6H_6^+ + Ar \rightarrow C_3H_3^+ + C_3H_3 + Ar$ was studied at 10 and 17 eV Center of Mass energy (figure 1), both show a forward scattering peak at 5.5 eV. As the appearance energy for this process is 5.51 eV, we can conclude that the $C_6H_6^+$ ion is in the ground electronic state at the crossing point, but may isomerize to a higher electronic state or isomeric structure after collision and then dissociate from there.

Figure 1

$C_6H_6^+ + He \rightarrow C_4H_4^+ + C_2H_2 + He$ was investigated at 5 eV (figure 2) and $C_6H_6^+ + Ar \rightarrow C_4H_4^+ + C_2H_2 + Ar$ was investigated at 6.8, 10.2 and 17 eV (figures 3). At 5 eV we see a peak at 4.5 eV; at 6.8 eV this shifts to 5.6 eV and at 10.2 and 17 eV, the peak shifts to 6 eV. Ion molecule reactions have demonstrated two structures for $C_4H_4^+$, a linear structure and a cyclic structure. The cyclic structure, which is more stable, is formed near the threshold, while the linear structure is formed at higher collision energies. It is likely that at above 7 eV, the dominant ion formed is the linear form of $C_4H_4^+$ ion.

Figure 2

Figure 3

CONCLUSION

Dissociation of $C_6H_6^+$ at low energies to $C_3H_3^+$ takes place at the thermochemical threshold energy required for the formation of that ion. Dissociation of $C_6H_6^+$ to $C_4H_4^+$ takes place at the thermochemical threshold for the process below 6 eV, but at higher collision energies, the peak shifts to 6 eV. It is proposed that the linear structure of $C_4H_4^+$ is formed at the higher energy. Apart from this, there is no evidence of isolated states in either of these dissociations.

REACTION DYNAMICS OF DIFLUOROETHYLENE IONS.

B. Leyh[‡], R. Locht and B. Franck
Département de Chimie, Bâtiment B6, Université de Liège,
B. 4000 SART-TILMAN (BELGIUM)

The gas phase chemistry of isolated ethylene ions and of small clusters of these compounds displays many interesting features: isolated state decay, isomerization processes to unconventional species, nonadiabatic couplings etc. In this work, we used metastable ion decompositions, collisional activation and photoionization to measure the kinetic energy release distributions of the dissociation fragments of singly ionized 1,1- and 1,2-difluoroethylene. We shall focus on the reaction channels associated with the F and HF losses.

Experimental

Metastable ion dissociations (MI) and collisionally activated processes (CAD) have been investigated using the accelerating voltage scan method with a forward geometry AEI-MS9 sector mass spectrometer. The associated kinetic energy release distributions (KERD) have been extracted from these spectra via the Holmes-Osborne procedure. Kinetic energy release distributions resulting from dissociative photoionization have been recorded using a retarding field method coupled with a quadrupole mass analyzer. The HeI α (21.21 eV) and NeI α (16.67 and 16.85 eV) resonance lines have been used. On the same experiment, a Lindau-type electron analyzer allows us to detect in coincidence mass selected ions and energy-selected electrons (PIPECO).

The lowest energy channel: $C_2H_2F_2^+ \rightarrow C_2HF^+ + HF$

Figure 1 shows the KERD obtained in the metastable time window and upon CAD for the $C_2H_2F_2^+ \rightarrow C_2HF^+ + HF$ reaction. Whereas the metastable dissociation only shows a high energy distribution starting at $\epsilon_{min} = 0.4$ eV, an additional low energy component clearly appears upon collisional activation. Electronic excitation of $FCCH^+$ or HF can be excluded: their first excited electronic states are located at, respectively, 6.5 eV and 7.5 eV above their ground electronic state. The most logical explanation would be therefore the production, at higher internal energy, of another isomer of C_2HF^+ . The $CCHF^+$ fluorovinylidene cation, located 1.22 eV higher in energy than the fluoroacetylene cation [1] is a good candidate, as shown by the AM1 calculations displayed in figure 2.

Fig.1. Kinetic energy release in the metastable window (left) and upon CAD (He, 30% transmittance) (right) for the $C_2H_2F_2^+ \rightarrow C_2HF^+ + HF$ reaction.

Fig.2. Energy diagram for the $C_2H_2F_2^+ \rightarrow C_2HF^+ + HF$ reaction, calculated at the semiempirical AM1 level. Experimental data are displayed as bold lines.

The F loss channel: $C_2H_2F_2^+ \rightarrow C_2HF^+ + F$

The breakdown curves obtained by photoion-photoelectron coincidence spectroscopy [this work and 2,3] show two maxima for the $C_2H_2F_2^+ + F$ channel. The first one coincides with the $\tilde{A}$ electronic state of $C_2H_2F_2^+$ and the second one with the $\tilde{C}$ state. Furthermore, in the energy range of this latter state, the F loss channel largely dominates. This cannot be accounted for by statistical models.

The KERD for the metastable F loss of 1,1- $C_2H_2F_2^+$ has an average kinetic energy release, $\langle \epsilon \rangle$, of 81 meV. Using Klotz' equation, this is calculated to correspond to an internal energy, E , of 14.79 eV (with respect to the neutral ground state). For 1,2- $C_2H_2F_2^+$, these values become $\langle \epsilon \rangle = 75$ meV and $E = 14.36$ eV. The F loss rate constant at these energies is estimated to be $2.2 \cdot 10^5 s^{-1}$ and $3.5 \cdot 10^5 s^{-1}$ for 1,1- and 1,2-difluoroethylene respectively.

The KERD obtained by collisional activation and by photoionization extend up to $\epsilon = 2.5$ eV and are bimodal. The first, narrow, regime, has an $\langle \epsilon \rangle$ of 180 meV and corresponds to the energy range of the $\tilde{A}$ electronic state of $C_2H_2F_2^+$, which decays rapidly by internal conversion to the ground state, leading to a statistical decomposition. The second, much broader, regime is characterized by $\langle \epsilon \rangle = 970$ meV. It can be associated to the second maximum observed in the breakdown curves. We suggest that this second process could lead to electronically excited $C_2H_2F^+$: $C_2H_2F_2^+(\tilde{C}) \rightarrow C_2H_2F^+(\tilde{A}^1A'') + F(^2P)$. This first excited state of $C_2H_2F^+$ is calculated, at the semiempirical AM1 level, at 1.5 eV above the ground state.

LOW-ENERGY COLLISION-INDUCED DISSOCIATION OF MOLECULE IONS GENERATED FROM RICINOLEIC AND RICINELAIDIC ACID

L. Nizigiyimana, H. Van den Heuvel and M. Claeys
University of Antwerp (UIA), Department of Pharmaceutical Sciences,
Universiteitsplein 1, B-2610 Antwerp, Belgium

In the frame of our studies on the structural characterization of fatty acid derivatives by fast atom bombardment (FAB), collision-induced dissociation (CID) and tandem mass spectrometry we have examined the low-energy CID behavior of molecule ions of ricinoleic acid and its *trans* isomer ricinelaic acid which contain a β -hydroxy unsaturated system, and of some derivatives.

The low-energy CID spectra obtained on deprotonated ricinoleic and ricinelaic acid show loss of H_2O and an abundant product ion at m/z 183 which is due to loss of heptaldehyde and is explained by a rearrangement in the β -hydroxy unsaturated part. Comparison of the spectra obtained for the two isomers indicates that loss of H_2O is most pronounced for deprotonated ricinoleic acid. This more facile loss of H_2O is also observed for ricinoleic acid in the low-energy CID spectra of protonated and monolithiated molecules and of dilithiated $[M - H + 2Li]^+$ molecule species. The rearrangement reaction typical of a β -hydroxy unsaturation (Scheme 1) is detected in the low-energy CID spectra of lithiated molecule species but not in those of protonated molecules. In addition to the typical loss of heptaldehyde, the low-energy CID spectra obtained for $[M + Li]^+$ ions also show ions at m/z 121 which correspond to lithiated heptaldehyde and can be rationalized by Li^+ adduct formation at the 12-hydroxy group and a charge-induced rearrangement in the lithiated β -hydroxy unsaturated part (Scheme 1). Figure 1 illustrates the low-energy CID spectra obtained for (A) protonated ricinoleic acid, (B) $[M - H + 2Li]^+$ molecule species of ricinoleic acid and $[M + Li]^+$ ions of (C) ricinoleic and (D) ricinelaic acid.

In addition, we also examined the low-energy CID spectra of molecule ions of corresponding methyl esters and of 1-monoricinoleoylglyceride. The typical loss of heptaldehyde is found for lithiated methyl esters but not for corresponding protonated molecules. With respect to 1-monoricinoleoylglyceride, the loss of heptaldehyde is detected in the product ion spectra of deprotonated and lithiated molecules but again not in that of the protonated ones. It may be concluded that the structurally informative rearrangement reaction is observed in the β -hydroxyalkene part upon low-energy CID of molecule ions of ricinoleic acid and its *trans* isomer ricinelaic acid as well as of derivatives if they contain a stable charge center.

The occurrence of a rearrangement reaction in a β -hydroxy alkene has been used as an argument in favor of a rearrangement involving 1,4- H_2 -elimination in saturated fatty acid derivatives containing a stable charge center [1]. However, our recent study clearly shows that a homolytic mechanism starting with cleavage of C-H bonds operates remote from the charge during high-energy CID of saturated fatty acid derivatives that contain a stable charge center [2]. In analogy, the present study indicates that a stable charge center is required to observe a charge-remote rearrangement in the β -hydroxy alkene part under low-energy CID conditions.

COLLISION-INDUCED DISSOCIATION OF BORON OXIDE ION CLUSTERS

Dilrukshi M. Peiris, Adam Łapicki and Scott L. Anderson

Department of Chemistry, University of Utah, Salt Lake City, UT 84112.

Boron oxide chemistry is an important factor in combustion of boron rich prospective fuels and propellants. Collision-induced dissociation (CID) studies of small boron oxide cations, $B_nO_m^+$ (where $n=1-3$ and $m=1-4$), is motivated by a need for more accurate and reliable structural and thermodynamic information on both neutral and ionic species. Results of CID studies are important in interpretation of boron oxide cluster chemistry (reactions with HF and D_2O have been investigated in our lab).

All experiments were performed using the cluster ion beam apparatus described elsewhere¹. Boron oxide cluster ions are generated by 12 keV argon atom bombardment of the sample maintained near its melting point. The hot nascent cluster ions are collected with RF octapole ion guide and thermalized by a labyrinthine RF trap using 0.01 Torr helium buffer gas.

The desired cluster is selected using a quadrupole filter and then the reactant beam is injected into another octapole ion guide system whose last part is surrounded by a collision cell filled with either argon or xenon (1×10^{-5} Torr). The collision energy can be selected by means of the computer controlled DC voltage between the end of the RF trap and the collision cell octapole. The remaining primary beam and daughter ions are guided by another octapole and mass analyzed by a second quadrupole.

Isotopically purified (94.11 At.% of ^{10}B) boron oxide (B_2O_3) was purchased as a polycrystalline powder. A metal substrate was covered by a thin layer of the loose powder which was subsequently heated in a furnace at 600°C for about 4 hours in oxygen environment. A vitreous film of boron oxide can be obtained after reaching at least 450°C and cooling the sample in the natural room conditions. Additional heating (several hours at 350-450°C) in high vacuum is required due to the hygroscopic nature of boron oxide.

Accurate CID threshold determinations require a possibly narrowest and well defined kinetic energy distribution for the primary beam that allows to evaluate quantitatively the effects diffusing the true dissociation limit. In order to model a high-energy "tail" of the ion beam (observed especially for bigger clusters) more precisely than by the standard Gaussian distribution the following function has been used:

$$F(x) = \frac{A}{\{1 + [(x - E_0)/b]^2\} \exp(x - E_0)^c}$$

This function can model an asymmetric distribution in which E_0 , A , b , and c are parameters that physically characterize the ion beam.

Reaction cross sections were measured for collision energies from 0.8 to 10 eV (CME) for major fragment ions produced by CID of $B_nO_m^+$. In addition, the total reaction cross sections and branching patterns for the dissociation of all the clusters studied (at 9.5 eV collision energy) are shown in Figure 1.

Cross sections in the threshold region were modeled using a "true" cross section function:

$$\sigma(E_{avail}) = \frac{A(E_{avail} - E_0)^n}{E_{avail}}$$

where:
 A - normalization factor,
 E_0 - dissociation threshold,
 n - adjustable parameter which varies the curvature of the function,
 E_{avail} - total energy available for the reaction.

The model of the above equation is convoluted (Monte Carlo simulation) with the kinetic energy distribution of the primary cluster ions, the internal energy of cluster ions, and the translational energy of the target gas. The parameters n and E_0 are optimized until a best fit is obtained.

The experimental CID cross section ("exp"), the "true" cross section, along with the best convoluted fit ("sim") are shown in Figure 2. The best fit thresholds (E_0) and n parameters for the lowest-energy dissociation channel of each cluster are shown in Table I. Also, the cluster stability, as a function of size, is shown in Figure 1 (scatter plot).

The branching ratios observed within this experimental series lead to the two conclusions contrary to the relations reported in the literature. Ionization potentials for both B_2O_2 and B_2O_3 seem to be lower than for BO . The data cited show the opposite relation. However, the real structure of both clusters is still uncertain and it is possible the existing controversy could be explained through different structural models (Table II).

Figure 1. The total reaction cross sections and branching patterns for the dissociation of $B_nO_m^+$ clusters at 9.5 eV collision energy. The scatter plot shows the stability as a function of the cluster size.

Table I. Best fit parameters and best fit dissociation energy thresholds (E_0) for boron oxide clusters.

dissociation channel	fit parameter (n)	fit threshold energy (E_0)
$BO^+ \rightarrow B^+$	1.95	2.75
$B_2O_2^+ \rightarrow BO^+$	1.90	1.00
$BO_2^+ \rightarrow BO^+$	1.90	6.00
$B_2O_2^+ \rightarrow B^+$	1.30	3.15
$B_2O_3^+ \rightarrow B_2O_2^+$	1.64	5.10
$B_3O_3^+ \rightarrow B^+$	2.05	2.00
$B_3O_4^+ \rightarrow B_2O_3^+$	2.10	4.25

MIXED-SITE vs. CHARGE-SITE-REMOTE FRAGMENTATIONS OF LONG-CHAIN QUATERNARY AMMONIUM IONS

K. Whalen and J.S. Grossert, Department of Chemistry Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3; J.M. Curtis and R.K. Boyd, Institute for Marine Biosciences, National Research Council, Halifax, Nova Scotia, Canada B3H 3Z1.

Gross *et al.* [1,2] discovered and characterized a new class of fragmentation mechanisms for closed-shell ions, which they termed charge-site-remote (CSR) fragmentations. As described in recent reviews [3,4], CSR reactions, characterized by expulsion of the elements of alkanes, involve portions of the molecular structure well removed from a site of fixed charge. The charge site itself does not appear to be involved in the reaction mechanism. A mechanism involving 1,4-elimination of H_2 to form two ω -unsaturated fragments is favored [3,4], although an alternative mechanism involving homolytic cleavage remote from the charge site, to form a neutral free radical plus a distonic radical cation which then expels a β -hydrogen atom to form the same functionalized 1-alkene, has been proposed [5].

Tuinman, Cook and Magid [6,7] discovered an entirely different competitive channel for CSR reactions of the trimethylalkylammonium ions $(CH_3)_3N^+C_nH_{2n+1}$. The crucial finding was that CA of $[(CH_3)_3N^+C_nD_{2n+1}]$ reactant ions, with a perdeuterated alkyl chain, resulted in a second series of fragment ions accompanying the predicted CSR fragments, but at 3 Da higher mass. This observation seems explicable only in terms of incorporation of one of the methyl groups into the neutral fragments, incompatible with a CSR mechanism. Tuinman *et al.* [6,7] proposed a cyclic intermediate in which the positive charge on the nitrogen interacts with the σ -backbone of the alkyl chain, and coined the name mixed-site-fragmentation (MSF) to describe this new reaction mechanism.

The objective of the present work was to further investigate the CSR and MSF mechanisms through use of complementary d-labelled precursors, $(CH_3)_3N^+C_{14}D_{29}$ and $(CD_3)_3N^+C_{14}H_{29}$, together with modern techniques of tandem mass spectrometry using an AutoSpec-oaTOF instrument comprising a double-focussing stage coupled to an orthogonal acceleration time-of-flight analyzer for MS/MS experiments. For MS/MS/MS experiments the precursor ion, together with the first generation fragment ion formed in the first field-free region (FFR1), were selected by setting the analyzer fields of the double-focussing stage to static values determined by the appropriate linked-scan law at constant B/E. The selected first-generation fragment ion (one of the CSR or MSF product ions) was transmitted to the collision cell/oa-TOF.

Figure 1 shows the MS/MS spectrum of $(CH_3)_3N^+C_{14}D_{29}$, in which the CSR and MSF product ions are indicated. Figure 2 shows MS/MS/MS spectra for the same precursor, and with each of the ions in the range m/z 121-125 (Figure 1) selected in turn as the intermediate. The MSF ions $(CH_3)_2N^+(CD_2)_m$ are prominent only for $m = 4, 5, 6$ in Figure 1, presumably reflecting favorable ring sizes in cyclic transition states. The fragment spectra (Figure 2) of the CSR and MSF ions are very different from one another. The MS/MS/MS experiments used to probe the structures of the CSR product ions produced no surprises, but those for the MSF ions were best accounted for in terms of an activated diradical form. The fragment at m/z 123 corresponds to expulsion of an alkyl radical, and appears (Figure 2) to be a typical CSR ion.

Ortho-cyclization of Substituted Arylcyclopropanes in Gas and Liquid Phase

Tretyakova, Natalia¹; Lebedev, Albert²; Mochalov, Sergei²; Hass, J. Ronald³

¹University of North Carolina, Chapel Hill, NC 27599-7400

²Moscow State University, Moscow, Russia

³Triangle Laboratories, Inc., Durham, NC

Mass spectrometry can be used as a tool for predicting the direction/yields of chemical monomolecular reactions taking place in solution. We have previously demonstrated the formation of 5-, 6-, and 7-membered heterocycles from ortho-cyclopropylbenzoic acid, its amide and some ortho-cyclopropyl diarylsulfones both in the gas phase (ion source of mass spectrometer) and in liquid phase (acid catalysis conditions). In this work, we continue our studies in this area by investigating the monomolecular reactions of N-(ortho-cyclopropylphenyl)acetamide **1**, N-(ortho-cyclopropylphenyl)benzamide **2**, N-(ortho-cyclopropylphenyl)-bromoacetamide **3** and 1,1-dicyano-2-(ortho-cyclopropylphenyl)ethylene **4** using EI and fragment ion spectra.

Our data (EI MS and MS/MS spectra of compounds **1-4** and/or their daughter ions) suggests *ortho*-interaction of the substituents which causes cyclization accompanied by the opening of the cyclopropane ring. The proposed mechanism of this process for compounds **1** and **2** is shown in Scheme 1. Compound **3** appears to lose a bromine radical prior cyclization. The resulting (M-Br[•]) ion rearranges giving a 5- and/or 6-membered ring (Scheme 2) with the former process being the predominant one. Compound **4** cyclizes yielding a naphthalene derivative **B** (Scheme 3). The cyclization of compounds **1** and **2** to the corresponding 5,6-benzo-4-ethyl-3,4-dihydrooxazines under EI conditions (Scheme 1) has been shown to take place in solution as well. The similarity of the structures of the molecular ions of cyclic compounds obtained in condensed phase and the gas-phase formed cyclic ions was proved by the similarity of their MS/MS spectra (Figure 1). Similar condensed-phase reactions involving other compounds are currently under investigation.

Internal Energy Effects on Low and High Energy Collision-Induced Dissociation

Maria Ospina, Richard A. Yost, David H. Powell

Department of Chemistry, University of Florida, Gainesville, FL 32611

Introduction. Tandem mass spectrometry is considered a standard method for structure elucidation of organic compounds, especially when the primary ionization process does not introduce sufficient energy for fragmentation. Ions formed in the source can undergo fragmentation that may be induced by internal energy deposited during the ionization process itself or by some other means of excitation such as collisional activation, surface-induced dissociation, etc..

Collision-induced dissociation (CID) experiments are commonly carried out in two energy regimes, high-energy (HE) and low-energy (LE). HE CID spectra (kV) are considered the result of single collisions between the precursor ions and a target gas; in contrast, LE CID spectra (eV) are the result of multiple collisions and multistep cleavage reactionsⁱ. Although CID spectra obtained from the two energy ranges often show similarities, differences due to the amount of internal energy deposited in the ions during the collision processes are observed. Thus, HE CID results in a broader range of fragmentation pathways, some of which are not observed in LE CID. Nevertheless, the complementary value of both techniques in structure elucidation has been documentedⁱⁱ.

The effect of the ionization technique on tandem mass spectrometry has not been extensively studied. Curtis, et. al.ⁱⁱⁱ, reported large differences between the fast atom bombardment (FAB) and field desorption (FD) tandem mass spectra of $(M+Na)^+$ ions and between FD and electron ionization (EI) tandem mass spectra of M^+ ions of valinomycin. These differences were attributed to the formation of ions having the same mass but different structures. In a more recent paper^{iv} the authors concluded that CID spectra of $(M+H)^+$ ions show similar fragments under a range of different collision and ionization conditions although the intensities are different. For $(M+Na)^+$ ions however, the fragments were not the same.

Here we are presenting some preliminary data of our efforts to investigate the effect of internal energy on the CID spectra obtained in high and low energy regimes.

Experimental. LE CID experiments were performed on a Finnigan triple stage instrument (TSQ 70). Argon was introduced in the octapole collision cell. Pressure was about 1 mTorr as measured by a Pirani gauge. Isovalerylcarbitine and Leucine-enkephalin were introduced into the ion source by a direct exposure probe (DEP) heated from 25 to 450 °C @ 200 °C/min. Methane, water and ammonia were used as reagent gases for chemical ionization (CI). Collision energy was varied from 5-60 eV for methane/CI analysis. For water and ammonia/CI, only 20 eV spectra were acquired. HE CID was performed at 5 kV on a Finnigan MAT MAT95Q (BEoQ configuration) hybrid mass spectrometer. Ionization was obtained by bombarding with Cs⁺ ions (LSIMS) and by CI. For the LSIMS experiments, Cs⁺ ions were generated with an impact energy of approximately 15 kV and an emission current of 3 μ A. Glycerol, magic bullet (dithiothreitol and dithioerythritol 5:1 w/w) and nitrobenzyl alcohol were used as matrices. For the CI experiments, samples were introduced into the source by a DEP probe. Methane, isobutane and ammonia were used as reagent gases. Mass-

analyzed ion kinetic energy spectra (MIKES) were obtained with Helium as target gas in the second field free region. CID spectra were measured with 50% attenuation of the parent ion signal.

Results. Leucine-enkephalin did not give $(MH)^+$ under high accelerating voltages with methane, isobutane or ammonia CI, but it gave $(MH)^+$ at low accelerating voltages. As can be seen in the figures, HE CID spectra of Leucine-enkephalin m/z 556 correlates to the methane LE CID spectra taken at 10 eV. Isovalerylcarbitine m/z 246 ions generated by CI methods gave similar CID spectra in LE and HE CID. At high energy collisions, isovalerylcarbitine m/z 246 ions generated by LSIMS gave different CID spectra than CI at high energy.

Conclusions. There are slight differences in the CID fragmentation patterns at low collision energies but they do not appear to correlate with the CI ionization techniques. More dramatic differences are seen with HE CID of ions produced by LSIMS. These studies will be extended to other ionization techniques especially ESI, CI and FAB correlations.

Introduction The dissociation mechanism of molecules and radicals to form neutral fragments gives fundamental insight into chemical reactions. Although the dissociation mechanism of ions has been investigated extensively, there are few studies on the dissociation mechanism of molecules or radicals forming neutral fragments. In this work, the dissociation mechanism of electronically excited C_3H_4 is investigated based on the results of a comparison of the peak intensities and peak widths of the charge inversion spectra of allene, propyne and partially deuterated propyne.

Experimental Charge inversion mass spectrometry was performed using an MS/MS instrument in which mass-selected positive ions were made to collide with alkali metal targets, and the resulting negative ions formed upon two electron transfer were mass analyzed. [1] Neutralization of precursor ions, dissociation of electronically excited neutrals formed from near-resonant neutralization and anionization of the neutral fragments took place in the target chamber filled with alkali metal targets.

Results and Discussion The charge inversion spectrum of CD_3CCH^+ , measured using Cs targets, is shown in Fig.1. Whereas $C_3HD_2^-$ ions are attributed to D loss from the methyl group, $C_3D_3^-$ ions are the result of H loss from the ethynyl group. The major pathway for H loss from electronically excited propyne was, thus, identified to arise from C-H bond cleavage in the methyl group.

Heats of formation of C_3H_4 , its fragments, and $C_3H_4^+$ ions are shown in Fig.2. Two independent C-H bond cleavages to form the lowest energy C_3H_2 isomer is 2.35 eV endothermic compared with H loss from the ethynyl group, whereas H_2 loss to form the highest energy C_3H_2 isomer is 1.21 eV exothermic compared with the H loss from the ethynyl group. Two C-H bond cleavages with

Fig.1 Charge inversion mass spectrum

larger endothermicity should result in a smaller branching ratio than H loss from the ethynyl group based on this energy difference, because simple bond cleavages do not generally have activation energies. However, as shown in Fig.1, the sum of the intensity of the peak associated with the $C_3HD_2^+$ ion and $C_3D_2^+$ ion formed by loss of two hydrogen atoms, is about five times larger than that of the $C_3D_3^+$ ion, formed from C-H bond cleavage in the ethynyl group. The dissociation process of the loss of two H atoms from the electronically excited hydrocarbons is attributed not to two independent C-H bond cleavages, but rather to loss of a H_2 molecule.

The intensity ratio of the peak associated with $C_3H_3^+$ to that of $C_3H_2^+$ for allene were 0.66 for Cs targets and 1.4 for K targets. Excited-state formation by near-resonant electron transfer for Cs targets is expected to be 0.45 eV higher than that for K target. The dependence of the branching ratio of H_2 loss to H loss upon target species shows that dissociation in the higher excited level favors H_2 loss to H loss. The activation energy for H_2 loss must be higher than that for H loss, though the heats of formation of H_2 loss are lower than those of H loss, as shown in Fig.2.

As shown in Fig.1, the peaks associated with $C_3H_n^+$ ($n=0-3$) resulting from loss of H atoms are predominant, whereas the peaks associated with $C_2H_m^+$ ($m=0-2$) resulting from C-C bond cleavage are very weak. Considering endothermicities in electron transfer process, the loss of H atoms to form $C_3H_n^+$ ($n=0-3$) is found to be much more favorable than C-C bond cleavage to form $C_2H_m^+$ ($m=0-1$), in the dissociation of electronically excited unsaturated hydrocarbons resulting from near-resonant electron transfer. Even the peak associated with C_3^+ is several times larger than that for C_2H^+ . The formation of $C_3 + 2 H_2$ is 1.3 eV endothermic compared with C-C bond cleavage in propyne, even if the former has no activation energy. The much lower intensity of the peaks associated with the C-C bond cleavage than that for H losses cannot be attributed to the energy difference.

The lower frequency of C-C vibration than that of the C-H bond may play a role in the observed intensity differences, because the C-C bond cleavage is energetically preferable.

Unraveling the Kinetics of Petroleum Destruction by Using 1,2-¹³C₂ Isotopically Labeled Dopants
 Hugh Gregg, Alan Burnham
 Lawrence Livermore National Laboratory, PO Box 808 L-310, Livermore, CA 94551

The stability of crude oil in the subsurface is of continuing interest as the search for new supplies pushes new frontiers.¹⁻⁴ Beyond mere stability, some investigators are developing kinetic models that would predict oil composition as well as occurrence.⁵⁻⁸ Two problems arise when deriving these compositional models: (1) it is difficult to unravel the reactions that simultaneously create and destroy a particular component in a complex mixture, and (2) the reactions of a given component by itself are not necessarily the same as in a complex matrix. A new isotopic method involving a double-¹³C label detected by gas chromatography-mass spectrometry (GC-MS) is presented here for unraveling these reactions.

The use of isotopic labels in kinetic studies is common (e.g., Hoering⁹) but investigations of skeletal reactions usually use a single labeled atom. A double-¹³C isotopic label is much easier to follow in an oil matrix by conventional GC-MS. The natural abundance of ¹³C is 0.011, so the normal probability of finding two ¹³C atoms in a small mass spectrometric fragment is very small: 0.00012 for an ethyl radical ($m/z = 31$) and 0.00036 for a propyl radical ($m/z = 45$). This low natural abundance makes it possible to follow both the disappearance and the appearance of doubly labeled species at very low dopant levels. A 1 wt % dopant of n-hexadecane-1,2-¹³C₂ is easily detected in a $m/z = 31$ chromatogram with a signal-to-noise ratio of several hundred. Even though the added ¹³C is only 10% of the total ¹³C in the oil, it represents 99% of all mass 31 ethyl groups in the oil.

Procedure: One percent of a carbon-13 labeled spike (n-hexadecane-1,2-¹³C₂ or 1-dodecene-1,2-¹³C₂ both from Isotec, Inc., Miamisburg, OH) was added to three dissimilar oils (a North Sea oil: 38.4° API gravity, 0.2 wt % S, 46% saturates; a high paraffin oil: 42.5° API gravity, 0.03 wt % S, 71% saturates; a high sulfur oil: 25.4° API gravity, 3.3 wt % S, 28% saturates) and n-hexadecane. A two microliter aliquot was added, along with space filling glass beads, to capillaries (internal volume ~20 µL). The capillaries were sealed with a torch, and pyrolyzed in GC ovens at temperatures from 280°C to 360°C for periods of hours to over a year. The capillaries were then broken open, rinsed with methylene chloride, and transferred to a clean vial for analysis by GC-MS.

The $m/z=31$ mass chromatogram in the unreacted hexadecane/oil mixture is void of interferences. After pyrolysis of the mixture, $m/z=31$ clearly indicates that the labeled hexadecane was cracked into lighter n-alkanes.

The double label also allows us to track reactions by following the appearance or disappearance of ($M+2$)⁺. Experiments with dodecene in oil show that one of the dominant reactions of dodecene is simple hydrogenation. Other experiments, spiking dodecene into hexadecane, shows the creation of dodecene-hexadecane adducts. Without the hydrogen donors found in oils, dodecene reacts with the matrix to form branched alkanes.

Identifying and following the creation and destruction reactions in complex matrices is nearly impossible without using isotopically labeled dopants. Reactions of a compound with a single ¹³C label can be followed using GC-combustion-isotope-ratio MS; however many operators of these instruments don't want to "contaminate" their stable isotope instruments with "large" levels of carbon-13. The method presented here, using a double ¹³C label, allows us to use traditional (i.e. relatively inexpensive) GC-MS to follow several reactions. The cost of the ¹³C labeled compounds is quite small (and very little is needed) compared to the cost of a stable isotope mass spectrometer.

Acknowledgments: Ken King has devised rapid methods for preparing the capillaries and extracting the products. To date, he has repeated this process over 200 times, with more samples still in the ovens! Discussions with John Reynolds and Tom Coburn have been most helpful. This work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W-7405-ENG-48 and cosponsored by DOE Basic Energy Sciences and industrial sponsors (ARCO, Exxon, Mobil, Conoco, Unocal, Norsk Hydro, Saga Petroleum, Statoil, IKU, AGIP, and Amoco). Eric Micheal of Conoco and Nigel Mills of Saga Petroleum provided the oil samples.

Naperville, IL 60566

Introduction: Current and future trends for petroleum processing is towards conversion of heavier and heavier fractions into useful products such as gasoline and diesel. Asphaltene, the heptane insoluble fraction of heavy oils, are a solubility class and not a specific boiling range and tend to be the hardest fraction to process in the refinery because of their high molecular mass, aromaticity and heteroatom (S, N, Ni, V) content. Molecular characterization of asphaltene is important since a more thorough understanding of the chemical nature of the constituents will lead to more efficient processing schemes.

A major hurdle in the accurate representation of the molecular structure of asphaltene has been the determination of the molecular weight. The main problem is the formation of molecular aggregates depending upon factors such as polarity of the solvent, temperature, concentration and others. Aggregation occurs even in very dilute solutions.

Experimental: The resid was obtained by vacuum distillation of an asphaltene rich Maya crude oil. Asphaltene was isolated by addition of a 40:1 excess of *n*-heptane to the Maya resid at 50 °C. The suspension was stirred overnight and filtered. The *n*-heptane was distilled from the filtrate to obtain the deasphalted oil (DAO). The yield of DAO was 83% of the resid. The precipitate was dissolved in a minimum of toluene and re-precipitated with a 40:1 excess of *n*-heptane. This precipitate was filtered, washed with *n*-pentane, and vacuum dried at 100 °C. The yield of asphaltene was 27% of the resid.

The LDMS system is a home-built time of flight instrument using 15kV accelerating voltage and either an N2 or quadrupled YAG. The flight path is 1.5 meters. A Kratos three-sector MS-50 mass spectrometer was used to obtain high resolution mass spectra of asphaltene and deasphalted oil. The sector instrument is a Kratos MS50 Triple analyzer, accelerating voltage 8kV, resolution 80,000. Such high resolution is necessary to adequately separate sulfur species in the mixture. Samples are heated from 200 to 700°C at 200°C on a probe directly in the source. The data was reduced using software written in house. Absolute response factors for each type of compound are not available, however, we have estimated and corrected for these factors using a series of model compounds. Equal molar ionization sensitivities are assumed for all homologs in the analysis. Neutron scattering was performed on the Intense Pulsed Neutron Source facility at Argonne National Laboratory.

Results: Using small angle neutron scattering we find that at room temperature that asphaltene are highly ordered rod like species with lengths up to 500Å. As asphaltene samples are heated up, these large aggregates are broken up into smaller species with a minimum of 12Å.

LDMS is known to access chiefly the aromatic content of a sample. Asphaltene LDMS spectra show higher molecular weight average and broader molecular weight distribution than DAO. However, greater ion intensities, in the mass range $m/z = 300-550$, are observed in the DAO spectra. The asphaltene spectrum has intense ions extending from a m/z range of ca. 300 and ca. 750. The mass distribution for the asphaltene extends to m/z 1500 with decreasing intensity. The number average molecular weight for the asphaltene is quite low, on the order of 500.

In order to identify important organic compounds, in-source desorption high resolution mass spectrometry has been used. Mass spectra for two standard compounds 4-Hexadecanethianaphthene and dodecanylphenanthrene show intense molecular ions with fragmentation to the aromatic nucleus. Almost no other fragmentation of the side chain species is observed. The observed H/C and S/C ratios are very close to the calculated values as is the aromatic fraction data.

*This work was performed under the auspices of the Office of Basic Energy Sciences, Division of Chemical Sciences, U.S. Department of Energy, under contract number W-31-109-ENG-38.

Table 1. Elemental Analysis by MS

Element	Asphaltene		Deasphalted oil	
	observed	Calculated MS	observed	Calculated MS
C	82.9	83.3	84	85.7
H	7.7	8.4	10.4	9.4
O	0.9	0.4	0.5	0.15
S	7.1	6.7	4.7	3.75
N	1.4	1.2	0.4	0.9

Table 1 shows the quantitative results of the elemental analysis of the Maya resid components, asphaltene and DAO by normal methods and by mass spectrometry. The distributions from the mass spectral data agree quite well with the observed values. This means that the mass spectral data is representative of the actual sample. Furthermore, at least 90% of the DAO and asphaltene is volatilized into the mass spectrometer. Aromaticity values for the asphaltene are slightly lower for the mass spectral data (0.42 versus 0.50 by NMR methods).

The extent of the ring size is consistent with high aromaticity of these resid samples. First, the DAO shows abundant hydrocarbon series with ring size of 3. This series contains molecular types representing trianaphthenonaphthalenes. The hydrocarbon species are chiefly in the DAO, while the asphaltene contains the bulk of the heteroatomic sulfur, nitrogen and oxygen. The sulfur heteroatomics are principally in the rings sizes from 1 to 5 rings, while the nitrogen heteroatomics are in larger ring size systems from 2 to 8 rings. It is clear that the asphaltene is depleted in hydrocarbons, but has excess of the nitrogen in low to high ring region compared to DAO. The asphaltene is chiefly constituted of ring systems with minimal side chains length, but multiply substituted positions. The nitrogen containing constituents also follow this pattern.

In order to better understand processing a sample of Maya resid is batch process and the asphaltene are extracted at various times during the reaction. The sulfur and nitrogen content as a function of degree of unsaturation is shown in figure 1.

Figure 1. The distributions of sulfur (white bars) and nitrogen (black bars) for asphaltenes.

Clearly the sulfur is easily remove, while the nitrogen is resistant to processing. We are in the process of characterizing the nitrogen containing species.

Comparison of MAB and EI for petroleum mass spectrometry

D. Faubert, M. Mousselmal, S.G. Roussis and M.J. Bertrand.

Departement of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7.

Petrochemical analysis, because of the complexity of the samples that have to be characterized, is one of the most demanding fields of mass spectrometry. Several analysis are conducted using EI in the so-called low-eV mode (LV-EI). The LV-EI mode is used to minimize fragmentation, thus, reducing the complexity of the mass spectra obtained from mixtures. However, because the ionization cross section in EI varies with the energy of electrons, a substantial loss in sensitivity is incurred when the ionization energy is reduced. A Metastable Atom Bombardment (MAB) ionization source in which the sample is bombarded with a beam of metastable atoms has been recently developed.^{1,2} It is possible with MAB to easily control fragmentation without loss in sensitivity, and selectively ionize molecules of interest in a mixture because the energy used for ionization can be easily and precisely controlled. The energy available for ionization and fragmentation is discrete and can be fixed by the choice of the rare-gas that is used in the atom gun. Excitation energies for the different rare-gases range from 8.3 to 20.6 eV.¹ The commercial version of the MAB source was provided by DEPHY Technologies (Quebec, Canada) and used on a magnetic sector instrument (VG AutospecQ, Manchester, UK). The calibration of the electron energy at 10 eV in LV-EI was made by adjusting the fragment at m/z 91 of *m*-xylene at 1 % relative to the molecular ion. The effect on fragmentation that is observed when the ionization energy is lowered with EI was measured using acetone as a model compound (Table 1). As the ionization energy is reduced (70 to 10 eV), the intensity of the fragment (m/z 43) relative to the molecular ion (M^+) is decreased indicating that at lower energies fragmentation is reduced and more simple spectra can be obtained. However, this reduction in the extent of fragmentation is obtained at the detriment of sensitivity.³ The sensitivity decreased by a factor of 525 from 70 eV to 10 eV. The fragmentation in MAB is controlled by the excitation energy of the metastable rare-gas atom that is used for ionization. No significant loss of sensitivity is observed in MAB as the energy is changed. Table 1 shows the mass spectra of acetone obtained in LV-EI and in MAB. As indicated by the intensity of the fragment m/z 43, it was not possible to reduced the fragmentation in EI (≤ 10 eV) as efficiently as MAB did with Kr. The result for LV-EI can only be explained by an important energy spread. In LV-EI, the ionization efficiency and the extent of fragmentation are also affected by source tuning parameters such as the ion repeller voltage, the emission current and any field penetration in the ion source.^{3,4} Figure 1 shows the effect of the repeller voltage on the ratio of the fragment m/z 43 on M^+ of acetone. From 4 to 10 V, the ratio of m/z 43 to M^+ varied by a factor of 12 and the ionization efficiency decreased by a factor of 13. Hence, any instability in the voltage applied on the repeller greatly affects the electron energy and, thus, affects the ionization efficiency and the extent of fragmentation. Similar trends were also observed with the variation of the extracting voltage. These results imply that LV-EI experiments require an experimented user to obtain reliable results while the MAB source is easy to use and does not require any fine tuning nor an energy calibrant to achieved low energy experiment. Experiments were conducted to evaluate the relative sensitivity of the MAB source with EI. Table 2 shows the TICs relative intensity of MAB with EI. As shown, MAB is less sensitive by a factor of 8-18 relative to EI (70 eV) depending on the gas used. According to the results, no significant loss of sensitivity is observed in the MAB source when the energy is changed (factor of ~2). Table 3 shows the relative sensitivity of MAB with EI for the detection of molecular ions. Results demonstrate that MAB has a comparable or higher sensitivity than EI. MAB has the ability to achieve selective ionization of compounds in a complex mixture. A mixture containing typical compounds present in petroleum samples and compounds having amino groups has been analyzed with MAB using xenon (Figure 2a).² The spectrum demonstrated that only molecules containing amino groups are ionized by

MAB Xe. Selective ionization is also possible with LV-EI (Figure 2b), however, fragments of significant intensities are still present as well as an important background due to the poor sensitivity. The stability and reproducibility of the MAB source were evaluated with the analysis of a mixture of alkenes. The stability of TICs observed with EI (70 eV), LV-EI and MAB are presented in Table 4. According to the results, MAB has a better stability over LV-EI and comparable to EI (70 eV). The reproducibilities of the three techniques were measured by the standard deviation of the percentage of decenes relative to nonenes. Here again, MAB has a better reproducibility than LV-EI and near to EI (70 eV). Results presented demonstrate the superiority of MAB over EI for low energy analysis of petroleum samples.

Table 1 - Relative ion intensities(%) obtained for acetone upon ionization with the MAB source and LV-EI source.

m/z	MAB Kr	LV-EI
58	100	100
43	0.07	12.3

Table 2 - Total ion current relative sensitivities of the MAB source versus EI (acetone was used as analyte)

<i>EI</i>		<i>MAB</i>

Analysis of the emanations from heated polyurethane foam using MAB-MS

Cyr M., Faubert D., Mousselm M., Potvin L., Bertrand M.J.
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7.

Polymers such as polyurethane foam (PUF), when subjected to heat may decompose into numerous compounds. Classical approaches to identify the major volatile constituents require a great deal of time and effort to collect, separate and analyse the various fractions. Direct probe insertion EI is possible, but results may prove difficult to interpret as in most pyrolysis experiments. The presence of a large number of compounds producing an equally large number of fragments in one mass spectrum makes direct interpretation almost impossible. In this study, a comparison of PUF pyrolysis analysis in electron impact (EI) and Metastable Atom Bombardement (MAB) is made. MAB/MS is then used to identify individual compounds found as molecular ions in the MAB spectrum. Structural elucidation is achieved using MAB/MS/MS. Pyrolysis data was collected using a recently developed ionization source based on the principle of Penning ionization (1). This source uses metastable atom bombardement (MAB) to ionize molecules in the gas phase. The commercial version of the MAB ion source was provided by Dephy Technologies (Quebec, Canada). The MAB source acts as an energy tunable ionization source, since different rare gases can be employed. The accessible energies for ionization are in the range of 8 to 20 eV depending on the metastable atom used (Xe, Kr, Ar, Ne and He). Figure 1 shows the mass spectra of pyrolyzed PUF by direct probe insertion at 200 °C. The MAB spectrum, Figure 1a, readily shows the advantages of MAB ionization over EI, Figure 1b. The problem of using pyrolysis MS with EI ionization lies in the presence of too many peaks most of which are fragment ions. From over 200 ion peaks obtained in EI, the problem is simplified to about a dozen using MAB. This technique, by eliminating fragmentation, simplifies the obtained spectrum, and highlights the molecular ion species. Because only the molecular ions are present in the MAB spectrum, it offers extremely advantageous conditions for structure elucidation using MS/MS. From this MAB data, the 8 most intense peaks, ions 122, 148, 174, 192, 210, 218, 236 and 296, were selected for structure elucidation. Empirical formulae were obtained by accurate mass measurement using MAB/MS (2). Figures 2 and 3, show typical MAB/MS/MS spectra of the selected ions as well as the proposed structures. The results show that three major events happen during PUF pyrolysis: 1) the polymer chain undergoes cleavage into smaller segments, 2) these segments undergo further cleavage through internal rearrangements, 3) during pyrolysis segments recombine to form new compounds. These results correspond very well with other investigations into PUF pyrolysis. Hileman et al. (3) proposed mechanisms for the formation of toluene diisocyanate (m/z 174), toluene diamine (TDI) (m/z 122) as well as toluene isocyanate amine (m/z 148) from PUF. This may explain why all of the observed compounds possess either an amine functional group or an isocyanate functional group. Compounds at m/z 210 and m/z 236 are interesting in that they seem to be intermediates between the polymer and the decomposition products. Their MS/MS spectra show that the side chain may rearrange after collision and produce either an amine or an isocyanate functional group. This would indicate that when these species are produced during the pyrolysis process, the heat involved would be sufficient to cause rearrangement and produce toluene isocyanates and amines. Compounds at m/z 192, 218 and 296 are different from the others in that they are produced by intermolecular reactions during pyrolysis. This can be deduced since for these compounds there is no urethane bond as in the polymer. This means that a recombination occurs during pyrolysis between available species. This type of reaction, known as macroradical, is another pathway in polymer decomposition during pyrolysis. MAB has shown itself to be an excellent replacement for

traditional pyrolysis analysis techniques. It provides a quick and easy way to obtain data from complex mixtures without requiring long preparative processes. It surpasses EI for molecular ion determination by limiting fragmentation thus making spectrum interpretation of complex mixtures very easy. MAB used in accurate mass measurement, allows the empirical formula of each constituent in a complex mixture to be determined in a matter of minutes from a raw sample. MAB ionization, when combined to MS/MS, provides a useful tool for structural elucidation of pyrolysis products.

The Influence of Pump Oil Purity on Roughing Pumps
Sanford V. Overton and John J. Manura
Scientific Instrument Services, Ringoes, NJ 08551

Pump oils contain a wide variety of volatile organics and the breakdown of these compounds can affect the life of a rough pump and is a major concern to mass spectrometer users. Analytical techniques are needed to identify and quantitate volatile organic compounds (VOC's) present in oils so that these techniques can be incorporated into troubleshooting problems that may arise as well as be used in a quality control program to ensure product purity. In addition, more sensitive techniques are needed to profile and identify VOC's in pump oils so that they can be used to ensure the life of the pump. Headspace GC analysis, cryofocusing techniques, and high-resolution GC have previously been used for the analysis of commercial oils. Static headspace techniques are limited in their detection and identification of many organic volatiles and especially the semi-volatile organics. The purpose of this investigation is to develop an analytical technique that could detect and identify a wide range of volatile and semi-volatile organic compounds in pump oils over time. For this study, volatile organic compounds are purged from oil samples followed by trapping on TenaxTMTA adsorbent resin using a dynamic purge and trap technique (P&T). The adsorbent traps are ballistically heated and together with the carrier gas flow through the samples the volatiles are outgassed into the GC injection port and onto the front of the GC column for subsequent analysis by thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS). The volatile organics present in the pump oils are quantified using matrix spiked deuterated standards.

All experiments were conducted using a Scientific Instrument Services model TD-3 Short Path Thermal Desorption System accessory connected to the injection port of an HP 5890 Series II GC interfaced to an HP 5971 Mass Selective Detector (MSD). The mass spectrometer was operated in the electron impact mode (EI) and scanned from 35 to 550 daltons during the GC run for the total ion chromatogram. The HP 5890 Series II GC contained a short 0.5 meter by 0.53 mm diameter fused silica precolumn attached to the injection port end of a 30 meter x 0.25 mm i.d. DB-5MS capillary column containing a 0.25 µm film thickness. The GC injection port was set to 260°C and a 10:1 split was used. The head of the column was maintained at -70°C using an S.I.S. Cryotrap model 951 during the desorption and extraction process and then ballistically heated to 200°C after which the oven was temperature programmed from 35°C (hold for 5 minutes) to 80°C at 10°C/min, then to 200°C at 4°C/min and finally to 260°C at a rate of 10°C/min.

Samples from 2 different kinds of pump oil (Inland 45 & Inland 19) were removed from two continuously running Alcatel model UM2021 vacuum pumps over a three month time period and analyzed by a dynamic purge and trap technique to compare and quantitate the volatile organics present. An additional fresh sample of Invoil 20 pump oil was also examined for comparison. For quantification, an internal standard was spiked into the adsorbent traps after the sample had been isolated. No correction for extraction efficiency or recovery is achieved using this technique; however, it functions as a useful means of quantifying the levels of components present on the adsorbent traps. Two ml aliquots of oil were removed monthly from each vacuum pump and transferred into a 10 ml test tube and heated to 60°C for 30 minutes. Samples were sparged with high purity helium at 20 ml/min with an additional 25 ml/min dry purge using an S.I.S. Purge and

Trap System. Volatile analytes were gas extracted and carried to a preconditioned 4.0 mm i.d. glass-lined stainless steel desorption tube packed with 200 mg of TenaxTMTA. The desorption tube with sample was then attached to the Short Path Thermal Desorption System and a syringe needle attached. The desorption tube was injected into the GC injection port at desorption block temperatures of 220°C for 5 minutes.

Fresh oil samples from Inland 45, Inland 19 and Invoil 20 pump oils were collected on January 20, 1996, followed by monthly collections of Inland 45 and Inland 19 pump oils from two continuously running Alcatel model UM2021 vacuum pumps. Monthly oil samples were taken for a period of 3 months on February 20, 1996, March 19, 1996 and April 16, 1996 and subsequently analyzed to determine the presence and changes of VOC's over time that would ultimately affect the life of the pump. Over 100 volatile organics were identified in the oil samples analyzed. The oil samples studied produced 50 or more volatile organics which were identified in addition to many more that were either too weak to identify or in which a good NBS library match was not achievable. Fresh Inland 19 pump oil was found to contain several hydrocarbons as well as numerous substituted benzenes, aldehydes and ketones. A high concentration of the aromatic compound toluene was also present. Numerous hydrocarbons and substituted benzenes were primarily found in the Inland 45 pump oil while aldehydes and ketones were identified in the Invoil 20 pump oil. The siloxanes hexamethyl-cyclotrisiloxane, octamethyl-cyclotetrasiloxane and decamethyl-cyclopentasiloxane which are related to cleaning and lubricating compounds were detected in both the fresh Inland 19 and Inland 45 pump oils. However, only hexamethyl-cyclotrisiloxane was detected in Invoil 20.

After 1 month the concentrations of VOC's in the Inland 19 pump oil slightly increased with the exception of the aromatic compound toluene which was significantly reduced. The compounds 5-ethylidihydro-2(3H)-furanone, dihydro-5-pentyl-2(3H)-furanone and 5-hexyldihydro-2(3H)-furanone were also identified at this time. Generally, the concentrations of VOC's in the Inland 19 pump oil remained approximately the same after 2 months with slight increases in hydrocarbons and siloxanes and continued decrease in the aromatic compound toluene. After 3 months, there were significant increases in the aldehydes butanal, pentanal, hexanal, heptanal, octanal, nonanal and decanal as compared to the 2 month sample of Inland 19 pump oil. Inland 45 pump oil exhibited significant increases in the butanoic, pentanoic, hexanoic and heptanoic acids as well as aldehydes, ketones and furanone derivatives after the initial month. Significant amounts of dihydro-5-methyl-2(3H)-furanone, dihydro-5-propyl-2(3H)-furanone and 5-butyldihydro-2(3H)-furanone were also detected at this time. After 2 months of continued use, the concentrations of VOC's in the Inland 45 pump oil were significantly reduced with the exception of the siloxanes. The same decreasing trend continued in the Inland 45 pump oil at 3 months with continued reduction in the concentrations of volatile organics. It appears that the most significant changes in pump oil occurs after its initial use with gradual changes in pump oil purity after continued use.

OLIGOM: A COMPUTERIZED MASS SPECTRUM ANALYSIS APPLICABLE TO OLIGOMERIC MIXTURES

Carmen Piemonti, Marta Hazos - INTEVEP, S.A. - P.O. Box 76343, Caracas 1070A, Venezuela

INTRODUCTION

An oligomeric mixture is formed by components sharing a base structure and one or more chains with a variable number of repetitive units. Surfactants are important oligomers with alkyl and/or ethoxylate variable length chain, providing one hydrophobic and one hydrophilic terminal; they modify the interfacial properties of a liquid and are used as detergents, emulsifiers, foams, etc.

Average properties are commonly measured for oligomers, this not always satisfies requirements for a behavior correlation. As an alternative, the characterization based on mass spectral analysis gives insights about the composition for individual members provided a single signal is registered for each component.

EXPERIMENTAL

Mass spectra were acquired from a VG ZAB-2SEQ Mass Spectrometer set for FAB acquisition. Data system is OPUS on a Digital VAX Station 3100 M38.

OLIGOM was developed in C language. The executable version is linked to the OPUS system and inputs mass spectral data generated by OPUS File System (OFS).

ANALYSIS DESCRIPTION

OLIGOM is a computerized tool to handle mass spectra from an oligomeric mixture. The following paragraphs are the more important tasks built into the code and available to user. The analysis of a nonylphenol ethoxylated is used as example as a practical application of OLIGOM.

PARAMETER DEFINITION: The user defines the base and the experimental structures. For the example, the base structure is C₆H₆O (for phenol) and the experimental structure is C₆H₆OK for the adduct with K⁺, since KCl was added to increase intensities for molecular ions under FAB conditions. Two repetitive units are declared (maximum is five): 1) CH₂ to allow a variable hydrophobic alkyl chain and 2) C₂H₄O to allow a variable hydrophilic ethoxylated chain. For a nonylphenol, CH₂ should present a maximum at 9. Finally, the isotopic domain should be declared to limit isotope effects to a significant distance for each signal; in this case, 2 is indicated.

MASS SPECTRUM INTERPRETATION: Based on the above parameter definition, OLIGOM scans the mass spectrum generating all possible combinations between an experimental structure and a variable length chain of repetitive units. Any combination with a mass displacement not bigger than mass/(resolving power) is considered as potential identification, a final assignment also discriminates multiple choices and increasing mass order. If the user manually defines a lock mass, the correction is extended to the rest of the spectrum by an exponential or linear expansion algorithm. The interpreted mass spectrum can be saved on disk and restored by future requests.

MASS SPECTRUM HANDLING: Tools are provided to partially list and/or graphic the spectrum by selecting particular mass intervals or particular assigned combinations. Internal lock masses may be defined by a numerical value or by formula assignment to a particular signal.

COMPONENTS QUANTITATION: Intensities, after isotope corrections, are directly associated to mole contribution for the particular repetitive units combination. Two groups are defined: 1) the total sample and 2) the selection for the output. The total sample group establishes the 100% of the sample; all output values are referred to this quantity. The output selection limits the list or graphic for individual entries or representations. The results can be expressed in tables or graphics; the figures are examples of some definitions and the corresponding outputs obtained for nonylphenol ethoxylate.

Differentiation of Isobaric Monomers Contained in Complex Polymers

Charles W. Ross, III. and William J. Simonsick, Jr.
DuPont Marshall R & D Laboratory, Philadelphia, PA 19146

Environmental regulations require that future generations of automotive coatings have a reduced volatile organic content (VOC). One approach to reducing VOC while maintaining sprayable viscosities is the use of highly functionalized low-molecular-weight polymers. It is imperative that we know the structures (monomers & endgroups) of the functionalized polymers because undesirable materials such as nonfunctional chains may have an adverse effect on enduse properties. Laser Desorption-Fourier Transform/Ion Cyclotron Resonance/MS (LD-FT/ICR/MS) with cation doping produces pseudomolecular ions ($[M]K^+$) from which molecular formulae can be derived. On occasion, some monomers have the same nominal mass in which case we cannot determine the number of each unique monomer in the chains. For example, glycidyl methacrylate (I) (GMA) and butyl methacrylate (II) (BMA) have the same nominal mass of 142 Daltons (Da).

We report on two methods to differentiate such monomers contained in complex chains. A reactive group, such as the epoxide on GMA, may be exploited to shift the ion signals a known mass for each group reacted. Higher resolving powers will separate the signals for each different polymer chain because GMA and BMA differ by 0.027 Da. We will show that Quadrupolar Axialization & Collisional Cooling (A&C) with LD-FT/ICR/MS can greatly increase the resolving power in the analysis of polymers.

Epoxy functional polymers react with both primary and secondary amines. N-methyl benzylamine (NMB) was selected as the reagent to react with the epoxy functionality of GMA. NMB has a molecular weight of 121 Da, and adds quantitatively to epoxides, which manifests as a predictable shift of 121 Da in the LD-FT/ICR mass spectrum. Infrared analysis showed that the reaction went to completion for the materials studied. Figure 1 shows the LD-FT/ICR mass spectrum of a GMA/BMA copolymer which was reacted with NMB. The expansion region shows the GMA-containing and reacted chains are shifted 121 Da. The polymer studied had a low GMA content, therefore, the maximum number of GMA groups per chain observed using the reaction chemistry approach was two. These data show that statistical copolymers were synthesized and we do not have a mixture of homopolymers.

Application of A&C to three oligomers of another GMA/BMA polymer is seen in Figure 3. The resolving power is ~ 9000 . The enlargement shown in Figure 4 shows isotopic resolution. Endgroup determination is now possible for the polymer chains. In the case of the signal at 3552 Da, there are 24 units of BMA/GMA, one endgroup is methyl methacrylate proton terminated (101 Da) and the other is a hydrogen atom. The remaining 39 Da is the cation, potassium. These data support the expectations of the organic polymer chemist.

Further improvements with the A&C conditions produced a signal lasting 8 seconds, which upon Fourier transformation afforded a resolving power of $\sim 60,000$. However, a resolving power of $>130,000$ is required in order to resolve these unique polymer chains. Moreover, the signals were analyzed for frequency drift, but no such drift was detected in our analysis of these data. We are working to improve our A&C conditions to achieve the necessary resolving power.

COMPUTERIZED SURFACTANT ANALYSIS BY FAB-MS

Marta Hazos, Carmen Piemonti, Jenny Bruzual, and Aaron Mendez.
Department of Analysis and Evaluation, INTEVEP S.A.
P.O.Box 76343, Caracas 1070A, Venezuela.

INTRODUCTION

Surfactants are commercially obtained as a result of chemical processes on large scale reactors. Consequently a mixture of homologous compounds differing in the length of alkyl and/or the alkyl ethoxylated chains is generally obtained. These raw materials contain unreacted species and excipients that are combined with some "trade mark compounds" often added as dummy substances to disguise the composition of the active ingredients. In fact the best performance comes from the synergy of secret formulations that constitutes real assets of valuable industrial property. The tasks to the analytical chemist that has to perform quality control analysis is therefore really challenging. The oil industry is far from an exception and surfactants are intensively and extensively used; as demulsifiers and detergents; and recently the production of stable water/heavy crudes emulsions demands for extra efforts to develop conveniently rapid and reliable analytical methods.

METHOD

The mass spectral analysis gives insights about the distribution for individual members. The quantitation is performed by OLIGOM, a computerized tool designed to handle the identification and establish the composition of oligomeric mixtures, described elsewhere¹. Analyses were performed on a VG ZAB-2SEQ mass spectrometer, at 8 kV, and a resolution of ca 2000 at 10 s/decade. The Cs ion gun was operated at 30 keV. Data were processed by a Digital VAXstation 3100 M38 computer using OPUS software for acquisition. OPUS file services provide the link to generate an ASCII file, used subsequently as input to OLIGOM. Different matrices were tested. Among them, m-nitrobenzyl alcohol (m-NBA) saturated with either KCl or NaCl was the most suitable matrix for non-ionic compounds, in terms of reproducibility, sensibility and ease of performance; while triethanolamine was adequate for anionic surfactants and mixtures of naphthenic acids which were acquired in negative ion mode.

RESULTS

The characterization of ethoxylated alkyl phenol, polyoxyethylene alkyl amines, polyoxyethylene fatty alcohol, naphthenic acids, ethoxylated alcohol sulphates, and polyethylene oxide were accomplished based on Cs-FAB-MS. FAB mass spectra obtained provide the complete and precise pattern of oligomer distribution, since it gives series of ions in the molecular region. The spectra of the surfactants were processed by OLIGOM, to identify and quantify alkyl and ethoxylated chain lengths in the oligomeric mixtures. An illustrative example shows in Figure 1 the FAB(+) mass spectrum of a commercial mixture of ethoxylated alcohols. Two main series of ions are clearly detectable that differ by 44 Daltons A_n and B_n , where n indicates the number of ethoxyl units, these series correspond to typical potassium adduct ions $[M+K]^+$.

Defining base structure as H_2O , and repetitive units as CH_2 and C_2H_4O , OLIGOM identifies fatty alcohols from C_{11} to C_{17} , with average figures of 13.4 for alkyl chain and 14.4 for the ethoxylated units

¹ Piemonti, C., and Hazos, M. "OLIGOM: A Computerized Mass Spectrum Analysis Applicable to Oligomer Mixtures" presented at the 44th ASMS Conference on Mass Spectrometry and Allied Topics, Portland, OR (1996).

The characterization of ethoxylated alkyl phenol, amines and ethoxylated alcohol sulphates were performed with a base structure of C_6H_5O , NH , and HSO_4Na , respectively. OLIGOM spectral processing gives information about the alkyl chain distribution as well as the hydrophilic part of the molecule due to polycondensation with ethylene oxide presenting a typical POISSON distributions.

Naphthenic acid analysis by FAB(-) consists exclusively of $[M-H]^-$. The naphthenic acid homologues are obtained by base structure: $C_7H_6O_2$ and the addition of the repetitive units CH_2 and H_2 , where H_2 simulates insaturations. OLIGOM reports averages of 2.5 rings and 9.5 CH_2 units.

OLIGOM analysis of the positive FAB spectrum of a commercial PEG 1000 mixture, gives the $[M+K]^+$ series distributions of individual members with C_2H_4O units and an average MW of 992.

CONCLUSIONS

- FAB(+) mass spectrometry furnishes the complete and precise pattern of oligomer distribution, since it gives series of ions in the molecular region with virtually no fragmentation.
- The FAB technique can be easily implemented in laboratory of manufacturers and users as an analytical tool for quality control of different types of detergents in raw materials
- For non-ionic surfactants, m-NBA in Cs-FAB-MS in positive mode has given better results in terms of reproducibility and ease of performance; whereas for the naphthenic acids mixtures sensitivity was enhanced in negative mode.
- OLIGOM is a computerized algorithm proved to be very useful for the identification and quantitation of complex oligomeric mixture of different nature and concentration.
- OLIGOM provides rapid and reliable identification of not only the main oligomeric distributions but also of those arising from side reaction during the industrial process

Characterization of Melamine Resins Using LC/MS

Ted Chang and Michael Piquette
CYTEC Industries Inc., Stamford, CT 06904-0060

Introduction

Melamine resins are important components of thermosetting resin products in polymer industry. They are widely used in the coatings industry as binders and cross-linkers. They are synthesized by reacting the primary amino groups of melamine with formaldehyde to form methylol groups and converting these methylols to methoxymethyl groups by condensation with methanol. The degrees of reactions are varied according to the intended end use applications.

Because of their complex nature, the structures of melamine resins are traditionally expressed by a "general formula" to indicate the mole ratios of formaldehyde and methyl groups to melamine in a particular resin mixture. However, this approach does not provide specific information about the individual constituents. The new approach is to characterize melamine resins based on knowledge of individual constituents in melamine resins. We have successfully developed an HPLC procedure to separate components in melamine resins for their subsequent LC/MS identifications. A "structure formula" is used to express the exact structures of its six functionalities as shown in the following examples.

HPLC Chromatograms of Melamine Resins

Since melamine has six substitution sites, it is apparent that melamine resins are highly complex mixtures. Figure 1 shows HPLC chromatograms of the monomeric fraction of a melamine resin. The employed mobile phase is a water/methanol system. For fast analysis of the dimeric fraction, the mobile phase is adjusted to be less polar.

Mass Spectrometry of Melamine Resins

Thermospray ionization produces stable MH⁺ ions for melamine resin compounds. It was found that loss of HCHO is a predominant fragmentation for all compounds containing methylol functionalities (-CH₂OH). The frequency of HCHO loss (30 daltons) corresponds directly to the number of methylol functionalities in the compound and subsequent identifications of the -NH and -CH₂OCH₂OCH₃ functionalities. This unique fragmentation provides useful structural information without resorting to an MS/MS study.

Figure 1. Chromatogram of a Mixed Melamine Resin

LC/MS Identification of Separated Compounds

Over twenty monomeric and over a dozen dimeric compounds were identified from the five investigated methoxymethylmelamine resins. Table I lists a few monomeric compounds with their identifications.

Table I: Structure of Monomeric Compounds in Melamine Resins

Peak	M.W.	General Formula	Functionality			Structure Formula
			F	FMe	FFMe	
1	258	MF ₃ Me ₃	-	3	-	M(FMe) ₃ H ₃
5	348	MF ₆ Me ₃	3	3	-	M(FMe) ₃ F ₃
10	362	MF ₆ Me ₄	1	3	1	M(FMe) ₃ (FFMe)FH
18	390	MF ₆ Me ₆	-	6	-	M(FMe) ₆
19	420	MF ₆ Me ₆	-	5	1	M(FMe) ₅ (FFMe)
20	450	MF ₆ Me ₆	-	4	2	M(FMe) ₄ (FFMe) ₂

Application to Other Melamine Resins

This new approach is equally applicable to melamine resins containing alkyl groups higher than methyl group. One example is a highly alkylated mixed methoxy-butoxymethylmelamine. The monomeric and dimeric fraction were separately collected by GPC and analyzed. No cross contamination between monomers and dimers was confirmed.

Summary

This new approach to characterization of melamine resins offers many advantages over the traditional method. Identity of components and their distribution profile are now available. Knowledge on functional groups also provides a powerful tool for the studies of reaction mechanisms and curing behaviors of melamine resins.

APCI LCMS of Metalloporphyrins

Elaine K. Fukuda, Yanping Wang* and Chang Samuel Hsu*, CAFT Mass Spectrometry Facility, Rutgers University, New Brunswick, NJ, and *Exxon Research & Engineering Co., Annandale, NJ

A viable on-line separation/characterization method for metalloporphyrins in high boiling crude fractions is needed. Metalloporphyrins in crude oils present processing and environmental problems. Experimental design for metal removal would be greatly aided by the characterization of metalloporphyrins in crude fractions.

We have utilized APCI LC/MS methodology to determine low levels of nickel and vanadyl octaethyl porphyrins, used as a model compounds. These compounds yield strong protonated molecular ions which can be detected using SIM techniques to sub ppm levels. Both normal phase and reverse phase chromatography may be used to effect separations. Additional specificity can be obtained by increasing the sampling cone voltage to cause "up-front" CID.

The APCI experiments were carried out on a Micromass Platform II. Typical positive ion APCI operating conditions were used (corona discharge voltage = 2.8 kV, ion source temperature = 150C, APCI probe temperature = 450C, cone voltage = 25V). Normal phase chromatography (100% hexane to 75:25 hexane:isopropanol gradient program, 1.0 mL/min) was carried out using an ES Industries Chromega Spherisorb silica column (25 cm x 4.6 mm). Reverse phase chromatography (water:methanol:acetonitrile 5:50:45 to methanol:acetonitrile 50:50 to 100% acetonitrile gradient program, 1.0 mL/min) was carried out using a Waters Bondapak C-18 column (15 cm x 3.9 mm). Both porphyrins were monitored at 406 nm with a Varian 9050 uv-vis detector.

Linear responses with the amount of porphyrin injected was observed from 100 ng to 200 pg (SIM of m/z 591 or m/z 600), for both model compounds. Additionally, the extent of fragmentation can be adjusted by varying the cone voltage (25V to 200V). Both model compounds exhibited the same pattern of fragmentation at the same cone voltage setting.

The analysis of organic polymer additives by mass spectrometry has, in the most part, been limited to molecular weight determination of the solvent extracted components. The few collision induced dissociation (CID) experiments undertaken have been generally performed in the low energy regime (10-200 eV). Through the use of high energy CID experiments, however, molecular ions have been shown to dissociate forming fragment ions that are characteristic of the class of polymer additive. For example, fragment ions observed at m/z 219 and 203 are normally associated with the Irganox class of polymer additives that have a 2,6-di-tert-butyl-4-R-phenol type structure.

Furthermore, precursor ion scanning techniques have also been utilised for the structural characterisation of polymer additives under low energy conditions. The difficulties in performing precursor ion scans and MS/MS/MS experiments in four sector instruments has limited the number of applications of these techniques in the high energy regime. The wide energy acceptance of MS2 of the ZAB-T four sector mass spectrometer (Micromass, Wythenshawe, Manchester, U.K.), however, has been shown to enable the generation of both precursor ion and MS/MS/MS spectra under high energy conditions. The ZAB-T has been used to generate precursor ion and MS/MS/MS spectra for polymer additives to give further information on the decomposition pathways of the molecular ions of these compounds.

The data generated from precursor ion (see Figure 1) and second generation product ion (see Figure 2) scans were consistent with fragmentation pathways that have been proposed previously for the Irganox class of compounds and Hostanox 03, which are employed as antioxidants in polymer blends. These decomposition routes include the proposed loss of 16 Da from the m/z 219 fragment of Irganox 1076, Irganox 1010 and Irganox 3114 to generate m/z 203 (see Scheme 1) and the generation of m/z 309 from the m/z 325 fragment ion of Hostanox 03. These ion peaks are the most intense fragments in the high energy CID spectra of these compounds.

FT/MS Analysis of Common Anionic and Nonionic Surfactants
J. Via, D.E. Doster and *R.A. Iudicky
Morton International, 1275 Lake Avenue, Woodstock IL 60098

Anionic and nonionic surfactants are utilized in a wide range of products including detergents, cosmetics and emulsion polymers. Anionic and nonionic surfactants can be analyzed by a wide variety of methods including GC/MS, LC/MS and NMR. These traditional methods of surfactant analysis, however, all suffer some limitations. GC/MS is not applicable to nonvolatile surfactants, NMR suffers from sensitivity problems and LC/MS may require considerable method development time. In many unknown surfactant analyses, multiple techniques have to be utilized to detect and fully characterize the unknown surfactant. Surfactant analysis is often a time consuming process.

Laser desorption FT/MS appears to be a very quick method of fully characterizing anionic and nonionic surfactants. Negative ion laser desorption FT/MS can ionize and detect several classes of anionic surfactants and positive ion laser desorption FT/MS is quite effective at detecting nonionic surfactants. The ability of FT/MS to fully characterize surfactants was checked by analyzing four anionic surfactants and nine nonionic surfactants. The surfactants analyzed are listed below:

Anionic Surfactants:

Sodium Octadecyl Sulfate, Sodium Dodecylbenzene Sulfonate, Sodium Laureth Sulfate, Sodium Dihexyl Sulfosuccinate

Nonionic Surfactants:

Octyl Phenol 10 mole Ethoxylate, Octyl Phenol 40 mole Ethoxylate, Ethylene Oxide / Propylene Oxide Block Copolymer MW = 1000, Ethylene Oxide / Propylene Oxide Block Copolymer MW = 2000, Stearic Acid 40 mole Ethoxylate, Polyethylene Oxide Distearate, Decanol 6 mole Ethoxylate, Sorbitan Stearate, Sorbitan Monolaurate 80 mole Ethoxylate.

FT/MS spectra were obtained on all the surfactants listed above. These spectra were obtained on an Extrel (now Finnigan) 2001 FT/MS. Anionic surfactants were analyzed as is in the negative ion mode. Nonionic surfactants were doped with potassium bromide and analyzed in the positive ion mode. All the surfactants were ionized by a Tachisto (3 Joules, 80 nanosecond pulse width) carbon dioxide laser.

All of the anionic surfactants listed above except Sodium Laureth Sulfate gave one peak mass spectra originating from the deprotonated sulfates or sulfonates. Sodium Laureth Sulfate gave a series of peaks because this surfactant contains components which contain differing numbers of ethylene oxide residues. The anionic surfactants, for the most part gave very simple spectra.

All of the nonionic surfactants with molecular weights below 2000 g/mole gave good spectra with little fragmentation. These spectra, except for Sorbitan Stearate, all show nice Gaussian peaks shapes originating from

the variable numbers of ethylene oxide residues contained in these surfactants. The two surfactants with molecular weights above 2000 g/mole, Sorbitan Monolaurate 80 mole Ethoxylate (MW = 4000) and Polyethylene Oxide Distearate (MW = 6000) both showed significant fragmentation. The Sorbitan Monolaurate showed both fragment and molecular ions while the Distearate showed only fragment ions. It appears that fragmentation becomes a major problem in the direct laser desorption analysis of high molecular weight surfactants.

After the four anionic and nine nonionic surfactants were analyzed three commercial coatings were analyzed for unknown surfactants by laser desorption FT/MS. These analyses were carried out to see if actual unknowns can be identified by laser desorption FT/MS. The three commercial coatings were a water resistant coating, a vinylidene chloride containing coating and a commercial adhesive. The water resistant coating was analyzed first.

The water resistant coating was analyzed for surfactants by precipitating out the polymeric portion of the sample with methanol. The methanol extract was then analyzed by positive ion FT/MS. The resultant spectra featured a cluster of ions at 1000 amu spaced by 58 and 44 amu. This unknown was identified as a 1000 molecular weight Ethylene Oxide / Propylene Oxide Block Copolymer by comparison to that of an authentic standard.

The vinylidene chloride containing coating was analyzed for surfactants by negative ion laser desorption FT/MS. Again, the surfactant was extracted with methanol. The negative ion spectrum of the extract featured a large ion at $m/z = 325$ amu. An exact mass experiment was carried out to verify that this ion was originating from Sodium Dodecylbenzene Sulfonate.

An acetonitrile extract obtained from the commercial adhesive was analyzed for surfactants by positive ion FT/MS. The extract's spectrum showed a nice series of peaks centered around 450 amu. An exact mass experiment was carried out to verify that this series was originating from an ethoxylated octyl phenol.

Direct laser desorption FT/MS appears to be a very effective way of analyzing for low and middle molecular weight surfactants. FT/MS is quick relative to NMR or HPLC, works on a broad range of surfactants and has the capabilities to positively identify unknown surfactants. Molecular weight distributions of unknown surfactants can be determined in seconds. The main disadvantage of laser desorption FT/MS appears to be fragmentation of high mass surfactants. Even with this disadvantage, which may be minimized in the future by MALDI, most surfactants appear to be very amenable to FT/MS analysis.

Title: Using phosphate and citrate buffers in online CE/MS: Trials and tribulations

Author 1: Andy Craze^{2,1}

Author 2: Andries Bruins¹

Institute 1: University Centre for Pharmacy, State University, A. Deusinglaan 2, 9713 AW Groningen, The Netherlands

Institute 2: University of Wales, Swansea, Singleton Park, Swansea, SA28PP, U.K.

CE/MS is a relatively new technique which promises to have much application to the worlds growing analytical demands. As separate entities, Capillary Electrophoresis, and especially Mass Spectrometry, have been well researched and documented. Coupling of the two is a relatively recent development in terms of analytical methods, and has therefore had less opportunity to be mastered.

If Mass Spectrometry is to be used for 'detection', then it must be compatible with the CE requirements placed upon it. Hence the interfaces designed have taken into account the need to 'ground' the CE outlet to the MS source, and with some ingenuity utilised the extra make-up flow needed for electrospray ionisation to provide the electrical contact to the outlet electrode. One area where compatibility has come into question is the composition of the CE buffer entering the MS source. To date most of the published literature deals with CE systems using only acetate or formate buffers, and while many separations are achievable using these, much of the offline work has been conducted using phosphate, borate and citrate buffers. These buffers are seen to be too dirty for online use, and predicted to block or clog-up the ion path in the source. The integrity of some separations suffers greatly on changing to the so called 'MS friendly' acetate and formate systems, and in some cases, co-elution, or partial reversal of elution order is seen. This being the case there is strong reason to attempt using phosphate and other buffers online.

Using formate as a reference system we investigated the use of phosphate and citrate buffers for CE/MS, using a source built in-house, and utilising a 'gas curtain' system, in which nitrogen gas is forced to flow out of the sampling orifice, hence preventing neutrals and salts from entering the source. Due to time considerations the choice of sheath (make-up) liquid composition was kept to a set solvent mixture in which the electrolyte concentration was varied. As ions have been reported to migrate into the CE column, from the sheath liquid, the electrolyte ions in the sheath

liquid were kept analogous to those of the CE buffer being investigated, e.g. Phosphoric acid for a phosphate buffer, citric acid for citrate buffer. The concentration of ions in the sheath liquid was found to have a profound effect on the data collected by the mass analyser, and the effect on sample intensity for both the amine, and quaternary ammonium ion studied were recorded. The abundance of sample ion signals obtained were of the same order of magnitude in the phosphate and citrate systems, as in the formate system used as a reference. The gas curtain source was found to be effective protection against the CE buffers and the sheath electrolytes used, and the transmission of ions from the source to the mass analyser was not a problem for in excess of a four month working period.

In order to gain greater insight into the effect of changing conditions within the system, a MacLab data acquisition module was employed to monitor CE current, atmospheric lens plate current, and the skimmer current. These signals proved invaluable in determining factors such as spray stability.

A highly unexpected phenomenon observed was the drift in CE current during CE/MS runs with citrate buffer and citric acid sheath liquid. CE migration times were found to alter with the concentration of acid used in the sheath electrolyte. The suspected cause of these changes in results is thought to be interaction between the CE buffer and sheath liquid, giving rise to amigration of ions into the CE capillary, and a scheme for this process has been suggested. Ion abundance varied from day to day, even for identical experiments, and a strong dependence was associated with the condition of the CE tip.

We conclude that phosphate and citrate systems can be used, but that the chemistry in the interface is poorly understood. CE/MS works well in one-off experiments, but highly reproducible operation is still beyond our reach.

Mass Spectrometry of Small Molecules Separated by Capillary Electrophoresis

Thomas E. Wheat¹, Kim A. Lilley¹, and J. Fred Banks²

¹Thermo Capillary Electrophoresis, 8 Forge Parkway, Franklin, MA 02038

²Analytica of Branford, 29 Business Park Drive, Branford, CT 06405

The combination of capillary electrophoresis with mass spectrometry should provide a useful analytical tool. Separations by CE generally give high plate counts with different selectivity from GC or HPLC. Its low flow rate is suited for introducing samples into the MS. It is also more tolerant of complex or "dirty" samples than the chromatographic techniques. The MS enhances the utility of CE with structural information to confirm peak purity and identity. It should also have the sensitivity required for the small volumes characteristic of CE. While the coupling of CE and MS presents several physical, electrical, and chemical problems, the technique has been successfully applied in many laboratories. Recently, routine application has become possible with commercial CE adapters, based on the use of a sheath liquid, for all the common electrospray interfaces. Some CE systems are compatible with such adapters. Chemical problems remain. CE separations use a wide range of buffers, often at high ionic strength. Surfactants are often incorporated to enhance selectivity, particularly for uncharged analytes. Many such methods can not be used with MS since ESI requires low ionic strength volatile buffers in a low surface tension liquid. Further, it has been shown that mismatches between the CE buffer and the sheath liquid can distort the separation. Further, chemical noise is a more significant problem with low molecular weight analytes than with proteins and peptides. The present study focuses on the interaction of CE separation chemistry with ESI. The effect of the sheath liquid on sensitivity is tested. The development of CE buffers is shown. The technique is applied to basic drugs in both pharmaceutical preparations and biological samples. Negative ESI is applied to singly and multiply charged species.

The sheath liquid was optimized physically and chemically. A four-fold increase in flow rate reduces the response by only a factor of two. Since useful adjustments are much smaller than this range, they can be used to stabilize the spray without compromising sensitivity. Conventionally, the sheath is an alcohol-water mix with acetic acid to meet the requirements of low surface tension, conductivity, and low ionic strength. With pure methanol as the sheath, the response for peptides was good, demonstrating stable spray and yield of positive ions. Acetic acid in the sheath degraded sensitivity because of chemical noise derived from the acid. Sensitivity is restored by restricting the scan range to include the peptides and exclude the noise. This approach is not a viable strategy, particularly for small molecules. The 100% methanol sheath was, therefore, used for all further experiments. Many parameters can be used to develop a CE separation of a peptide mixture. However, the constraints of ESI have restricted most studies to minor adjustments of pH in the range of 3-5. More dramatic changes in selectivity are obtained by using ammonium acetate at pH 4.6

and ammonium bicarbonate at pH 10.4. Usable yields of positive ions are obtained even at the high pH.

A CE separation was developed for the active ingredients in a mixture of cough syrups. Full resolution of these basic drugs required a pH of 9.2, 100mM ammonium bicarbonate. The basic drugs were well-resolved and gave good signal. Guaifenesin, a neutral drug, and acetaminophen, an anion in solution, were both detected as M+1 positive ions.

A human urine sample was collected after a single pseudoephedrine dose. The urine was diluted with water and directly analyzed by CE-ESI-MS without further sample preparation. Both pseudoephedrine and phenylpropanolamine, its major metabolite were detected.

Negative ionization electrospray has generally proven more difficult to implement and less sensitive than the positive mode. Alkyl sulfonates surfactants are generally a difficult analytical problem because of detectability and because they form aggregates at modest concentrations. The separation of a C1-C10 + C12 series by CE is shown as the negative ion TIC (Figure 1) and the RIC's for the eleven individual masses show that they are symmetrical peaks with no evidence of aggregation.

A mixture of commercial food colorings was selected as a model for analytes with multiple negative charges. This set of compounds gives easily interpreted mass spectra following the CE separation (TIC in Figure 2). The yield of alternative charge states depends on the chemical structure. The partially charged ion corresponds to protonation. There is no evidence of sodiated or ammoniated species.

CE-ESI-MS can be easily implemented with commercial components. Small adjustments in sheath flow rate do not compromise sensitivity. A simple sheath liquid of 100% methanol is preferred for many samples. Methods development does not require reformulation of sheath liquid. Basic drugs can be identified from CE at high pH and ionic strength. Drugs and metabolites in urine are identified with minimal sample prep. Anionic surfactants can be separated and identified with negative ESI. Multiply charged species give distinctive negative ion spectra.

CAPILLARY ELECTROPHORESIS / MASS SPECTROMETRY FOR THE ROUTINE ANALYSIS OF ORGANIC ACIDS

Jim Scrivens, Nick Cotton, Steve Rumbelow, Mike Taylor, Hilary Yates
ICI Research and Technology Centre, PO Box No 90, Wilton, Cleveland, England, TS90 8JE

Introduction

Capillary electrophoresis (CE) in its many modes is currently experiencing one of the largest growth areas in analytical science. CE is capable of rapidly separating charged compounds with efficiencies of up to orders of magnitude greater than high performance liquid chromatography (HPLC). One of the limitations of the technique is that the small capillary volumes employed restrict the quantities of materials that can be analysed. Only picograms of material are typically used which in turn presents problems for detection, particularly if high degrees of sensitivity are required such as for the determination of trace levels of compounds in food simulants. The use of mass spectrometry (MS) for detection provides this technique with the capability to detect and quantify trace (ppb) levels of known compounds as well as identifying unknowns. The utility of a combination of current commercial instruments to provide routine reproducible results for the analysis of a series of organic acids has been evaluated. Organic acids are important components in a number of industrial formulations which are often present as building blocks or as part of catalyst systems. A number of these acids need to be analysed at trace (50 ppb) levels as a result of regulatory legislation. The formulations in which they are found are themselves complex mixtures and the analysis presents considerable practical difficulties.

Experimental

The instrumentation used in this study was a Dionex CES1 capillary electrophoresis system coupled to a Platform quadrupole mass spectrometer (Micromass UK Ltd., Floats Rd, Manchester, England) fitted with an electrospray source and operated in negative ion mode. Connection was made via the commercially available triaxial probe using a make up flow of IPA/H₂O in a ratio of 4:1 at a flow of 10 µl/min. Gravity injection of the CE was used since it was found to provide good reproducibility. Conventional CE detection commonly employs UV, or if a chromophore is not present in the compounds to be analysed, inverse detection is used. Here a UV chromophore similar to the compounds in question is added to the system. These modes of detection do not always provide the selectivity and sensitivity required. The experimental setup of the inlet region is shown below:-

Figure 1 shows the CE-MS multiple ion recording trace obtained for a mixture of five organic acids of industrial relevance.

Figure 1
CE-MS trace for organic acid mixture

The sensitivity obtained is excellent, considering the small injection size, and the reproducibility and linearity of the data is good.

It is often required to analyse specific acids at low levels for regulatory reasons. Figure 2 shows the data obtained for octyl phosphoric acid which has the structure shown:-

Octyl phosphoric acid 68ppb

Figure 2
Single ion current trace for octyl phosphoric acid

This gives the required sensitivity and selectivity. A linear plot is obtained of response against injection time. In conclusion therefore we see that CE-MS provides a suitable analytical method for the determination of this compound class.

Analysis of Dyes by CE/MS

Lee W Tetler¹, P A Cooper² and B Powell³.

¹Sheffield Hallam University, Sheffield, UK. ²Zeneca Agrochemicals, Bracknell, UK. ³Zeneca Specialties, Blackley, UK.

Introduction

Many water soluble dyes used in the textile industry are relatively small aromatic molecules, usually with one or more ionic groups associated. We have shown¹ previously that CZE/MS can play an important role in many aspects of analysis within the field. One of the most obvious applications is the monitoring of effluents and dyebaths, especially in the current climate of environmental concern. However CZE/MS potentially offers an insight into more fundamental mechanisms that occur during the dyeing process. Two modified analogues from the indigo family were investigated and a reactive dye, Remazol Brilliant Blue R (reactive blue 19) was subjected to CZE/MS/MS.

Experimental

Data for the Indigo dye analogues was obtained using a Waters Quanta 4000 CE interfaced to a VG Quattro. The sheath liquid was 2-propanol/water (1:1) + 0.1% w/v NH₄OAc pumped at 10 µl/min. The CE buffer was 10mM NH₄OAc (pH 10) with 12.5% CH₃CN added. A 5s hydrostatic injection at 10 cm was made from a 500nmole/ml solution and the effective CE voltage was 242 V/cm. CZE/MS/MS was carried out on the reactive dyes using a home built CE coupled to a Sciex API 111. The sheath liquid was 2-propanol/water (1:1) + 0.1% w/v NH₄OAc pumped at 10 µl/min. 10mM NH₄OAc (pH 8.7) with 20% CH₃CN added was the CE buffer. A 2s hydrostatic injection at 10cm. was made loading 2.5ng. The effective CE voltage was 250 V/cm and the collision gas Ar with a target thickness of 4 X 10¹¹ atoms/cm².

Results

The molecular weights of the sulfonated dyes differ by 2 mass units (466Da and 468Da), hence the m/z values of the doubly charged (M-2H)²⁻ ions differ by only one mass unit. The summed ion chromatogram shows the dyes to be fully resolved with reasonable peak efficiencies.

The TIC trace (fig. 1) from the separation of the components in the aqueous solution of Remazol Brilliant Blue R shows two major peaks arising from the vinyl sulfone form and the native form of the dye. The two smaller peaks are impurities, the MS/MS spectra of which show no fragments which are typical of this type of dye. (As yet these compounds are still unidentified.) The hydroxide form of the dye elutes just before the vinyl sulfone but is not present in sufficient quantity to allow detection by this method. The peak widths and signal to noise ratio suggest a detection limit for these compounds in the mid to high femtomole range.

The MS/MS characteristics of the native dye have been reported previously² using LSIMS. The product ion spectra obtained from our CZE/MS/MS analysis are in good agreement with the literature, showing major fragment ions corresponding to the loss of SO₃, the loss of the sulfur containing side chain and the loss of SO₂. The fragmentation pathways are shown in figures 2 & 3. Each of the forms of the dye show at least three characteristic fragments, which would be adequate

for unambiguous identification of the dye from waste water etc. using multi-reaction monitoring techniques.

Conclusions

We have shown that CZE/MS and CZE/MS/MS provides useful information relating to textile dyes. The separation of the two closely related indigo dyes suggests that CZE/MS may be a suitable technique for the investigation of historical dyed textiles, however it must be taken into consideration that the original indigotin dye is uncharged (CEC/MS has been shown to be applicable to neutral dyes³).

The different species present in an aqueous solution of the reactive dye Remazol Blue have been separated and identified using CZE/MS/MS indicating the possibility of using the technique to investigate the mechanisms and processes involved during textile dyeing, or to environmentally monitor for the species.

COMPARISON OF MICROBORE LC/MS, CZE/MS AND CEC/MS FOR AGROCHEMICAL ANALYSIS

P. A. Cooper, K. M. Jessop and F. Moffatt, Zeneca Agrochemicals, Jeallots Hill Research Station, Bracknell, RG42 6ET, UK

Introduction

Regulators demand the identification of low levels of agrochemical residues through plant and animal metabolism studies. These often generate limited amounts of metabolites in a complex biological matrix. HPLC/mass spectrometry is usually the analytical method of choice because of its sensitivity and specificity. Ideally, high chromatographic separation efficiency and high absolute sensitivity are required. Microbore HPLC, CZE and CEC all offer improvements to MS analysis over conventional HPLC. Microbore LC/MS using 0.8-1.0 mm i.d. columns avoids the wasteful use of flow splitters so preserves precious samples. Analytes are eluted at higher concentrations therefore MS sensitivity is increased. Capillary zone electrophoresis (CZE) causes ions to migrate along an unpacked capillary using an electric field. Separation is effected by the differential electrophoretic mobility of the ions. Therefore CZE is inapplicable to mixtures of neutral species. Capillary electrochromatography (CEC) is a CZE/HPLC hybrid technique but is not yet routinely used. CEC uses a capillary filled with HPLC packing and separates by a unique combination of CZE and HPLC mechanisms. The flow of liquid through both CZE and CEC capillaries is electrically driven and is capable of producing extremely high separation efficiencies - at least an order of magnitude greater than HPLC. Peak volumes are smaller therefore sensitivity is increased.

Results/Discussion

HPLC methodology is firmly established. Scale-down from conventional-LC to microbore-LC is well understood. Microbore flow rates are directly compatible with MS so no special interface is required. Flow rates in CZE and CEC are of the order of nanolitres per minute. This is insufficient for commonly used electrospray ionisation inlets therefore an MS interface with an extra make-up flow is required which adds to the complexity of the system in comparison to HPLC. CZE is cost effective - no stationary phases are required. Selectivity is affected by altering the composition of the charge carrying buffer, by varying the pH, concentration and additives. Being neutral the phthalates could not be analysed by CZE. The pyrimidones on the other hand showed CZE separation efficiencies about 15 times greater than microbore-LC (200 000 theoretical plates compared to 1300, fig 1). Analysis of the phthalates by CEC showed efficiencies of about 30 times that of microbore-LC (300 000 theoretical plates compared to 1000, fig 2.). This verifies the anticipated advantage of electrically driven flow in both capillary techniques. Rapid analysis is a commonly quoted advantage of CZE and CEC. The phthalates were better resolved by CEC in less than 3 minutes (fig.3) than by HPLC in 20 minutes. However, interfacing CZE or CEC with MS requires longer capillaries but the voltage that can be applied has an upper limit. The field strength and flow through the capillary are therefore reduced, resulting in increased analysis times. Thus the separation of pyrimidones by CZE/MS took about 30 minutes, nearly double that of microbore-LC.

Analysis of Anions by CE-MS on a Magnetic Sector Mass Spectrometer

Albert J. Nitowski, Colin Moore, David W. Bairley, Areej A. Al-Mudamgha *

Uniroyal Chemical Co. Inc.
*Beckman Instruments Inc.

Introduction Surfactants have important significant roles as process aids in the manufacturing of industrial chemicals. This work focuses on the qualitative analysis of one complex anionic surfactant, the sodium salt of the formaldehyde polymer of naphthalenesulfonic acid (NSA-FP) to support previous quantitative CE data ^{♦1} Due to the hydrophilic properties of NSA-FP, CE is the method of choice over HPLC for the efficacious separation of these surfactant components. CE coupled to MS via Electrospray Ionization using a home-built triaxial probe employs a set of model compounds (peptides) to demonstrate CEMS probe efficiency. The use of these techniques on a Magnetic Sector allows the determination of analyte charge state (and resultant MW) and therefore aids in the structural elucidation of unknown anions. Mass resolutions up to 5000 have been demonstrated on a little as 300 pmole of sample. Our previous CE studies of NSA-FP employed PEG-coated columns and reverse polarity of electrodes (anode at detector) to negate electroosmotic flow and eliminate cations and neutral species. The Borate buffer used in that work was incompatible with mass spectrometry due to volatility concerns. Additionally, the larger anions did not migrate fast enough for reasonable experiment times without EOF. The Ammonium Acetate system used in this work relies on conventional fused silica column technology, normal polarity, and robust EOF to sweep all components into the mass spec. The mass spec is an advanced filtering device, discriminating between anions and cations with ease. Small modifications in sheath flow and applied CE power are employed to optimize specific experiments of unknowns. The high pH of this system ensures a robust EOF flow which effectively overcomes the natural tendency of the NSA-FP anions to migrate towards the anode (injector) due to their strong electrophoretic migration.

CE: METHODS Capillary Electrophoresis of NSA-FP was performed on a Beckman P/ACE 5500 with DAD, Cathode at the Detector Side. Conditions for the experiments are as follows. **5 Peptide Test Mix:** Column: 115 cm x 75u I.D x 375u OD Fused Silica, Electrolyte 1% Acetic Acid in Water, Conditions 25kV, grounded at MS. **NSA-FP Experiment:** Column: 88 cm x 50u I.D x 375 u O.D. Fused Silica, Electrolyte 15mM Ammonium Acetate in Water, pH=9.0; Conditions. 20uA, @ approx. 22kV, grounded at MS.

MS METHODS Kratos MS890-RFAQ Hybrid EBqQ Mass Spectrometer, Analytica of Branford ESI Source, CEMS Homebuilt probe

RESULTS

An acceptable separation of the 5 component mix after 21 cm of capillary migration is observed in the CE-UV e-gram. Reconstructed-Ion-Electropherograms (RIEs) of the advanced separation of components through the remaining 80 cm of column into the Electrospray probe gives good component separation and protonated molecular ions for each mixture component. Direct infusion of the NSA-FP standard mixture is preceded by a CE-UV separation experiment (Fig. 1). This separation displays suspect naphthalene sulfonic acid monomer separated from the bulk polymerized NSA-FP.

Figure 1

Figure 2

Direct infusion of the NSA-FP standard mixture results in complex multiple charge state clusters of the formaldehyde homologs in the negative ion ESI spectrum. Using these ions as markers, peak assignments in the CE separation are easily achieved. The CEMS Total-Ion-Electropherogram (TIE, Figure 2) is noisy but contains useful information. RIEs display distinct separation of major NSA-FP components. Raw data ESI mass spectra obtained from this experiment shows greater signal-to-noise than expected, >100:1. Oligomers of NSA-FP have been identified as follows:

	Anion (m/z)	Charge State	MW-Theory	MW-Observed
	213.0	2	426	426
	215.0	3	645	645
	216.0	4	864	864
	216.6	5	1083	1083

CONCLUSIONS. High and Low Resolution Mass Spec. data was obtained on model peptide mixture compounds to demonstrate the utility of a homebuilt triaxial sheath CEMS probe. Sensitivities to 2.8 pmole (low res., Bradykinin) were demonstrated. Lesser sensitivities were obtained at 5000 resolution, as expected (336 pmole). Practical application of the homebuilt triaxial probe was demonstrated on the surfactant, Naphthalene sulfonic acid, formaldehyde polymer by obtaining separation and identification of specific anionic components which comprise this material. Validation of the determination of NSA-FP in Waste Water by CE-UV was supported by this study, resulting in the efficacious testing of the surfactant for use in biodegradation studies and waste effluent monitoring.

Capillary Electrophoresis-Mass Spectrometry of Drugs and Metabolites in Biological Matrices

Lilley, K.A.¹, Wheat, T.E.¹, and J. Fred Banks²

¹Thermo Capillary Electrophoresis, 8 Forge Parkway, Franklin, MA 02038

²Analytica of Branford, Inc., 29 Business Park Drive, Branford, CT 06405

The high resolution separations of capillary electrophoresis analyses make the technique attractive for the assessment of drugs in clinical research studies, forensic specimens and pharmaceutical formulations. Samples of biological origin are, however, particularly challenging because of the complex matrix. Matrix interferences give rise to data uncertainties because of loss of peak resolution, migration time shifts, and comigration of analyte and matrix components. Difficulties with precise identification and accurate quantitation can occur.

Linking capillary electrophoresis with electrospray mass spectrometry would provide unequalled identification and enhanced detection. Further, the combination should often require simpler sample preparation than common LC or GC-MS procedures.

This technique is illustrated with a common clinical assay. In general, urine samples are screened for particular drugs with immunoassay kits. This screening yields a significant number of false positives. Confirmation by an independent test is, therefore, required. The capability of CE-MS for this purpose is tested here with urine samples containing amphetamine. Immunoassays for this drug are compromised by the presence of many pharmaceuticals, including over the counter cold relief medications. In this example, CE-MS is used to distinguish urine containing amphetamine from that with pseudoephedrine.

Separations were performed in a Crystal 310 system (Thermo Capillary Electrophoresis) using a pH 9.2 ammonium acetate buffer containing 25% methanol. The samples were introduced into the MS through an electrospray probe (Analytica of Branford) with 100% methanol as the sheath liquid. To enhance the signal-to-noise ratio and simplify the sample component identification, selected ions were monitored.

A fresh human urine sample was spiked with the standard mixture at the expected physiological limit of detection. The spiked urine was diluted four fold with water to reduce sample ionic strength. The TIC is similar to that of the standard in dilute electrolyte. A blank urine was spiked with amphetamine at 300ng/ml, the approximate limit of detection of standard immunoassays. Prior to analysis the spiked urine was diluted four fold with water to a final concentration of 75ng/ml. Amphetamine was identified.

A urine sample obtained from a self-medicating human cold sufferer after a single therapeutic dose of pseudoephedrine. The analysis confirms the presence of pseudoephedrine. A smaller amount of phenylpropanolamine, the primary metabolite of pseudoephedrine was also detected.

In conclusion, capillary electrophoresis separations can be readily interfaced with mass spectrometry detection using commercially available components. Selected ion monitoring gave better sensitivity and simpler total ion chromatograms in a challenging matrix. Drugs and their metabolites at therapeutic concentrations can be analyzed in urine without extensive sample preparation.

PRACTICAL CONSIDERATIONS: ANALYSIS OF DRUG/ XENOBIOTIC METABOLITES, PEPTIDES, AND PROTEINS BY CE-MS

L. M. Benson, A. J. Tomlinson, S. Naylor
Biomedical Mass Spectrometry Facility
Mayo Clinic, Rochester, MN, 55905 USA

In this work we describe a systematic approach for optimizing CE separation conditions as well as illustrate practical considerations of performing CE-MS and CE-MS/MS in the structural characterization of drug metabolite mixtures, adducted peptides, and modified proteins. Optimization in five main areas is discussed:

1.) CE-MS for ultimate sensitivity.

- A good electrical contact at the outlet of the CE capillary is needed.
- Position of the CE capillary within the ESI source is critical.
- Volatile salts in low ionic strength are used for the separation media.
- Minimize internal diameters of the CE capillary.

2.) Advantages of mPC-CE-MS.

- Membrane preconcentration CE-MS (mPC-CE-MS) incorporates the use of a membrane to allow large sample injection volumes.
- An impregnated membrane is inserted into Teflon between two adjoining segments of uncoated silica tubing which is connected at the capillary inlet. (Figure 1).
- Sample (1-200 μ l) can be loaded onto the membrane under pressure.
- The membrane can be washed with an aqueous buffer solution to remove unwanted salts and contaminants.
- The cartridge is connected to the CE capillary by PE tubing and the whole assembly is filled with separation media.
- Analytes are eluted off the membrane with organic solvent followed by a small volume of separation media.
- tITP and analyte stacking techniques can be used in conjunction with mPC-CE-MS to enhance recovery and resolution.

3.) Problems associated with CE-MS of small molecules.

- Closely related analytes can be separated by pH modifications.
- The resolution can be increased with higher ionic strength.
- Non-aqueous separation media can be used for hydrophobic molecules to increase recovery and detection.
- mPC-CE-MS can be used to concentrate low level analytes present in biological matrices.

4.) Problems associated with CE-MS of proteins.

- A coated capillary is needed to minimize protein-wall interactions.
- Less hydrophobic membranes (C4, C8) allow the use of protein amenable buffers for analyte elution in mPC-CE-MS.
- Ultra filtration devices can be used on-line (ex. Centricon MW filter) with protein buffers to eliminate all organic solvent in the elution buffer.

5.) mPC-CE-MS/MS optimization for peptide sequencing.

- The efficient removal of peptide from membrane necessitates 50-200 nl of elution buffer.
- tITP can be used in conjunction with mPC-CE to increase resolution.
- Smaller internal diameters of the CE capillary improve ESI-MS sensitivity.
- Optimize collision gas pressure and composition.
- Reduce resolution in MS₁ to allow greater transmission of ions for sequencing.
- Reduce the acidic nature of acid functional groups by esterification to minimize the negative effects observed in positive mode and collision cell fragmentation processes.

Charge Concentration for High Sensitivity ITMS Detection of Biopolymers

R.S. Ramsey, D.E. Goeringer, and S.A. McLuckey
Chemical and Analytical Sciences Division
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365

The electrospray ionization of high mass biopolymers typically results in the formation of multiply-charged ions with a distribution of charge states. The ion current that is spread over this range may be focussed into a single mass using gas-phase proton transfer reactions. Multiply-charged protein ions, for example, readily transfer protons to strong neutral bases producing a singly-charged base. Detection limits for targeted compounds may be significantly improved as a result of this charge concentration. Results obtained to date indicate that the concentration limits of detection for some proteins may be improved by up to two orders of magnitude and that mass detection limits are in the low attomole range.

Experiments were performed on a Finnigan Mat ITMS modified for electrospray ionization (1). The base, 1,8-bis(dimethylamino)naphthalene or "proton sponge" [MW = 214, $-\Delta G^\circ$ 242 kcal/mol (2)] was admitted into the vacuum system with a leak valve to a pressure of ca. 1×10^{-7} Torr. Ions were introduced for periods ranging from 100 to 300 msec, subjected to a desolvation ramp, and then reacted with the base for 100 to 300 msec. Resonance ejection was used to extend the m/z range by a factor of six. Protein samples were either continuously infused through the electrospray source or introduced by an injection valve with a 1 μ L sample loop into a stream of solvent flowing at 2-3 μ L/min.

Figure 1 shows a typical ES mass spectrum obtained for an 8 μ M solution of myoglobin. The charge states, ranging from +15 to +9, are clearly evident although at lower concentrations of the protein (i.e., 0.08 μ M) the charge states can no longer be detected above background. The spectrum resulting after proton sponge was allowed to react with the ions from a 0.08 μ M myoglobin solution is also shown. An intense signal for the protonated base that is ca. 35 fold greater than the background signal from the sample solvent is obtained, indicating that low nanomolar levels of the protein may be detected in continuous infusion experiments. In another example using flow injection analysis shown in Figure 2, albumin could not be detected in either the extracted or total ion chromatograms at 0.16 μ M levels although signals for the protonated base are readily apparent following a charge focussing reaction with the proton sponge. To retain some selectivity, since mass information is lost in this type of experiment, ions that do not fall within specified, narrowly-defined m/z windows that correspond to certain charge states of the targeted biopolymer, may be ejected prior to the reaction period. This may be accomplished using tailored waveforms or filtered noise fields (3).

Pharmaceutical Applications of CE/MS for Structural Determination of Peptide Mixtures

Stephen Chan*, Barbara Armstrong, David Burinsky and Alan Oyler
Analytical Research & Development, R. W. Johnson Pharmaceutical Research Institute,
Raritan, NJ 08869 USA

Capillary electrophoresis (CE) has gradually been recognized as an important technique in separation science. For the most part, the mechanism for CE separation is very much different from that for the conventional liquid chromatography (HPLC) separation. In general, CE requires less sample consumption and provides better separation efficiency than HPLC. The solvent consumption in CE is only a tiny fraction that in HPLC. It also often provides additional information which is not obtainable by HPLC. Clearly, the two separation techniques are complementary to each other.

With the coupling between HPLC and mass spectrometry (MS) becoming a routine technique for many pharmaceutical applications, interfacing CE and MS would greatly enhance the analytical power and usefulness of CE. On-line CE/MS allows CE separated components to be identified by a mass spectrometer without the need for collecting each component individually. With CE coupling with tandem mass spectrometry (MS/MS), detailed structural information for all the separated components can also be obtained within a single CE run. The major hurdle for a successful CE/MS interface is the compatibility between the CE buffer electrolyte and the electrospray ionization (ESI) source of a mass spectrometer. Generally, commonly used CE buffers such as phosphate and borate are not compatible with ESI. More volatile buffers such as ammonium acetate or formate are often used as substitutes for CE/MS so that stable mass spectrometric signals can be maintained. These substitutes may, sometimes, compromise resolution for certain separations. However, with on-line CE/MS, the demand for resolution is less stringent as even closely overlapped components could be identified by MS.

In our research work, we explored the use of CE/MS and CE/MS/MS to analyze peptide mixtures of pharmaceutical interest. These mixtures were derived from different degradation studies. We used 5 mM of ammonium acetate in 1% of acetic acid (pH=2.8) as the CE buffer for our analyses. Although we have found that using higher concentration of ammonium acetate would enhance peak resolution for the separation of our peptide mixtures, the higher concentration also considerably lengthens the migration time for all the components. At 20 mM of ammonium acetate, it would take over 2 hours for the last component to be eluted from the column. Such a lengthy separation would not be so practical for MS as it would create tremendously amount of mass spectrometric data.

Figure 1 shows the CE/MS electropherogram for one of the peptide mixture derived from a degradation study. All the six expected components are at least partially separated in this analysis. The mass spectrometric electropherogram clearly shows a somewhat greater component resolving power than the UV electropherogram because the end of the CE column is about 55 cm further away from the UV window. After the components passing through the UV detector, they are still subjected to further separation by the continuous electro-osmotic force applied to the system until they reach the ESI source of a mass spectrometer. With on-line CE/MS/MS using a triple quadrupole mass spectrometer, detailed structural information was also obtained for all the components within a single 50 minutes CE run.

**Attomole Sensitivity Protein Characterization by
Picospray-CE/ESI Tandem FTMS**

Gary A. Valaskovic, Neil L. Kelleher, and Fred W. McLafferty, Department of Chemistry,
Cornell University, Ithaca, NY 14853

Capillary electrophoresis (CE) is an efficient separation method capable of handling biochemical mixtures in the picoliter range, a level suitable for single cell analysis [1]. CE, however, lacks a detection system combining high chemical specificity with sufficiently wide chemical applicability. As a result, most CE analysis are targeted compound methods yielding limited information as to chemical structure/function/reactivity; direct unknown analysis is generally not possible [1]. MS offers suitable specificity, but detection limits are generally 3-6 orders of magnitude higher than optical or electrochemical methods, typically in the femtomole/sub-femtomole range. High mass resolution Fourier transform ion cyclotron resonance mass spectrometry (FTMS), results in the nearly ideal CE detector [2], and even more so when combined with improved sensitivity "micro" electrospray (ESI) sources [3,4].

We have developed a method to integrate ESI tips, capable of flow rates below 1 nL/min, directly with small bore (5 μ m i.d.) fused silica CE columns. The column is first coated with 3-aminopropyltrimethoxysilane [2] to generate a positive electroosmotic flow for ESI compatibility. Tips are formed by pulling the column at one end in a specially modified pipette puller [4], followed by chemical etching with HF, taking care to prevent HF from entering the column; the 1-5 μ m i.d. tips are then coated with gold via vacuum sputtering. The direct coupling of the low flow rate ESI tip with the capillary column generates a zero dead volume system that does not require secondary liquid sheath flow.

Figure 1 shows a total ion electropherogram (from a Faraday ion collector) and nozzle-skimmer mass spectra (FTMS at 6 T), from a subsequent identical CE injection, obtained from a mixture of bovine ubiquitin (U), bovine carbonic anhydrase (CA) and equine cytochrome c. The amount of CA injected electrokinetically was 9 ± 2 attomole (10^{-18} mol), taking care to eliminate hydrodynamic sampling errors [5]. The high signal-to-noise (S/N) combined with resolving power $>10^5$, provides for the accurate determination of molecular weight (M_r , calculated (*)), most abundant ^{13}C values shown) to better than 5 ppm at 29 kDa and allows the confident assignment of five b_n and four y_n fragment ions, with S/N as low as 2:1. The fragmentation data provides sufficient information for identification from sequence databases using protein sequence tags [7]. The vast improvement in sensitivity provides a sub-attomole detection limit (Figure 2) with a S/N of 3:1 for 0.9 amol of U and 4:1 for 0.7 amol of Cy obtained from a single CE injection; CA was not observed. Accurate M_r values are still obtainable (<35 ppm error) with external calibration.

Direct Analysis of Cellular Components by CE- FTICR MS

*Steven A. Hofstadler¹, Joanne Severs¹, Frank D. Swanek², Andrew G. Ewing², and Richard D Smith¹

¹Macromolecular Structure and Dynamics Group, Pacific Northwest National Laboratory Richland, WA 99352

²Dept. of Chemistry, The Pennsylvania State University, University Park, PA 16802

Recent results with on-line capillary electrophoresis (CE) electrospray ionization (ESI) Fourier transform ion cyclotron resonance (FTICR) mass spectrometry suggest that CE-ESI-FTICR can provide a powerful technique for micro-sample analyses owing to the inherent sensitivity of the technique and the enhanced information content derived from high performance mass measurements. Using micro-sampling methods, a 'sheathless' CE-ESI-MS interface and ion accumulation techniques based on quadrupolar excitation, we demonstrate that adequate sensitivity exists to characterize the hemoglobin from a single human erythrocyte (≈ 450 amol)(1). In these studies mass spectra with average mass resolution in excess of 45,000 (FWHM) were obtained for both the α and β chain of hemoglobin following in-column lysing of a single erythrocyte.

Shown in Figure a) is a spectrum acquired during the elution of the lysate from a single human erythrocyte, in which species corresponding to both the α chain (average MW = 15,126 Da) and the β chain (average MW = 15865) of human hemoglobin are evident. While the molecular ions are dispersed over multiple species due to sodium and other cation adduction, signal-to-noise ratios in excess of 13:1 are observed for the unadducted molecular ions; the average resolving power is in excess of 45,000 (FWHM). Both the α and β chains are present in this single scan mass spectrum owing to the limited resolution of the CE separation and relatively long ion injection interval. Species known to be present in erythrocytes at low abundance, such as carbonic anhydrase at ≈ 7 amol/cell, were not observed. Implementation of CE separations giving better separation efficiency should be feasible with future optimization of trapping conditions (e.g., the average ion kinetic energy, trapping potentials, QE amplitude, and buffer gas pressure). Improved separations would also increase sensitivity since more of the analyte would elute during the trapping/accumulation interval. These studies suggest that significant improvement in ionization duty cycle could be obtained with the implementation of a dual cell arrangement.

In some cases, the low abundance of specific analytes presently preclude direct analysis of them from individual cells. In such instances a population of cells, or cell extracts, must be pooled to provide detectable quantities. Additional on-line pre-concentration is then a prerequisite to successful mass spectrometric characterization. A number of microcapillary-based preconcentration schemes, particularly those based on capillary isotachopheresis and capillary isoelectric focusing, appear to be well suited to provide the necessary degree of enrichment or concentration. A distinct advantage of capillary isoelectric focusing is that ampholyte mixtures are commercially available which cover numerous pH ranges. Because an ampholyte can be selected which will focus only those species possessing a narrow range of isoelectric points, CIEF has the potential to focus analytes from a complex mixture (e.g. a cellular extract) with a high degree of specificity.

Figure b) shows an example of CIEF of ≈ 700 nL of a 1% solution of whole blood in 20 mM NH₄OAc. A pH 5-7 ampholyte mixture was employed to preferentially focus carbonic anhydrase (pI = 6.63). The primary peak observed on scans 20 to 60 corresponds to the α and β chains of hemoglobin (pI = 6.9) while the smaller peak observed on scans 85 to 95 corresponds to carbonic anhydrase as shown in the inset.

While sheath-flow CE-ESI interface was used in these CIEF studies to facilitate efficient ionization of the ampholyte/analyte solution, we have recently developed a CE-microESI-MS interface based on a dialysis-tubing junction which appears to combine favorable features of both the sheathless and sheath-flow CE-ESI interfaces (2).

AN INVESTIGATION OF PHYSIOLOGICALLY DERIVED FLUIDS USING A NEW MICROSPRAY cIEF-MS SYSTEM IN THE PRESENCE OF ISOTONIC SALT CONCENTRATIONS.

Nigel J. Clarke¹, Kenneth L. Johnson¹, Andy J. Tomlinson¹, Daniel P. Kirby², Barry L. Karger² and Stephen Naylor^{1,3}.

¹ Biomedical Mass Spectrometry Facility and Dept. of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN 55905 USA, ² Mugar Building, Barnett Institute, Northeastern University, Boston, MA 02115, USA, ³ Biomedical Mass Spectrometry Facility, Dept. of Pharmacology and Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN 55905, USA.

Introduction

The purpose of this investigation was to demonstrate the use of capillary isoelectric focusing (cIEF) to separate and detect complex biological mixtures containing isotonic salt concentrations. This was accomplished on-line using a simple alteration in the cIEF focusing procedure which allowed the gentle removal of the salt automatically.

To this end both cIEF with ultraviolet (cIEF-UV) and mass spectral (cIEF-MS) detection using coated capillaries were applied to standard samples doped with high salt concentrations (200mM) as well as direct examination of human cerebrospinal fluid with no prior workup.

Desalting Methodology

Capillaries were coated in house using a variant of the technique described by Schomburg¹. This coating was of the permanent type and was effected with polyvinyl alcohol.

The desalting procedure was applied as follows:

1. A coated capillary with extremely low EOF is required. This was provided by the PVA coating.
2. The applied desalting voltage was ramped slowly and the current at no time allowed to rise above 15 μ A (This was found to be the highest current at which good peak shape can still be attained). A typical ramp for 100mM NaCl concentration solution was 12kV DC maximum reached over 5 minutes.
3. Once the current steadied it remained approximately constant for a period of time as the salt was removed electrostatically, and then dropped extremely sharply. This was the point at which the majority of the salt had been removed and the beginning of analyte focusing.

Figure 1 shows sample data obtained from a protein mix doped with 200mM sodium chloride. This sample was desalted on-line as described above and then analysed using cIEF-MS.

Conclusions

- cIEF is a very valuable separation technique allowing complex biological mixtures to be resolved and identified easily and quickly on-line.
- Due to the new desalting technique described here the minimum of sample preparation is required, allowing physiological fluids to be examined directly.
- The process of cIEF concentrates the compounds on-line, aiding in the detection of low concentration compounds within complex mixtures.
- cIEF-UV allows cheap and quick examination of samples and is easily automated. cIEF-MS is more complex and time-consuming but allows real-time identification of separated compounds and the possibility of tandem MS for greater structural information.

Figure 1. Example of cIEF-MS data gathered from protein mix originally containing 200mM sodium chloride

CERAMIDE PROFILING OF COMPLEX LIPID MIXTURES BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY

Ming Gu[†], Julian Watts[†], James Kerwin^{*}, and Ruedi Aebersold^{†,1}

Departments of [†]Molecular Biotechnology, Box 357730, and ^{*}Botany, Box 351330 University of Washington, Seattle, WA 98195

Ceramides, cerebroside and related lipids such as sphingomyelin and glycosphingolipids mediate diverse biological processes. These compounds are characterized by N-acyl fatty acids linked to sphingoid (long-chain amino alcohols) bases. Direct observation of the qualitative and quantitative changes in cellular ceramide composition induced by agonists has previously been impractical due to the absence of analytical methods with sufficient sensitivity and selectivity. Here we present the first description of a technique with sufficient resolution and sensitivity to characterize individual ceramide species derived from small quantities of biological material.

EXPERIMENTAL: Ceramide standards were obtained from Sigma. Cerebroside from *Aspergillus fumigatus*, a human fungal parasite, were provided by E. Bergter. Jurkat T cells were grown in a modified RPMI 1640 medium. Lipid samples in 5 mM ammonium acetate in CH₃OH were analyzed using either a triple-quadrupole Sciex API III instrument or a Finnigan MAT model TSQ 7000. For the API III, samples were infused into the electrospray source via a 50 μ m i.d. fused silica transfer line using a Harvard Apparatus pump at 2-3 μ l/min. Positive ion ESI-MS and ESI-MS/MS used an orifice voltage from 40 to 90 volts. The interface temperature was maintained at 52 $^{\circ}$ C. For the TSQ 7000, a sample flow rate of 3 μ l/min was delivered by a Harvard apparatus, and analysis was performed at a capillary tube temperature of 200 $^{\circ}$ C, an electrospray potential of 4.5 kV, a sheath gas pressure of 45 psi and a collision gas pressure of 1 mtorr. Precursor ion scan experiments were done by selecting the third quadrupole for a fixed m/z value (e.g. 264) while scanning the first quadrupole at with a mass step of 0.1 Da and 0.14 ms/step.

RESULTS AND DISCUSSION: Product ion spectra of a C6 (Figure 1) and other ceramide standards demonstrated that sphingosine-containing species were characterized by product ions at m/z = 264 and 282. Ceramides with dihydrosphingosine moieties produced characteristic ions at m/z = 266 and 284. *Threo* and *erythro* isoforms gave identical product ion spectra. These characteristic fragmentation patterns were found for ceramides with fatty acyl moieties ranging from 2 to 24 carbons in length, as well as for complementary cerebroside. Modification of the sphingoid headgroup, e.g. by hydroxylation or introduction of double bonds or methyl groups, or the presence of hydroxy fatty acids, produced quite different spectra (Figure 2). ESI-MS/MS of the cerebroside *N*-2'-hydroxyoctadecenoyl-1-*O*- β -D-glucopyranosyl-9-methyl-4,8-sphingadiene produced a range of product ions, notably at m/z = 276, 280 and 294. By performing precursor ion scans for m/z values of 264 and 266, ceramide and dihydroceramide MS signals were distinguished. We were able to detect a C2:0 ceramide standard via precursor ion scanning at concentrations as low as 25 nM. We characterized, by precursor ion scanning, ceramide species present in a commercial ceramide preparation. Full ESI-MS spectra in the mass range in which naturally occurring ceramides are expected (m/z = 500-670) showed numerous peaks with $[M+H]^+$ values compatible with ceramides, along with complementary peaks of variable intensity ($[M+H]^+ - 18$) due to loss of a water molecule. Precursor ion scanning at m/z = 264 was used to identify the major ceramide species in the mixture (Figure 3). Comparable profiling was possible using a lipid extract from less than 10⁶ human T-cells. It is now possible to detect, identify and follow the metabolism of these physiologically important molecules at the cellular and subcellular level.

Identification of ceramides and dihydroceramides using derivatization and HPLC/APCI-MS

National Center for Toxicological Research, U.S. Food and Drug Administration, Jefferson, AR USA 72079

INTRODUCTION

The *Fusarium* species of fungi grow on many different plants around the world, yet are found predominantly on corn. Episodes of elevated *Fusarium* species growth have been correlated with outbreaks of equine leukoencephalomalacia or porcine pulmonary edema. Recently the presence of the fungi have been associated with areas of high incidence of human esophageal cancer. The predominant mycotoxins associated with these fungi are the fumonisins, the most abundant being fumonisin B₁. Fumonisin B₁ has been shown to directly cause equine leukoencephalomalacia. We and others have shown in *in vitro* and *in vivo* mechanistic studies that fumonisin B₁ interrupts cellular biosynthesis of sphingolipids, a group of biomolecules responsible for cellular membrane integrity, membrane receptor function, and growth and differentiation. The inhibition of ceramide synthetase results in the accumulation of sphinganine, and decreased ceramides and complex sphingolipids. Ceramides are critically involved in the signalling of cellular apoptosis, and adequate methods for their quantitation do not exist. As part of our studies to determine the mechanism of fumonisin B₁-based cellular apoptosis, we have developed HPLC-based methods for ceramide identification and quantitation. In this report, we have compared methods for separation of non-derivatized ceramides using reversed-phase HPLC with APCI-MS detection, perbenzoyl-ceramides using reverse-phase HPLC with UV-VIS and APCI/MS detection, and FMOc-ceramides using reverse-phase HPLC with fluorescence and APCI/MS detection.

EXPERIMENTAL

Individual ceramides and a ceramide mixture (bovine brain) were obtained from Sigma (St. Louis, MO). HL-60 cells were obtained from American Type Culture Collection (Rockville, MD) and cultured at 37°C in a humidified incubator (5% CO₂) in RPMI-1640 medium (GIBCO, Grand Island, NY) supplemented with 20% heat-inactivated (55°C, 30 min) fetal bovine serum containing penicillin and streptomycin. The cells were removed from plates with trypsin, and centrifuged for collection. Ceramides were extracted from the cells with chloroform:methanol (2:1) and chloroform. Dried ceramides were reconstituted in acetonitrile and separated on a Beckman 5 µm Ultrasphere C₁₈ column (4.6 x 150 mm) using 2.5% tetrahydrofuran in methanol (1 ml/min). The ceramides were detected with a VG Platform II MS (MicroMass) using APCI mode. Dried ceramides were also perbenzoylated in 0.5 ml of pyridine:benzoyl chloride (9:1) at 70°C for 3 hr. The reaction was stopped by the addition of water (22°C, 30 min). The ceramides were extracted into hexane following the addition of 5% sodium bicarbonate. The benzoylated ceramides were separated on a Phenomenex 5 µm IBSIL C₈ column (4.6 x 150 mm) using methanol:acetonitrile (49:51) at 1 ml/min. Benzoylated ceramides were detected using UV-VIS detection (230 nm), and by APCI/MS as described above. Ceramides were derivatized with 0.25 ml 9-fluorenylmethyl chloroformate in acetonitrile (10 mg/ml) at 50°C for 30 min. The reaction was stopped by the addition of 0.25 ml water, and the FMOc-ceramides extracted into hexane following addition of 5% sodium bicarbonate. The FMOc-ceramides were separated on a

Beckman 5 µm Ultrasphere C₁₈ column (4.6 x 150 mm) using 2.5% tetrahydrofuran in methanol (1 ml/min). FMOc-ceramides were detected with fluorescence detection (Ex. 263, Em. 313 nm), and APCI/MS as described above.

CONCLUSIONS

- (1) Non-derivatized ceramides were separated using reversed-phase HPLC (RP/HPLC), with APCI/MS detection. In HL-60 cells, the primary ceramides identified were N-(palmitoyl)-sphingosine and N-(nervonyl)-sphingosine.
- (2) Benzoylation of each ceramide results in the generation of tris-benzoyl derivatives. N-(Palmitoyl)-sphingosine and N-(nervonyl)-sphingosine were detected as the primary ceramides in HL-60 cells.
- (3) The FMOc derivatization of ceramides affords high sensitivity in detecting derivatives. Although this technique results in mono-FMOc derivatization of the ceramides, the formation of isomeric derivatives complicates separation. FMOc derivatives of N-(palmitoyl)-sphingosine and N-(nervonyl)-sphingosine were detected in the HL-60 cells; however, quantitation was not reliable due to changing derivatization (isomerization) pattern.
- (4) New techniques are being developed to allow more consistent derivatization of ceramides with fluorescent compounds, allowing quantitation of fmol levels of ceramides.

Figure. RP-HPLC separation of benzoylated N-(palmitoyl)-sphingosine, N-(palmitoyl)-sphinganine, and N-(nervonyl)-sphingosine. The derivatives were detected by UV-VIS absorbance at 230 nm (upper left), and by APCI/MS, with TIC shown in lower left panel. The corresponding mass spectra of N-(palmitoyl)-sphingosine (8.0 min) is shown in the upper right panel, N-(palmitoyl)-sphinganine (8.7 min) in middle left panel, and N-(nervonyl)-sphingosine (15.7 min) in lower right panel.

MALDI-FT-MS OF FULLY BLOCKED GLUCURONIDES AND GLUCOSIDES OF STEROIDS AND BILE ACIDS

Jan St. Pyrek, Jiangao Song, and Harry E. Hadd; University of Kentucky Mass Spectrometry Facility & Division of Medicinal Chemistry, College of Pharmacy, Lexington, KY 40506-0286

Attachment of metal ions is commonly encountered in positive FAB and MALDI either due to the contamination of a matrix or, most frequently, due to difficulties in the sample purification. Propensity of certain compounds to form $M(\text{Metal})^+$ ions, even at 'zero' salt concentrations, can complicate spectral patterns by adding multiple ions to the 'expected' MH^+ ion. On a contrary, since early days of FAB-MS, purposely added salts have been successfully utilized especially for the characterization of natural products.

For many years, our interest is focused on the identification and structure elucidation of bile and steroidal acids and their metabolites. In this area, glucuronides and more recently recognized glucosides of C_{24} bile acids (BA) play especially important role. For example, in addition to the well recognized hydroxyl-attachment ('O-glucuronides'), we have been able to demonstrate the formation of glucuronides attached at a carboxyl group. Metabolic formation of such glucuronides is especially significant for the short side chain steroidal acids and may even lead to di-glucuronides. Carboxyl attached glucuronides ('C-glucuronides', ester bond) are relatively unstable and their chemical synthesis is troublesome. Consequently, for a more universal characterization we utilize derivation of natural and metabolic glucuronides and glucosides by methylation and acetylation. These compounds can be directly compared with blocked standards prepared by the Koenigs-Knorr reaction. This well established method utilizes acetylated sugar α -bromides and partly blocked aglycones and leads to fully protected products. Alternatively only partly blocked aglycones can be used if some site-selectivity can be expected. Although for hydroxyl-attached glucuronides the removal of methyl and acetyl groups and glucosides is feasible, it can not be applied to 'carboxyl-attached' isomers due to instability of an ester bond. Importantly, if compared to free conjugates, the complete derivation enables much more informative characterization by NMR, the method which (if one can mentioned it at the ASMS Meeting) most adequately depicts all structural features. Based solely upon the determination of a MW of a free glucosides and glucuronides point of substitution can not be determined. On a contrary, fully blocked derivatives differ in their MW. For example, O- and C-glucuronides of a mono-hydroxylated BA form respectively "di-Me/tri-Ac" and "mono-Me/tetra-Ac" with the difference of 28 amu. Moreover, in this derivation process, stable label Me and AcO groups can easily be introduced both to facilitate assignments and to serve as standards for quantification.

Using positive FAB measured in NBA saturated with different alkali metal iodides, we have already screened over 100 blocked glucuronides and glucosides prepared either by synthesis or isolated during different metabolic studies. All these compounds produce distinct $M(\text{Metal})^+$ ions with further attachment of salts (especially important for LiI). In FAB-MS, these compounds do not produce a significant MH^+ ion and, in most cases, their EI spectra showed extensive elimination of multiple AcOH molecules and fragments due to splitting of the glycosidic bonds. This collection is now being screened by MALDI performed also in the presence of alkali metal salts added to the matrix. Their MALDI spectra show prominent metal attachment ions which, for mono-glucuronides, are accompanied only by the consecutive losses of one to three AcOH molecules. As a rule, contribution of these fragment ions diminishes in the series MLi^+ , MNa^+ , MK^+ , and MCs^+ . Usually, for the Cs⁺ attachment, fragment ions are completely absent and provide an unambiguous mass assignment applicable to the characterization of mixtures. Obviously, in

comparison to FAB spectra, the absence of matrix derived ions and additional salt clusters greatly increases the clarity of the spectral characterization.

Most importantly, these measurement performed with the FT-MS instrument allows to determine of the accurate mass verified, with the Li to Cs salt mixture, for four (or six if Rb is included) different ions in a single measurement. Measurement performed in presence of the internal calibrant (we use metal attachment ions of PEG) further increases already high precision of the mass measurement to 1 PPM and no significant suppression effects are observed with the added PEG. Until now, for mono-substituted compounds, with the ion isolation and SORI, we failed to obtain fragments derived from splitting of a glycosidic bond. This may be due to low energy of collisions or loss of a charge. The loss of one sugar moiety, however, is observed for a C_{20} di-glucuronide (see Figure). Further insight into this simple elimination process is possible by selective labeling of acetyl groups. For this we first selected cholic acid 3-glucuronide in which both acetyl groups blocking the bile acid part have been deuterated. Direct spectra and SORI indicates that the first two eliminations of AcOH groups are limited exclusively to 7 α and 12 α OAc groups (the exclusive loss of 63 units) and only the subsequent loss is from the sugar moiety.

All synthetic compounds were obtained by the standard Koenigs-Knorr reaction, carefully purified by chromatography and crystallization and characterized by NMR. All MALDI spectra were obtained in the DHB matrix. Alkali metal salts (usually iodides) were added either as spikes or concentrated solution in acetonitrile. Solutions were either premixed or applied to the probe tip (about 0.4-0.5 μ l each) and allowed to crystallize in ambient conditions. Measurements were performed with the IonSpec 4.7 Tesla FT-MS system with the external MALDI ion source (nitrogen laser 337 nm) and quadrupole ion guide. With the broad band detection and 256k data points mass resolution was in excess of 15,000. Mass calibration was performed with low intensity ions of PEG spiked with NaI and CsI. Similar mixture were also used for 'peak matching' measurements. All FAB spectra were measured in NBA saturated with alkali metal iodides using CONCEPT IH (Kratos).

Figure. MALDI spectrum of blocked '3 β ,5 β -etianic acid' di-glucuronide in DHB/NaI. (m/z 975 (MNa^+), 915 (MNa -AcOH), 855 (MNa -2xAcOH), 659 (MNa -sugar fragment+H), 641 (MNa -sugar fragment with OH), 599 and 581 (the additional loss of AcOH)).

LC/IonSpray/MS/MS Analysis of Bile Acids

Takeo Sakuma, Gabriel Sanchez, Lyle Burton and Bori Shushan
PE SCIEX, 71 Four Valley Drive, Concord, Ontario L4K 4V8, Canada

There are 25 million Americans - 1 in every 10 - suffering from liver, bile duct or gallbladder diseases. Total deaths from liver diseases in 1992 were 43,967 (Source: *American Liver Foundation Fact Sheet*). In Canada over two million people are afflicted with these diseases. It is the 4th most common cause of death among Canadian between 35 and 55 years of age. Accurate analysis of bile acids (BA) is essential in the hepatic disease research as BA undergo complex biotransformation in both healthy and sick people. Mass spectrometry has opened up the field of inborn errors of BA metabolism and greatly increased the understanding of the metabolism and biosynthesis of BA. At the last years ASMS conference we discussed the examination of 17 BA standards and crude human bile samples using a microbore HPLC/IonSpray/MS/MS technique under several scanning modes.

In this poster we wish to report our continuing efforts in improving the rapid BA identification and quantitation capabilities. Our efforts were directed to (1) the development of looped mixed-mode scans combining selected ion monitoring (SIM) of marker ions plus Q1 scan from 300 - 550 amu (for the loss of 1, 2, 3 or 4 water molecules) under CID/MS conditions, followed by Q1 scan from 350-600 amu for the determination of the protonated molecular ions under low energy conditions; (2) the application of AppleScripting for quick identification and determination of the ratios of BA that may be used to indicate a certain disease state.

BA are made of a steroid skeleton (cholane) with 4 variable side chains. There are many forms of both conjugated (taurine, glycine, ornithine, sulfate, etc.) and non-conjugated BA. However, we focused our current study on major components found in experimental animals and human, because of easy availability of standards from commercial sources. For the majority of cases the following structure applies:

Seventeen BA standards, ox gull powder and porcine bile extracts, a composite bile sample from 10 male Sprague-Dawley rats and a human bile sample were dissolved in a mixture of 20% acetonitrile + 80% water in order to prevent from bacterial degradation during the analysis. HPLC column used: 1 x 100 mm Hypersil BDS C18, 5 μm . Solvent A = water + 0.05% trifluoroacetic acid, B=acetonitrile + 0.05% TFA, 30 - 100% B/20 min at 50 $\mu\text{L}/\text{min}$. A PE-SCIEX API 300 triple quadrupole mass spectrometer was used in the MS/MS mode for the acquisition of product ion, precursor ion and neutral loss scan spectra. The information acquired from these spectra was used to select marker ions for subsequent CID/MS SIM followed by high/low orifice Q1 scans in the single MS mode. For the screening purpose ion species 76, 126, 201, 203, 207, 213, 215, 229, 243, 319, 321, 323, 337, 339 and 341 were measured with an orifice potential of 120 V to induce fragmentation (Experiment 1). Experiment 2 was a Q1 scan from 300 amu to 550 amu with the same lens parameter settings as for Experiment 1 in order to determine the number of hydroxyl groups present in each compound. Experiment 3 consisted of Q1 scan from 350 amu to 600 amu to determine the protonated molecular ion under more gentle ion energy with OR=20. Experiments

1 through 3 were looped with a total scan time of 3.167 seconds. The following figure is a typical example obtained from taurochenodeoxycholic acid. In the second pane the presence of 126 ion species indicates that this BA is conjugated with taurine. The third pane shows the presence of 2 OH groups attached on the backbone (482 and 464 due to loss of 1 and 2 water molecules). It was found easy to cleave off OH groups from the cholane skeleton, but difficult to remove the acidic OH group from taurine or glycine. The last pane shows the protonated molecular ion at 500 and its ammoniated species at 517 amu.

A customized BA script was prepared. It first determines the retention time (RT) of glycocholic acid, and then calculates the expected RT of the remaining BA based on relative RT. The RT of the largest peak in the corresponding SIM in a window centered at the expected RT is determined. For the isomers which had similar RT, the script determined whether there are 1 or 2 peaks within the RT window. If there is only one, it is assumed to be whichever of the 2 isomers had the closest RT. Otherwise the script sets the RT so that the peak with the largest expected RT corresponds to the observed peak with the larger of the 2 RT (and vice versa). It then makes sure that the calculated RT actually correspond to the expected peak by ensuring that 2 characteristic fragment ions are present. The intensities for the protonated molecular ion are transferred to an scriptable EXCEL spreadsheet. In EXCEL, the intensity of each species is converted to a percentage of the total and the ratio of the sum of glycine- and taurine-conjugated BA calculated and displayed.

In conclusion we determined characteristic product ions and fragmentation pathways using MS/MS. This information was used to define LC/MS experiments involving simultaneous acquisition of high and low energy SIM and full scan data. Such a comprehensive experiment captures all the information required to make a determination of BA present in the sample. An AppleScript is used to automatically process the data and output the identity and relative concentration of BA in the sample into a Microsoft EXCEL spreadsheet.

Mass Spectrometric Analysis of Arachidonyl-Containing Phospholipids in DMSO Differentiated Human U937 Cells

Chun Li*, Elizabeth Wong and James A. Yergey
Medicinal Chemistry Department
Merck Frosst Centre for Therapeutic Research
P.O.Box 1005, Pointe-Claire-Dorval, Quebec, Canada, H9R 4P8

Arachidonic acid metabolites such as prostaglandins and leukotrienes play an important role in inflammatory processes. The production of these metabolites is believed to be initiated by the activation of a specific phospholipase A₂ (PLA₂), which releases arachidonic acid from endogenous phospholipids. However, it remains unknown as to the exact phospholipid sources of endogenous arachidonic acid which was utilized for eicosanoid production during cell activation. In our early efforts of finding PLA₂ inhibitors as potential anti-inflammatory agents, DMSO-differentiated human U937 cells were used as our primary cell line for the screening assay. Upon Ca²⁺ ionophore challenge, free arachidonic acid is released from arachidonyl-containing phospholipids. Analysis of phospholipid molecular species before and after Ca²⁺ ionophore challenge can provide an insight whether or not there is a specific phospholipid precursor pool within the cell that preferably releases arachidonic acid. In this study, the arachidonyl-containing phospholipids before and after cell activation were measured using capillary HPLC / continuous flow liquid secondary ion mass spectrometry and selected-reaction-monitoring. The total arachidonate content and free arachidonic acid released from differentiated human U937 cells upon Ca²⁺ ionophore challenge were measured. The arachidonic acid distribution in each of the major phospholipid classes before and after ionophore challenge was also determined.

The human U937 cell line was grown in suspension culture in RPMI 1640 medium supplemented with 10% fetal bovine serum. The cells were induced to differentiate to a neutrophil-like phenotype by culture in 1.3% DMSO for 4 days. They were resuspended in Hank's Balanced Salt Solution (HBSS) and adjusted to 2.0x10⁶ cells/mL. Cells (2 mL each) were challenged with vehicle or with A23187 (10 µM) for 3 minutes at 37°C. Two sets of experiments were carried out in parallel. One set was used for free arachidonate measurements, incubations were terminated by adding Dole's solvent. The other was used for phospholipid analysis, lipids were extracted by the method of Bligh & Dyer. Lipid extract was isolated using normal phase HPLC, isolated phospholipid classes and a fraction of total lipids were base hydrolyzed. Extracted free AA was derivatized to its pentafluorobenzyl ester in the presence of d8-AA as internal standard, and quantified by GC/MS using negative ion chemical ionization and selected-ion-monitoring. Isolated phospholipid classes PE, PI, PS and PC were also analyzed using CF-LSIMS. The arachidonyl-containing phospholipids before and after cell activation were measured using selected-reaction-monitoring.

Very little free arachidonate is found in resting cells (4.6 ng/4x10⁶ cells). Both CoA-dependent and CoA-independent mechanisms are responsible for regulating cellular arachidonate levels. During cell stimulation with Ca²⁺ ionophore, arachidonate is rapidly released from membrane phospholipids leading to an increase in cellular levels of unesterified AA (329 ng/4x10⁶ cells). In differentiated human U937 cells, the predominate pools of endogenous arachidonate were found to be PE, PI and PC, while phosphatidylserine contained no arachidonate. Upon Ca²⁺ ionophore stimulation, arachidonate was lost from both PE and PC, with PE being the major source of liberated arachidonate (Table 1). Depletion of arachidonate from PE or PC is due to the direct liberation of arachidonate by phospholipase A₂ or the conversion of the phosphoglyceride to another product such as diglyceride via phospholipase C. Interestingly, arachidonate was not lost from PI, instead, a small gain of arachidonate content was found in PI. This suggests that

arachidonate is rapidly released from and shuttled between specific phospholipid pools during cell activation, a portion of AA released from PE or PC may be rapidly reacylated into PI.

CF-LSIMS provided a useful and effective way of detecting intact phospholipid molecular species. Complete quantification of arachidonyl-containing phospholipids is extremely difficult due to lack of proper internal standards. Selected-reaction-monitoring measurements using MS/MS, however, showed good selectivity and gave relative distribution of AA-containing species in each class. SRM measurements of arachidonyl-containing species in resting and stimulated human dU937 cells indicated that there is no selective molecular species producing AA upon stimulation (Figure 1). This reflects the non-specific nature by which Ca²⁺ ionophore stimulates dU937 cells. Using this technique, we can further investigate if a more physiological stimulus releases arachidonate selectively from a given phospholipid precursor in human dU937 cells or other cell types.

Table 1: Total Cellular AA Content and AA Distribution in Human dU937 Cells
AA Distribution (ng / 0.72x10⁶ cells)
(18% of lipid extract of 4x10⁶ cells was used.)

	NL	PE	PI	PS	PC	TOTAL
Resting	15.8±1.0	285.8±13.0	71.9±3.5		45.6±0.9	460±23.0
Stimulated	73.0±5.5	184.1±12.9	76.3±1.8		33.7±2.7	
Change	+57.3	-101.7	+4.3		-11.9	

(Data are the mean ± SEM of four separate experiments. The Bligh & Dyer extraction under neutral conditions used in this experiment did not extract free AA quantitatively, AA found in neutral lipid fraction, therefore, did not represents all free AA released.)

Effect of Ethanol on Incorporation of Polyunsaturated Fatty Acids in C-6 Glioma Cells.

Hee-Yong Kim and Yee-Chung Ma, Section of Mass Spectrometry, LMBS, NIAAA, NIH, 12501 Washington Avenue, Rockville, MD 20852.

Docosahexaenoic (22:6n3) and arachidonic (20:4n6) acids are the major polyunsaturated fatty acid (PUFA) in the brain. Normal brain development, visual acuity and retinal function have been suggested to correlate with the enrichment of 22:6n3 in neuronal tissues. Although the lipid composition in the brain is generally well maintained, it has been demonstrated that ethanol can alter the lipid composition in neuronal membranes, with possible detrimental consequences in neuronal function. In the brain, astroglia are the most populated cell type and contribute substantially to the function of central nervous system by supporting neurons. One of the supporting roles of astroglia may include neuronal accumulation of 22:6n3 and 20:4n6 through facilitated incorporation and release of these fatty acids. In this study, we investigated the effect of ethanol on the incorporation of these polyunsaturated fatty acids into astroglia using rat C6 glioma cells.

C-6 glioma cells were cultured in Dulbecco Modified Eagle's Medium (DMEM) containing 0-100 mM ethanol by replenishing the medium daily. After 4 weeks of ethanol treatment, 2.5×10^5 cells/well were incubated with 50 μ M 22:6n3 or 20:4n6 for 24 h. Unincorporated fatty acids were washed off and the cells were further incubated in the medium for an additional 24 h. At the end of the incubation period, cells were scraped and lipids were extracted according to Bligh and Dyer in the presence of tricosanoic acid (23:0) for GC analysis or deuterium labeled phospholipid standards for phospholipid analysis. Phospholipid molecular species were separated and determined using reversed phase HPLC/electrospray mass spectrometry using the conditions as described previously (Kim et al. Anal. Chem. 66, 3977, 1994).

HPLC Column: a C-18 column (Prodigy, 5 μ , 2.1 mm I.D. x 15 cm)
Mobile phase: 0.5% ammonium hydroxide in water: methanol: hexane changing from 12:88:0 to 0:88:12 in 17 min after holding at the initial composition for 3 min with a flow rate of 0.4 mL/min which was split 1:100 to deliver 4 μ L/min to the electrospray needle.

ESI Instrument Finnigan TSQ-700 with ESI Source
Capillary temperature 250°C
Sheath gas pressure 70 psi
Auxiliary gas flow 15 flow unit
Tube lens potential 63 V

Electrospray mass spectrometry with acceleration potential of approximately 60 V induced the fragmentation for phosphatidylserine (PS), phosphatidic acid (PA), phosphatidylinositol (PI) and phosphatidylethanolamine (PE), producing abundant diglyceride ions as shown in Figure 1 for PE species. Phosphatidylcholine species were detected as (M+H)⁺ ions. C-6 glioma cells quickly incorporated both polyunsaturated fatty acids into various phospholipids. After 24 hours, 22:6n3 was mostly found in 18:0,22:6-PS followed by 16:0,22:6-PE and 16:0,22:6-PC (Figure 2). In contrast, 20:4n6 and its elongated product 22:4n6 accumulated mainly in PC, indicating that preferred incorporation and remodeling pathways are different for 20:4n6 and 22:6n3. Total incorporation of 22:6n3 and 20:4n6 into C-6 cells assessed by gas chromatography did not change considerably in comparison to the untreated cells, after treatment with ethanol up to 25 mM. A slight decrease in total incorporation was observed with ethanol concentration higher than 50 mM. Phospholipid molecular species analysis revealed that ethanol selectively and significantly decreased the accumulation of both 22:6n3 and 20:4n6 in PS. These data indicate that the phospholipid remodeling process is impaired by chronic ethanol exposure, which may be one of the significant effect of ethanol resulting in neuronal dysfunction.

Figure 1. Electrospray mass spectrum of 18:0,20:4-PE.

Figure 2. Reversed phase HPLC/Electrospray MS chromatogram of phospholipids obtained from C-6 glioma cells enriched with 22:6n3 for 24 hours. Diglyceride and MH⁺ ions of the molecular species containing 22:6n3 were selectively monitored.

The Determination of Catechol Estrogen Levels in Breast Tissue

*Zongwei Cai¹, Ronald L. Cerny¹, Eleanor G. Rogan², Ercole L. Cavalieri²

¹ Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588

² Eppley Institute for Research in Cancer and Allied Disease, Univ. of Nebraska-Medical Center

The metabolic pathways of estrogens in humans largely involve hydroxylations and methoxylations at C-2 or C-4 positions of estrone and 17 β -estradiol (1-3). The hydroxylated metabolites, catechol estrogens (CE), are considered as a major group of active metabolites of estrogens (2, 3). The CE could be activated to either quinone or semiquinone forms, which can covalently bind to DNA, by peroxidases and cytochrome P-450 (1, 3). In normal mammalian cells these CE are believed to be regulated by conversion to their monomethoxy forms by enzymes classified as catechol-O-transferases (1). The monomethoxy forms cannot undergo the oxidative conversion to quinones and semiquinones (1-3). Determination of levels of CE and methylated CE in breast tissues, therefore, constitutes important evidence for the hypothesis that human breast cancer and certain other cancers are initiated by activation of CE to CE-3,4-quinones (CE-3,4-Q), which form depurinating DNA adducts (Figure 1). Because only non-methylated CE can be oxidized to CE-Q, the ratio of non-methylated vs methylated CE levels should be higher in tissue from women with breast cancer compared to women without cancer. To support studies of CE, a sensitive and specific analytical method was developed to determine trace levels of estrogens and their metabolites in tissue samples from pre- and post-menopausal women with and without breast cancer. The method consists of a derivatization procedure using N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA) and GC/high resolution MS analysis. Low nanogram levels of the analytes were derivatized by using BSTFA. The sample was then analyzed by GC/MS at mass resolution of 10,000, monitoring the molecular ion of each derivatized compound. Mass chromatograms presented in Figure 2 were obtained by injecting 170 pg of each derivative into a DB-5 capillary column (30 m X 0.32 mm, 0.32 μ). The data were acquired on a Kratos MS-50 double-focusing mass spectrometer/Kratos-Mach 3 data system. The results in Figure 2 shows a good separation of the targeted analytes under the GC conditions. The high resolution mass spectrometry operated in mass profiles mode (4) combined with the capillary GC separation provides good method specificity. The quantitative method employs isotope-labeled analogs of the analytes as internal standards. Several deuterated analogue of the analytes were synthesized and used as internal standards. Typical instrumental detection limits are 30 pg for derivatized estrogens and metabolites by considering a signal to noise (S/N) of 3:1. The most accurate way to evaluate a method, however, is to examine the lowest amount needed to use for derivatization in order to see a clear GC/MS signal. The procedure detection limit is in sub-nanogram range. The accuracy and precision of the method are good. Analysis of six spiked blank samples gives the average relative error of less than 11% and the relative standard deviation less than 13%. Figure 3 demonstrates mass chromatogram and mass profile spectra for the determination of 100 ng 4-OCH₃-E1. The spiked level of the internal standard 4-OCD₃-E1 was 30 ng. The developed GC/high resolution MS method can be applied for the determination of trace levels of estrogens and their metabolites CE and monomethoxy CE. We are expect to compare the concentration ratios of non-methylated CE vs methylated CE in tissues from normal and abnormal breast tissues.

Identification of PAF and acyl-PAF species in human blister fluid *in vivo*.

Chris A. Johnson, Jeffrey B. Travers, Keith L. Clay, Tami Zekman, Joseph G. Morrelli, Robert C. Murphy

Introduction

Platelet-activating factor (PAF, 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a family of sn-2 acetyl phosphocholines with diverse and significant pathophysiological effects [reviewed in 1]. The first step in PAF production appears to be the generation of lyso-PAF (1-O-alkyl-2-lysoGPC) from 1-O-alkyl-2-acylGPC. The enzymes thought to be responsible for this reaction include phospholipase A2 and/or transacylase activity which would remove the sn-2 fatty acid (often arachidonate) from 1-O-alkyl-2-acyl-GPC. Lyso-PAF is subsequently acetylated by acetyl-CoA:lyso-PAF acetyltransferase (EC 2.3.1.67) to form PAF, or is reacylated with long chain unsaturated fatty acids. Once synthesized, PAF is quickly degraded to the biologically inactive lyso-PAF by acetylhydrolases, enzymes found both in cytosol and in serum.

In addition to ether-linked PAF species, sn-1 acyl-linked sn-2 acetyl-GPC species have also been shown to have biological activity, albeit with only a fraction (0.1 - 1 %) of the potency of PAF. Sn-1 acyl-linked sn-2 acetyl GPC species have been shown to comprise the majority of sn-2 acetyl GPC synthesized by activated endothelial cells, mast cells and B cell lines.

Several lines of evidence suggest that PAF may play a role in epidermal inflammation. First, PAF and/or PAF activity has been demonstrated in the skin. PAF has been identified in psoriatic scale [2], and fluid from traumatic [3] blisters using mass spectrometric techniques. PAF-like activity (as measured by platelet aggregation) has also been found in primary cultures of human keratinocytes when stimulated with the calcium ionophore A23187 [4]. Because the latter study [4] measured PAF activity by bioassay, the species of sn-2 acetyl-GPC synthesized which resulted in the PAF-like activity could not be assessed. Second, intradermal injections of PAF result in wheal and flare reactions [5]. Third, human keratinocytes express functional PAF receptors [6]. Finally, PAF receptor antagonists either systemically or topically administered have antiinflammatory effects in murine model systems of contact dermatitis [7,8].

The objectives of this study are two-fold. The first was to test the ability of ionophore-stimulated cultured human neonatal foreskin keratinocytes (HK) to synthesize PAF and other sn-2 acetyl-GPC *in vitro* as measured by mass spectrometry. Because PAF is thought to play a role in epidermal inflammation, fresh blister fluid was studied both from noninflammatory (suction; n=8) and inflammatory (bullous pemphigoid; n=8) bullae *in vivo* for the presence of PAF species.

SIM Chromatograms for the PFB ester of PAF

Conclusions

Molecular Species of PAF

sample	C-16 alkyl	C-18 alkyl	C-16 acyl	C-18 acyl
Human Keratinocytes (ng/10 ⁶ cells)	0.8	0.3	0.5	0.2
Suction Blister (ng/ml)	0.6	0.9	3.3	0.5
Bullous Pemphigoid (ng/ml)	4.7	1.1	14	1.7

These studies demonstrate that primary cultures of neonatal foreskin keratinocytes synthesize both PAF and 1-acyl PAF analogs when stimulated with the ionophore A23187. The initial time course of sn-2 acetyl-GPC production was similar to arachidonic acid release. Sn-2 acetyl-GPC species were found in fluid obtained from patients with blistering diseases.

Inasmuch as PAF has potent proinflammatory activities, the presence of these lipid mediators in blister fluid suggest that they may contribute to the clinical inflammation seen in these inflammatory blistering diseases.

HPLC-MS/MS method for detection of benzene metabolites S-phenylmercapturic acid and *trans,trans*-muconic acid in urine

Coleman, S., O'Connor, R., Hu, P.F., Melikian, A.A.
American Health Foundation, Valhalla, New York, 10595

Benzene is an important human leukemogen. The molecular mechanisms responsible for benzene toxicity and carcinogenicity have not yet been fully elucidated. Several studies have indicated that metabolism of benzene to active intermediates is a prerequisite for its toxic and carcinogenic effects. However, the ultimate toxic and carcinogenic metabolites of benzene are not clearly defined. The metabolism of benzene is complex. Benzene is metabolically activated through benzene epoxide and/or to the hydroxycyclohexadienyl radical to either ring-hydroxylated, or ring-opened products such as *trans,trans*-muconic acid, (*t,t*-MA). Alternatively, benzene oxide can react with glutathione. The resulting conjugate is excreted in the urine as S-phenylmercapturic acid, (S-PMA), Figure 1, (1,2).

Current risk assessment of benzene is based primarily on the epidemiological data from occupationally exposed populations which suggest an association between high doses of benzene exposure and leukemia. Still, there is uncertainty concerning low doses of benzene exposure and its acceptable risk. Studies on biological monitoring must consider the need to identify biomarkers that are sensitive and reliable at these low exposure concentrations. Because several benzene metabolites can be detected in human urine of exposed animals and humans we have developed a selective and sensitive HPLC-MS/MS-SRM method for monitoring the benzene metabolites S-PMA and *t,t*-MA (Figure 1), in urine.

Figure 1. Pathways of urinary metabolites of benzene

The characteristic negative-ESI-MS spectrum of S-PMA showed a dominant deprotonated molecular ion at m/z 244 (M-1)⁻, which lost -CH₂CHNHCOCH₂COO⁻, resulting in a product ion at m/z 109. Negative-ESI-MS of [¹³C]S-PMA also gave ions at m/z 244 (M-1)⁻ and m/z 115 (M-130)⁻. Tandem MS data were obtained by selection of deprotonated precursor molecular ions, namely m/z 238 for S-PMA and m/z 244 for internal standard [¹³C]S-PMA and monitoring product ions m/z 109 and 115, respectively. Negative-ESI-MS spectra of *t,t*-MA showed ions at m/z 141 (M-1)⁻ which eliminated CO₂ to produce an ion at m/z 97 (M-45)⁻. Similarly the dominant ions for [¹³C]*t,t*-MA are m/z 147 (M-1)⁻ and m/z 102 (M-46)⁻. The MS/MS data obtained by selection of precursor ions m/z 141 for *t,t*-MA and m/z 147 for [¹³C]*t,t*-MA internal standard and monitoring product ions at m/z 97 and 102, respectively.

The applicability, sensitivity and reproducibility of this method have been examined in a pilot study with urine specimens from smokers and nonsmokers, both men and women. Both analytes were detected in 44 of 46 samples. The mean concentration of urinary S-PMA in smokers was 45.1±5.7 SE µg/g creatinine. Corresponding values in nonsmokers were 27.5±4.7SE µg/g creatinine, as shown in Figure 2. The mean levels of *t,t*-MA in smokers were 0.83±0.26SE mg/g creatinine; corresponding data in nonsmokers were 0.51±0.16SE mg/g, (Figure 3). The levels of S-PMA and *t,t*-MA in smokers were significantly higher than those in nonsmokers. There was a significant correlation between S-PMA and *t,t*-MA ($r=0.46$, $p=0.01$).

ANALYSIS OF DOLICHOLS AND POLYPRENOLS BY EI, FAB AND ES TANDEM MASS SPECTROMETRY

W. J. Griffiths, M. Hjertman, A. Lundsjö, J. Wejde, J. Sjövall and O. Larsson

Department of Medical Biochemistry and Biophysics, Karolinska Institutet,
S-17177 Stockholm, Sweden.

Dolichols and polyprenols are polyisoprenoid lipids found in all cells. Polyisoprenoids have recently been found covalently bound to cellular proteins constituting a new type of post-translational modification. To study these compounds effectively in biological systems a sensitive mass spectrometric procedure giving molecular weight and structural information is required. In the present study an assessment has been made of possible mass spectrometric procedures.

Experiments were performed on a hybrid magnetic sector - orthogonal time-of-flight (OATOF) mass spectrometer equipped with point, multichannel plate and focal plane array detectors (FPD). Dolichols and polyprenols were analysed by EI mass spectrometry on the pmole level in their underivatized form. Sulphated dolichols and polyprenols were analysed on a pmole level by fast atom-bombardment and on the sub pmole level by electrospray mass spectrometry. Collision-induced dissociation spectra of the underivatized and sulphated-polyisoprenoids were recorded. These spectra provide structural information from only pmoles of sample.

1. Negative-ion CID spectra of $[M-H]^-$ ions of D-19-SO₄ (m/z 1392.2).

(a) ES ionization 20 ng D-19-SO₄ consumed.

(b) ES ionization 100 ng D-19-SO₄ consumed.

The spectrum shown in (a) was recorded as a B/E linked scan on the FPD and spectrum (b) was recorded using the OATOF analyser.

ELECTROSPRAY TANDEM MASS SPECTROMETRY OF CYSTEINYL LEUKOTRIENES

William J. Griffiths, Yang Yang, Jan Sjövall and Jan Åke Lindgren

Department of Medical Biochemistry & Biophysics, Karolinska Institutet,
S-171 77 Stockholm, Sweden.

The cysteinyl leukotrienes LTC₄, LTD₄ and LTE₄ were originally identified as the constituents of slow-reacting substance of anaphylaxis [R. C. Murphy, S. Hammarström and B. Samuelsson, *Proc. Natl. Acad. Sci. USA* **76**, 4275 (1979)], a biologically active factor thought to be an important mediator of asthma. Mass spectrometry of cysteinyl leukotrienes has challenged the imagination of mass spectroscopists for almost two decades. Early work involved the removal of the cysteine-containing moiety and the subsequent reduction, esterification and trimethylsilylation of the remaining lipid before analysis by electron impact mass spectrometry [R.C. Murphy, *J. Mass Spectrom.*, **30**, 5 (1995)]. It was not until the advent of the fast atom bombardment method of ionization that cysteinyl leukotrienes could be analysed in their intact and underivatized form [R.C. Murphy, *J. Mass Spectrom.*, **30**, 5 (1995)].

In the present study negative-ion electrospray has been used as the method of ionisation and spectra have been recorded on a VG AutoSpec TOFFPD hybrid magnetic sector - time-of-flight tandem instrument. When using negative-ion ES, LTE₄ gave the weakest [M-H]⁻ ion, but with array detection, 10 pg could be detected. Collision induced dissociation (CID) spectra were recorded. [M-H]⁻ ions were induced to fragment in 400 eV collisions with Xe atoms. The spectra shown below were obtained from 100 ng of sample, although spectra with all the significant fragment ions could be obtained from 10 ng of sample, but at a reduced signal to noise ratio. This degree of sensitivity is sufficiently high to allow the study of leukotrienes extracted from biological samples. Such studies are currently being performed in this laboratory and will be the subject of forthcoming publications.

**Characterization of Lipid Fatty Acids in Whole-Cell Microorganisms
Using *In Situ* Supercritical Fluid Derivatization/Extraction
and Gas Chromatography/Mass Spectrometry**

Ahmad A. Gharaibeh and Kent J. Voorhees
Department of Chemistry and Geochemistry
Golden, CO 80401

In situ supercritical derivatization and extraction (SFDE) was used as a sample preparation technique for the classification of bacteria using fatty acid profiling. Lipid and free fatty acids in whole-cell bacteria were saponified and methylated with phenyltrimethylammonium hydroxide (PTAH) under conventional supercritical fluid extraction conditions. The resulting fatty acid methyl esters (FAME) were then extracted with supercritical CO₂ and analyzed without further sample treatment using GC/MS. The application of principal components analysis (PCA) to the FAME GC data resulted in the classification of the microorganisms according to their Gram type.

EXPERIMENTAL: Extractions were performed using Lee Scientific SFC pump and a Hewlett Packard chromatographic oven. Lyophilized bacterial cells and the derivatization reagent (PTAH in methanol) were placed in the extraction cell and brought to supercritical conditions, 100°C and 400 atm CO₂ pressure for 15 minutes. The cell contents were then extracted dynamically for 15 minutes while collecting the analytes in methanol in a 3 mL vial. The extracts were analyzed by GC/MS using a Perkin Elmer Q-Mass 910 system. Chromatographic peaks were digitized for multivariate statistical analysis by normalizing each individual peak area to the total peak area. These data were autoscaled prior to principal component analysis.

RESULTS AND DISCUSSION: The branched-chain saturated fatty acids, in addition to C18:0, were characteristic of Gram-positive bacteria, while the unsaturated and cyclopropyl fatty acids were characteristic of the Gram-negative bacteria. Hexadecanoic acid (C16:0) was not useful for Gram-type differentiation in this study since it was extracted in major amounts in both types. Principal components analysis (PCA) was applied to the GC/MS total ion chromatograms (TIC) of the extracted FAMES. Figure 1 shows the score plot of principal components 1 and 2. All Gram-negative bacteria (F-J) were grouped in one cluster with negative values for principal component 1, while all Gram-positive (A-D) were separated along the positive side of the principal component 1 axis. Species level differentiation is also apparent in this Figure among the Gram-positive bacteria. The loading plots of components 1 and 2 showed that the branched-chain fatty acids, as well as C18:0 and C18:2 were the most discriminant factor in Gram-positive bacteria, while C14:0, C16:1, C16:0, and cyclopropyl fatty acids were discriminant in Gram-negative *E. faecalis* (E), although a Gram-positive bacterium, was classified as Gram-negative. This reflects the similarity of the fatty acid profiles of *E. faecalis* to that found in Gram-negative bacteria.¹ Separation between the species of Gram-negative type bacteria was enhanced by applying linear discriminant analysis to this group as shown in Figure 2. Two main groups are found in this Figure, one for the genus *Pseudomonas* (H, I) and the other for the family *Enterobacteriaceae* (F, G, J). All bacteria in this Figure were also differentiated on species level.

SEARCHING FOR NOVEL BILE ACIDS IN MARSUPIALS WITH MASS SPECTROMETRY

J. St. Pyrek¹ and J. Song; University of Kentucky Mass Spectrometry Facility, Lexington, KY

Bile acids (BA) are quantitatively the major metabolites of cholesterol and play central role in the gastrointestinal system. Biliary C_{24} BA occur as conjugated with amino acids and help in solubilization of cholesterol in the bile and participate in the digestion of lipids. BA that are directly biosynthesized in the liver (primary BA) are deconjugated by the intestinal flora which also removes 7α -hydroxyl leading to the secondary BA. As an apparent rule, early investigations of the mammalian bile indicate that only about twenty C_{24} BA are encountered as constituents. These BA are derived from 3α -hydroxy- 5β -cholan-24-oic acid with hydroxyl groups at C- 7α and C- 12α ; BA hydroxylated at other positions and derivatives of 5α -cholan-24-oic acid ("allo-BA") are less frequent. Precursors of C_{24} BA, i.e. C_{27} BA, are commonly secreted in the bile of "lower" vertebrates but are found in mammalian bile as trace constituents. Preservation of a similar pattern of BA in mammals may indicate relatively conservative evolution of BA biochemistry. This conclusion, however, is based upon studies of bile of only about 100 species out of 4,000 contemporary mammals. Recent data, however, question such a uniformity of mammalian biliary BA and indicate that in some cases bile composition considerably deviates from that considered as a "typical". A novel BA, vulpecholic acid ($1\alpha,3\alpha,7\alpha$ -trihydroxy- 5β -cholan-24-oic acid), recently identified by us as the predominant primary of the Australian opossum *Trichosurus vulpecula*, is present in the bile mostly as a free acid (J. St. Pyrek et al., 1986 and 1991). Chenodeoxycholic acid, present in this bile together with its allo-isomer, serves as an efficient substrate for 1α -hydroxylation. Notably, these two isomeric $3\alpha,7\alpha$ -dihydroxylated acids are efficiently conjugated with taurine pointing to a remarkable selectivity in the amino acid conjugation. Other novel BA detected in the bile of *T. vulpecula* include mono-keto compounds, i.e. 1-, 3-, and 7-dehydrovulpecholic acids. In addition, trace of 1α -hydroxy-lithocholic acid are also present in as well as nor and bis-nor BA (to be published). Our separate study of the horse bile indicate that the exclusive production of C_{24} BA by mammals is not a strict rule because C_{27} BA are quite abundant for this animal. In another astounding discovery, West Indian manatee *Trichechus manatus latirostris*, has been found to produce only C_{27} bile alcohols (Kuroki et al., 1988).

Our examination of nine marsupial species indicates an apparent diversity of their BA. As mentioned above, it resulted in the discovery of vulpecholic acid and, as described here, three 15-functionalized BA in two wombats *Vombatus ursinus* and *Lasiorhinus latifrons* (Figure). This adds eight novel BA to the list of the known biliary components and leads to interesting considerations in relation to the evolution of BA biosynthesis in mammals with the apparent impact upon the classification of Marsupials.

Bile, obtained from wombats remaining in the captivity (courtesy of Dr. Perry Barboza), was hydrolyzed either enzymatically or under the alkaline conditions. Profiling of bile components was done with capillary GC-MS (EI and CI, isobutane, detection). Derivation was performed by (a) methylation and silylation, (b) methylation in CH_3OD to give D_1 methyl esters and silylation, (c) formation of TMS esters-TMS ether in one step, and (d) Jones' oxidation of labeled and unlabeled Me esters. After initial mass spectral characterization and preliminary identification of novel BA components, larger samples of bile were enzymatically deconjugated and separated by reverse phase chromatography and preparative TLC. All novel components were further characterized by HR-MS in the form of several derivatives and characteristic transformation products (e.g. splitting of 14-15 double bond in the 14-dehydrolithocholic

acid), correlation as well as by proton and carbon NMR in order to confirm configuration and location of functional groups. Prior to hydrolysis, taurine conjugates were identified by the negative FAB-MS.

In this identification, especially informative was the characterization of ketone derivatives which immediately revealed the presence of 15-oxygenated compounds with the highly diagnostic fragmentation pattern as well as the expected isomerization occurring during the chromatographic separation due to enolization at C-14. The following are the data for novel keto-derivatives, "d" indicates one amu shift upon the deuteration of OMe)

Methyl 3-oxo- 5β -chol-14-en-24-oate, EI-MS at 20 eV: m/z 386 (M^+ , 6, d), 355 (M-MeO, 3), 354 (M-MeOH, 3), 353 (M-Me-H₂O, 2), 297 (probably M-C22-24-2H, 24), 271 (M-SC, 100), 269 (M-C22-24-2H-28, 10), 253 (M-H₂O-SC, 33), 213 (12), 208 (ring D+C12 fragment, 16, d), 201 (M-C1-C4-SC, 17), 115 SC fragment, 18, d)

Methyl 3,15-dioxo- $5\beta,14\beta$ -cholan-24-oate, minor early eluting isomer, EI-MS, 20 eV m/z 402 (M^+ , 1, d), 387 (M-Me, 3, d), 384 (M-H₂O, 4, d), 332 (M-C1-4, 2, d), 287 (M-SC, 10), 269 (M-SC-H₂O, 5), 259 (3), 217 (M-C1-4-SC, 6), 215 (M-SC-C15-17+H-H₂O, 5), 211 (ring D ion, 100, d), 179 (ring D ion-MeOH, 25)

Methyl 3,15-dioxo- $5\beta,14\alpha$ -cholan-24-oate, major late eluting isomer, EI-MS, 20 eV m/z 402 (M^+ , 7, d), 387 (M-Me, 19, d), 384 (M-H₂O, 15, d), 371 (M-MeO, 8), 369 (M-Me-H₂O, 4, d), 355 (M-MeOH-Me, 5), 329 (M-C23-24, 7), 315 (M-C22-24, 5), 311 (M-C23-24-H₂O, 4), 297 (M-C22-24-H₂O, 5), 287 (M-SC, 61), 269 (M-SC-H₂O, 12), 259 (M-SC-CO or M-SC-C16-16-H, 37), 217 (M-C1-4-SC, 27), 215 (M-SC-C15-17+H-H₂O, 23), 211 (ring D-ion, 74, d), 199 (M-C1-4-SC-H₂O, 31), 179 (ring D ion-MeOH, 14), 175 (25), 162 (65), 110 (100).

In addition to novel BA listed below (Figure) the following known C_{24} BA have been detected in the bile of both wombat species: chenodeoxycholic ($3\alpha,7\alpha$ -dihydroxy- 5β -cholan-24-oic acid), allo-chenodeoxycholic ($3\alpha,7\alpha$ -dihydroxy- 5α -cholan-24-oic acid), ursodeoxycholic ($3\alpha,7\beta$ -dihydroxy- 5β -cholan-24-oic acid), and lithocholic (3α -hydroxy- 5β -cholan-24-oic acid). For both animals, bile profiles differ mostly in the amount of allo-chenodeoxycholic acid much less abundant for *L. latifrons*. Identification of other minor components is currently in progress. At this point it is difficult to ascertain if the major $3\alpha,15\alpha$ -dihydroxy BA represent a primary BA and more animal experiments are required.

METABOLISM OF SAPONINS BY MASS SPECTROMETRY TRANSFORMATION OF NUATIGENIN - SAPOGENIN FROM OATS

J. St. Pyrek,¹ S. K. Aggarwal, J. P. Goodman, P. Barboza, P.-Y. Yang, J. Song, and J. A. Jackson; University of Kentucky Mass Spectrometry Facility, Lexington, KY

Nuatigenin ((2*S*,2*S*)22,25-epoxy-3 β ,26-dihydroxy-furost-5-ene) and iso-nuatigenin ((2*S*,2*S*)3 β ,25-dihydroxy-spirost-5-ene) are known as sapogenols of certain *Solanum* and oats.² Structurally, these two compounds are similar to cholegenin ((2*S*,2*S*)22,25-epoxy-3 α ,26-dihydroxy-5 β -furostane) and iso-cholegenin ((2*S*,2*S*)3 α ,25-dihydroxy-5 β -spirostane). These two unique sapogenols have been isolated only once in England from 40 gallons of ox bile,³ but their subsequent re-isolation from bile collected in the US has failed.⁴ Because sapogenols are known as plant products, it has been postulated that cholegenin may be formed from nuatigenin as an intestinal microbial product¹, but experimental verification, however, has been provided at that time.

Continuing the search for new bile acids in marsupials (compare **ThPG165**), we have isolated from the bile of two wombats a novel sapogenic acid identified as cholegenic acid ((2*S*,2*S*)-22,25-epoxy-3 α -hydroxy-5 β -furostan-26-oic, ~0.4%)⁵ which may also originate from a plant source. Wombats (kept in Australia) received diet containing barley which has been suspected as the most probable source of saponin. Subsequently, we have been able to demonstrate that barley (of the US origin) contains small amount of saponins derived from nuatigenin. In order to confirm that nuatigenin is metabolized to cholegenin and cholegenic acid, we have analyzed the bile obtained from rabbits fed oats and oats sprouts. Oats have been selected as a rich source of nuatigenin as well as because of potential implications of such metabolites in human and livestock nutrition.

In spite of frequent occurrence of steroidal saponins in many nutritionally important plants, little is known about their metabolism and only relatively recent data indicate that saponins are of a considerable health significance to livestock and this toxicity may be related to metabolites of sapogenols identified in the bile. These data, however, are limited to the identification of a bile-insoluble material formed under conditions of the extreme intoxication and indicate that steroidal saponins are hydrolyzed and metabolized by the intestinal flora in analogy to cholesterol converted to coprostanol, i.e. 3 β -hydroxy-spirost-5-enes are reduced to 3 α -hydroxy-5 β -spirostanols. In none of these known cases, however, formation of carboxylic acids has been detected. In this respect, cholegenic acid represent the first example.

Bile and feces, obtained from rabbits and more recently cows fed oats, was submitted to hydrolysis and extensive chromatographic separation of minor components from the prevalent amount of bile acids. Analysis by capillary GC-MS (EI detection at 20 and 70 eV for Me-TMS derivatives) was employed to detect metabolites of nuatigenin. It was facilitated by the series of characteristic fragment ions due to the loss of the side chain (**Figure**, a-h).

For the rabbit, this analysis confirms that cholegenin and cholegenic acid originate from the dietary nuatigenin. Apparently, in case of wombats, cholegenic acid is the only metabolite. Rabbits, however, display a complex metabolism leading to cholegenic acid and at least six different hydroxylation products, three for cholegenin and three for cholegenic acid. The major hydroxylation occurs at C-6 (6 α ?) as indicated by mass spectra obtained for ketone derivatives and their TMS-enol in comparison with model compounds obtained from 5 α and 5 β 3,6-dioxo-cholan-24-oic acid. Moreover, preliminary experiments confirm that feeding oats to a cow results not only in the accumulation of cholegenin and iso-cholegenin but also cholegenic acid.

Appearance of these metabolites in the bile, as a result of feeding oats, indicates that the initial hydrolysis of saponins and reduction of nuatigenin by the intestinal flora leads to cholegenin. It is evidently absorbed from the intestine and undergoes a subsequent hepatic transformation. With this notion we can explain the failure of the large-scale attempt to isolate cholegenin from the ox bile in the US.⁴ This is because the common feed used for cattle in this country usually does not contain oats. Oats, however, are widely used in Europe, where the only isolation of cholegenin has been reported.³

Formation of metabolites from certain dietary sapogenols has health consequences and, evidently, bile-insoluble products are responsible for the toxicity of sapogenols hydroxylated only at C-3. The content of saponins in oats is low with no apparent toxicity.⁶ On the contrary, noted beneficial effects of the consumption of oat-derived products, especially upon the level of serum cholesterol, are not explained solely by the fiber content.⁷ Consequently, it would be attractive to test if nuatigenin metabolites are of any consequence. The lack of toxicity of oat saponins may be due to the very fact that both nuatigenin and cholegenin represent a rare case of 22,25-epoxy-furostanes with a primary hydroxyl group in their side chain and, unlike most common spirostanols, are susceptible to the hepatic oxidation. Easy formation of cholegenic acid may not only prevent deposition of bile-insoluble products but may enable further hepatic hydroxylation. Retention of such metabolites in the enterohepatic circulation, in view of their apparent structural resemblance to the common bile acids, may impact specific liver functions and, because of the significance of oats in human and livestock nutrition, the formation, distribution, and a possible role of nuatigenin metabolites requires greater scrutiny.

Figure. X = CH₂OH - **cholegenin**, X = COOH - **cholegenic acid**; X = CH₂OH, 5-6 double bond and 3 β -OH - **nuatigenin**. Major fragment ions observed for Me-TMS derivatives (R = TMS, X = CH₂OTMS or COOMe).

THE DETERMINATION OF THE ANTI-CONVULSANT 534U87 IN PLASMA BY AUTOMATED SOLID PHASE EXTRACTION AND LC-MS-MS

Robert A. Biddlecombe, C. Jane Eaves, Anne E. Jones and Stephen Pleasance

Bioanalysis, Langley Court, Beckenham, Kent, BR3 3BS, U.K.

INTRODUCTION

The world-wide prevalence of epilepsy is currently estimated at approximately 1% of the population. Chronic administration of anti-epileptic drugs (AED's) is the most common treatment for epilepsy. Although well established AED's such as carbamazepine, phenytoin and valproic acid can be highly effective in individual patients, nearly all can suffer from unwanted side effects and/or pharmacokinetic problems. For many there is a narrow margin between effective anti-convulsant action and CNS side effects and current clinical approach is to adjust AED doses and/or combinations to maximise seizure control and minimise side effects. 534U87 is currently being developed as a potential AED with improved efficacy and side effect profile, particularly for use in treatment-resistant patients with partial seizure disorders. Bioanalytical support to 534U87 was initially provided by a conventional HPLC method using fluorescence detection, however the continued pre-clinical and clinical development has required the application of a more sensitive LC-MS-MS method with the ability to monitor concentrations of a metabolite. The opportunity was also taken to improve the sample throughput.

EXPERIMENTAL

The solid phase extraction (SPE) procedure used for the original HPLC method was modified and transferred onto the MicroLute™ system of SPE in the "96 well" format (Porvair Filtronic, U.K.). All liquid handling (i.e. condition, load, wash and elute) was performed by a Packard MultiPROBE 104DT robotic sample processor (RSP). Plasma samples (100 µl for pre-clinical species) were loaded onto 50 mg C18 MicroLute™ SPE blocks and were eluted into 96 well collection plates with mobile phase (250 µl). The plates were transferred to a modified Gilson 233 XL autosampler and the extracts (10 µl) analysed by LC-MS-MS using a Jasco HPLC coupled to a PE-Sciex API-III+ triple quadrupole mass spectrometer via a TurbolonSpray interface operated at 450°C. The analytes were separated on a PrimeSphere C18 30 x 4.6 mm (40°C) using a mobile phase of 80% 0.1% CH₃CO₂H and 20 % MeCN 0.1% CH₃CO₂H (1 ml/min). Analytes were detected by selected reaction monitoring using argon as the collision gas (indicated thickness 300) and a dwell time of 200 msec per transition.

DISCUSSION

The full scan spectrum of 534U87 obtained by positive ion TurbolonSpray is presented opposite. 534U87, its N-oxide metabolite (2329U90) and the internal standard (385U87) all give an abundant MH⁺ ion with little fragmentation. The corresponding product ion MS-MS spectra of all three compounds are presented and reveal abundant product ions suitable for selected reaction monitoring (SRM) transitions. A 3 cm C18 column and a simple aqueous acetonitrile mobile phase provides resolution of 534U87, 2329U90 and the internal standard within 2 minutes (see Figure). The sensitivity and selectivity of the LC-MS-MS method are illustrated by the signal to noise and lack of interferences in the selected reaction monitoring chromatograms of a 10 ng/ml calibration standard in human plasma shown opposite. The method has been validated in both rat and dog plasma (50 ng/ml) and also in human plasma after slight modification in order to provide the lower LLOQ.

CONCLUSION

The MultiPROBE RSP takes approximately 20-25 minutes to prepare a MicroLute™ block (96 samples) using the SPE procedure for 534U87. With an LC-MS-MS run time of 1.5-2.0 minutes, each 96 well collection plate then takes between 2.4 and 3.2 hours to be analysed. This approach to automated SPE represents a significant improvement in sample throughput over the original HPLC method. To date some 5000 pre-clinical and clinical samples for 534U87 have been analysed using the MicroLute™ system. The technology has been successfully applied to several Projects in our Laboratory.

Determination of ZD6169 in Human Plasma by LC/APCI-MS/MS: Comparison to a Traditional LC/UV Method

K. H. Bui, V. C.X. Gao, D. P. Raybuck, M. C. Dyroff, B. K. Birmingham
Zeneca Pharmaceuticals, 1800 Concorde Pike, Wilmington DE 19897

Introduction

Zeneca ZD6169 is currently in clinical trials for treatment of urge type urinary incontinence. A traditional LC method with UV detection had previously been developed for the quantitation of ZD6169 in clinical plasma samples. The method uses a labor intensive liquid/liquid extraction procedure and requires a 25 minutes chromatographic run time to resolve ZD6169 from various endogenous peaks. To improve the sample throughput and selectivity, a LC/MS/MS method was developed. Salient development and validation features of the LC/MS/MS method and its comparison against the LC/UV method are summarized.

Methods

LC/MS/MS analysis was performed with a PE-Sciex API-III^{plus} triple quadrupole mass spectrometer equipped with a standard heated nebulizer APCI interface. The API source was operated in the negative-ion APCI mode and the heated nebulizer interface was maintained at 550° c. Selected-reaction monitoring (m/z 336 $\rightarrow$ 196) was used for quantitative analysis, with a dwell time of 500 ms/transition. Argon was employed as the target gas at a thickness of 2.6×10^{14} atoms/cm². Mass spectrometer was coupled to an HP 1050 HPLC system equipped with 2 pumps and the chromatographic analysis was conducted on a YMC J sphere, 4 x 50 mm ODS column with a mobile phase composing of 70% ACN in 0.025 M ammonium formate solution (pH =3). A Valco Model E60 switching valve was used to divert the solvent front (the first 0.6 min. of the analysis) from the mass spectrometer and a second pump was used to continuously feed the mass spectrometer with mobile phase during the diversion. Plasma sample was prepared by a 2:1 (v:v) dilution with acetonitrile. The sample was mixed with a vortex, centrifuged and the resulting supernatant was transferred to an HPLC vial of which 10 μ L was injected.

Results

The LC/MS/MS method is linear in the range of 1 to 200 ng/mL. For quality control samples at the low, mid, and high concentrations levels (4, 40, and 150 ng/mL), the within-day precisions were 12.1, 3.58, and 1.07% RSD and the between-day precisions were 5.70, 8.46 and 8.95 %RSD. The accuracy of quality control samples (at all concentration levels) averaged within ± 10.0 of theory. A comparison of various analytical attributes of the LC/MS/MS and the LC/UV methods are summarized in Table 1.

Table 1

Attributes	LC/MS/MS	LC/UV
Sample Preparation	protein precipitation	liquid/liquid extraction
Sample Throughput	250/technician/day	100/technician/day
Quantitation Limit	1 ng/mL	2 ng/mL
	3.3 pg on column	330 pg on column
Linearity	1 - 200 ng/mL	2 - 5000 ng/mL
Analysis Time	1.8 min	25 min
Selectivity	high (no endo. peaks)	Low (many endo. peaks)

The LC/MS/MS method has been cross-validated against the LC/UV method. A plot of the correlation of ZD6169 concentrations in unknown plasma samples determined by the two methods is shown in Figure 1. Data points in the figure are scattered narrowly and randomly along a line of unity indicating no difference or bias between the two methods.

The LC/MS/MS has been used to support 2 clinical trials. The method was capable of monitoring ZD6169 in human volunteers for at least 24 h following a single oral dose of 20 mg.

Figure 1

Conclusions

The LC/MS/MS method is accurate, precise and rugged and has been successfully applied in 2 clinical trials. The method has been successfully cross validated against a LC/UV method and offers the following advantages: 1) simpler sample preparation, 2) reduced analysis time, and 3) higher sensitivity and selectivity.

VALIDATION OF A LC/MS METHOD FOR QUANTIFYING MDL 100,907 AND ITS METABOLITE, MDL 105,725, IN HUMAN PLASMA

James S. McElvain¹, Pamela D. Perkins², Val J. Vandiver² and Larry S. Eichmeier²

¹Analytical R&D Department, Amgen, Thousand Oaks, CA,

²US Bioanalytics Department, Hoechst Marion Roussel Inc., Kansas City, MO

INTRODUCTION

MDL 100,907 is a 5-HT_{2A} receptor antagonist that is currently being developed by Hoechst Marion Roussel as an antipsychotic for treating patients suffering from schizophrenia.¹ Once administered, MDL 100,907 is converted to the O-desmethyl metabolite, MDL 105,725, which has also been demonstrated to have biological activity. The structure of both compounds are shown in Figure 1. Due to their high potency a sensitive bioanalytical assay was required to quantitate both of these analytes in human plasma to support Phase I pharmacokinetic studies.

METHODS

Equipment

1. ESA model 580 isocratic pump.
2. Two SSI model LP-21 pulse dampeners.
3. Gilson model 231 autosampler.
4. Finnigan model SSQ 710 ESI MS detector.

HPLC Conditions

Column: YMC C18 Basic, 100 x 2.1mm
Mobile phase: 16% ACN/water with 50 mM ammonia acetate, pH 4.0
Flow rate: 0.2 mL/min
Injection vol: 100 µL

API MS Conditions

Interface: Electrospray
Source temp: 70°C
Capillary temp: 250°C
Spray voltage: 5.0 kV
SIM ions: 344, 360, 374 amu
Scan time: 1.5 seconds

SPE Procedure

Cation exchanger:
Condition: Benzene sulfonyl
1 mL MeOH
1 mL water
Load: 1 mL plasma
Wash: 1 mL water
1 mL 200 mM NH₄Ac, pH 4
Elute: 1 mL 0.6% TEA in MeOH
Evaporate: 15 minutes under N₂ at 45°C
Reconstitute: 0.5 mL 30% MeOH/70% water

REFERENCES

1. Sorensen, S.M., Kehne, J.H., Fadayel, G.M., Humphreys, T.M., Ketteler, H.J., Sullivan, C.K., Taylor, V.L., and Schmidt, C.J. (1993) Journal of Pharmacology and Experimental Therapeutics, 266: 684-691.

RESULTS

Recovery

The extraction efficiency was estimated to be ca. 60% for MDL 100,907 and the internal standard and ca. 50% for MDL 105,725, based on a direct comparison to neat standards. Additional studies demonstrated that during the extraction procedure there is no interconversion of the analytes.

Specificity

Both analytes were baseline separated from each other at the 5.0 ng/mL concentration level, but MDL 100,907 was not completely resolved from the internal standard (Figure 2). Figure 3 demonstrates that the signal to noise ratio is still quite high even at the limit of quantification of this assay (0.10 ng/mL for both analytes). Chromatograms of blank plasma samples indicated no interferences at the retention times of the analytes or the internal standard (Figure 4).

Validation

The assay was validated over the concentration range of 0.10 to 5.0 ng/mL for both MDL 100,907 and MDL 105,725. Two replicates of seven freshly prepared calibration standards (0.10 - 340 ng/mL) and a minimum of fifteen replicates of five quality control (QC) standards were assayed on three separate days. The line of best fit for calibration standards was calculated for each day of analysis by

weighted (1/x) quadratic least squares regression based on peak height ratios. The *r*² values were greater than 0.99 for all batches for both analytes. Accuracy and precision of the QC samples were determined using the back calculated values from the calculated regression line for that day and are summarized in Table 1.

Stability

Both MDL 100,907 and MDL 105,725 were found to be stable in whole blood at room temperature for at least 1 hour and in plasma at room temperature for at least 24 hours. In addition, it was found that both analytes are stable for at least 8 months in plasma stored at -20°C and through at least four freeze-thaw cycles. It was also demonstrated that both MDL 100,907 and MDL 105,725 were stable for at least 24 hours at room temperature when stored in the HPLC injection solvent.

CONCLUSIONS

An accurate, precise, and specific method for quantification of both MDL 100,907 and MDL 105,725 in human plasma has been developed and validated over the concentration range 0.10 - 5.0 ng/mL. This method is relatively simple and rapid allowing the analysis of at least 144 samples per batch (110 unknowns, 16 SC samples, and 18 QC samples). Because of its short run time of 6 minutes per injection, it requires less than 16 hours to analyze all 144 samples thus maximizing the overall sample throughput of a single LC/MS system. This method has been used to quantitate the relative concentrations of both MDL 100,907 and MDL 105,725 in oral MDL 100,907 pharmacokinetic studies (Figure 5).

HPLC-MS/MS Quantification of a 5HT_{2a} Antagonist and a Metabolite in Rat Brain by Microdialysis

Timothy G. Heath and Dennis O. Scott

Hoechst Marion Roussel, P.O. Box 9627, Kansas City, MO 64134

INTRODUCTION

Microdialysis sampling of *in-vivo* systems has emerged as a powerful tool for investigations of drug pharmacokinetics and metabolism. Application of this technique has proven its use in sampling many tissues and organs. Specific placement of the microdialysis probe within the tissue accesses the extracellular fluid (ECF) for sampling small molecules, either endogenous compounds or drugs. These molecules diffuse through the microdialysis membrane and are swept away by the perfusion medium which is then collected for analysis.

Microdialysis sampling potentially offers greater temporal resolution than does serial sampling, which is advantageous in pharmacokinetic studies. However, inherent features of microdialysis sampling present analytical challenges for measuring analyte concentration. The perfusion medium flow typically is 1 μ l/min or less. Quantification of analyte concentration in these samples requires the handling of a low volume sample which contains high salt concentrations and dilute analyte concentrations.

MDL 100,907, a potent and highly selective 5-HT_{2a} receptor antagonist, is being developed for use as a novel therapy for treating schizophrenic patients. Depending on the brain region, it has been proposed that MDL 100,907 may either reduce or increase dopamine production. It has been shown previously that MDL 100,907 increases dopamine levels in the medial prefrontal cortex (mPFC) region of the brain (1), however there was no direct evidence indicating the presence of drug in the brain. In our studies, microdialysis sampling was used to obtain samples representative of the brain ECF following administration of the drug to rats. A LC-MS/MS assay was developed which enabled the quantification of analytes in both brain ECF (via microdialysis sampling) and plasma (samples serially collected). These experiments were performed to provide direct evidence as to the ability of these compounds to penetrate the blood-brain-barrier (BBB) and compare the brain levels with plasma concentrations. While the sample processing for the two matrices differed slightly, the LC-SRM detection was identical (2).

METHOD

Microdialysis: Surgical implantation of the microdialysis probe consisting of a polycarbonate membrane in the medial prefrontal cortex (mPFC) region of the rat brain was conducted as previously described (3).

Microdialysis Perfusate and Plasma Sample Preparation: Microdialysis perfusate (artificial CSF, (aCSF)) was delivered via a syringe pump through the probe at a rate of 1 μ l/min. Samples were collected at ten minute intervals for up to six hours. Each sample consisted of 10 μ l of perfusate and 10 μ l of internal standard (IS) solution which was introduced into the sample vial by the Gilson autosampler. The sample was mixed, and 10 μ l was injected onto the HPLC column. Calibration standards were prepared and analyzed at concentrations of 0.5 ng/ml to 1000 ng/ml in aCSF. Blood samples were collected post-dose and centrifuged at 3500 rpm for 15 min. To 25 μ l of plasma was added 50 μ l of acetonitrile fortified with the IS. Following precipitation of the plasma proteins and centrifugation, 5 μ l of the resulting supernatant was injected onto the chromatograph. The range of the calibration curve for plasma was from 1-500 ng/ml.

LC-MS/MS Analysis: Chromatographic separations were achieved with a Michrom BioResources UMA HPLC. The HPLC column was an Alltima C8, 5 μ m, 100A (150 $\times$ 1 mm i.d.) while the mobile phase consisted of acetate buffer-acetonitrile (42-58, v/v). The flow was 65 μ l/min. A Finnigan MAT TSQ 700 mass spectrometer, operated in the electrospray mode, was used for detection. Q2 was filled with argon at 2.2 mTorr and

the collision energy was 35 eV (Lab). Protonated molecules of m/z 374, m/z 360 and m/z 344 were subjected to CID and the ion of m/z 123 was monitored.

RESULTS

The structure and routes of fragmentation for MDL 100,907 are depicted in Figure 1. The metabolite MDL 105,725, represents des-methylation occurring at the 3-methoxy group on the phenyl ring. The IS differs in that a -H is at this ring position. All of these compounds yield a prominent ion of m/z 123 when subjected to CID.

Shown in Figure 2 are the chromatographic profiles obtained following the analysis of aCSF fortified to 1 ng/ml. This analysis represents an on-column injection of 5 pg, or 14 femtomoles. Both within-day and between-day precision and accuracy data was generated for analytes in aCSF and plasma at three concentrations. Overall, the RSD < 19% while the RE < 18%. The LLQ in plasma was 1 ng/ml while in aCSF, it was determined to be 500 pg/ml.

Figure 1: MDL 100,907, MW 373

Figure 2: Chromatographic profiles obtained following the analysis of 1 ng/ml aCSF.

The source of the background noise in the SRM analyses was determined to be electronic in nature (2). This is evident from the analysis of a 5 ng/ml plasma extract at different electron multiplier voltages (EMV) (data not shown). At a EMV of 1000V, the analyte signal is not detected. However at 1600V, the analyte peak is readily observed while there is only a 4-fold increase in the background noise. If the background was chemical noise, there would be a much greater increase in the noise with increasing EMV. A similar experiment was conducted in SIM mode and the background noise increased ~100 times with an increase in EMV.

APPLICATION

This method was used to determine the concentration of MDL 100,907 and MDL 105,725 in brain ECF and rat plasma following i.v dosing of 5 mg/kg and oral dosing of 50 mg/kg in rat. Both compounds were detected in the microdialysis perfusate. By comparing the AUC's in brain ECF and plasma, it was determined that MDL 100,907 has much greater permeability through the BBB than does MDL 105,725.

Determination of 3,4-Dihydroxyphenylacetic Acid (DOPAC) in Equine Urine by Ion Spray LC-MS

Mohammed R. Koupai-Abyazani, Barbara Esaw and Barbara Laviolette
Can Test Ltd., 1523 West 3rd Avenue, Vancouver, B.C., V6J 1J8, Canada

DOPAC (3,4-dihydroxyphenylacetic acid) is one of the major metabolites of levodopa, a dopaminergic anti-Parkinsonian agent, in both man and horse. The use of levodopa at Canadian racetracks has been reported. We have previously described a liquid chromatographic-atmospheric pressure ionisation mass spectrometric (API LC-MS) method for the detection of levodopa and its metabolites in equine biological fluids. The analysis of two sets of urine samples collected following an administration of levodopa showed that DOPAC was the major metabolite in the horse along with dopamine and HVA at lower concentrations.

As the parent drug was not detected in urine, DOPAC was selected as a marker to control the use of levodopa at the racetracks. In the present work we applied the previously developed method with some modifications to determine the concentration of DOPAC in urine collected after the administration of Sinemet® and to measure endogenous DOPAC concentrations in horse urine.

An oral dose of 1500 mg levodopa and 375 mg carbidopa, as the product Sinemet® was administered to a standardbred mare. Urine samples were collected at various times (Table 1) after the administration and kept frozen until analysis. The extraction was carried out using acid-washed alumina.

The positive ion mass spectrum of DOPAC exhibited a strong quasimolecular ion at m/z 186 corresponding to $[M+NH_4]^+$ with a few weak fragments at m/z 169, $[M+H]^+$, and m/z 123, $[M-COOH]^+$.

Urine samples collected following the drug administration were analysed using the MRM mode. The standard calibration curve used for determination of DOPAC concentrations in urine samples was linear for samples fortified in the range of 5 to 100 $\mu\text{g/ml}$ ($r = 0.9998$). DOPAC concentrations in urine samples are listed in Table 1. The maximum level of DOPAC in the samples (59.7 $\mu\text{g/ml}$) was at 4 h after drug administration. Pre-administration (blank) urine also showed a peak for DOPAC with a concentration of 1.3 $\mu\text{g/ml}$.

The presence of DOPAC in the pre-administration urine sample prompted us to investigate the natural occurrence of DOPAC in the horse. Three sets of blank urine samples (I, II, III) were collected from 12 horses (A-F, H, I, K-N) in February, July and September 1995, respectively. These samples were extracted and analysed upon receipt from the farm using the procedure previously described. In the first set DOPAC was detected only in the urine sample of horse N and traces in the samples from horses A, B and F. However, all blank urine samples collected in sets II and III showed a peak for DOPAC. Additional work has been carried out to ensure the authenticity of the detection. The extraction and analysis of a few samples from sets I and II on the same day under the same instrumental conditions was carried out. Results obtained were in agreement with our primary findings. Figure 1 shows LC/MS/MS chromatograms obtained for urine samples of horses L and D collected in sets I and II.

The results of the quantitative analysis of the blank urine samples is presented in Table 2. The endogenous DOPAC concentrations varied from 4.3 to 10.8 $\mu\text{g/ml}$ (set II) and 3.1 to 26.0 $\mu\text{g/ml}$ in set III. Mean endogenous level of DOPAC was 9.5 $\mu\text{g/ml}$. To use DOPAC as a marker to detect levodopa a threshold should be set. Extensive study would be required to determine a threshold.

Method Development for the LC/MS/MS Quantitative Determination of Ondansetron Glucuronide and Sulfate Metabolites in Human Urine

¹Victoria Campbell, ²John Walsh, and ¹Jack Henion

¹Advanced BioAnalytical Services, 15 Catherwood Road, Ithaca, New York 14850

²GlaxoWellcome, Research Triangle Park, North Carolina 27709

Introduction

Ondansetron is an antiemetic used in the treatment of post-operative nausea. In humans, it is metabolized by hydroxylation followed by subsequent conjugation to glucuronides and sulfates. The glucuronide and sulfate conjugates increase the solubility of ondansetron in water, which in turn causes it to be excreted via the kidneys. The objective of this study is to develop a selected reaction monitoring (SRM) liquid chromatography mass spectrometry (LC/MS) method for the quantitative determination of 7-OH ondansetron glucuronide, 8-OH ondansetron glucuronide, 6-OH ondansetron sulfate, 7-OH ondansetron sulfate, and 8-OH ondansetron sulfate in human urine. Chromatographic resolution is required prior to the mass spectrometric analysis because the mass spectrometer cannot differentiate the positional isomers. The ondansetron metabolites are successfully extracted from human urine with solid-phase extraction (SPE) and are quantified from 5 ng/mL to 1000 ng/mL.

Experimental

The chromatography was accomplished with a 2 mm x 150 mm Deltabond Cyanopropyl HPLC column using a flow rate of 200 μ L/min delivered by a Shimadzu LC-10AD HPLC pump. The eluent was an isocratic solution of acetonitrile and ammonium formate buffer. The HPLC column was maintained at ambient temperature and was equipped with a Waters WISP 717^{Plus} autosampler for sample injection. The mass spectrometer, a PE-SCIEX API III^{Plus}, was operated in the positive ion detection mode with a 150 ms dwell time for each selected transition. The Turbo IonSprayTM ionization source was operated at 500 degrees C. Selected reaction monitoring was used for detection: m/z 486.2 $\rightarrow$ m/z 310.2 for glucuronide metabolites and m/z 390.1 $\rightarrow$ m/z 186.1 for sulfate metabolites.

Ondansetron glucuronide and sulfate metabolites were extracted from 1 mL aliquots of human urine using C₈ solid-phase extraction cartridges. The SPE cartridges were conditioned with methanol followed by ammonium formate buffer prior to the addition of the urine. Then the cartridges were rinse with ammonium formate buffer followed by a solution of acetonitrile/ammonium formate buffer. Cartridges were dried under vacuum and eluted with methanol. The methanol was evaporated under nitrogen. Dry extracts were reconstituted in 100 μ L of ammonium formate buffer; 5 μ L aliquots were injected onto the HPLC column for analysis.

Results and Discussion

A sensitive, specific, accurate and reproducible analytical method for the quantitation of 7-OH ondansetron glucuronide, 8-OH ondansetron glucuronide, 6-OH ondansetron sulfate, 7-OH ondansetron sulfate, and 8-OH ondansetron sulfate in human urine was

developed. The glucuronide isomers and sulfate isomers were chromatographically resolved prior to quantitation by mass spectrometry (Figure 1). Linear calibration curves from 5 ng/mL to 1000 ng/mL in human urine were achieved for all five ondansetron metabolites. Representative calibration curves are shown for 7-OH ondansetron glucuronide and 7-OH ondansetron sulfate in Figures 2 and 3, respectively. All five of the calibration curves use a 1/x weighted linear regression and each has a coefficient of determination greater than 0.998. The deviation from true values was within 15% for all metabolites at all concentrations.

**QUANTITATION OF LEVORPHANOL IN HUMAN PLASMA BY
LC/MS/MS WITH APCI INTERFACE**

Lana Peng, Karl H. Linderholm, Allan S. Xu*, James D. Hulse
Harris Laboratories, 624 Peach Street, P.O. Box 80837,
Lincoln, NE 68501

Levorphanol, a morphine congener, is a common narcotic analgesic used orally and parenterally in the management of patients with moderate to severe pain associated with cancer and terminal illness (1). The therapeutic dose of levorphanol is only 2 mg, resulting in a great difficulty in quantitation of steady state of levorphanol in plasma. Previously the most suitable method of levorphanol analysis was radioimmunoassay (2). Here we present a sensitive and specific assay for determination of free and total levorphanol in human plasma utilizing liquid chromatography with triple-stage quadrupole mass spectrometry.

In free levorphanol analysis, 20 μ l of internal standard, codeine at 100 ng/ml, was added into each calibration standard and quality control sample which was in 1.0 ml of plasma. The compounds were alkalized with 2 ml of 1.0 N ammonium hydroxide and extracted with 5 ml of isopropanol and dichloromethane (20:80, v/v). The organic phase was then dried down under N_2 at 50°C and subsequently reconstituted with 100 μ l of mobile phase, and 20 μ l was injected onto the LC/MS/MS. In total levorphanol (free + conjugated) analysis, the sample treatment was the same except for a pre-incubation step with acetate buffer (pH 5.0) and beta-glucuronidase (1000 unit/ml) at 35°C overnight.

A PE Sciex API III MS/MS was employed in this method. An atmospheric pressure chemical ionization (APCI) interface was used to connect the MS/MS to a Keystone BDS Hypersil C18 column (50 x 3.0 mm, 3 μ m). The flowrate was at 0.8 ml/min. Each run time was 1.0 min. Ions monitored were m/z 258.2 $\rightarrow$ 157.0 for levorphanol and m/z 300.2 $\rightarrow$ 165.0 for codeine (I.S.).

A Q1 mass spectrum and a daughter ion mass spectrum of levorphanol are shown in Fig 1. In Fig 1(A), protonated molecular ion (MH^+) is at m/z 258.2, with two major acetonitrile adducts at m/z 299.2 and 340.2. In Fig 1(B), a base daughter ion peak is shown at m/z 157.0. The protonated molecular ion and the major daughter ion were monitored in the multiple reaction monitoring (MRM) mode to determine levorphanol levels in plasma.

The method was validated over a linear range of 0.10 - 5.00 ng/ml for both free and total levorphanol, with a limit of quantitation at 0.1 ng/ml. The extraction recovery were 62.7% for free levorphanol and 74.0% for total levorphanol over the entire calibration range. Interday and intraday precision and accuracy of QC samples and sample stabilities in processing and in biological matrix were also established and the results was satisfactory.

This method has been successfully applied to a total of 1000 clinical samples in pharmacokinetic investigation of levorphanol in human body following oral administration. More than 200 samples were analyzed per day. Fig 2 shows a total ion chromatogram of an extracted subject sample,

with levorphanol concentration at 4.46 ng/ml. The method was found to be sensitive, simple, and fast.

Figure 1. Mass spectra of levorphanol: A) Q1 scan; B) Daughter ion scan.

Quantitative determination of CP-93,393 in Serum at trace levels by HPLC/MS/MS

M.J. Avery and H.G. Fouda
Central Research Division, Pfizer INC., Groton, CT 06340

CP-93,393 (Figure 1) is an anxiolytic agent currently undergoing clinical evaluation. An analytical method for its determination in serum was desired to support pharmacokinetic and pharmacodynamic studies.

Attempts to develop a quantitative assay by HPLC with UV detection were not successful at expected low therapeutically relevant concentrations. A successful assay was developed using a simple liquid-liquid extraction and detection by HPLC/APCIMS/MS. A stable isotope internal standard (I.S.) was used to correct for differences in extraction efficiency and to improve accuracy and precision.

Drug and I.S. were isolated from 1 mL samples by extraction with n-butyl chloride. Extraction efficiency was enhanced by adjusting the pH to 10. The organic layer was isolated after freezing the aqueous layer in dry ice/i-propanol and the solvent removed by evaporation. The reconstituted sample was chromatographed on a Zorbax Rx C8 column using a mobile phase of 50/50 MeOH/ water containing 0.1% trifluoroacetic acid and 6 mM triethylamine. The entire HPLC column effluent was introduced into the APCI ion source of a SCIEX API III+ mass spectrometer where positive molecular ions were generated in a Corona discharge. MH⁺ ions at m/z 330 were dissociated by collision with Argon and the major product ion at m/z 122 monitored. This Multiple Reaction Monitoring (MRM) experiment produced high sensitivity and selectivity (Figure 2). Since the internal standard contained 4 deuterium's, the MRM reaction m/z 334->122 was used to measure the I.S.. Typical responses for blank samples and LLOQ (20 pg/mL) are shown in Figure 2.

Quantitative performance of the assay was determined using fortified control serum. Six replicates of samples fortified at 0.02, 0.06, 0.6, 3.0, and 5.0 ng/mL were prepared and their concentrations determined. The results (Table I) demonstrate minimal accuracy and precision of 96% and 14% respectively.

Figure 1. Structure of CP-93,393 (X=H) and its internal standard (X=²H).

Table 1. Analysis of serum samples containing known amounts of CP-93,393: intra-assay parameters; 6 samples at each concentration.

Fortified drug conc. (pg/mL)	Mean Conc. found (pg/mL)	C.V. (%)	Mean Accuracy (%)
20	20.1	8%	100%
60	61.2	13%	102%
600	582	14%	97%
3000	3130	3%	104%
5000	4810	2%	96%

Figure 2. MRM responses for HPLC/APCIMS/MS analysis of extracts of human plasma fortified with CP-93,393 and D4-CP-93,393 internal standard.

Quantification of Selegiline and Three Metabolites in Human Plasma by Positive Electrospray MS/MS

Qimin Li, Gordon McKay and Kamal K. Midha

College of Pharmacy and Nutrition, University of Saskatchewan, Canada, S7N 5C9

Selegiline, previously named *l*-Deprenyl (DP), is an irreversible inhibitor of monoamine oxidase type B (MAO-B), which enhances dopaminergic transmission in the brain.⁽¹⁾ It has been used widely in the treatment of Parkinson's disease, either alone in the early phase of the disease or together with levodopa. Selegiline is rapidly distributed throughout the body and disappears rapidly from serum, with a half-life of about 0.15 h. 94% of selegiline is bound to plasma proteins at therapeutic concentrations. Due to the hepatic biotransformation and large volume of distribution the concentrations of selegiline after an oral dose of 10 mg are

too low to be detected with conventional chromatographic methods. For this reason the main three metabolites desmethylselegiline (DMS), methamphetamine (MAM) and amphetamine (Am) were used in pharmacokinetic study and bioavailability comparison of various pharmaceutical preparations of selegiline. Until recently it has not been possible to reliably measure the concentration of selegiline after oral dosage. Although Michaelis et al.⁽²⁾ have succeeded in measuring the concentration of selegiline in plasma using capillary gas chromatography and mass spectrometry with a detection limit of 50 pg/mL, the sensitivity of the method is not sufficient for single dose pharmacokinetic studies.

The present assay has been developed for single dose studies and is also applicable for clinical research. The linear concentration ranges investigated and validated were 0.01-2 ng/mL for selegiline, 0.05-2 ng/mL for desmethylselegiline, 0.1-40 ng/mL for methamphetamine and 0.25-20 ng/mL for amphetamine in human plasma as shown in the illustrated standard curves. The method relies on selected reaction monitoring of precursor/product ion transitions after flow injection analysis on a triple quadrupole mass spectrometer (VG Quattro-II) equipped with an electrospray ion source. The developed +ES-MS-MS method is sufficiently specific and sensitive to allow sample analysis using direct loop injection without any chromatographic separation. The lower limits of quantification are 10, 50, 100 and 250 pg/mL for selegiline, desmethylselegiline, methamphetamine and amphetamine in plasma, respectively. The recoveries of selegiline, DMS, MAM, Am and internal standard are 99%, 99%, 89%, 70% and 101%, respectively using this procedure.

The steady state concentration of the intact drug and three metabolites have been investigated using this method in 5 individual patients as shown in the following Table.

Patients	Oral dose/day	Selegiline	DMS	MAM	Am
		Ave.C (pg/mL)	Ave.C (pg/mL)	Ave.C (pg/mL)	Ave.C (pg/mL)
A	5 mg x 2	43.1±15.9	368±99	10369±4463	2855±1211
B	5 mg x 2	54.5±15.2	363±107	17372±4309	5160±1436
C	5 mg x 1	124.5±22.2	703±150	11882±623	3985±163
D	2.5 mg x 2	57.5±6.3	322±16	14004±1480	3135±192
E (female)	5 mg x 1	40.2±6.9	437±65	16935±2932	4306±720

The described method is both precise and accurate. It demonstrates sufficient sensitivity and specificity to allow samples to be analyzed with a minimum of sample handling and a total analytical cycle time of less than one minute per injection. The method is easily applied to clinical monitoring of the drug and its major metabolites and would also appear suitable for studies aimed at assessing the bioavailability of the drug.

Determination of Selegiline, Desmethylselegiline and Related Compounds in Human Plasma by LC/MS/MS

Daniel Mulvana, John Perkins and Jack Henion
Advanced BioAnalytical Services, 15 Catherwood Rd., Ithaca, New York 14850

Introduction

Selegiline (SEL, L-deprenyl, Figure #1) is an irreversible inhibitor of monoamine oxidase, type B and is being currently marketed for the treatment of Parkinson's disease. Following oral dosing, selegiline is extensively metabolized to N-desmethylselegiline (DES, Figure #1), methamphetamine (MET, Figure #1) and amphetamine (AMP, Figure #1). Since all compounds are present in the plasma, the objective of this project was to develop a single analytical method for all analytes which would have a quantitation range encompassing the expected plasma levels found in dosed patients. An analytical method was developed and validated for the simultaneous determination of SEL and its metabolites in heparinized human plasma. The method uses a deuterium-labelled internal standard (MET-D₈, Figure #1) and separation and detection are accomplished using Turbo ion spray high performance liquid chromatography tandem mass spectrometry (LC/MS/MS), operated in the selected reaction monitoring (SRM) mode.

Method

The plasma sample (1 mL) is added to a polypropylene test tube, followed by the internal standard, sodium carbonate and n-butyl chloride. After rotation and centrifugation, the organic layer is transferred to a test tube containing HCl. The organic layer is then evaporated under nitrogen in a 40°C water bath.

The dry extract is then reconstituted in 40 µL of acetonitrile:aqueous ammonium acetate and transferred into autosampler vials. Chromatographic separation is accomplished using a cyanopropyl HPLC column with an eluent consisting of acetonitrile, aqueous ammonium acetate and dilute trifluoroacetic acid. The sample injection volume is 10 µL. The eluent is monitored by Turbo® ion spray LC/MS/MS using the following transitions:

SEL: m/z 188.3 → m/z 119.2	AMP: m/z 136.2 → m/z 119.2
DES: m/z 174.3 → m/z 119.2	Dg-MET: m/z 158.2 → m/z 124.2
MET: m/z 150.2 → m/z 119.2	

Results and Discussion

Under these conditions, the selegilines are chromatographically resolved from the amphetamines. SRM chromatograms of a blank plasma extract and an extracted standard containing 100 pg/mL of SEL and DES and 500 pg/mL of MET and AMP are presented in Figures #2 and #3, respectively. Calibration curves were constructed over the ranges of 50-2000 pg/mL for SEL and DES and 50-10,000 pg/mL for MET and AMP. Regression lines were drawn using a quadratic regression weighted by the reciprocal of the area ratio (1/y). Accuracy and precision data were obtained by analyzing QC samples at low, medium and high concentrations in replicates of five over four separate days. The inter-assay accuracies were within 7% (DEV) and the inter- and intra-assay precisions were within 6% (C.V.) for all analytes. The extraction recoveries were >87% for all analytes. The analytes were found to be stable in plasma at ambient temperature for at least 24 hours, for at least 32 days at -30°C in plasma, as dry extract for at least 6 days at 4°C, after reconstitution for at least 43 hours and after being subjected to 3 freeze-thaw cycles in plasma.

An interfering peak was observed in the blank SRM chromatogram of AMP when the product ion at m/z 91 was monitored. This was eliminated when the collision energy was changed and the product ion at m/z 119 was monitored. A significant amount of Q2 crosstalk was observed in the above transitions since all product ions are identical. This was eliminated when "dummy" transitions were incorporated into the acquisition method.

QUANTITATION OF MUSCLE RELAXANTS IN PLASMA USING HPLC/TANDEM MASS SPECTROMETRY

Diane Rindgen¹, Lisa A. Marzilli¹, Jeevendra Martyn², Paul Vouros¹
¹Barnett Institute and Dept. of Chemistry, Northeastern University, Boston, MA
²Shriners Burns Institute, Boston, MA

Pancuronium and vecuronium bromide are quarternary ammonium steroids used to induce muscle relaxation during anesthesia. Both neuromuscular blocking agents are metabolized to the deacetylated derivatives at the 3 and 17 positions of the steroid ring. The parent compounds generate characteristic ions under conditions of electrospray ionization which allow for their differentiation namely, m/z 286.3 ($[M - 2Br]^{+2}$ of pancuronium) and m/z 279.2 ($[M - Br + H]^{+2}$ of vecuronium). The m/z 286.3 ion of pancuronium bromide fragments to produce a doubly-charged product ion at m/z 206.6 (loss of acetic acid and N-methyl piperidine) and a singly-charged ion at m/z 430.5 (loss of protonated N-methyl piperidine and ketene or N-methyl piperidine and an acetyl group). Monitoring these two transitions, m/z 286.3 $\rightarrow$ m/z 206.6 and m/z 286.3 $\rightarrow$ m/z 430.5, formed the basis for the development of an on-line HPLC/ESI/MS/MS method that allowed for the quantitation of pancuronium bromide in plasma. In addition, the ESI fragmentation behavior of the metabolites of vecuronium bromide was investigated in an effort to extend the methodology to the detection of these compounds.

A VG Quattro triple quadrupole mass spectrometer (Fisons Instruments, VG Biotech, Altrincham, UK) equipped with a VG electrospray source was used for all phases of this work. Chromatography was performed with a Carlo Erba (Fisons Instruments, Beverly, MA) capillary HPLC system consisting of a Phoenix 20 syringe pump operating in an isocratic mode. A Nucleosil silica column (Phenomenex, Torrance CA) was utilized for sample separation (10 mm x 10.0 cm). Samples were introduced through a Rheodyne Model 7125 injector (Cotati, CA) equipped with a 10 μ L external loop. CID and MRM experiments were performed using argon as the collision gas with the optimal pressure determined using the relevant standard.

Pancuronium and vecuronium bromide (Organon Laboratories, Ltd, Lanarkshire, Scotland) were separated from plasma constituents using the procedure outlined by Ducharme et al. (1). C₁₈ Bond Elut solid phase extraction columns from Varian Sample Preparation Products (Harbor City, CA - 3 mL/500mg) were conditioned with methanol (3 x 2 mL) and water (3 x 2 mL). Plasma (1 mL), water (1 mL), analyte and internal standard (d_4 -vecuronium, 51 ng) spikes were added then aspirated through the cartridge. The plasma had previously been acidified with 12 μ L of 2 M H₂SO₄ per mL to prevent analyte degradation. The columns were washed with water (3 x 1 mL), acetonitrile (3 x 1 mL) and methanol (3 x 1 mL) and the analytes were then eluted into silanized 5 mL V-vials (Kimax; Fisher Scientific) using 10 mM KI in methanol (2 x 500 μ L). The eluents were dried down using a Savant Speed Vac Plus (Model SC110A-Farmingdale, NY). The plasma extracts were reconstituted in mobile phase (20 - 100 μ L) with 5 μ L injected onto the separation column. The mobile phase consisted of 60/40 acetonitrile/220 mM ammonium carbonate (v/v). The vecuronium metabolites were dissolved in acetonitrile containing 1% acetic acid for acquisition of CID spectra. The concentration of each metabolite standard solution was 25 μ M and each solution was introduced into the ESI source by direct infusion using a Harvard Apparatus syringe pump (South Natick, MA) at a flow rate of 3 μ L/min.

Several interface parameters were optimized prior to the analysis of the plasma samples. The transition S/N ratio improved by approximately a factor of five following reduction in the flow rate from 20 μ L/min to 4.4 μ L/min through the use of a post-column split. The ESI source temperature also had an effect on signal intensity with the best results obtained between 90°C and 95°C. Figure 1 displays

representative TIC signals for the analyte and internal standard from a reconstituted plasma extract. The developed method was shown to be linear in the range 2-100 ng pancuronium/mL plasma with an analyte recovery of greater than 60%. It was observed that pancuronium had a tendency to stick to the silica column and this behavior would become more pronounced at higher sample levels, ca. 5 ng on column. Future work will include the evaluation of a cyano stationary phase for analyte detection.

The 3-OH and 17-OH metabolites of vecuronium lose the bromide counterion under conditions of electrospray ionization to produce isobaric ions appearing at m/z 515.5. The fragmentation patterns of the m/z 515.5 ions are, however, distinct and allow for the differentiation of the two compounds. For example, the m/z 515.5 ion of 3-OH vecuronium produces a product ion at m/z 374.4 resulting from the loss of N-methyl piperidine and ketene (Figure 2). This ion is not observed at an appreciable level in the product ion spectrum of the 17-OH derivative (Figure 3). Thus, a selective transition is available for the detection of the 3-OH metabolite in the presence of 17-OH vecuronium.

Picogram Determination of a Novel Dopamine D4 Receptor Antagonist in Human Plasma and Urine by Liquid Chromatography with Atmospheric Pressure Chemical Ionization Tandem Mass Spectrometry, C. M. Chavez-Eng, M. L. Constanzer, and B. K. Matuszewski, Merck Research Laboratories, West Point, Pennsylvania 19486, USA

A sensitive and specific assay for the determination of 3-[[4-(4-chlorophenyl)piperazin-1-yl]methyl]-1*H*-pyrrolo[2,3-*b*]pyridine (I, L-745, 870), a potential antipsychotic agent, has been developed, utilizing high pressure liquid chromatography (HPLC) with tandem mass spectrometric (MS-MS) detection. The analyte and internal standard (II) were isolated from basified biological matrix using a liquid-liquid extraction with methyl-*t*-butyl ether (MTBE). The organic extract was evaporated to dryness, the residue was reconstituted in a mobile phase and injected into the HPLC system.

The chromatographic conditions used for the analysis were a Keystone Scientific C-18 BDS 150 x 4.6 mm 5 μ m column with a mobile phase consisting of a 40:60 mixture of acetonitrile and water containing 10 mM ammonium acetate and 0.1 % formic acid pumped at a flow rate of 1.0 mL per minute yielding retention times of 3.4 and 5.0 minutes for I and II, respectively.

The MS/MS detection was performed on a PE Sciex API III Plus tandem mass spectrometer using a heated nebulizer interface. Multiple reaction monitoring using the parent-product ion combinations of m/z 327-131 and 361-131 were utilized to quantitate I and II, respectively. The assays were validated in the concentration range of 0.1 to 100 and 0.5 to 500 ng per mL for plasma and urine, respectively. The precision of the assays, expressed as coefficients of variation (C.V.) were less than 10% over the entire concentration range, with adequate assay accuracy, sensitivity and specificity to determine pharmacokinetics in human subjects following a single 1 mg dose.

LC-MS/MS METHOD FOR PROFILING NICOTINE AND ITS METABOLITES IN BIOLOGICAL FLUIDS, Gary D. Byrd, R. J. Reynolds Tobacco Company, Winston-Salem, NC.

Nicotine is widely used as a biomarker for exposure to tobacco smoke. Most of the nicotine absorbed by smokers is excreted in the urine as unmetabolized nicotine and several metabolites. These metabolites are also present in other biological fluids such as saliva and blood. By monitoring multiple metabolites in these samples, a more complete picture of nicotine absorption and metabolism can be developed. In addition to assessment of exposure to nicotine, such data are useful in describing the pharmacokinetic behavior of nicotine. Previously, a method monitoring nicotine and its metabolites using thermospray LC/MS was developed and implemented in our laboratory [1,2]. This method has provided useful information on the amounts of nicotine and its metabolites in urine, including glucuronides, and also media from liver samples incubated with nicotine. The strength of this method was its ability to analyze complex samples directly with minimal preparation (simply filter and inject). As described in this presentation, the method has been updated by taking advantage of improvements in LC/MS interfaces and ionization methods, and MS/MS techniques. The method was transferred to a triple stage quadrupole mass spectrometer equipped with an atmospheric pressure chemical ionization (APCI) source. This presentation demonstrates an application on three different biological samples, each as a pooled sample from smokers. The metabolites profiled in addition to nicotine (NIC) included nicotine-N'-oxide (NNO), cotinine-N-oxide (CNO), *trans*-3'-hydroxycotinine (3HC), demethylcotinine (DMC), cotinine (COT), and norcotinine (NNC).

The serum analyzed was taken from a blood sample pooled from 11 male smokers 21-45 years of age. The saliva analyzed was taken from a sample pooled from 20 male and female smokers 21-60 years of age. The urine analyzed was a standard pooled sample taken from 9 male smokers as previously described [3]. Sample preparation was minimal and each fluid was prepared in the same way. Internal standards (methyl-d₃ analogs of NIC, COT, and 3HC) were added and the samples were passed through a 0.2 µm filter prior to injection onto the LC system. Analyses were performed using a Fisons (Cheshire, UK) VG Quattro II triple stage quadrupole mass spectrometer equipped with an atmospheric pressure chemical ionization (APCI) probe. A Hewlett Packard (Palo Alto, CA) 1090 HPLC with a Polymer Labs (Amherst, MA) 4.6 mm x 5.0 cm polymer column preceded by a polymer guard column was used for separation of the analytes. A binary gradient was used to elute the components in less than 8 minutes: mobile phase A = 0.2 mM ammonium acetate in water, pH 9; mobile phase B = 0.2 mM ammonium acetate in methanol. Flow was 0.5 mL/min with 90% A 0-1 min, decreasing linearly to 5% A 1-4 min, and maintaining 5% A to 8 minutes. The seven analytes and three internal standards were detected by multiple reaction monitoring. Ten reaction channels were monitored, selecting the (M+H)⁺ ion and following a specific fragmentation. Collision energy was optimized for each compound and ranged from 10 to 20 eV. Collision pressure was 1x10⁻³ mbar. The most abundant MS/MS fragments for these protonated parents were either m/z 80 (protonated pyridine) or m/z 132 (presumably (C₅H₅N-C₄H₃)⁺).

Limits of detection, based on blank signal plus 3 standard deviations, ranged from 2 to 40 ng/mL for these analytes. The concentrations found are summarized below. Precision, based on triplicate analyses, was less than 10% relative standard deviation for concentrations above 250 ng/mL and less than 22% for all detected analytes.

SUMMARY OF METABOLITES DETECTED IN POOLED SAMPLES FROM SMOKERS
(ng/mL ± std. dev. of three analyses)

ANALYTE	URINE	SERUM	SALIVA
NIC	1220 ± 20	<40	1380 ± 60
3HC	4720 ± 430	77 ± 1	131 ± 10
COT	1450 ± 70	190 ± 6	303 ± 9
NNO	640 ± 50	<28	<28
CNO	502 ± 27	< 2	< 2
DMC	228 ± 31	10 ± 1	19 ± 1
NNC	60 ± 13	< 6	< 6

These concentrations do not include the presence of conjugates. Concentrations for the unconjugated nicotine and its metabolites found were similar to those reported in recent literature for fluids taken from smokers [2-5]. Nicotine and all six metabolites were detected in urine with 3HC the most abundant. Nicotine was observed in serum at 8.5 ng/mL but was below the determined limit of detection (40 ng/mL). COT was the most abundant species in serum and second most abundant in saliva after nicotine.

The method described here was used to determine these metabolites in the low ng/mL concentration range without sample preconcentration or extraction from their complex biological matrices. Thus, this method could be applied for the determination of exposure to tobacco smoke; however, sample clean-up and pre-concentration may be necessary to detect these metabolites in fluids from people exposed to very low concentrations of tobacco smoke such as ETS. Future work will survey blood, saliva, and urine samples from numerous individuals to better define correlations between metabolites in these fluids and total nicotine absorption.

Flow-Injection ESI (MS/MS) of PCV-TP & ACV-TP in Extracts of a Herpesvirus-Infected Neural Cell line.

Elie M. Smyrnis¹, Stephen Sacks², Roland Burton³, and Frank Abbott³

¹Departments of Pharmacology & Therapeutics, ²Medicine and ³Pharmaceutical Sciences; University of British Columbia, Vancouver, Canada, V6T 1Z3.

Introduction:

The compounds, 9-[(2-hydroxyethoxy)methyl]guanine (acyclovir; ACV) and 9-(4-hydroxy-3-hydroxymethylbut-1-yl)guanine (penciclovir; PCV), are both acyclic analogues of the naturally occurring nucleoside 2'-deoxyguanosine. Each compound demonstrates marked anti-herpesvirus activity; yet both possess little or no cytotoxic effect. Because it is the triphosphate (TP) form of these analogues which exhibits antiviral activity, we have endeavored to develop a rapid and sensitive method for detecting intracellular ACV-TP and PCV-TP, directly, from extracts of varicella-zoster virus (VZV) and herpes simplex virus (HSV) type-I-infected schwannoma (SW) cells.

Materials and Methods:

The metabolism of ACV and PCV was determined using, either, 10%-subconfluent monolayers of SW cells growing in 75cc flasks which had been infected with 1×10^5 plaque forming (PF)-cells of VZV (Ellen strain)-infected SW cells, or alternatively, using fully-confluent SW cultures infected with 1×10^5 PF-units of HSV-I (KOS strain); such that a multiplicity of infection of ~ 0.1 for both systems was attained. Culture media was replaced at 9h-72h using a 1.5ml overlay of fresh media containing 10 μ M of PCV or ACV, treated with drug for 9h; washed (10s/4°C) in 10ml of 5mM ammonium formate (AF)/1mM dimethylhexylamine (DMHA): "A" (pH 9.0); and extracted for 1min at 4°C with 3ml of 20mM AF/1mM DMHA/70% MeOH: "B" (pH 9.0). Extracts (20 μ l) were delivered to the ESI interface using a 50 μ l/min flow rate in a mobile phase of 70%A/30%B. The instrument used was a Fisons Quattro VG triple quadrupole mass spectrometer operated in negative ion mode. The [M-1]⁻ ions of ACV-TP and PCV-TP were mass filtered into the collision cell. CID generated the transitions m/z 464>158 (ACV-TP specific) and m/z 492>158 (PCV-TP specific). In some cases extracts were spiked with a given concentration of the reciprocal triphosphate (ACV-TP or PCV-TP) to serve as an internal standard (IS).

Results:

Multiple reaction monitoring (MRM) demonstrated that even though ACV-TP could be detected as an IS, the amount synthesized by herpesvirus-infected cells was not sufficient, using the described conditions, to generate a measurable signal. Alternatively, the amounts of PCV-TP which were produced in virus-infected cultures (2.7-4.2 nmol/10⁶ SW), could be readily detected by ESI MS/MS. CID generation of the transition m/z 492>158 was not apparent in control extracts. There was no significant difference observed between the cellular levels of PCV-TP synthesized by HSV-I or VZV-infected SW cultures.

Conclusion:

Flow-injection ESI MS/MS is a highly sensitive and selective method which may be used for the ultratrace detection of the bioactive metabolites of PCV in extracts of herpesvirus-infected neural cells. Although the assay, as described, was not sufficiently sensitive to measure the lower ACV-TP levels which were synthesized in corresponding sister cultures, the ability to detect these metabolites at such very low concentrations should prove useful in the further pharmacological characterizations of these, and related, antiviral agents.

Quantification of the Prodrugs Alatrofloxacin and CP-114,099 from Human Plasma by HPLC/ESI/MS/MS

R. Schneider, K. Hoffmaster, and H. Fouda; Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT, 06340

Quinolone carboxylic acids such as trovafloxacin are highly potent and orally active antibacterial agents¹ with activity against both Gram-positive and Gram-negative organisms, as well as anaerobes². Alatrofloxacin is an inactive prodrug for trovafloxacin. Alatrofloxacin is metabolized to the inactive des-alanine intermediate, CP-114,099, which is in turn metabolized to the active species trovafloxacin. A specific assay for the quantitative analysis of alatrofloxacin and CP-114,099 has been developed.

Plasma was buffered with phosphate buffer at pH 3 at the time of collection to assure analyte stability. Aliquots (200 µl) of buffered plasma were denatured with acetonitrile. Following centrifugation, the supernatant was transferred to a clean tube and evaporated to dryness. The extract residues were reconstituted in HPLC mobile phase; each analyte was detected by multiple reaction monitoring (MRM) of precursor and product ions. The collision induced dissociation spectra of alatrofloxacin and CP-114,099 are shown below. The MRM's that were used for quantitation for alatrofloxacin and CP-114,099 were m/z 559 to 488, and m/z 488 to 348, respectively.

The elution of phosphate salts in the chromatographic void volume produced a charging effect in the ionspray interface region, causing a disruption to the ion current. To alleviate this, a switching valve was used to divert the phosphate salts to waste, and subsequently divert the retained analytes to the mass spectrometer. This modification allowed the development of a rugged and reproducible method. The dynamic range of the assay is 25 - 2500 ng/mL for each analyte. Over this range, the precision of the assay was better than 12.3% and its accuracy was within 13% (TABLE 1).

INTRODUCTION

Astemizole (AS) is a long-acting, selective histamine H₁ receptor antagonist widely used to treat allergic rhinitis. Pharmacokinetic studies of AS require an exceptionally sensitive analytical method, capable of quantitating AS and its active metabolite desmethylastemizole (DMAS) at the subnanogram level. The analysis of free astemizole in human plasma is complicated by the distribution of AS in tissues (e.g. liver, pancreas, lung) at several hundred times the concentration observed in the plasma, and by up to 97% protein binding of the remaining plasma-borne drug.

A new APCI-LC/MS/MS analytical method capable of quantitating AS and DMAS in human plasma down to 10 pg/mL and 50 pg/mL, respectively, has been developed using the PE SCIEX API-300 mass spectrometer. These LLOQs are attained using only 1 mL of plasma. The drug and metabolite peaks at the LLOQ exhibit a S/N ratio of better than 10:1 for both analytes, making the method robust, with a minimum of rejected runs and good between-run precision and accuracy. The new method overcomes the lack of specificity typical of previous RIA methods, while achieving greater sensitivity than previous HPLC methods.

Optimized chromatographic, extraction and MS/MS conditions result in a 2.5 minute chromatographic run time, making possible up to 400 injections per day per LC/MS/MS system. Both AS and DMAS are isolated in a single, high-yield extraction step, contributing to rapid analytical turnaround with this method.

CHEMICAL STRUCTURES

METHODS

Matrix: Human plasma

Extraction: Liquid-liquid, pentane and methylene chloride

Chromatography:

HP 1090 HPLC

C-18, 3.3 cm x 4.6 mm x 3 micron column

3° mobile phase, acetonitrile, ammonium acetate and acetic acid

2.5 min runtime

Mass Spectrometry

SCIEX API-300 LC/MS/MS operating in the positive APCI mode

Mass spectrum acquired in the MRM mode

Ion transitions monitored (m/z): 459→135 for AS, 445→204 for

DMAS, and 477→266 for internal standard (loperamide)

Analyte quantification by peak area ratio

MASS SPECTROMETRY

Q1 Mass Spectrum of Astemizole Showing Abundant Base Peak at [M+H]⁺

Q1 Mass Spectrum of Desmethylastemizole Showing Abundant Base Peak at [M+H]⁺

Daughter Ion Spectrum of Astemizole

Daughter Ion Spectrum of Desmethylastemizole

RESULTS

After method validation, the lower limit of quantitation (LLOQ) was set at the lowest calibration standard concentration, i.e. 10 pg/mL for AS and 50 pg/mL for DMAS. There were no significant interferences with the analytes or the internal standard, from either endogenous components or other sources.

The analyte concentrations were determined by comparison of their peak area ratios with calibration curves prepared in human plasma and fitted to a weighted 1/c linear relationship. (Correlation coefficients (r) for the calibration curves (4 curves per analyte) were greater than 0.9968 for AS and 0.9976 for DMAS, over concentration ranges of 10-3,000 pg/mL and 50-5,000 pg/mL, respectively.)

CONCLUSION

- The application of the SCIEX API-300 coupled with a tertiary HPLC system has significantly improved the analysis of astemizole and desmethylastemizole in human plasma. We have shown an improvement in LLOQ from 50 pg/mL to 10 pg/mL for AS and from 100 pg/mL to 50 pg/mL for DMAS, along with increased reproducibility due to improved S/N, over the previous method which used API-III instruments.
- This novel assay exhibits the sensitivity required for pharmacokinetic studies (AS 10 pg/mL, DMAS 50 pg/mL), and uses the specificity of LC/MS/MS to full advantage.
- Efficient separation and high yields in extraction contribute to accurate, reliable operation well above the noise threshold of the baseline.
- Analytical turnaround time is very short with this assay, due to short run times attained through optimized extraction and chromatography conditions, and MS/MS detection.

ACKNOWLEDGEMENT

CHROMATOGRAPHY

The Analysis of SOD Mimetic SC-68328 in Dog Plasma using Flow-Injection ESI/MS/MS

Vinod Arora¹, Frank Belas¹, Ji Zhang³, Doug Fast³, Grant Schoenhard³ and Ian Blair^{1,2}

Department of Pharmacology¹ and Department of Chemistry², Vanderbilt University School of Medicine, Nashville, TN 37232 and G.D.Searle & Co.³, Skokie, IL, 60077-2980

Superoxide radicals have been implicated in tissue injury associated with inflammation, organ ischemia associated with thrombosis, adult respiratory distress syndrome, rheumatoid arthritis, atherosclerosis and asthma(1). Low molecular weight manganese based superoxide dismutase mimetics have been shown to attenuate neutrophil mediated oxygen-radical injury to endothelial cells *in vitro* (1) and ischemia/reperfusion endothelial injury *in vivo* (2). Thus, these compounds may have potential as cardioprotective agents. These compounds are generally difficult to analyze due to their pH instability, chelation to other metals, and propensity for adsorption to surfaces. Chromatography using reverse phase HPLC systems results in ligand exchange; whereas, chromatography under normal phase conditions is not reproducible.

In the present study, a flow injection-ESI/MS/MS method has been developed to quantitate SC-68328 (Scheme 1) in dog plasma. The assay utilized ¹³C-SC-68328 as an internal standard. Dog plasma pools were prepared for both the standard curve points as well as for quality control samples. Because of the instability of the analyte in plasma, the pools were prepared within three minutes and were stored at -80 °C until they were used. The analyte and the internal standard were converted to their *bis*-NCS derivatives (Scheme 1) in the plasma. After derivatization, the analyte and internal standard were extracted from the plasma (200 µL) with dichloromethane (500 µL) using liquid/liquid extraction. The organic layer was separated and combined with methanol (200 µL). After mixing, the resulting solution was analyzed. Samples were injected into the mass spectrometer using a Hitachi AS 4000 autoinjector. A 90/10 mixture of dichloromethane/methanol containing ammonium thiocyanate (4 mM) was used as the wash solvent. The mobile phase was dichloromethane/methanol (90/10 v/v) containing ammonium thiocyanate (200 µM). The flow rate was 400 µL/min. Flow injection ESI/MS/MS was performed using a Finnigan TSQ 7000 triple quadrupole mass spectrometer operating in the positive ion mode. The mass spectrometer was interfaced to the Hitachi L-6200 intelligent pump for the delivery of mobile phase, and a Hewlett-Packard HP 1090 LC system was used for the delivery of sheath liquid at a flow rate of 10 µL/min. The sheath liquid was a mixture of methanol/water (80/20 v/v) containing ammonium thiocyanate (2 mM).

Selected Reaction Monitoring (SRM) experiments were conducted, simultaneously monitoring both the analyte and internal standard. A SRM experiment was conducted for the analyte by monitoring the *m/z* 356 to *m/z* 295 transition. Similarly, for the internal standard, the *m/z* 360 to *m/z* 299 transition was monitored. An SRM ion current profile from dog plasma containing SC-68328 (250 ng/mL) and the internal standard (10

µg/mL) is shown in Figure 1. Calibration curves were obtained by plotting the peak height ratio of the analyte to internal standard against the amount of analyte added to the plasma. The assay was linear over the range of 250 ng/mL to 10 µg/mL using a weighted (1/concentration) least squares regression analysis. The quality control samples at three different levels (LQC, 300 ng/mL; MQC, 1000 ng/mL; and UQC, 8000 ng/mL), were evaluated to confirm the ruggedness of the analytical procedure. The quality control samples exhibited an overall precision of 6 % for both the LQC (n=12) and the MQC (n=11) and 2 % for the UQC (n=12). The LLQ (n=12) level was set at 250 ng/mL; a precision of 12 % was obtained. The overall mean values for the quality control samples, including the LLQ were within 15 % of their expected values. The 1:20 dilution samples (n=12) were within 6 % of their expected value with a precision of 3 %.

Therefore, a reproducible, accurate, and robust assay has been developed to quantitate SC-68328 in dog plasma. The assay is amenable to high sample throughput and should be adaptable to other analogues of SC-68328 with minor modifications.

QUANTITATIVE ANALYSIS OF PACLITAXEL IN PLASMA BY IONSpray LC-MS/MS

Stanley Murakami, Robert Bethem, and Elaine Fukuda

Alta Analytical Laboratory, El Dorado Hills, CA 95762

Paclitaxel (Taxol) is a compound isolated from the bark of the Pacific Yew tree which has anticancer properties. This compound has been shown to be effective in the treatment of various human tumors, including breast and ovarian cancer. As with most chemotherapeutic agents, they are toxic to the patient. In order to reduce the side effects, the dose is simply lowered or alternatively, the drug is combined with other drugs to minimize the toxicity.

The current methodology to quantitate paclitaxel in plasma will not meet the sensitivity requirement to fully determine the pharmacokinetics at these lowered dosing regimens. In support of new lowered dosing regimens, measurements of the drug concentrations in plasma are required by the FDA to determine efficacy and safety. An improved LC-MS/MS method for the quantitation of paclitaxel was developed with a sensitivity of 50 pg/mL.

This method involves the extraction of paclitaxel from human plasma by an SPE cartridge. The plasma is fortified with deuterated paclitaxel and is loaded onto a C18 SPE cartridge. The cartridge is washed with water and the analytes are eluted with ACN. The eluent is evaporated to dryness, reconstituted and injected onto a C18 analytical column. The mobile phase (NH_4OAc / ACN) flows at 0.3 mL/min directly into a PE-Sciex API III+ mass spectrometer via a turbo ionspray interface. Under the ionization conditions employed, the ammonium adduct of paclitaxel and its deuterated analog are produced and subjected to CID. The product ion mass spectrum of the ammonium adduct of paclitaxel is shown in Figure 1. Utilizing MRM (multiple reaction monitoring) technique, the product ions of m/z 509 and 514 are monitored for the quantitation of paclitaxel. MRM of the product ions affords high sensitivity and specificity for the quantitation of paclitaxel. The ion chromatograms, m/z 509 and 514 of paclitaxel and its deuterated IS from a 0.05 ng/mL standard is shown in Figure 2. The sensitivity of the method is 0.05 ng of paclitaxel per mL of plasma. Linear calibration curves are obtained in the range of 0.05 to 10 ng of paclitaxel per mL of plasma. The range of the method is from 0.05 to 40 ng of paclitaxel per aliquot of plasma using 0.25 to 1 mL of plasma for analysis.

The validation for the quantitation of paclitaxel includes accuracy, precision, extraction efficiency, and stability. QC samples (prepared at 0.05, 0.15, 8.0, and 32.5 ng/mL) were used in the validation of the analytical method. The accuracy (% recovery) and precision (%CV) for the 0.05 ng/mL QC samples during the inter-assay variability experiments were determined to be 97.4 and 10.7 respectively. The extraction efficiency of paclitaxel from plasma was determined to be 83.6%. The stability of paclitaxel was determined in the plasma at room temperature for 24 hours, during three cycles of freeze-thaw, and at -20°C (still in progress). The stability of paclitaxel was also determined in the extract at 4°C for 24 and 120 hours, and on the autosampler for 24 hours. Under all storage and experimental conditions, paclitaxel has been shown to be stable.

In conclusion, a rapid, sensitive, and specific method for the quantitation of paclitaxel in human plasma has been developed and validated. This method fulfills the analytical requirements necessary to support pharmacokinetic studies of paclitaxel at the lowered dosing regimens.

Quantitation of Ecteinascidin 743 In Blood By Mass Spectrometry

Sharon Lau and Kenneth L. Rinehart
Chemistry Department, University of Illinois, 600 S. Mathews, Urbana, IL 61801

INTRODUCTION

Ecteinascidin 743 (Et743), isolated from the tunicate *Ecteinascidia turbinata* [1], is a potent anti-cancer agent that is currently in Phase I clinical trials. Quantitation of the drug is absolutely necessary for monitoring the drug's administration. Electrospray ionization mass spectrometry (ESI-MS) and matrix-assisted laser desorption/ionization/time-of-flight mass spectrometry (MALDI/TOF-MS) provide the reproducibility and the sensitivity that are necessary for quantitative analyses. In this work, they were applied to quantitate Et743 in blood. Limits of detection (LOD) and relative uncertainties of both methods were determined and compared. In order to enhance the sample-to-sample reproducibility, the closely related ecteinascidin 729 (Et729) was used as an internal standard. The structures of Et743 and Et729 are shown in Figure 1.

EXPERIMENTAL

Drug spiking and extraction. Human whole blood was spiked to desired concentrations with ecteinascidins dissolved in CH_2Cl_2 . Et743 of various concentrations was added along with a constant amount of Et729. The amounts of analytes added were known, ranging from 5 μg to 0.1 μg . The ecteinascidins were extracted with CH_2Cl_2 . The procedure was repeated at least four times to maximize the recovery of the ecteinascidins. The combined extracts were dried and redissolved in MeOH for ESI-MS analysis and in MeOH/ H_2O for MALDI/TOF-MS analysis.

ESI-MS analysis. Separate analyses in both the continuum and the multichannel analysis (MCA) modes were performed on the VG Quattro mass spectrometer. Analytes were introduced by loop injection into the spectrometer (10 μL). CsI was used for calibration. Samples with increasing concentrations were analyzed to minimize the contamination due to previous samples.

MALDI/TOF-MS. The Micromass ToFSpec MALDI mass spectrometer was operated in the linear mode, employing a 337 nm N_2 laser. Spectra were acquired in the MCA mode, by averaging ca. 40 laser shots' data. Insulin was used for the calibration. The matrix, α -cyano-*p*-hydroxycinnamic acid (ACHC), was dissolved in acetone (5 mg/mL), and a matrix solution (0.75 μL) was applied to a 2.5 mm diameter target as a thin film [2]. A ecteinascidin sample (0.5 μL) was then added to the film.

Data Processing. The intensity of the Et743 peak was compared to that of the Et729 peak, after background subtraction and smoothing. The ratios were plotted against concentrations of Et743 to obtain calibration curves, from which the LOD was determined.

RESULTS

The extract was quite clean, containing only triglycerides, phospholipids, and very small amounts of cholesterol and salts. The simplicity of spectra obtained made the quantitation possible.

A typical ESI-MS spectrum of the extracted analytes showed $[\text{M}+\text{H}]^+$ of Et743 and Et729 at m/z 744 and 730, respectively, and their doubly charged ions at m/z 372 and 365. No significant difference was observed in spectra obtained using the MCA mode or the continuum mode. The relative uncertainties and the LODs obtained in both modes were very similar: ca. 13% and 50 pmol respectively. The calibration curve is shown in Figure 2.

Reproducible results, with mass accuracies of $<0.1\%$, were obtained by MALDI-MS by dissolving the extracted drug in a 13% MeOH/ H_2O mixture. Figure 3 shows a typical spectrum of analytes by MALDI-MS analysis. The slow evaporation of water allowed the analytes to co-crystallize with the matrix, resulting in the formation of a uniform layer of crystals. Successful MALDI analysis depended on the quality of the analyte-matrix crystals formed during the sample preparation. The relative uncertainties of MALDI-MS analysis were much lower than those of ESI-MS analysis (ca. 30%), and the LOD was determined to be ca. 500 fmol, two orders of magnitude lower than that of ESI-MS.

GCMS Studies of 4-Phenylbutyric Acid and its Metabolites and the Synthesis of *L*-Phenylacetylglutamine

Alexander Candelario¹, Earle G. Stone¹, Robert T. Streeper², and Stephan B.H. Bach¹

¹Chemistry Program, Division of Earth and Physical Sciences
University of Texas at San Antonio, San Antonio, TX 78249

²Department of Biochemistry and Pharmacology
University of Texas Health Science Center at San Antonio
San Antonio, TX 78284-7760

Introduction

Cancer cells, like normal cells, need specific compounds for their metabolism. It was felt that certain chemicals might possess the binding affinity of a normally occurring, essential compound but not be able to function exactly as the normal compound should. If this type of compound were incorporated into a metabolic process, the product would be inactive and the cell involved in this process would be inhibited or killed. Antimetabolites inhibit a metabolic pathway essential for the survival or reproduction of cancer cells through inhibition of folate, purine, pyrimidine, and pyrimidine nucleoside pathways required for DNA synthesis. Based on this assumption, many antimetabolites have been prepared as anticancer agents¹.

Sodium-4-phenylbutyrate is currently under investigation as a potent differentiating agent in Phase I clinical trials of cancer research that may potentially alter tumor growth and slow or inhibit metastases^{1,2}. However, systemic toxicities from sodium-4-phenylbutyrate have prevented it from being administered clinically. Sodium-4-phenylbutyrate and its metabolite, phenylacetate, suppress tumor cell growth and are potent differentiating agents *in vitro*. Phenylacetate, a metabolite of phenylbutyrate and phenylalanine, is present in human serum and urine in micromolar concentration. In humans, phenylacetate is conjugated with glutamine by the hepatic enzyme glutamineacetyl transferase and phenylacetyl CoA to yield phenylacetylglutamine which is then excreted in the urine³⁻⁵.

Since phenylacetate is only toxic at high concentration, it has been used in the studies of hyperammonemia associated with inborn errors of urea synthesis or liver failure resulting from high dose chemotherapy for leukemia and transplant therapies^{6,7}. Thibault and colleagues have performed a Phase I and pharmacokinetic study of the intravenous uptake of phenylacetate in cancer patients with advanced solid tumors. Their study further showed that phenylacetate underwent a rapid conversion to phenylacetylglutamine, whose molar excretion was found to increase in direct proportion to the dose of drug administered. However, the exact quantitation of phenylacetate in the plasma and urine was not determined. A strong phenylacetate odor was detected on patients' clothes and examiners' hands after physical examination suggests the possibility that phenylacetate may also be excreted transdermally⁵.

Although the exact mechanism of action and clearance of phenylacetate is unclear, Burzynski and colleagues have found an accelerated excretion rate of differentiating agent and their metabolites in cancer patients. Therefore the quantitative assay of serum and urinary 4-phenylbutyrate, phenylacetate and phenylacetylglutamine is an extremely useful parameter for the evaluation and prognosis of cancer patients undergoing antineoplastic therapy and a quantitative assay is currently not available⁸.

Results and Discussion

The successful synthesis of the *L*-phenylacetylglutamine metabolite was confirmed by ESI-MS (Fig 1) and GCMS (Fig. 2). The fragmentation pattern produced by the compound serves as a fingerprint for this metabolite. The molecular ion peak was identified as 264 *m/z*. This was followed by the loss of CO₂ and the tropylium ion (*m/z* 91) yielding the most abundant and stable ion identified at 129 *m/z* and 100%

intensity. Phenylacetylglutamine was also analyzed by ¹H NMR spectroscopy. The signals obtained were consistent with the literature values for this compound.

Figure 1

Figure 2

Conclusion

The procedure utilized for the synthesis of phenylacetylglutamine provides an easy route for the acquisition of the metabolite versus its isolation from blood plasma and urine in human samples. The reproducibility of the mass spectra for the same synthesis further supports this method to obtain this particular metabolite. The development of a definitive quantitative assay utilizing GCMS for determining the amounts of target substances present in serum and urine is currently underway. Further research will focus in this area as this information is critical in monitoring and maintaining therapeutic levels in cancer patients.

Quantitation of rapamycin: Comparison between curtain-gas and heated capillary API interfaces. H.K. Lim, T. Cinque, J. Cantone, H. Gu, M. Osman, R. Strohane, S. Sisenwine and K. Chan, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000.

Rapamycin (sirolimus), a 51-carbon macrolactam with antifungal, antitumor and immunosuppressive activities, was first isolated from a strain of *Streptomyces hygroscopicus* (1). It has been shown to be a more potent immunosuppressant than cyclosporine and the structurally similar 44-carbon macrolactam FK-506 (2). A notable desirable feature of rapamycin is the reported synergistic effects of rapamycin with cyclosporine but no similar synergistic effects was observed for FK-506 with cyclosporine (3). Ongoing clinical trials are being conducted to establish the efficacy of rapamycin in preventing organ rejection in transplantations. As a result there is a need for a sensitive and specific analytical method for quantitation of rapamycin in biological specimens during clinical trials.

Initially an ESI LC/MS/MS assay, with a linear dynamic range of 0.1 to 50 ng/mL whole blood, was developed for rapamycin using an LC/MS equipped with a curtain-gas API interface. The assay was based on monitoring the most abundant product ions generated from CAD of the $(M+NH_4)^+$ ions of rapamycin and the internal standard 32-O-desmethoxyrapamycin. The correlation coefficient of the weighted $1/x^2$ linear regression line was at least 0.99. The precisions (% CV) and accuracies (% difference) obtained for the concentration range in both intra- and inter-assay studies range from 5.2 to 18.2% and 0.0 to -12.0%. This assay has been used to analyze rapamycin samples from both preclinical and clinical studies for 3 years.

When increased sample load required the direct transfer of the assay to another LC/MS with a heated capillary API interface, technology transfer was unsuccessful due to the greater abundance of $(M+Na)^+$ than $(M+NH_4)^+$ ions of rapamycin in such an API interface. As a result, 1 mM sodium formate was added to the mobile phase to assure that the $(M+Na)^+$ ions are always greater than $(M+NH_4)^+$ ions. The observed stability of the $(M+Na)^+$ ions during CAD prompted the initial assay development using SIM. However, the lowest detectable concentration was 0.5 ng/mL. A rather dramatic improvement in the limit of detection (LOD) was observed when the product ions monitored were the same as the precursor ions following CAD. The collision energy and pressure were set to cause CAD of $(M+NH_4)^+$ but not $(M+Na)^+$ ions. This pseudo-SRM technique permits lower LOQ than true SRM where the ion current was distributed amongst many product ions. Consequently, an ESI LC/MS/MS assay with a linear dynamic range of 0.1 to 50 ng/mL was developed based on pseudo-SRM of $(M+Na)^+$ ions of rapamycin and internal standard. However, this $(M+Na)^+$ assay was found to lack specificity in a particular clinical study (Figure 1) despite its success in analysis of other preclinical and clinical samples.

Recently the heated capillary API interface has been demonstrated to analyze successfully thermally labile compounds by lowering heated capillary temperature and relying on increasing nebulizing gas pressure and in-source CAD to aid desolvation (4). The abundance of $(M+NH_4)^+$ ions of rapamycin can be made greater than the $(M+Na)^+$ ions in the heated capillary API interface by further lowering the capillary temperature to 80°C and with the LC eluate split to 50 µL/min. The desolvation of solvent droplets was based on increasing nebulizing gas pressure and in-source CAD. As a result, an ESI LC/MS/MS assay, linear from 0.25 to 50 ng/mL, was successfully validated (Table 1).

High Pressure CID Spectra of Isoflavonoids and Application to Analysis of Isoflavones in Plasma

Marion Kirk, Lori Coward & Stephen Barnes

Comprehensive Cancer Center Mass Spectrometry Shared Facility, University of Alabama at Birmingham, Birmingham, AL 35294

Introduction

There is much current interest in the potential role of soybean isoflavones in the prevention and treatment of cancer, heart disease, and osteoporosis (Barnes *et al.* *J. Cellular Biochem* 1995, 22: 181-187). This has led to several clinical trials in which soy products are being used as a dietary source of isoflavones. As a result, the need has arisen for rapid, precise, and sensitive analytical methods for the measurement of isoflavones in plasma samples.

In the past, methods based on gas chromatography-mass spectrometry have been used (Setchell *et al.* *Am J Clin Nutr* 1984, 40: 569-587; Adlercreutz *et al.* *Cancer Detection and Prevention* 1994, 18: 259-271; Morton *et al.* *J. Endocrinol* 1994, 142: 251-259). Since the isoflavones are present in plasma predominantly as their sulfate esters and glucuronide conjugates, these methods have required time consuming purification, fractionation, hydrolysis, and derivatization of the samples prior to analysis.

A more rapid method is needed to accurately measure isoflavones and their metabolites in plasma (Fig. 1). In the present study, HPLC-HN-APCI-MS using multiple reaction monitoring based on MS-MS information has been utilized. Enhanced sensitivity has been achieved with the use of a high pressure collision cell.

Method

Isoflavone sulfate and glucuronide conjugates were hydrolyzed enzymatically in plasma, and the free isoflavones were extracted into ether. The samples were injected onto a 10 cm x 4.6 mm i.d. Aquapore C₈ reversed-phase column, and eluted by isocratic elution with 40% acetonitrile in 10 mM ammonium acetate, pH 7.0. After chromatographic separation, the eluate stream was mixed with concentrated ammonium hydroxide (12 µl/min) provided by a Harvard infusion pump and then passed into the heated nebulizer-atmospheric pressure chemical ionization (HN-APCI) interface of a PE-Sciex API III mass spectrometer. The orifice potential of the mass spectrometer was set at -70 V. Multiple reaction monitoring was carried out by selecting the aglucone ion (present in all spectra) and causing collision-induced dissociation to produce unique fragment ions for quantitative measurement purposes. The peak areas were integrated using MacQuan.

Experiments were carried out using both a low pressure and a high pressure collision cell.

Conclusions

High pressure, collision-induced dissociation of the molecular ions of isoflavones and their metabolites substantially increases the degree of fragmentation (Fig. 2), and lowers the detection limit. Isoflavones in plasma are easily detected at less than 5 nM, with coefficients of variation of an equivalent standard of 10% (Fig. 3). The revised method is well suited for use in clinical trials on the effects of isoflavones.

INTRODUCTION

SCH 51866 is a new drug which selectively inhibits type I and V phosphodiesterase (PDE). The structure of SCH 51866 is shown in Figure 1. In order to study the effectiveness of the drug, it was necessary to dose it into Yucatan micropigs. An assay was needed to measure the levels of SCH 51866 in small volumes of the micropig plasma. It was decided that the technique of HPLC combined with atmospheric pressure chemical ionization (APCI) tandem mass spectrometry (MS/MS) should provide the necessary sensitivity and selectivity to determine this drug at low levels.

EXPERIMENTAL

Yucatan micropigs were dosed orally (in diet) with a single 10 mg/kg dose of SCH 51866. Plasma samples were obtained at 0.5, 1, 2, 3, and 4 hr post dosing. Micropig plasma samples (40 µl) were subjected to protein precipitation using 100 µl acetonitrile containing the internal standard. The internal standard (IS) was a similar compound. The sample was vortexed and centrifuged and the liquid layer was transferred to a micro-vial for analysis. An aliquot (20 µl) of the sample was injected into the Finnigan-MAT TSQ 7000 LC-APCI/MS/MS system equipped with the Finnigan APCI source. The MS analyses were performed using the selected reaction monitoring (SRM) technique. The mass spectrum for SCH 51866 showed a strong $[M + H]^+$ ion at m/z 390 under APCI conditions. For both SCH 51866 and the IS, the $[M + H]^+$ molecule was chosen as the precursor ion by MS1 (Q1) and a suitable product ion was selected for MS2 (Q3).

RESULTS AND DISCUSSION

An HPLC system using a reversed phase column (YMC Basic, 4.0 x 50 mm) and a gradient elution based on methanol, water and 0.01 M ammonium acetate provided a good chromatographic system for this compound and the internal standard.

Figure 2 shows a typical mass chromatogram for the 10 ng/ml (LOQ) spiked plasma samples. The calibration curve was found to be linear from 10 to 10,000 ng/ml plasma. Figure 3 shows the resulting mass chromatogram for a 3 hour plasma sample from a micropig dosed (10 mg/kg) with SCH 51866. The sample results showed that the plasma levels reached a mean value of about 800 ng/ml for the 10 mg/kg oral dose.

Delayed extraction and Laser Desorption: Time-lag Focusing and Beyond.

Steven M. Colby, Scientific Instrument Services, Inc. 1027 Old York Rd. Ringoes, NJ 08551
and James P. Reilly, Dept. of Chemistry, Indiana University, Bloomington, IN 47405

An expanded version of this abstract can be found at <http://www.sisweb.com>.

Overview: Recent experiments have shown that the proper use of delayed ion extraction can dramatically improve the mass resolution of laser desorption time-of-flight mass spectrometry (LD-TOFMS)¹⁻⁴. This poster explores two algorithms for the identification of optimal instrumental parameters in these experiments. The first, described in Wiley and McLaren's 1955 paper is an analytical approach that has been in use for over 40 years⁵. The second, space-velocity correlation focusing, is a recently published computational method that depends on numerical optimization techniques to determine instrumental parameters⁶. We consider the validity of the assumptions made in each approach when they are applied to surface desorption.

Time-lag Focusing: In their landmark 1955 paper⁵, Wiley and McLaren described two focusing techniques for time-of-flight mass spectrometry: space and time-lag focusing. Both of these methods were applicable to ions generated in the gas phase. Time-lag focusing employs a time delay between the formation of ions and their (time delayed) extraction from the source to reduce the impact of the analyte's initial velocity distribution on the detected peak width. Wiley and McLaren point out that during the delay time τ ions will move a distance $v_0\tau$ where v_0 is the initial velocity along the coordinate of interest. This will result in a flight time change of approximately $(\delta T/\delta X_0)v_0\tau$. Without a delay the flight time difference between ions of velocity v_0 and 0 is approximately "one-half turn-around time" or $m v_0/q E_f$. Where m is the mass, q is the charge, and E_f is the electric field after the extraction voltage is applied. (Wiley and McLaren included a factor of 1.02 for unit conversion.) This equation is derived by taking the derivative $\delta T/\delta v_0$ and assuming the average initial velocity equals zero. Focusing conditions are found when the change in flight time due to the delay compensates for the differences in flight time expected from the various kinetic energies, i.e. $(\delta T/\delta X_0)v_0\tau = -\delta T/\delta v_0$.

There are a number of assumptions made in the derivations of Wiley and McLaren's equations. $\delta T/\delta X_0$ and $\delta T/\delta v_0$ are assumed to be relatively constant over the ranges of interest. The derivation also assumes that the average value of v_0 be equal to zero. Finally, one must choose a value of X_0 in order to calculate $\delta T/\delta X_0$. Thus a single X_0 is assumed to represent the positions of all of the ions.

The Application of Time-Lag Focusing to Samples Desorbed From a Surface: It is clear that the time-lag focusing algorithm, as described by Wiley and McLaren cannot be applied directly to this problem because the average v_0 does not equal zero. Fortunately, it is possible to change their approach and remove the assumption that v_0 equals zero. In this case the equation for the derivative $\delta T/\delta v_0$ is

$$\frac{\delta T}{\delta v_0} = v_0 \left[\frac{1}{a_1} \left(\frac{1}{v_1} - \frac{1}{v_0} \right) + \frac{1}{a_2} \left(\frac{1}{v_2} - \frac{1}{v_1} \right) - \frac{L}{v_2^3} \right] \text{ where } a_i \text{ is the acceleration in each region, } v_1 \text{ and } v_2 \text{ are the}$$

velocities after the first two regions, and L is the length of the drift region.

Included in the additional assumptions discussed above are that the values of $\delta T/\delta X_0$ and $\delta T/\delta v_0$ are uniform over the spatial and velocity distributions of the ions at the time of ion extraction. These can be studied by examining plots of flight time versus initial position or initial velocity. An example can be found in reference 6. It shows that these values vary substantially over the expected⁷⁻¹¹ initial velocity ranges.

In order to calculate a value for τ , using Wiley and McLaren's approach one assumes that there is a single value of X_0 that adequately represents all of the ions. When the sample is desorbed from a surface one must also select a value for v_0 since $\delta T/\delta v_0$ is no longer independent of the initial velocity. Figure 1 shows how critical the selection of these variables are. For example, the values of $\delta T/\delta X_0$ and $\delta T/\delta v_0$ change substantially between 850 and 950 m/s. This suggests that the calculated τ will properly focus only a small fraction of the ions. In addition, X_0 should be approximately related to v_0 by the relation $X_0 = v_0\tau$. However, a value of τ is needed to solve this equation and τ cannot be calculated until X_0 is known.

Space-Velocity Correlation Focusing (SVCF): SVCF is an alternative method for determining delayed extraction conditions. It is a numerical process in which iterative calculations are used to optimize instrumental

parameters⁶. Briefly, the approach involves finding a relationship between the two distributions, using the resulting expression to eliminate a variable (X_0 or v_0) from the equation for ion time-of-flight, and then calculating flight times as a function of the remaining variable. The results can be used to produce plots such as those shown in Figure 1. With these one can examine the flight time spread expected as a result of the remaining variable. This spread is then used as a figure of merit for the optimization of instrumental parameters, such as, but not restricted to, the delay time τ . Optimization may then be accomplished by simple parameter variation or by any of a variety of established numerical optimization routines (i. e. Simplex).

SVCF has a number of advantages over the time-lag focusing algorithm presented in 1955. In particular it involves none of the assumptions discussed above and can be used to optimize any or all of the instrumental parameters. These are the most important factors differentiating it from time-lag focusing. SVCF does, however, require other assumptions. Most of these are listed in Table 1. A full description of the implementation of SVCF is presented in Reference 6.

Conclusions: It is clear that the application of Wiley and McLaren's time-lag focusing algorithm to samples desorbed from a surface must be made with caution. Many of the assumptions made in this approach are questionable when the sample does not originate in the gas phase.

Table 1. Assumptions Required in each calculation algorithm.

Time-lag Focusing	Space-Velocity Correlation Focusing
Initial spatial and velocity distributions are the primary factors limiting resolution.	Initial spatial and velocity distributions are the primary factors limiting resolution.
$\delta T/\delta X_0$ and $\delta T/\delta v_0$ are constant over applicable ranges.	$\delta T/\delta X_0$ and $\delta T/\delta v_0$ may take any values over the applicable ranges.
A single value of X_0 represents all ions.	A range of X_0 values represents all ions.
Average v_0 equals zero or, if the method is extended, a single value of v_0 represents all ions.	A range of positive v_0 values represents all ions.
X_0 is approximated before τ is known.	No approximations are needed.
$\delta T/\delta X_0$ must be negative.	$\delta T/\delta X_0$ may be positive, zero, or negative.
Variables other than τ can be optimized by trial & error.	All parameters may be optimized through a well defined algorithm.
Initial distributions do not need to be related.	Initial distributions are related by a quantifiable dependence. (i.e. $X_0 = v_0\tau$)
Collisions do not affect the distance ions travel during the delay time.	Collisions do not invalidate the stated dependence between distributions.
Metastable decay does not occur during the delay time.	Metastable decay do not invalidate the stated dependence.
Ions are formed over a spatial volume represented by a single value of X_0 .	Ions are formed in the same position.

USE OF IMMOBILIZED AND SOLUTION-PHASE ENZYMES WITH DELAYED EXTRACTION MALDI-TOF FOR PROTEIN CHARACTERIZATION

Dale H. Patterson, George E. Tarr, Wade M. Hines, Marvin L. Vestal and Stephen A. Martin, PerSeptive Biosystems, 500 Old Connecticut Path, Framingham, MA 01701

Coupling enzymatic digestions with MALDI analysis has proven to be a rapid and sensitive mode by which structural characterization of proteins can be accomplished. The use of endo- and exoproteases are required to effectively solve both mapping and sequencing problems. These two enzyme classes possess unique abilities and limitations when coupled with mass analysis and subsequently lend themselves to different optimal modes of use.

Endoproteases, such as trypsin, allow for protein characterization through fragment mapping. Used in solution, these enzymes often require long digestion times at the enzyme concentration required to avoid contamination from autolytic behavior. Endoproteases immobilized to the MALDI surface afford distinct advantages over the traditional solution-phase approaches including: 1) the mechanical stability of the immobilized enzyme that circumvents autolysis problems allowing the use of higher enzyme-to-protein ratios (i.e. more rapid digestion), 2) higher tolerance to biologically inactive impurities in the crude enzyme as well as denaturants in the digestion, 3) simple control over reaction time and 4) less method development and experimental setup time. This easy-to-use format affords the ability to perform fast, reproducible digestions. Given in Figure 1 are 4 tryptic digestions (12.5 min. at 37°C) of myoglobin performed on different spots on an active MALDI surface. Reproducible digestions in terms of formation of partial cleavages and relative abundances of the fragments is demonstrated. Using this approach, temporally mapping endoprotease digestions for information as to the relative lability of cleavage sites is a simple matter of running parallel digestions across a row, stopping the reactions at different times and then mass analyzing.

Exoproteases coupled with MALDI analysis yield ladders which are easily interpreted to give terminal sequence information. Unlike the endoproteases, autolytic digestion from the exoproteases is not a concern as they are typically less susceptible to autolysis and any autolytic fragments formed are outside the mass range of interest. Therefore, exoproteases lend themselves to solution-phase digestions which can be carried out directly on the plate. The increased instrument performance of delayed extraction MALDI-TOF (DE-MALDI-TOF) has expanded the useful mass range of "ladder sequencing" to include proteins up to 30 kDa. Shown in Figure 2 is a C-terminal ladder from pyridylethylated β -lactoglobulin B. Delayed extraction MALDI analysis affords >1000 resolution allowing for 3 consecutive residues to be elucidated following the 10 min. digestion at 37°C.

For proteins that possess structural microheterogeneity (i.e. glycosylated proteins) a coupling of the solution-phase exoprotease digestion with an immobilized endoprotease digestion can reduce the complexity of the data interpretation. Ribonuclease B is an example of a protein that possesses microheterogeneity of the N-linked glycan that hinders the direct analysis of a C-terminal ladder. By performing a solution-phase carboxypeptidase digestion followed by an on-plate immobilized tryptic digestion and analyzing the ladder on a C-terminal fragment, the glycan can be removed from the analysis. Figure 3A shows that the C-terminal sequencing of the parent pyridylethylated ribonuclease B is complicated by the presence of the high mannose heterogeneity. The peaks indicated by *, & and # are the Man₆ peaks of the parent, -V and -DAS peaks respectively. The analysis can be simplified as shown in Figure 3B by performing an immobilized on-plate trypsin digestion following the carboxypeptidase digestion and reading the ladder from a C-terminal fragment that does not contain the N-linked glycan. In this case, the large partial T₇₋₁₄ is sufficient due to the glycosylation site residing near the N-terminus.

MALDI TOF MS Analysis of Glycoproteins Using Delayed Extraction

U. Bahr, M. Karas*

Div. of Instrum. Analyt. Chemistry, JWGoethe University,

Although recombinant technology has provided the means to produce therapeutic drugs in large quantities, it has not eliminated the heterogeneity of the final product. This heterogeneity is resulting from either changes in the protein primary structure, or the presence of carbohydrate(s). In the case of glycoprotein therapeutic products, they have to be monitored for batch-to-batch consistency and checked for uniformity of batches produced by different fermentation or purification methods. Therefore, rapid and accurate molecular mass determination by MALDI MS is especially important for the analysis of glycosylated proteins, since mass determinations by the classical method of SDS-PAGE are usually erroneous and the electrospray technique provides results with great difficulty (especially above 20-25 kDa). However, problems arise from metastable fragmentations which strongly affect MALDI TOF results especially in reflectron instruments. In an ongoing investigation these effects have been exemplified for several glycoproteins (CHO-derived IL-4, IL-4R and SF9-derived IL-5R(1,2).

These investigations have been continued using "delayed-extraction" MALDI TOF analysis which promises to generate virtually optimal ion-source and ion generation conditions to improve MALDI TOF glycoprotein analysis. Firstly, DE-MALDI (using a PerSeptive Voyager RP system, a delay of 400 ns for switching the first acceleration gap making 10% of the total 25 kV acceleration potential) results in a dramatically improved mass resolution and thus separation of the individual components of the heterogeneous glycoprotein IL-4 when applying DE-linear-TOF mass analysis; the gain in resolution (approx by a factor of 5 compared to non-DE linear TOF analysis) is observed within the complete relevant mass range between the triply and singly charged molecule ion (Figure 1). Secondly, the mass accuracy is reaching an unprecedented level. Practically even more important, mass determination in this concrete case was obtained without any calibration (neither internal nor external), but simply by using the instrumental default calibration. In further experiments, larger-mass glycoprotein have been inspected. For a 30-kDa glycoprotein, derived from SF9 cells, the improvement was still remarkable and made possible the differentiation between the individual components, even though the gain in

- (1) M. Karas, U. Bahr, K. Strupat, F. Hillenkamp, A. Tsarbopoulos, B.N. Pramanik
Anal. Chem. 67 (1995) 675-679.
- (2) A. Tsarbopoulos, B.N. Pramanik, M. Karas, U. Bahr, J.-R. Zeng-Stahl
J. Mass Spectrom./Rapid Commun. Mass Spectrom. (1995) S207-S209.

mass resolution was already much smaller. And finally, for the large heterogeneous IL-4 and IL-5 receptor proteins with masses around 40 kDa no improvement was found. It is suggested that future optimization of the DE technique and experimental conditions presumably by focusing on the more highly charged molecule ion species will shift these limits to larger masses. Therefore it is noteworthy that for CHO IL-4, measured for an identical sample, when using a DHBs matrix DE resulted in a relevantly enhanced yield of the more highly charged molecule ions which e.g. was not observed for a sinapic acid matrix.

Finally, it was inspected whether these desirable effects are also observed for reflectron TOF analysis and whether problems arising from metastable loss of sialic acids are minimized or at least reduced. However, even though the use of a weak extraction field (without DE) shows a prominent shift to the intact sialylated glycoproteins, the non-DE and the DE reflectron mass spectra showed nearly the same degree of fragmentation. This indicates that the excitation energy responsible for this fragmentation is only partly due to the collisional heating in the initially dense plume and that there is a matrix-dependent fundamental energy load. This means that problems in MALDI arising from (metastable) fragmentation can finally only be overcome by a better understanding of the chemical processes involved in ion generation and presumably by an optimized matrix system and preparation protocol.

Comparison of PSD and CID Data Obtained from Tryptic Peptides Using Delayed Extraction MALDI-TOF MS

John M. Peltier, Keith Waddell, J. Mark and Arnold Falick
PerSeptive Biosystems, Inc. Framingham, MA 01701, USA

Matrix-Assisted-Laser-Desorption/Ionization (MALDI) Post-Source-Decay (PSD) analysis has been demonstrated to be an effective method for obtaining sequence information from peptides generated by tryptic digestion of proteins¹. Delayed Extraction™ (DE™) has been shown to improve the resolution and signal to noise obtained in the MALDI-TOF MS analysis of peptides². This poster demonstrates the advantages of DE™ as applied to the MS/MS analysis of tryptic peptides.

Mass spectrometry was performed on a Voyager Elite™ Biospectrometry workstation (PerSeptive Biosystems, Inc.; Framingham, MA). An aliquot of each sample was spotted onto the target surface followed by addition of the matrix solution (α -cyano-4-hydroxycinnamic acid saturated in 50% aqueous acetonitrile + 0.1 % TFA). All mass spectra were externally calibrated with suitable standards. Spectra were acquired using 20 kV accelerating voltage and a grid setting of 75%. For those fractions which were mixtures, peptides were selected using the timed ion selector. For CID a sufficient quantity of air was allowed into the collision cell to raise the source pressure from 1×10^{-7} Torr to 1.4×10^{-6} Torr. MS/MS spectra were acquired in 8-10 segments

In the comparison of conventional PSD spectra with those obtained using DE™ there was no difference in the number or type of fragment ions observed. Generally, the spectra both contained prominent a_n , b_n and y_n ions. Additionally, prominent b_n -NH₃ and y_n -NH₃ ions were present. None of the peptides in this study contained arginine which would provide an obvious source for loss of ammonia from its side-chain. Consequently, the loss of 17 u is deemed likely to result by loss of NH₃ from either Asn or Gln. The DE™- PSD spectrum did differ from the conventional PSD spectrum in that the signal to noise was better. This was true at both high and low mass. Additionally, the focusing conditions in DE™-PSD can be adjusted to afford higher resolution of the fragment ions across a segment; thereby by making it possible to achieve isotopic resolution across a whole spectrum without having to acquire extra segments.

The addition of air to the collision cell, a process which takes only a few minutes, results in spectra which exhibit abundant side-chain fragments of the d_n , w_n and v_n - type. In the immonium ion region of the MS/MS spectra CID yields much more information on the amino acid content of the peptides under study. The combination of CID and DE™ is particularly informative since there is no loss of resolution and therefore information in the spectrum. This is illustrated below for the case of the

T1,2,3 tryptic peptide from Ribonuclease B (sequence. KETAAKFER). Isotopic resolution is maintained at both the high and low end of the segments visible in the spectrum. The high resolution obtained allows the w_4 and v_4 ion to be easily resolved.

Examination Of The Use Of MALDI In-Source Decay For Sequencing Peptides

*Duane Reiber and Robert S. Brown, Department of Chemistry and Biochemistry, Utah State University, Logan, UT 84322-0300

Matrix-assisted laser desorption/ionization (MALDI) has evolved into an important tool for the biochemical researcher. While MALDI was initially employed as a means for accurately characterizing the molecular weights of very small quantities of analytes, the metastable ion decay which occurs in MALDI can be employed to obtain information on the primary sequence of peptides and some small proteins. The development of delayed extraction (DE) of MALDI generated ions in time-of-flight (TOF) mass spectrometry has significantly improved the sensitivity and mass resolution that can be obtained. The DE technique also facilitates the observation of early time frame (< 300 nsec) metastable ion decay in the MALDI source prior to ion extraction. This allows overlapping C and N terminal sequence specific metastable ion fragments to be rapidly acquired with a linear TOF mass spectrometer under a single set of experimental conditions. This approach has been demonstrated to provide fragment ion mass accuracy's of typically ± 0.2 Da for peptide standards of known sequence up to m/z 10,000.

Three commercially available peptides were submitted in a single blind study for analysis as "unknowns." Two of the peptides (#1 and #2) were purified by HPLC prior to submission. One μ L of a 10 μ M peptide solution (10 pmol) was deposited directly onto the probe tip, followed by 2 μ L of a 2 mg/mL matrix solution. The sample was allowed to air dry and the probe was then introduced into the mass spectrometer.

The in-source decay (ISD) mass spectrum of the first unknown peptide (#1) is shown in Figure 1. It has a molecular weight of 2150.40 Da. The proposed and correct sequences are given below.

Correct Sequence Q A T V G D I N T E R P G M L D F T G K

Proposed Sequence P T T R D L I N T E R P G M N D F T G A G

Several mistakes were made in this initial attempt at using ISD data for peptide sequencing. The most serious error was misidentifying the c ions as y ions. This resulted in the proposed sequence being backwards. The peak that would have distinguished the V and G residues (positions 5 and 6) was mistakenly overlooked. This omission coupled with the occurrence that the sum of the V and G residue masses happens to be equal to the mass of an R residue, resulted in the incorrect assignment of R (proposed position 4). A similar error was made when an extra peak was found that corresponded to the proposed C-terminal A and G assignment (proposed positions 19 and 20). The sum of the residue masses of A and G just happen to equal the mass of the true amino acid (K at the correct position 20). Finally, the end terminal amino acids have identical nominal masses. This results in two unresolved peaks separated by one amu. This peak was assigned as a y ion. This mistake threw off the mass differences for the correctly reported residues until the L residue at position 15 in the correct sequence was reported as an N and this mass difference was corrected for (there is a one amu difference in mass between these two residues).

Sequencing the second unknown peptide (#2) turned out to be much easier, mainly because several unsuspected difficulties were identified when the proposed sequence of #1 was analyzed. It has a molecular weight of 1076.27 Da. In this case, our predicted sequence is the same as the true sequence with the exception of the hydroxyproline being reported as leucine/isoleucine. This peptide

has identical end terminal amino acids, but this time, the unresolved "double" peak was correctly identified. Only one incorrect assignment was made in the analysis of the final unknown peptide (#3). It has a molecular weight of 3482.79. Two amino acids near the C-terminus were assigned incorrectly as a result of a missing peak. Also, one ion was obscured by the doubly charged molecular ion. Because of this there were four possible assignments for this section of the peptide. Once again a "double" peak was found in the spectrum. This time an attempt was made to deconvolve this peak using maximum likelihood based methods. This approach resulted in correct assignment of the two overlapping peaks with excellent mass accuracy's (absolute errors of 0.24 and 0.18).

These preliminary studies have clearly shown the potential for using the DE technique as a method for peptide sequencing. Of the 58 amino acids included in the three peptides 47 were correctly identified (81%). More than half of the incorrect assignments occurred in the first attempt. Two additional amino acids were narrowed down to four combinations of two amino acids one of which was the correct combination. Seven amino acids were assigned incorrectly as a result of the researchers inexperience in the analysis of unknowns. Only two amino acids were missed because of incomplete information contained in the ISD spectrum. It should be noted that these analyses were performed without the aid of any computer algorithms to help in amino acid assignment. The development of software to aid in the analysis of ISD mass spectra would be very beneficial and will be explored in the near future.

Accurate Mass Measurements Using Delayed Extraction MALDI Time-of-Flight Mass Spectrometry

Edward J. Takach, Dale H. Patterson, Wade M. Hines, Peter Juhasz, Richard Lee, Marvin L. Vestal, Stephen A. Martin

PerSeptive Biosystems, Framingham, MA, 01701, USA

The introduction of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has revolutionized the analysis of biopolymers by providing enhanced sensitivity and mass range. The greatest limitations of this technique have been resolution and mass accuracy. The introduction of Delayed Extraction (DE) use in MALDI-TOF analysis has greatly enhanced resolution, achieving single mass unit resolution up to 6000 daltons.¹ In delayed extraction, ions formed by MALDI are extracted out of the ion source using a high voltage pulse applied after a specified time delay. This improvement in MALDI-TOF instrumentation has also made possible more accurate mass measurements. The ability to measure exact mass values for peptides improves the assignment of peak identity, ruling out certain possibilities due to elemental or amino acid composition. Accurate peptide masses resulting from a tryptic digest can be used for database searching to determine an unknown or suspected protein. Peptides and small organic molecules are used to evaluate the ability of DE MALDI-TOF to determine accurate mass values over a mass range of 100 to 3700 daltons.

Instrumentation used for this study were VoyagerTM Elite or Elite-XL (PerSeptive Biosystems, Framingham, MA) having a reflector geometry of 3.0 meters (Elite) or 6.5 meters (Elite-XL). Reflector mode was used to achieve the highest degree of precision and accuracy.

Results from a mixture of peptides are shown in Table 1. A total of 6 data sets are averaged, resulting in errors less than 5 ppm for the Elite instrument and less than 3 ppm for the Elite-XL; confidence intervals are noted in daltons next to each mass. The spectra located below the table shows data from a single mass measurement with all errors less than 5 ppm; an expanded view of different peaks in this mass range, displaying resolution (FWHM), is shown below the spectra.

ENHANCEMENT OF MALDI-TOF MS AND MS/MS PERFORMANCE USING TIME-LAG-FOCUSING

J.M. Brown, R.H. Bateman, W.G. Critchley, R.G. Kingston, J.B. Hoyes Micromass UK Ltd. Manchester

Time-Lag-Focusing (TLF) is now the preferred instrumental technique for MALDI-TOF mass spectrometry. It significantly improves the quality of data in terms of resolution, sensitivity, mass accuracy and reproducibility relative to non-TLF instruments in both MS and MS/MS modes.

Further advantages of TLF include the ability to analyse more labile molecules such as oligonucleotides with less difficulty (because of the initially zero extraction field used). Synthetic polymers also show enhanced sensitivity and the mass range for resolved oligomers is significantly extended. Similarly, the mass range for isotopic resolution on peptides is increased.

Another feature of TLF is the ability to observe "in source decay" (ISD) species in linear mode. Furthermore, experiments to analyse in source fragments by PSD have been successful.

The time lag focusing technique was first described by Wiley and McLaren⁽¹⁾ in 1955 and applied to MALDI-TOF by Brown^(2,3) et al. Ions are initially allowed to disperse in a zero electric field for several hundred nano-seconds until the extraction field is applied. By correct arrangement of the extraction field lag time, extraction field magnitude and source geometry the initial ion energy differences inherent in the MALDI ionisation process may be corrected for.

The following MALDI-TOF data were obtained using the Micromass ToFSpec-E mass spectrometer fitted without and with Time Lag Focusing.

The instrument effective path lengths are 1.2m in linear mode and 2.3m in reflectron mode. Two dual microchannel plate detectors are fitted for linear and reflectron mode detection. Each detector may be sampled at 500 MHz. The laser employed was a Laser Science Inc. VSL-337i nitrogen laser operating at 337 nm with a pulse width of 4 ns. The extraction field lag time may be varied between 0.5 and 5 microseconds and the extraction pulse voltage between 100 and 5000 volts for optimum resolution.

Figure 1(a) and 1(b) show spectra of a 28-mer oligonucleotide analysed without and with TLF respectively in linear mode. This is an extreme case where TLF provides significantly enhanced data for more labile molecules.

For glycoprotein applications, the enhanced resolution and signal to noise of TLF allows one to observe for example the glycoforms of Ribonuclease B, **Figure 2** (linear mode).

Enhanced resolution for peptides upto 10000(FWHM) allows improved mass accuracy. Mass measurement errors for substance-P (MH+1347.736) acquired from 6 different sample spots (using angiotensin 1 (MH+1296.685) and ACTH (MH+2465.199) as internal calibrant peaks) resulted in mass measurement accurate to a **9.1 ppm (RMS)**. Externally calibrated data was measured to an accuracy of **49 ppm (RMS)**.

It can be concluded that the application of the TLF technique to MALDI-TOF results in significantly enhanced performance over a wider range of applications.

**MALDI/MS and the Aging Process:
Oxidative Protein Damage**

L.J. Deterding, D.P. Barr, R. Mason and K.B. Tomer

**National Institute of Environmental Health Sciences
Research Triangle Park, NC 27709**

The study of oxidative stress has attracted considerable interest and has been the focus of much research in recent years. Cumulative oxidative damage to tissues has been implicated in a number of disease states, e.g. the aging process, cancer, and ischemia-reperfusion. The study of oxidative stress in the mitochondria has shown that hydrogen peroxide is produced via the incomplete reduction of oxygen during oxidative phosphorylation. Hydrogen peroxide levels are kept relatively low (10^{-9} - 10^{-7} M) under normal physiological conditions. Under certain conditions, such as inflammation, excessive amounts of hydrogen peroxide are produced. The production of excess hydrogen peroxide is thought to precede several occurrences, such as lipid peroxidation, DNA and/or protein damage, and glutathione depletion, that are characteristic of oxidative stress. Several possible mechanisms by which endogenously-produced hydrogen peroxide can initiate cellular damage have been reported. One mechanism postulates initial free-radical oxidation of cytochrome *c*. The cytochrome *c* radical can then initiate free-radical formation on endogenous compounds. Oxidation of exogenous compounds by cytochrome *c* was observed to be dependent on hydrogen peroxide, but not to involve a hydroxyl radical, and that mitochondrial lipid peroxidation could be initiated by hydrogen peroxide and cytochrome *c*. These researchers postulated that hydrogen peroxide oxidized cytochrome *c* to a ferryl-radical type species similar to that seen with peroxidases and metmyoglobin, which could then catalyze the oxidation of biomolecules. No direct evidence, however, has been obtained for a ferryl-protein radical of cytochrome *c*.

We have begun an investigation of the role of cytochrome *c* free-radicals in oxidative stress by probing the reaction between horse heart cytochrome *c* and hydrogen peroxide. Using the combination of electron spin resonance (ESR) spin-trapping and MALDI/MS, the reactions of proteins subjected to oxidative stress have been investigated. ESR spin-trapping is a highly selective and sensitive technique used for the detection of free radicals, however, little information about the structure can be obtained. MALDI/MS in combination with proteolysis can be very useful for structure identification. When cytochrome *c* is allowed to react with hydrogen peroxide in the presence of a spin trap, DNBBS, the ESR spectrum (data not shown) reveals that one major and, possibly, one minor species is formed. In comparison, the MALDI spectrum of the same reaction mixture shows at least four distinct DNBBS adducts of cytochrome *c* (Fig. 1). Using proteolysis techniques, it has been determined that at least one DNBBS adduct is located on a tyrosine residue. We have also explored the possibility that an oxidatively-induced free-radical on horse heart cytochrome *c* can initiate free-radical oxidation of other proteins that do not, by themselves, undergo free-radical oxidation under identical reaction conditions. The reaction of cytochrome *c*, hydrogen peroxide, and DNBBS was repeated in the presence of 500 μ M RNase A. The ESR spectrum of this reaction mixture (data not shown) is identical to the ESR spectrum acquired in the absence of RNase A. It was not possible, therefore, to ascertain whether or not the cytochrome *c* radical could initiate free-radical oxidation of the RNase A. Upon MALDI/MS analysis, however, it was determined that two free-radical adducts of RNase A were trapped by DNBBS (Fig. 2). These data show that MALDI/MS is very useful in detecting spin-trapped free-radicals of proteins, including ESR silent adducts, and mixtures of adducts.

Figure 1. MALDI/MS spectrum of the DNBBS-trapped radicals of horse heart cytochrome *c*.

Figure 2. MALDI/MS spectrum from the reaction of horse heart cytochrome *c*, hydrogen peroxide, and DNBBS in the presence of 500 μ M RNase A.

Characterization of recombinant human annexin I domain 2 expressed in *Escherichia Coli* by mass mapping and PSD-MALDI-MS

Tun-Li Shen, Yue Li, Hong-Gao Yan, Douglas A. Gage
Department of Biochemistry, Michigan State University, East Lansing, MI 48824

Introduction

Annexins are newly defined family of eukaryotic calcium- and phospholipid-binding proteins that have $M_r = 35,000$ to $40,000$. The proposed roles for these proteins include cell-adhesion, growth factors, receptors for virus, and protein kinase C inhibitors. The sequence of annexins are characterized by four or eight repeats of a conserved 70 amino acid domain. The structure of annexin I reveals that the repeat sequences correspond to four homologous domains. Individual domains were expressed for the study of their structure and function. In this study, we report the mass spectrometric characterization of the primary structure of human annexin I domain 2 expressed in *Escherichia Coli*.

The usual strategy for structural characterization based on mass spectrometry involves molecular weight determination enzymatic digestion, separation of digests by reversed-phase high performance liquid chromatography and mass spectrometric analysis. Here, we employed a simple strategy to characterize recombinant proteins; protein mass determination, tryptic digestion and peptide mass mapping, and selected peptide sequencing by PSD-MALDI-MS

Experimental

The cDNA encoding the human annexin I was purchased from ACTT. Domain 2 was subcloned into a pET 17b expression vector by PCR method. Nde I site was introduced into the forward primer with sequence 5'GGAATTCATAGACTCCAGCC AATTG3', and a BamH I site was introduced into the reversed primer (see Figure 1). The expression construct was transformed into *E. Coli* BL 21 (DE3) containing the plasmid pLys S. The expression was induced by IPTG. To characterize the primary sequence of hANXI-2, the purified protein was treated with TCPK-trypsin (Sigma). Approximately 20 μ g of protein dissolved in 50 mM ammonia bicarbonate buffer (PH 8.6) at a enzyme to protein ratio 1:50. The sample was incubated at 37°C for two hours. All mass spectrometry experiments were performed on a PerSeptive Voyager Elite matrix-assisted laser desorption ionization time-of-flight mass spectrometer equipped with a reflector. All experiments were performed by using α -cyano-4-hydroxycinnamic acid (Aldrich) as the matrix. Saturated matrix solution were prepared in the 1:1 solution of acetonitrile/aqueous 0.1% TFA.

Results and Discussion

Although SDS-PAGE mobility was as expected, the molecular mass of hANXI-2 measured by MALDI-MS show the presence of a single peak at m/z 8945.8, a value of 544.4 Da higher than that of the expected mass of 8401.4 with the N-terminal methionine. The contradictory cDNA predicted molecular weight and mass measurement prompted us to further analyze the amino acid sequence by mass mapping.

The inconsistency of the predicted and measured molecular weight of hANXI-2 lead us to reinspect the protein coding region and consequently we discovered an extra ATG initiation codon was created during protein expression, which lead to the translation of four extra amino acid residues at the N-terminal of the recombinant protein. Figure 2 shows the MALDI-MS spectrum of the unfractionated trypsin digest of hANXI-2, the peak at m/z 1937 occurred at a mass 544.4 higher than the expected mass for the tryptic peptide [1-12], suggesting that this represents the modified N-terminal peptide, this peptide was further analyzed by PSD-MALDI-MS.

The PSD-MALDI-MS spectrum of the $[M+H]^+$ ion, m/z 1937.9 is shown in Figure 2. Most of the ions observed were consistent with the expected N-terminal fragment 1-12. However, an additional set of fragment indicated that this peptide was modified at the N-terminal. For example, strong y_{14} accompanied by weak y_{13} ion indicates that the residues FH were present. Examination of the PSD spectrum indicated a series of b_n ions that covered partial sequence -Glu-Phe-His-Met-Thr- (b_2 to b_6) For example, the mass difference between b_x and b_{x+1} is 147 Da, this suggesting a phenylalanine in

position 3 of the m/z 1937.8 peptide sequence, peak b_4 is 137 Da higher, indicating a histidine in position 4, thus b_n ions corroborate with the amino acid sequence 2 to 6 of the N-extended annexin I domain 2 protein. [1-16]: **MEFHMT**PAQFDADLR (m/z 1937)

In conclusion, mass mapping, and PSD-MALDI-MS has been used for characterizing the recombinant protein hANXI-2. From the mass spectrometric measurements, we have discovered a cloning error during the expression was introduced by coincidental addition of an extra AT at the 5' ends, which in effect created a false initiation codon upstream of the true initiation site, resulted in an N-extended modified with four extra residues.

Figure 1. Schematic representation of pET 17b/hANXI-2 expression plasmid. The arrow with small squares shows hANXI-2 cDNA insert cloned in the Nde I-BamH I site in the pET 17b vector. The black and white arrows show the position of the *bla* coding sequence and the replication origin. CHARACTERIZATION OF PROTEIN GLYCOSYLATION BY POST SOURCE DECAY AND EXOGLYCOSIDASE DIGESTIONS

Thomas N. Krogh, Ekaterina Mirgorodskaya, Ejvind Mørtz, Peter Højrup and Peter Roepstorff.
Dept. of Molecular Biology, Odense University, Campusvej 55, DK-5230 Odense M, Denmark.

INTRODUCTION

MALDI-MS has over the years proven to be a valuable tool in the analysis of glycoproteins and glycopeptides, making it possible to obtain structural information of both the peptide and the glycan moiety. Further has the introduction of Post Source Decay (PSD)¹ on time-of-flight (tof) instruments made it possible to obtain sequence information of peptides, carbohydrates and DNA^{2,3}. In this study we present how MALDI-MS in combination with sequential degradation of glycopeptides with glycosidases, can be used to elucidate the glycan structures present on glycopeptides. Further we demonstrate that MALDI-PSD can be used in combination with traditionally glycobiology methods to localize glycosylation sites, giving information of both the glycan and the peptide structure.

PROCEDURES

To the glycopeptide dissolved in 5 µl 50 mM NH₄OAc pH 5.0, 0.5 mU neuraminidase (Newcastle Disease Virus; NDV or *Arthrobacter ureafaciens*) was added and left to react overnight at 37°C. O-glycosidase digestion were performed after digestion with neuraminidase, using the same buffer. Mass spectra were acquired on a Perseptive Biosystems Voyager Elite MALDI-tof mass spectrometer, equipped with delayed extraction. Post source decay (PSD) spectra were acquired using an acceleration voltage of 20 kV and without delayed extraction or with delayed extraction using a time delay of 250 ns. Spectra were obtained at various reflector voltages, and stitched together using the software supplied by Perseptive Biosystems.

RESULTS

Sequential digestion of glycopeptide with exoglycosidases

The C-terminal peptide L5 from murine fetal antigen 1, was digested with first neuraminidase (NDV), which reduced the mass of the higher mass variants by 289.7 and 291.9 Da, corresponding to the loss of one α2-3 linked NeuNAc. *A. ureafaciens* neuraminidase digestion reduced the mass further by 292.8 and 292.1 Da corresponding to the loss of one α2-6 linked NeuNAc. A partial PSD spectrum using a parent ion of 1771.3 was acquired, to obtain information about the core structure. Fragment ions due to the loss of a hexose residue and hexose+Glc/GalNAc residues could be identified, indicating the structure GalNAcβ1-3Gal on the peptide. This was further confirmed by digestion of the peptide with O-glycosidase, which reduced the mass by 364.7 and 365.0 Da. Partial truncation of the C-terminal glycine residue was observed in all the spectra (-57.1 Da)

Proposed glycan structure present at the C-terminal peptide L5 from murine fetal antigen 1.

Localization of O-linked glycosylation on Muc1b⁴ by MALDI-PSD

The glycosylated peptide Muc1b was determined to contain one GalNAc residue. The peptide has two vicinal potential glycosylation sites, i.e. Ser6 and Thr7. Since no specific protease can separate the two sites, PSD analysis was used to localize the glycosylation site (Fig. 1A,B). The MALDI PSD spectrum of the non-glycosylated peptide (Fig. 1A) contains series of N-terminal fragment ions (a_n, a_n-17, b_n, b_n-17). In comparison, the PSD spectrum of the glycosylated peptide (Fig. 1B) shows identical N-terminal fragment ions plus additional ions, which correspond to N-terminal fragment ions carrying the sugar residue (a_n^{*}, a_n^{*}-17, b_n^{*}). The presence of a₇^{*} and a₇^{*}-17 as well as the absence of a₆^{*} and a₆^{*}-17 indicates Thr7 to be the glycosylated residue. This result was confirmed by sequencing.

Fig. 1 PSD spectra of peptide Muc1b. A) Nonglycosylated peptide, B) Glycosylated peptide.

Peptide Muc1b, the glycosylated residue is marked by *.

CONCLUSION

In this study we have demonstrated that post source decay in combination with glycosidases can be used to determine the glycosylation sites and the glycan structures on glycopeptides. Combining post source decay with glycosidase digestion resulted in information of isomeric sugar residues and linkage positions and thus complete structural information.

ACKNOWLEDGEMENTS

Perseptive Biosystems is greatly acknowledged for setting a Voyager Elite MALDI mass spectrometer equipped with delayed extraction to our disposal. Muc1b was kindly supplied by Henrik Clausen, Dental School, University of Copenhagen. This study was supported by the Danish Biotechnology Program.

Laboratory of Microbiology, The Rockefeller University, New York, New York 10021

Polymeric peptidoglycan is part of the bacterial cell wall surrounding the cytoplasmic membrane, and it protects the cell from osmotic rupture. The biosynthesis of peptidoglycan has been used successfully as a target for antibiotics. However, recently, resistance against this class of antibiotics has emerged, and infections caused by methicillin-resistant *S. aureus* and vancomycin-resistant enterococci have now become difficult to treat, presenting a potential world-wide health crisis.

We have been investigating structurally modified peptidoglycans found in antibiotic-resistant bacteria. FAB-MS, ²⁵²Cf PD-MS, and ESI-MS have been used in the past¹ to characterize these molecules with some success. Here we report the development of MALDI-based methods for the analysis of peptidoglycans. Prior MALDI-MS analysis, peptidoglycan samples were subjected to enzymatic digestion with muramidase. The resulting muropeptides were purified by HPLC.

A new matrix, 5-chloro-2-mercaptobenzothiazole (CMBT)², was employed for the routine MALDI-MS analysis of muropeptides. Our results have demonstrated that sub-picomole to femtomole detection can be achieved in both positive mode and negative mode allowing unambiguous determination of molecular masses of muropeptides of peptidoglycans. Structural information of peptidoglycans was obtained by further post-source decay (PSD) analysis. Fragmentation patterns in positive mode and negative mode PSD are complementary to each other for the elucidation of the composition of the peptide chains and oligosaccharide moieties.

Enzymatic digestion was also incorporated with MALDI-MS in solving structural problems of muropeptides, particularly those related to peptide chain cross-linking patterns. Specific cleavage between pentaglycine bridge residues was performed by lysostaphin digestion for the muropeptides derived from *S. aureus*. Amino acid substitutions and an unusual cyclic structure were identified by mass mapping after lysostaphin digestion.

Normal and modified oligonucleotides are widely synthesized for various purposes including research for therapeutic application. Though checking the sequences of synthetic oligonucleotides is an important task, currently available sequencing methods have a limited sensitivity and/or a limited flexibility especially for both 3'- and 5'-end modified oligonucleotides. Fast atom bombardment (FAB) or liquid secondary ionization (LSI) mass spectrometry and collisionally activated dissociation (CAD) tandem mass spectrometry with FAB or LSI have been applied to the sequencing of normal and modified oligonucleotides[1, 2]. However, the poor ionizing efficiency of FAB and LSI has limited the applicability of these methods to the nucleotide sequencing.

Recently, matrix-assisted laser desorption/ionization (MALDI) coupled with time-of-flight (TOF) mass spectrometry has enabled a rapid and facile mass determination of biomolecules with very high sensitivity. Since MALDI post-source decay (PSD) mass spectrometry has been successfully applied to peptide sequencing, we are investigating application of the method to oligonucleotide sequencing.

The nucleotide sequences of 3'- and/or 5'-end modified synthetic oligonucleotides (5-6mer) having an anti-HIV activity were analyzed by MALDI mass spectrometry. All MALDI mass spectra were obtained with a VG ToFSpec SE MALDI TOF MS instrument equipped with a N₂ pulsed laser (337nm). Molecular weight determination of the modified oligonucleotides by negative-ion MALDI mass spectrometry was feasible with low-picomole amounts. It was much more sensitive than negative-ion LSI mass spectrometry which may require a few nanomoles of sample. MALDI PSD experiments were also carried out on deprotonated molecules of the modified oligonucleotides with low-picomole amounts. The PSD spectrum of MODN-2 (5'-(3,4-dibenzoyloxybenzyl)-d(TTGGG)) is shown in Figure 1. Three series of fragment ions, X_n, Y_n, and X_n+80, were observed in the PSD spectrum of MODN-2. The X_n-ions are the sequence ions containing n nucleotides from the original 5'-terminal group, whereas the Y_n-ions consist of n nucleotides including the original 3'-terminal group and a newly generated 5'-end phosphate[3]. Another characteristic fragment ion series, X_n+80, are attributable to the loss of the base and the phosphoric acid from the 3'-end residue of X_n+1-ions[4]. These ion series provided sufficient information for the nucleotide sequence confirmation. MALDI PSD was also applicable to the 3'-end modified, 3'- and 5'-end modified, and normal oligonucleotides. In the PSD spectra of these oligonucleotides, X_n-ions were typically observed with low signal intensity or not detected. Instead of X_n-ions, X_n+80-ions were generally observed with high signal intensities. On the other hand, Y_n+80-ions were not observed and Y_n-ions were generally observed with high signal intensities. No additional fragmentation was induced by the use of a collision gas (Ar). Collisionally activated dissociation increased the abundances of product ions relative to the parent ions.

Matrix dependence of the PSD spectral patterns of the modified oligonucleotides was also examined. Two mixed matrix systems, α -cyano-4-hydroxycinnamic acid (CHCA)/3-

hydroxypicolinic acid (HPA) or anthranilic acid/nicotinic acid[5], induced metastable fragmentation of modified oligonucleotides. And the nucleotide sequence information was available from PSD spectra with these systems (see Figure 1). On the other hand, minimal metastable ions were generated with HPA alone (see Figure 2). The HPA matrix was ideal for checking the molecular weight and purity of modified oligonucleotides. In brief, the choice of an appropriate matrix was very important for the successful MALDI analysis of modified oligonucleotides.

Biopolymer Sequencing by MALDI-TOF MS

Detlev Suckau, Armin Holle and Anja Resemann, Bruker-Franzen Analytik GmbH
Postfach 33 01 26, D-28331 Bremen, Germany

Post source decay (PSD)¹ is widely used in MALDI-TOF mass spectrometers with ion reflector to obtain structural information from, e.g., peptides and carbohydrates. Sequence determinations from complex mixtures like proteolytic digests and of modified or irregular building blocks are possible. While the verification of a known structure is fast and straightforward in many cases, sequence determinations of unknowns are clearly more tedious and often only partial sequences are obtained. In order to facilitate such analysis, structural modifications like isotopic labeling by H/D or O/¹⁸O exchange have been used. Amongst the instrumental parameters allowing to obtain more and more specific information, the use of a collision cell allowing high energy CAD² and a high mass accuracy (reliably better than 0.3 Da) are of key importance. This accuracy is well achieved with the current calibration method³ and was even improved to an average mass error of 0.1 Da for Angiotensin II by using gridless delayed extraction (GDE).

Among the most relevant applications of mass spectrometric sequencing are analyses of molecules with irregular or modified building blocks. As a nice feature of PSD spectra, the low molecular immonium (i) -ions (see Table) allow the identification of such building blocks before analysis of the sequence-specific b and y ions. Particularly interesting in protein chemistry is the state of the reactive cysteine residues. Alkylated cysteine residues are stable and can be identified by the corresponding i-ion. However, sulfated and cystine-cross linked peptides are known to suffer elimination⁴ and disulfide-bond cleavage⁵, respectively, under the high laser fluence conditions typical for PSD analyses. To elucidate the behavior of intact disulfide bonds under PSD conditions in positive mode we analyzed several peptides containing intramolecular disulfides.

Methods: The disulfide bonds were reduced by a 10-fold excess of dithioerythritol in 50 mM NH₄HCO₃ at 37°C for 60 min followed by acidification with TFA. Spectra were obtained in α -cyano-4-hydroxycinnamic acid on a REFLEX II MALDI-TOF mass spectrometer equipped with a gridless delayed extraction ion source with visualization optics, two-stage gridless ion reflector and 1 GHz digitization board (Bruker-Franzen, Germany). 2-5 pmol of sample were used for PSD analysis and spectra were obtained at 20 kV accelerating voltage. The reflector voltage was reduced in 25 % steps to obtain ca. 10 segment spectra. The individual segments were calibrated with ACTH (18-39)³ with a mass error of less than 0.3 Da and pasted under control of the data system. Isotopic resolution of all fragment ions was obtained up to parent molecular weights of ca. 1200 Da.

Results: GDE-PSD spectra were obtained from the native oxytocin with intact disulfide bond and after its reductive cleavage. Extensive b and y ion series were observed with reduced oxytocin (bottom), while the crosslinked peptide only generated those ions which contain the complete cyclic part of the molecule, predominantly b₆ and y₃ (top). The corresponding close-up view of the b₆ isotopic patterns shows an increased intensity of m/z 725 (ca 2000 rp) from the oxidized peptide indicating the presence of a low amount of the reduced species (top). Internal fragments of the (yb)⁺ type were also identified (not labeled) from sequence stretches bracketed by cystine. Similar results were obtained from other crosslinked peptides like somatostatin, Arg⁸-vasopressin and somatostatin 28.

The i-ions of cysteine/cystine are a good indication of the reductive state, however they are usually very weak. Moreover, cysteic acid residues in oxidized insulin B chain did not form i-ions but induced a strong fragmentation at the respective C-terminal peptide bonds (data not shown).

Conclusion: Spectra of reduced and cystine containing peptides indicate that intrachain disulfide bonds remain intact under GDE-PSD conditions. This contrasts the observed lability of interchain disulfide bonds in negative ions of insulin⁶ and the observed prompt fragmentation of interchain disulfide bonds⁵. The occurrence of b and y ions of the reduced peptide in the oxidized sample could suggest that reduction processes occur, e.g., during desorption/ionization, which then allow fragmentation to occur.

Optimization of the Parameters Effecting MALDI-TOF Mass Resolution

Ricky D. Edmondson, Damon C. Barbacci, and David H. Russell
Laboratory for Biological Mass Spectrometry, Department of Chemistry
Texas A&M University
College Station, Texas 77843

The resolution of MALDI-TOF is evaluated in three modes of operation: continuous reflected (RTOF), delayed extraction linear (DE-LTOF), and delayed extraction reflected (DE-RTOF). The mass resolution of MALDI/RTOF can be improved by optimizing the sample preparation. An overlayer method of sample preparation allows mass resolution ($m/\Delta m$ FWHM) of 9500 to be obtained for analytes up to 3500 Da. We calculated theoretical peak profiles of ions formed with a range of initial velocities, from these calculations we conclude that the peak broadening observed in reflected MALDI mass spectra is largely due to a time component of the ionization process (delayed ion formation). We would argue the significant increase in resolution observed from samples prepared by the overlayer method is due to a reduction in the delayed ion formation.

The mass resolution of MALDI/DE-LTOF mass spectra of a peptide mixture containing Angiotensin II (1045.534), melittin (2844.754) and bovine insulin b-chain (3493.643) was examined. Tuning the parameters of DE (*i.e.* adjusting the pulse voltage and delay time) for each peptide resulted in spectra with baseline separation of the isotopes for that particular peptide; however, using one set of pulse parameters it was not possible to obtain high resolution over the entire mass range of the peptides present as is shown in Figure 1. The largest mass window over which good resolution (isotopes resolved) is achieved is ~ 1500-2000 Da. The pulse parameters required to achieve good resolution in the DE-LTOF mode on our instrument (this varies from instrument to instrument based on instrumental geometry) have a narrow tolerance window. That is, for a given pulse voltage, the mass resolution of a peak decreases dramatically if the delay time varies by more than 100 ns from the optimum value. This window narrows further as the mass of the analyte increases.

The mass resolution of MALDI/DE-RTOF mass spectrum of a peptide mixture is shown in Figure 2. The parameters of MALDI/DE-RTOF must be tuned to give optimum resolution, but unlike DE-LTOF, DE-RTOF has a large tolerance window for focusing. Good resolution can be obtained several hundred ns away from the optimum value. The entire range of peptides can be acquired at high resolution ($m/\Delta m = 7700$ -10600).

MALDI/DE-LTOF

Delayed Ion Extraction for the Analysis of Metastable Fragmentation in MALDI-MS

Hans-Christian Luedemann, Jianru Stahl-Zeng and Franz Hillenkamp
Institute for Medical Physics and Biophysics, University of Muenster, 48149 Muenster, Germany

Mass spectrometric sequencing of biopolymers in the mass range up to 3 kDa by an analysis of their metastable fragmentation in the first field-free drift region of a reflectron time-of-flight mass spectrometer (post-source decay) has recently become an established method.¹ In this paper, metastable fragment ion analysis with delayed ion extraction (DE)² is demonstrated. Originally, DE was employed to enhance the resolution of the precursor ion selection³. It is demonstrated that DE can also improve the overall performance of PSD analysis besides the improved precursor ion selection.

The Vision 2000 instrument used³ has an open ion-optics and a gridless reflectron. Ions are accelerated to 10 keV and detected with a secondary electron multiplier with a conversion dynode (postacceleration voltage -6kV). The equivalent flight path length is 1.7m. A frequency tripled Nd:YAG laser (355nm) with a pulse duration of 5 ns was used. Vacuum pressure in the ion source was $1 \cdot 10^{-4}$ Pa and $8 \cdot 10^{-5}$ Pa in the field-free drift region.

For DE the potential of the sample relative to the extraction element in the open ion-optical arrangement is switched with a delay. Delay times were between 20 ns and 1 μ s. The sample potential was switched from -200 V to maximally +4.5 kV relative to the extraction electrode.

The total ion acceleration potential was always maintained at 10 kV.

Care was taken to keep the laser pulse energy constant at ca. 1.4 times its threshold value for parent ion detection for all extraction conditions tested. It was monitored with a pyroelectric detector.

α -Endorphin (YGGFMTSEKSQTPLVT; 1747.0 Da) was chosen as a test peptide. It yields, among others, intense signals corresponding to metastable fragment ions b_8 to b_{15} . 0.5 μ l of a $5 \cdot 10^{-5}$ M peptide solution and 2.0 μ l of a 0.06-0.1M 2,5-DHB aqueous solution were prepared as usual.

Although in the DE case initial electric field strengths at the sample surface are lower by several orders of magnitude compared to the static extraction (SE) case ($5 \cdot 10^3$ vs. $1.8 \cdot 10^6$ Vm⁻¹), a 2-3 fold increase in absolute fragment ion intensities was observed. This increase could not unambiguously be assigned to either enhanced transmission of the instrument or to differences in plume dynamics.

Fragment ion intensities normalized to parent ion intensities are lower in the DE case than in the SE case by a factor of 3-5.

Mass resolutions for the fragment ions were comparable to those in the SE mode, if the potential distribution of the reflectron was suitably adapted.

This observations have been verified for the entire fragment ion range of a variety of peptides investigated.

For laser pulse energies close to threshold a moderate shift in fragment ion pattern towards less small neutral loss (less a_x-17 , b_x-17) has been observed when using DE instead of SE. At higher laser energies this difference vanishes, yielding higher a_x-17 and b_x-17 peaks than the respective a_x and b_x peaks independent of the extraction mode.

STATIC EXTRACTION

DELAYED EXTRACTION

A BENCH-TOP MALDI-TOF FOR THE RAPID SEQUENCING OF PEPTIDES AND PROTEINS

Andrew R Bowdler, David C Dingley & Paul Humphrey
Kratos Analytical, Barton Dock Road, Manchester, M41 7LD, UK.

Fragmentation of peptides in a MALDI-TOF by post source decay (PSD) can be stimulated by the use of excess laser power during the ionisation process. Detection of the ion fragments is not achieved in linear time-of-flight systems as any fragment ions formed within the field free region will have essentially the same velocity as their precursors. Consequently they will appear at the same time as if they had not fragmented and so will not be observed as separate entities.

PSD acquisition is difficult in conventional reflectron systems as the ions are not brought into a time focus under the same conditions as the precursor ion. As the fragments are energy deficient relative to the precursor they will be incorrectly analysed. Until recently the product ion spectrum has only been accessible by a complicated process involving incrementally adjusting the reflectron voltage and collecting multiple spectra. The retarding voltage of the reflectron must be reduced in a series of steps. Each step time focuses progressively lower kinetic energy ions in separate mass ranges thus ultimately allowing the build-up of the entire spectrum. This takes time to acquire and each step must be individually calibrated and then painstakingly stitched together to build up a complete spectrum.

Using a novel curved field reflectron^{1,2} geometry in the Kratos KOMPACT Research MALDI IV (figure 1), the fragment ions can be brought into *simultaneous* time focus without the need for voltage stepping. The

Figure 1 - Schematic of Kompact Research MALDI IV

entire fragment spectrum can therefore be acquired in a single run representing a considerable saving in time and effort.

The first stage of analysis is to acquire a standard (non-PSD) spectrum at the threshold laser power when fragmentation of peptides is not usually observed (Figure 2). Having first identified the different species present in the sample, one species must be selected for initial PSD. This is

Figure 2 - Non-PSD spectrum of mixture of angiotensin peptides

done by using cursors to bracket the peak of interest. These then determine the timings for the switching off and on of an ion gate. A spectrum acquired at this stage will show only the precursor ion of interest with no other peptides or matrix ions.

The method used to induce fragmentation is to increase the laser power beyond the threshold. The excess energy induces molecules (e.g. peptides) to fragment. With the curved field the fragmentations appear immediately, with

the parent, as a sequence spectrum and can be maximised by interactively tuning the laser power. For example, the spectrum in figure 3 was acquired under typical conditions and is the sum of 50 laser shots and the total time for acquisition was ≈ 30 s

The gate can then be moved to select other species in the mixture and their PSD spectra can be acquired.

Conclusions

The KOMPACT Research MALDI IV provides fast seamless data acquisition (SDA). Calibration is simplified and all PSD data can be automatically calibrated with a single keystroke. With the advent of SDA, the sequencing of peptides by MALDI becomes a realistic proposition for the busy peptide laboratory.

Optically Isolated Microchannel Plate Detector for High Voltage Postacceleration of MALDI Ions

W. Henry Benner and David Horn

Engineering Division, MS: 70A-3363, Lawrence Berkeley National Laboratory
1 Cyclotron Road, Berkeley, CA 94720

Two major problems with the use of microchannel plates (MCP) ion detectors in time-of-flight mass spectrometry are: 1) Ion detection efficiency decreases with increasing ion mass due to a velocity threshold¹ inherent in secondary electron emission. For metals and semiconductor surfaces, the velocity threshold is about 2×10^6 cm/s which corresponds to mass 15000 Da for 30 keV ions. The microchannel plates exhibit similar characteristics, so it is assumed that they have about the same velocity threshold. 2) The absolute efficiency for detection of an ion by the microchannel plates is unknown and is likely to be less than 100% even if the velocity threshold is exceeded. The maximum efficiency would be 90% if the inactive web space that covers 10% of the detector is considered. A larger inefficiency could be due to poor coupling of impact-generated electrons into the microchannels.

We have developed a way to float electrically a set of microchannel plates at high voltage (Fig. 1) in order to postaccelerate primary ions. We decouple the signal from the high voltage detector via an optical fiber, thus avoiding the need for a conversion dynode. The current configuration allows the detector to be floated to ± 20 kV limited only by electrical feedthrough ratings and higher postacceleration is possible with more highly rated feedthroughs. Pulses sampled at the input to the fiber optic transmitter are approximately 5 ns FWHM and after passing through the transmitter and receiver are stretched to 8 ns FWHM, which will not significantly change the mass spectra.

This detector assembly provides flexibility in the study of secondary electron and ion formation, including the study of ion processes on the surface of the MCP. Using a previously described MALDI mass spectrometer², we looked for the secondary ions and electrons emitted from a 90% transmission grid (Buckbee Meers, nickel, 90 lines/in) kept at ground potential placed 1 cm in front of the microchannel plates floated at positive postacceleration voltages. Normally, the microchannel plates are at negative potential which does not allow the secondary electrons to hit the detector. With the fiber optic assembly, a positive postacceleration voltage can be maintained on the detector. The primary ion used was a 15-mer mixed base oligonucleotide and was launched using 3-hydroxypicolinic acid as the matrix (5000:1 matrix:analyte) and diammonium citrate as a salt adduct suppresser. The DNA was ionized by a N_2 laser pulse (337 nm) and was accelerated to -25 kV. The large peak in Fig. 2 occurring about 500 ns before the primary ion peak corresponds to secondary ions and secondary electrons. A surprising result was that the peak consisting of secondary electrons and ions was as large as the primary DNA peak. Assuming that only 10% of the primary ions hit the grid and the remaining 90% reach the MCP, the equally-sized peaks suggest that the generation and detection of secondary electrons/ions from the grid is perhaps a more sensitive detection scheme than detection of primary ions directly hitting the MCP. The secondary electron/ion peak does not show much degradation in resolution probably because many more electrons than ions are emitted. Electrons only take a few nanoseconds to reach the MCP from the grid, so the resolution will not change much. This has applications as a detector of increased sensitivity in MALDI.

Fig. 1. Schematic of the HV-optically isolated microchannel plate detector assembly. An inner cylinder houses the MCP detector, a dc-dc power supply to power the MCP with -2 kV and -0.1 kV, a dc-dc power supply to generate ± 15 V for the optical transmitter, and a 10X preamplifier. The dc-dc power supplies require 24 V input power and this is provided to the assembly by two cables, one of which is at HV (the virtual ground for the assembly) and the other at HV + 24V. "HV" and "HV+24V" are generated in a separate module where a 40 kV isolation transformer is used to float a 24 V d.c. power supply to high voltage. The inner cylinder is protected by an outer ground shield. The optical fiber passes through the grounded shield and provides the necessary electrical isolation between the MCP and amplifiers at ground.

Fig. 2. Secondary ion/electron emission from the grid with +3 kV postacceleration.

LBNL report 38186

POST-SOURCE DECAY WITHOUT SCANNING THE REFLECTRON: APPLICATIONS TO BIOMOLECULES

Marcela M. Cordero, Amina S. Woods, Timothy J. Cornish and Robert J. Cotter
The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Post-source decay has rapidly become a widespread analytical tool for peptide and biomolecular sequencing. A curved-field reflectron TOF mass spectrometer developed in our lab^{1,2} enables acquisition of focused product ion mass spectra at a single reflectron voltage. In this poster we present some applications of this technique for sequencing of cyclopeptides, sulfated- and phospho- peptides and in-situ enzymatic fragments from endo- and exo- peptidases.

Sample preparation. Peptides (purchased from SIGMA or obtained from biological samples) were dissolved in 80% H₂O 20% ACN 0.1% TFA typically in a concentration of 10-100 pmol/ μ L. 1 μ L was pre-mixed with 1 μ L of saturated solution of 50% EtOH 50% H₂O α -cyano-4-hydroxycinnamic acid matrix, from which 1 μ L was taken and deposited on the probe tip. The spectra were generated using a 600 ps/pulse N₂ laser. 100-500 averaged shots were collected on a LeCroy 9354-M oscilloscope, downloaded onto a 486 PC and processed using TOFWARE (ILYS Software, PA).

a. Cyclopeptides Cyclopeptides³, even though essentially peptides, present a series of structural features which makes them a family of their own. Interest in cyclopeptides arises from the wide range of biological functions, for example antibiotic (gramicidin S), toxic (tentoxin) and immunosuppressant (cyclosporine). In general, cyclic peptides were observed to undergo abundant metastable decay. The main ions detected correspond formally to acylium ions, immonium ions and NH₃ losses from basic residues. Among the cyclopeptides used for PSD were: Cyclo (D-Trp-Lys-Thr-Phe-Pro-Phe) (Fig. 1), Gramicidin S, Cyclo (D-Glu-Ala-D-allo-Ile-Leu-d-Trp) and tentoxin.

b. Peptides and modified peptides. Post-source decay of a peptide with an N-acetylated terminus and an amidated C-terminus [CH₃CO-CTTTSSSKSYRQ-NH₂] produced abundant sequence indicative ions (Fig. 2). A sulfated peptide, [Tyr(SO₃H)²⁷]-Cholecystokinin Fragment 26-33, cleaves H₂SO₃ in-source. The PSD products of the resulting de-sulfated peptide DYMGWMDF-NH₂ were obtained. For the phosphorylated peptide KPSGRRE-S[PO₃H]LTSFG metastable losses of H₂PO₃ and H₃PO₄ were detected. PFR-7-amido-4-methylcoumarin produced, as expected from the presence of the chromophore, an intense protonated ion which also decays metastably to give the sequence-indicative spectrum presented in Figure 3, which includes the presence of protonated 7-amino-4-methyl coumarin.

c. In-situ enzymatic digests. AMAPRTLTL (Qa-1^b), an MHC class Ib peptide, has been recently sequenced in our lab⁴ by MALDI / enzyme digestion. In-situ exo- and endo- enzyme digestion combined with *post-source decay* of selected enzymatic fragments were used for fast confirmation of the Qa-1^b sequence. Figure 4 shows the PSD products of AMAPR obtained from tryptic digest of AMAPRTLTL.

Conclusions. The curved field coaxial reflectron TOF MS provides fast and accurate analysis of cyclopeptides, modified peptides and enzymatic mixtures. Post-source sequencing without scanning the reflectron is fast, simple and requires no calibration parameters except for the molecular ion of the precursor. Bidimensional analysis using enzyme digests and post-source decay is a very powerful tool for sequence determination of peptides. This high sensitivity technique is very well suited for biopeptides, usually available only at low concentrations.

Figures 1-4. Product ion mass spectra of Cyclo (D-Trp-Lys-Thr-Phe-Pro-Phe) (1) CH₃CO-CTTTSSSKS-YRQ-NH₂ (2) PFR-7-amido-4-methyl coumarin (3) Gate-selected AMAPR from tryptic digestion of AMAPRTLTL (4).

Mass Spectrometric Characterization of Neutral Products in the Laser Photolysis of Monolayer Organosiloxane Films

Stephen McElvany, Andrienne Friedli, Charles Dulcey and Christopher Holliman
Analytical Chemistry Section / Code 6113
Naval Research Laboratory
Washington, D.C. 20375

Monolayer organosiloxane films covalently bound to a variety of substrates (R-Si-O-S; where S is a surface such as silicon) are of interest for applications involving high resolution surface patterning such as microlithography. The energy dose required for photochemically activated bond scission is dependent upon film structure, chromophore, reactive site, and substrate participation. A variety of analytical techniques such as ellipsometry, UV spectroscopy, X-Ray photoelectron spectroscopy and atomic force microscopy have been used to characterize these films before and after laser irradiation. The changes observed in the film morphology and chemical nature on the surface can be used to monitor the photocleavage rate and subsequently propose possible mechanisms through systematic variation of the R group and chromophore.

Determination of the neutral products using mass spectrometry would provide significantly more conclusive information on the reaction mechanisms and the resulting chemical composition of the irradiated films. We have successfully ionized and mass-analyzed the neutral products from a variety of these films which are placed just outside the trapped ion cell of a Fourier transform mass spectrometer. The 193 or 248 nm laser-induced photoproducts from the films are typically ionized by conventional electron ionization (15-70 eV). In some cases chemical ionization is used to confirm the molecular weight of the desorbed neutrals.

In most cases, photocleavage is believed to occur at the Si-R bond which is further supported by the mass spectra. These films are a series of arylalkylsiloxanes in which the chromophore is a benzene or naphthalene ring. In contrast, halogen-substituted rings, X-CH₂-Ph-Si-O-S where X is Cl or I, do not undergo cleavage at the surface Si-C bond, but eliminate either HCl or I following laser irradiation. The loss of the halogen and retention of the ring in these films is confirmed by both XPS and spectrochemical methods.

The effect of alkyl chain length and position relative to the surface, i.e. CH₃-(CH₂)_n-Ph-Si-O-S and Ph-(CH₂)_n-Si-O-S with n up to 16, has been examined with somewhat surprising results. In the first case in which the ring chromophore is next to the surface, simple Si-C cleavage occurs as might be expected and an intact molecular ion of the entire hydrocarbon is observed in the mass spectra. In the case in which the alkyl chain is between the chromophore and the surface a similar result is obtained for n up to 3. For n > 3, however, Si-C cleavage no longer occurs to eliminate the entire R group as shown in Figure 1. The mechanism apparently changes such that a constant neutral product at m/z 120 is eliminated that does not change as the chain length is increased. In contrast, electron ionization of the corresponding gas-phase molecular species yield abundant molecular ions. Chemical ionization of the desorbed neutrals yields exclusively m/z 121 confirming the loss of mass 120 as the largest neutral photolysis product. This loss corresponds to C₉H₁₂, or nominally propylbenzene. Photoinduced cleavage between the C₃-C₄ bond of the

alkyl chain is specific and independent of the laser photolysis wavelength. This fragmentation is unique to these species being bound to the surface. The cause of this unusual behavior is not known, but may indicate that there is a strong interaction of the alkyl chain with the surface which results in only the C₉H₁₂ species as the neutral lost upon photolysis. There are numerous possibilities for the structure of the C₉H₁₂⁺ observed from these films. The electron ionization mass spectra can not differentiate between these isomers. Experiments are planned to compare the CAD of this ion with that obtained from molecular ions of known C₉H₁₂ precursors. Determination of the structure may provide insights into the unusual mechanism that results in this common neutral photoproduct.

FRAGMENTATION OF PHOSPHORYLATED PEPTIDES:
MALDI ON A FOURIER TRANSFORM MASS SPECTROMETER

Beth L. Gillece-Castro and John T. Stults
Genentech, Inc., 460 Point San Bruno Blvd.
South San Francisco, CA 94080

Phosphorylation of proteins is an enzymatically-controlled method of signal transduction within cells, whereby the sites and level of phosphorylation determine the activity of these signals. Mass spectrometric methods have been developed in recent years for phosphorylation site identification which rely on the mass shifts of +80 Da on peptides, and have been demonstrated using LSIMS¹, ESI² and MALDI³⁻⁵ ionization techniques. Characteristic fragments may be produced in collision-induced dissociation (CID) to confirm the presence of phosphorylation on particular peptides. For example, phosphoric acid (H_3PO_4) is often lost from phosphorylated residues producing fragment ions 98 Da lower in mass than the protonated or deprotonated molecules. Fragment ions of this type have been observed by MALDI-TOF post-source decay.⁶

This study used MALDI ionization on a Fourier transform mass spectrometer (FTMS) to identify its usefulness for phosphopeptide analysis. As shown in Figure 1, the phosphotyrosine peptide, LKRApYLG-NH₂, was identified by the loss of phosphoric acid ($-\text{H}_3\text{PO}_4 = -97.977$ Da). The mass accuracy determined for the mass difference ($\Delta = .002$ to $+.008$ Da) made identification unambiguous. At lower laser fluence the ratio of fragments to parents was decreased, but the $-\text{H}_3\text{PO}_4$ fragment was always present. Similar fragmentation occurred during sustained off-resonance irradiation (SORI) CID of the MH^+ ion (Fig. 2). No additional information was gained from the SORI-CID in this case, but for mixture analysis the SORI-CID experiment may be helpful.

Peptide sequence affected the observation of phosphoryl fragments in positive or negative ion modes. For example, in the negative ion FTMS spectrum of the peptide TFLPVPEpYINQSV (Fig. 3) the primary fragment was $-\text{H}_3\text{PO}_4$. However in positive ion mode this peptide gave only sequence related backbone fragments and no phosphate was lost (data not shown). Since the peptide structure determined whether positive or negative ion mode was diagnostic, all peptides should be analyzed in both modes.

Presence and Location of Disulfide Bonding in Biologically Active Peptides/Proteins by Multistage Fragmentation: A MALDI FT-ICR Mass Spectral Analysis

Touradj Solouki, Mark R. Emmett, Shenheng Guan*, Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Lab, Florida State University, 1800 East Paul Dirac Drive, Tallahassee, FL 32310

* Member of the Department of Chemistry, Florida State University

Matrix-assisted laser desorption/ionization (MALDI) of relatively impure samples generates peptide and protein ions for rapid and direct FT-ICR mass spectral accurate-mass measurement and amino acid sequence analysis. Combined use of ion axialization [1] and ion remeasurement makes possible orders-of-magnitude improvement in sensitivity to the low-attomole detection level.[2] Here, we present MALDI-FT-ICR/MS results that verify the presence and location of disulfide bridges in selected biologically active peptides.

Covalent disulfide bridges formed between cysteine residues in peptide/protein structures help to define tertiary conformation by cyclizing the molecule. This cyclization is important in dictating the ligand-receptor specificity and ultimate receptor response for many biologically active peptides. We show that MALDI induced fragments of disulfide containing peptides provide a rapid method to verify the presence and identify the location of disulfide bridges in peptides. To verify the presence and location of disulfide bridges, we mass analyze the peptide samples before and after dithiothreitol treatment *i.e.*, reduction of disulfide linkages. The two unit mass shift in mass spectrum of the reduced sample, relative to mass spectrum of the untreated sample, indicates the presence of a single disulfide linkage. In addition, ultra-high resolution MALDI FT-ICR mass spectra with mass-resolved ^{34}S and $^{13}\text{C}_2$ isotope peaks help to verify the presence of disulfide bonds as well as the number of sulfurs present. MALDI FT-ICR mass spectra were acquired with an FTMS-2000 mass spectrometer (Finnigan-FTMS, Madison, WI) equipped with a 3 T superconducting magnet and an Odyssey® data system. Figure 1 shows high-resolution MALDI FT-ICR mass spectra of the quasimolecular $[M+\text{Na}]^+$ region of oxytocin before (top) and after (bottom) reduction of the disulfide linkage. The two unit mass shift shows the complete reduction of the disulfide bond. The disulfide bond also confers structural rigidity to the peptide, as seen from peptide fragmentation. The vertical bars within the peptide sequence indicate the most prominent fragmentation sites after MALDI. Figure 2 shows the molecular ion region of reduced and non-reduced [D-Pen^{2,5}]-Enkephalin. The number of sulfurs present in the molecule and the degree of reduction may be inferred from a single ultra-high resolution MALDI-FTICR MS. We have investigated peptide fragmentation patterns of several disulfide containing species. Micro-Spot MALDI for Ultrasensitive Detection of Nanoscale Samples

Rafael E. Golding, Randy M. Whittal and Liang Li

Department of Chemistry, University of Alberta, Edmonton, AB Canada T6G 2G2

In a typical MALDI experiment 0.5 to 1.0 μL of a 1 to 10 μM solution of analyte is delivered along with matrix to a sample probe which is 3 to 10 mm^2 in area. The desorption laser beam is typically 50 to 150 μm in diameter, thus much of the sample is not used. If one can control sample deposition and laser position then the sample may be located only within the small area where desorption takes place [1].

In this work a nanodelivery system was further developed and tested that is capable of accurate sample delivery onto a known location of the sample probe on a routine basis. Such a system may be applied to samples for which there exists only a very limited amount of sample; e.g., intracellular fluid.

All spectra were collected on the previously described TLF MALDI instrument, modified for operation up to 30 kV [2]. All proteins were purchased from Sigma and used without further purification. Sinapinic acid (SA) and α -cyano-4-hydroxycinnamic acid (HCCA) were purchased from Aldrich. HCCA was recrystallized before use. Matrices were loaded in two layers onto a polished stainless steel sample probe [3]. The matrix used with peptides was HCCA, according to the following procedure. To form the first layer 0.9 μL of 5 mg/mL HCCA in 60% methanol/acetone was loaded to the sample probe and allowed to dry. To form the second layer, 0.35 μL matrix saturated in 25% methanol was loaded to the sample probe and allowed to dry. The sample was loaded on top using the nanodelivery system. Protein samples were analysed using SA as the matrix. To form the first layer 0.9 μL of 6 mg/mL SA in 60% methanol/acetone was loaded to the probe and allowed to dry. To form the second layer 0.35 μL of 2.5 mg/mL SA in 20% acetonitrile/water was loaded to the sample probe and allowed to dry.

Figure 1 is a schematic of the nanodelivery system capable of accurately delivering as little as 20 pL of sample solution. The system consists of two capillaries attached to a moveable holder and connected to disposable syringes. The capillaries are deactivated using a silylation fluid in order to reduce sample adsorption. Moving the capillary holder, it is possible to deliver subnanoliter volumes of sample exactly in the center of the probe tip, providing a sample spot of typically 150 μm in diameter.

Figure 2 is a spectrum of 0.97 amol (0.195 nL of 0.005 μM) of substance P (oxidized form) using HCCA as the matrix. The signal to background noise ratio (S/N) is 16. Other peptides and proteins have been examined using the nanodelivery system. For example, for 4.6 amol of bradykinin the S/N is 22, for 13 amol of human insulin the S/N is 8 and for 54 amol of equine myoglobin the S/N is 13.

Single Cell Analysis

The nanodelivery system has been applied in the examination of hemoglobin from human erythrocytes. Figure 3 is a spectrum of the content of a single human red blood cell. The observed peaks correspond to the subunits of hemoglobin without the heme prosthetic group.

Oxidation of Methionine-Containing Peptides Under *In Vitro* and *In Vivo* Conditions with Analysis by MALDI MS

Hong Zhang and Richard M. Caprioli
University of Texas Medical School, 6431 Fannin Street, Houston, Texas 77030

The oxidation of methionine residues in some proteins is believed to not only affect biological activity, but also may be involved in some regulatory processes. Comparatively little has been done to study both the *in vitro* and *in vivo* oxidation of methionine-containing peptides. *In vivo* studies can be performed using a combination of microdialysis and mass spectrometry, providing a new tool for such studies. However, significant levels of oxidation have been observed in handling and analyzing such peptides. The first priority was to study the cause of *in vitro* oxidation that was observed within our apparatus. Methionine-containing peptides are known to be readily oxidized when exposed to air or oxygenated solutions during sample handling. Using MALDI-MS analysis, we have examined the non-physiological oxidation of substance P (SP), α -neurokinin, neuromedin B, bombesin, α -endorphin, met-enkephalin, met-lys-bradykinin, and small cardioactive peptide B.

Methods and Results:

To access the *in vitro* oxidation which occurred within the experimental apparatus, we continuously infused 1 pmol/ μ L SP dissolved in water through a 90 cm length of FEP (fluorinated ethyl propylene) microdialysis tubing at a flow rate of 0.3 μ L/min. The samples were collected every 15 minutes and were analyzed directly by MALDI MS. The results are shown in Figure 1a. We found that the first fraction which showed peptide signals contained over 85% oxidized SP, observed at m/z 1364.6, a mono-oxygenated species 16 daltons higher than that of SP. After 30 minutes, the percentage of oxidized SP dropped to the same level as it has been before infusion, to approximately 6-8%. We also tested 7 other peptides which contain methionine residues in N-terminal, C-terminal and internal positions in the peptide chain. The sequences of these peptides are listed in Table 1. Results were obtained similar to that of SP and are shown in Table 1. These data show that the auto-oxidation of methionine residues in peptides can occur with ease inside FEP microcapillary tubing. Although there appears to be a trend showing higher oxidation levels where methionine is in the C-terminal position, the number of peptides tested is too small to draw firm conclusions.

In order to eliminate this oxidation artefact, i.e., non-physiological oxidation of methionine residues in peptides, we precoated the tubing surface with BSA by flowing a 1% BSA solution through the tubing by using a flow rate of 0.3 μ L/min for 30 minutes. A reinjection of SP showed that nearly all of the oxidation was eliminated (see Figure 1b). The addition of other compounds, such as L-methionine, methionine-containing proteins, and peptides, and non-methionine-containing peptides (such as neurotensin), can inhibit the auto-oxidation of methionine. For example, pre-treatment of the tubing with a 0.01% prolactin solution completely eliminates the non-physiological oxidation.

An *in vivo* microdialysis experiment was performed to study the metabolism of SP by infusion of 1 pmol/ μ L of SP into rat brain at a flow rate of 0.3 μ L/min. A 4 mm CMA/10 microdialysis probe was stereotactically implanted in the brain (striatum) of an anesthetized rat. The probe was used both to deliver the peptide into the brain and to collect the metabolized products. Artificial CSF was perfused through the probe for 1 hour before the infusion of peptides or precoating solutions. The system was then precoated with 0.01% prolactin for 30 minutes prior to SP infusion. The resulting dialysate samples collected after SP

infusion contained approximately 10% oxidized SP, compared to 6.5% for the original SP solution.

Conclusions:

1. The oxidation of methionine residues to methionine sulfoxide residues in peptides can occur in the experimental apparatus in addition to any physiological oxidation which might take place. Precoating the capillary tubing before peptide infusion and collection can eliminate this oxidation.
2. *In vivo* experiments involving SP using precoated tubing showed a small (3-5%) increase in the oxidation of methionyl residues. Thus, the physiological oxidation of this neuropeptide appears not to be a major metabolic reaction.

The peculiar property of MALDI-TOFMS to determine the molecular mass of biomolecules in the femtomol-pmol range has been applied to the analysis of peptide-protein interactions. The present study concerns the interactions of Substance P (peptide) with its human receptor NK-1 (protein, mw ~46kDa) which has been expressed in Chinese Hamster Ovary (CHO) cells. A specific strategy has been developed to minimize sample manipulations. A photoactive residue has been introduced in the sequence of a biotinylated Substance P analogue. After UV irradiation, the peptide is covalently bound to the NK-1 receptor. Enzymatic and/or chemical digestion yields proteolytic photolabeled fragments which can be extracted using streptavidin-coated magnetic beads (1). The high affinity of biotin for streptavidin implies an efficient trapping of fragments having a biotinylated moiety. A magnet allows the separation of the beads from the supernatant which is aspirated and discarded. The elution of the biotinylated fragments from the beads is directly achieved by mixing the beads with a few microliters of the matrix (α -cyano-4-hydroxycinnamic acid)(1). Trapping of the beads with the magnet allows to deposit one microliter of the mixture matrix and biotinylated fragments onto the target which is classically analyzed by MALDI.

This procedure was applied to a Substance P derivative, [biotinylsulfone-Apa⁰, para-benzoyl-Phe⁸] SP mw=1848 Da, with a photoreactive group in position 8. In order to precise the fixation site, consecutive digestions (trypsin and V8 endoprotease) of the photolabeled protein were performed for various incubation times (2). After trypsin digestion (24h), biotinylated fragments were extracted using streptavidin magnetic beads and the biotinylated fragments still linked to the beads were subsequently submitted to V8 endoprotease digestion (1, 4 or 22h). After washing procedures, free biotin was then added to saturate the streptavidin sites giving a more efficient elution of biotinylated species in the matrix (1). MALDI mass spectra were directly obtained. A second MALDI analysis was performed using a diluted peptide (Angiotensin I and Insulin) deposited onto the target for precise calibration. The figure shows the MALDI mass spectra after trypsin cleavage (a), the same experiment but without photoreaction (b). Peaks at 2857, 2873, 2889, 3020 and 3036 Da characterize the fragments of photolabeled NK1 receptor. After subsequent V8 endoprotease cleavage for 1h (c) or 22h (d), a new peak at 2470 Da appears whose relative intensity depends on the V8 incubation time (22h without photoactivation (e), for the control experiment). This clearly indicates that the fragment at 2470 Da originates from the V8 cleavage of the fragments previously cleaved by trypsin. In addition, fragments at 2873, 2889 and 3036

Da are likely oxidised species of the fragments at 2857 and 3020 Da. Chemical digestion using CNBr cleavage of the photolabeled NK-1 receptor and MALDI analysis indicated that the SP analogue is covalently attached to the methyl group of a methionine residue (2).

Taking into account the chymotrypsin activity of trypsin in our experiments (large incubation time and high concentration), the corresponding fragments of the NK-1 receptor involved in the photoreaction can be unambiguously attributed to Thr¹⁷⁰-Arg¹⁷⁷ (peak at 2857 Da), Tyr¹⁶⁹-Arg¹⁷⁷ (peak at 3020 Da) and Thr¹⁷³-Arg¹⁷⁷ (peak at 2470 Da). Altogether, these experiments identify Met¹⁷⁴ as the modified residue. New experiments using SP derivatives with a photoreactive probe located at different positions are currently under investigations.

ORIGIN AND NATURE OF BIOSPECIFIC PEPTIDE-METAL ION COMPLEXES OBSERVED IN THE GAS PHASE AFTER LASER-INDUCED DESORPTION

Martin P. Hornshaw and T. William Hutchens

Department of Food Science and Technology, University of California, Davis, CA 95616

Both matrix-assisted laser desorption/ionisation (MALDI) time-of-flight (TOF) mass spectrometry (MS) and electrospray ionisation (ESI) MS have recently been demonstrated to be enabling technologies that are potentially useful for detailed investigations of the structural determinants required for specific peptide-metal ion interactions (1,2). ESI has been shown to preserve non-covalent interactions in general (3) whereas MALDI is generally considered to disrupt non-covalent interactions, with peptide-metal ion interactions the possible exception. There is some doubt as to the origin (i.e., gas phase or solution/solid phase) of peptide-metal ion complexes observed as a result of the MALDI process. Consequently, we have evaluated the origin of biospecific peptide-metal ion complexes detected in the gas phase after their initial formation in solution and desorption from probe surfaces.

The detection of peptide-metal ion complexes in the gas phase may be explained either by preservation of interactions formed in the solution/solid phase or by formation of *de novo* complexes by gas phase collisional processes after disruption of solution/solid phase complexes during the desorption/ionization processes. If the latter is correct then new complexes could be formed in the gas phase that were not initially present in the solution/solid phase.

To test this hypothesis we examined evidence for *de novo* formation of peptide-metal ion complexes in the gas phase. Different populations of transition metal ion-binding peptides (with and without bound metal ions) were prepared, dried and crystallized separately in matrix, then presented on the same MALDI TOF MS probe surface as a mixture of crystals, each crystal containing only one population of a different apo or holopeptide prior to simultaneous desorption. The desorption/ionization of distinct and separate peptide-metal ion complexes (or apopeptides), allowed to mix only in the gas phase, demonstrated the preservation of existing peptide-metal ion complexes as formed in solution. There was no evidence for the gas phase formation of new complexes. Thus, biospecific peptide-metal ion complexes observed by MALDI TOF MS are indeed the result of preserved, stable solution/solid phase interactions and are not the result of dissociation during the desorption/ionization process followed by reassociation in the gas phase. These results suggest the maintenance of peptide/protein higher order structure during and after the MALDI process, at least those structures responsible for (and possibly stabilized by) metal ion binding. Consequently, it may be possible to utilize MALDI and related techniques as probes of not only protein/peptide-metal ion interactions but also of higher order protein structure.

Formation of fragments from biopolymers during the Matrix-Assisted Laser Desorption/Ionization process.

Matthias Amft, Johann M. Grundwürmer and Jürgen Grotemeyer;
Institut für Physikalische Chemie, Universität Würzburg
Marcusstr. 9/11, 97070 Würzburg

The application of matrix assisted laser desorption/ionization (MALDI) to biochemical problems is growing rapidly. It is a generally accepted method to get information about large biomolecules like enzymes or peptides particularly if other spectroscopic methods fail. The unique feature of the MALDI technique is the production of quasi-molecular ions with the absence of fragmentation. It is a fast and easy to handle method to identify biopolymers or mixtures of them. A large number of papers dealing with overcoming the lack of fragmentation have appeared throughout the years. In this poster we demonstrate the generation of structure specific fragments in the matrix-assisted laser desorption/ionization simultaneous with the ionisation process.

Figure 1: Flighttime spectrum of Bradykinin, increased desorption laser intensity

Figure 1: Mass spectrum of Bradykinin (sequence: ArgProGlyPheSerProPheArg)

Under normal MALDI conditions only the molecular ions are formed, but by increasing the desorption laser intensity also fragments of the investigated peptides could be observed. The experiments are performed in a home made two meter linear time-of-flight mass spectrometer, and the very low intensity fragment ion signals can only be seen in the area of the spectrum which is affected by the Post Source Pulse Focusing (PSPF)(1) method. Structural information can be derived from these measurements, because many signals are caused by backbone fragmentation of the investigated peptides. Fig. 1 and 2 shows a MALDI spectrum of Bradykinin. In Fig. 2 the focused part of the flighttime spectrum is calibrated, and one can see C- and N-terminal back bone fragments of the analyte. In the presented Poster it is also pointed out that a linear time-of-flight mass spectrometer in combination with the previously described PSPF device is suitable to produce high resolution spectra. The mass spectra were calibrated with external standards. The achieved reproducibility from measurement to measurement was clearly better than one per thousand.

Mercaptobenzothiazoles: New Matrices for Laser Desorption Ionization Mass Spectrometry

Naxing Xu¹, Zhi-Heng Huang², Douglas A. Gage² and J. Throck Watson^{1,2}
Department of ¹Chemistry and ²Biochemistry, Michigan State University, East Lansing, Michigan 48824, USA

Since Karas and Hillenkamp first reported nicotinic acid (3-pyridine carboxylic acid) as the matrix to desorb large proteins with 266-nm laser radiation, a number of new matrices of substantial utility have been discovered. Most of the matrices reported to date are substituted aromatic compounds containing carboxylic acid moieties. We report here on mercaptobenzothiazoles, a group of compounds lacking of a carboxylic acid functional group, as new matrices for MALDI at 337 nm

Matrix	Structure	λ_{max} (nm)	ϵ_{337} (l mol ⁻¹ cm ⁻¹)	MW
MBT	X = H, Y = H	326.8	1.4×10^3	167.25
CMBT	X = Cl, Y = H	331.7	1.4×10^4	201.70
AMBT	X = H, Y = NH ₂	339.0	1.0×10^4	182.27
MMBT	X = OMe, Y = H	337.0	4.4×10^3	197.29
EMBT	X = H, Y = OEt	330.0	1.1×10^4	211.32

2-Mercaptobenzothiazole (MBT) has been used successfully for the desorption of proteins up to 100,000 Da. A comparison with sinapinic acid and α -cyano-4-hydroxycinnamic acid indicates that MBT provides the same level of sensitivity and resolution, but offers the advantage of higher tolerance to sample contaminants such as ionic detergents. This new matrix was also found to be useful for oligonucleotide analysis

5-Chloro-2-mercapto-benzothiazole (CMBT), one analog of MBT, has been found not only effective for the analysis of peptides, low-mass proteins, and glycolipids, but also superior to conventional matrices for the analysis of oligosaccharides and complex carbohydrates such as muropeptides derived from peptidoglycans. CMBT also exhibits excellent experimental reproducibility of MALDI results owing to the homogeneous crystallization of the analyte/matrix mixture over the entire sample surface area.

Finally, all five mercaptobenzothiazoles studied in this work are shown to be well suited for synthetic polymer analysis. Both polar polymers such as polyethylene glycol (PEG) and non-polar polymers such as polymethyl methacrylate (PMMA) can be analyzed by MALDI-MS using the new matrices.

MALDI-TOF/MS for The Analysis of Potential Blood Substitutes

X. Gu, S. Kondubhotla, A.A. Aldridge, K.W. Olsen, and M.P. Chiarelli,
Dept. of Chemistry, Loyola University, Chicago, IL 60626.

Introduction

Many potential blood substitutes consist of two identical hemoglobin chains cross-linked through the ϵ -amino groups of lysines at the same position in either chain. Here we evaluate a strategy (outlined in scheme 1) based on MALDI-TOF/MS for discerning the major reaction products formed by the cross-linking of hemoglobins by a novel tetra-linker, 3,3',4,4'-benzophenone tetra(3,5-dibromosalicylate) (BPTA). This strategy involves comparing MALDI spectra of CNBr digests of Hb, and the cross-linked hemoglobins β 82XLHb, α 99XLHb, and the BPTA cross-linked reaction products, followed by isolation and tryptic digestion of the cross-linked CNBr fragments for further MALDI analysis to determine the positions of the lysines bound by the linker. Such a strategy is motivated by the low relative abundance of the cross-linked fragment observed in the MALDI mass spectra of the tryptic digest of the β 82XLHb and α 99XLHb, standard cross-linked Hbs where only one XL fragment (i.e., reaction product) is expected.

Experimental

All MALDI spectra were acquired with a TOF mass spectrometer of a modified Wiley-McLaren design (R.M. Jordan Co., Grass Valley, CA.) at a total acceleration of 20 kV, similar to an instrument described elsewhere (1). A N_2 laser (Laser Science, Newton, MA) was used to induce to desorption (337 nm). The matrix employed throughout these studies was 4-HCCA. The β 82XLHb and BPTA-XLHb were synthesized as described previously (2). The BPTA tetra-linker was anticipated to bind the β chains through the Valine N-terminus and lysine 82 ϵ -amino group. The α 99XLHb was obtained from Baxter Scientific (McGaw Park, IL). The α 99XLHb and β 82XLHb were characterized by x-ray crystallography.

Results and Discussion

Comparison of the MALDI spectra of the CNBr digests of the normal (Figure 1) and XLHb's show that the fragments containing lysines α 99 and β 82 in the mass spectrum of normal Hb are absent in the MALDI spectra of the α 99XLHb and β 82XLHb blood substitutes where these lysines are bound by the fumarate cross-linker. The MALDI spectrum of the CNBr digest of the BPTA-XLHb indicate that more than one product is formed in the BPTA cross-linking reaction (Figure 2). The absence of the peak at m/z 7026 in the BPTA-XLHb spectrum suggests the α chain fragments containing the C-terminus are bound by the linker. The presence of the peak at m/z 6065 corresponding to the β chain fragment containing the N-terminus indicates that the binding of valine is incomplete.

Isolation and tryptic digestion of the CNBr cross-linked fragments produced fragments that verified the positions of lysines bound by the fumarate. The MALDI spectra of the tryptic digest of the β 82XL CNBr peptide showed a tryptic fragment (m/z 7337) formed by the failure of the trypsin to cleave at lysine 95 as has been observed previously (3). Tryptic digestion and MALDI analysis of the BPTA cross-linked CNBr fragments is being carried out to determine the sites of BPTA binding.

MALDI MS for the Analysis of Modified and Unmodified Polymer Surfaces

Angela K. Walker, Elisa H. Benedetti, Kari Kukanski, Gary R. Kinsel,
J.-S. Wang, Richard B. Timmons

Department of Chemistry, The University of Texas at Arlington, Arlington, Texas 76019-0065

Matrix assisted laser desorption/ionization (MALDI) mass spectrometry (MS) of biological material adsorbed to polymer substrates has emerged as an important bioanalytical tool. In our research group, we are investigating the use of MALDI-MS to characterize the bioaffinity of polymer surfaces which have been modified by pulsed RF plasma deposition. Pulsed RF plasma deposition can be used to covalently attach thin films having controllable functionality to polymer substrates. The functionality of the film can significantly alter the adsorptive/repulsive properties of the surface and allow unprecedented control of the bioaffinity of the polymer/film surface.

These studies have focused on exploring the effect of surface modification on the signal obtained for biomolecules by MALDI-MS. The polymer substrate in these studies was polyvinylidene difluoride (PVDF). Two pulsed RF plasma modifications of the PVDF were performed. The first modification involved the attachment of allyl amine to produce an $-NH_2$ modified surface which has been shown by radiolabelling studies to increase surface affinities for biomolecule adsorption. The second modification involved the attachment of perfluoro-2-butyl tetrahydrofuran to produce $-CF_3$ modified surfaces which have been shown to slightly decrease surface affinities for biomolecule adsorption.

Initial studies have focused on the comparison of MALDI-MS signal intensities (integrated peak areas) from the application of identical quantities of bovine insulin to unmodified (control) PVDF, $-NH_2$ modified PVDF, and $-CF_3$ modified PVDF. All experiments were performed using conventional MALDI methods with α -cyano-4-hydroxy cinnamic acid (α CN) as the matrix. These studies have demonstrated that a significant difference in MALDI-MS signal intensity is observed depending on the nature of the substrate. Specifically, the $-NH_2$ modified PVDF surface reproducibly gives significantly lower MALDI-MS signal intensities than either the control PVDF surface or the $-CF_3$ modified PVDF surface. Figure 1 illustrates the differences in the signal intensity of 2 μ l of a 1 μ g/ μ l solution of bovine insulin on each of the three surfaces. The implications of these results are that the stronger binding of the protein to the $-NH_2$ modified substrate surface reduces the intensity of the MALDI-MS signal.

The time dependent adsorption of bovine insulin to RF plasma modified and unmodified PVDF surfaces was probed in exposure studies. In these experiments, 5 mm disks of the polymer were incubated in an aqueous buffered solution containing 1.5 mg/ml bovine insulin. Following incubation, the polymer was rinsed to remove unbound protein. 2 μ l of 15 μ g/ μ l solution of α CN was applied to the surface and MALDI mass spectra were recorded in a linear TOFMS. These studies show that adsorption of bovine insulin to even the unmodified control PVDF is extremely rapid. In as little as 1 minute, detectable MALDI-MS signals were observed on unmodified PVDF. MALDI-MS signals were observed for the $-NH_2$ and $-CF_3$ modified PVDF at 1 and 2 min., respectively. Figure 2 illustrates the time dependent adsorption of insulin to the polymer surfaces. No further increase in protein signal was observed after 15 minutes, suggesting saturation of the polymer surface.

Since initial studies demonstrate that MALDI-MS signal intensities vary with substrate functionality, quantitation curves were constructed for the control PVDF, the $-NH_2$ modified PVDF, and the $-CF_3$ modified PVDF. Preliminary results suggest that this approach can be used to quantitate the insulin adsorbed to the polymer surface.

Future directions involve expanding these studies to include additional polymers and surface modifications. The effects of changing the on/off duty cycle involved in the deposition of the functional groups will also be probed. Additionally, the time dependent competitive adsorption of peptides and proteins to modified and unmodified polymer surfaces will be investigated.

Figure 1 The top spectra is of bovine insulin applied to an unmodified PVDF polymer surface. The middle spectra is insulin on the $-NH_2$ modified PVDF, and the lower spectra is insulin applied to the $-CF_3$ modified PVDF.

Figure 2 The rapid adsorption of bovine insulin to the unmodified PVDF, allyl amine modified PVDF, and CF_3 modified PVDF can be observed.

MALDI-MS of biotinylated peptides and proteins affinity-bound to magnetic beads carrying immobilized streptavidin.

Martin R. Larsen, Eckhard Nordhoff, Marie Godtfredsen, Kenn Gerdes, Inge Madsen, Karsten Kristiansen and Peter Roepstorff.

Department of Molecular Biology, University of Odense, DK-5230 Odense M, Denmark

Introduction

The strong interaction between streptavidin and biotin has been used in molecular biology in the last decade to improve methods like affinity chromatography, immunoassay, affinity targeting and epitope mapping (1). In the present study we demonstrate the use of the streptavidin-biotin interaction (use of streptavidin-Dynal beads (sD-beads), i.e. streptavidin immobilized on magnetic beads) in combination with MALDI-MS as a fast and sensitive tool to analyze biotinylated compounds and DNA-protein interactions. The results can be summarized as follows: Isolation and identification of (A) specific biotinylated peptides in complex peptide mixtures, (B) biotinylated peptides obtained from *in situ* gel digestion of biotinylated proteins, the latter being separated by SDS-PAGE and (C) DNA-binding proteins by use of biotinylated ds DNA probes.

Experimental and Results

Mass spectrometric analysis was performed on a Voyager Elite equipped with delayed extraction (PerSeptive Biosystems, USA) or on a Bruker Reflex (Bruker-Franzen, Germany).

A: Isolation and identification of a biotinylated peptide from a complex peptide mixture

A mixture of tryptic lactoglobulin peptides and one biotinylated peptide (ratio 50:1) was prepared. Fig. 1A shows the MALDI mass spectrum of the mixture with α -cyano-4-hydroxy cinnamic acid (4HCCA) in 70% MeCN (20g/l) as the matrix. In a second step this mixture was incubated for 1h with sD-beads, washed several times with PBS buffer, resuspended in 30%MeCN/2%TFA, and analyzed by MALDI-MS as above. Fig. 1B demonstrates that the biotinylated peptide was isolated from the mixture by this procedure.

B: Isolation and identification of biotinylated peptides from a mixture of in gel generated peptides.

Randomly biotinylated alkaline phosphatase (2 μ g) was isolated from SDS-PAGE and digested *in situ* (2) with endoproteinase Asp-N. The extracted peptides were analyzed in PBS buffer by MALDI-MS using 4HCCA as the matrix (Fig. 2A). The biotinylated peptides were then isolated with sD-beads as described above and analyzed by MALDI-MS (Fig. 2B). All the peaks in this spectrum could be assigned to peptides carrying either one or two biotin groups.

C: Isolation and identification of DNA-binding proteins using biotinylated ds DNA probes

Different DNA-binding proteins were isolated from complex mixtures using biotinylated ds DNA probes linked to sD-beads by the streptavidin-biotin interaction. In one example a 40-mer biotinylated ds DNA probe carrying the binding site for the C/EBP protein, was used to isolate the recombinant bZIP-region of C/EBP β (used here as a defined model compound) from rat liver extract. After incubation, the beads bound DNA-protein-complex was washed and analysed by MALDI-MS using sinapic acid as the matrix. Fig. 3 shows the mass spectrum obtained from 20% of the final product. In this case 50 pmol protein in 12.5 μ l nuclear extract was used as starting material.

Conclusion

In this study we have demonstrated the isolation and identification of biotinylated peptides by the combination of streptavidin-Dynal beads and MALDI-MS. The procedure is simple, fast and sensitive. It opens for new concepts in protein interaction studies and epitope mapping. By binding a biotinylated ds DNA probe - carrying a binding site for a specific DNA-binding protein - to the streptavidin-Dynal beads we have furthermore demonstrated the isolation and identification of the protein using the same combination as above.

INTRODUCTION

Sample preparation is the crucial procedure in analysis of proteins and peptides by MALDI MS. It includes two steps. The first is the preparation of a peptide or protein sample, either a single compound or a mixture, pure in terms of separation from contaminants of any kind, e.g. salts, detergents, stain or other additives. The second step is the preparation of the sample on the target, i.e. choice of matrix, matrix and analyte concentration, pH, crystallization conditions and use of additives. We have tried to minimize or entirely eliminate the first step by selecting procedures in step 2 which tolerate the presence of salts, contaminants and additives in the peptide/protein preparation.

METHODS

MALDI spectra were recorded on a prototype linear time-of-flight mass spectrometer (Biolon, Uppsala, Sweden), a Bruker reflex mass spectrometer, or a Perceptive Voyager Elite mass spectrometer equipped with delayed extraction.

The following matrices are commonly used in our laboratory:

α -Cyano-4-hydroxy cinnamic acid, 4-HCCA (Sigma) dissolved in a variety of solvents.

Smagic acid, SA (Fluka), 10 g/l in 50% acetonitrile.

Dihydroxy benzoic acid, DHB (Aldrich or Helwett Packard) or super DHB, DHBs, containing 10% 2-Hydroxy-5-methoxybenzoic acid (Aldrich) dissolved in 30% methanol 0.1% TFA (25 g/l).

2,4,6-Trihydroxyacetophenone, THAP (Aldrich), saturated solution in acetone.

Three different methods for sample preparation were used.

1. **The dried droplet method** in which equal volumes of sample and matrix solution, or in the case of acidifying the sample, matrix and acid solutions are mixed on the target and allowed to dry in air or with a gentle stream of argon. This method can be used for all matrices described.

2. **The thin layer method** (1) in which a matrix layer is preformed on the target by fast evaporation of the solvent. The matrix is dissolved in acetone, 1% water (4-HCCA) or methanol (THAP). This technique is only applicable with these matrices. The analyte is then placed on top of the matrix layer. After evaporation of the solvent the target is washed 1 to 3 times with 5-10 μ l 0.1% TFA.

3. **The sandwich method** (illustrated in Fig 1) in which a thin layer of matrix is prepared as in method 2. Subsequently, droplets of a) 1-5 μ l of 2 to 5 % trifluoroacetic acid (TFA), b) 0.2 to 1 μ l of sample solution and c) 0.5 μ l matrix solution (15 g/l in 70% acetonitrile) are added. After 1 to 2 min, in which period crystallization commences, additional 10 to 50 μ l of 0.1% TFA are added. After partial evaporation of the solvent, the remaining droplet is removed. This preparation method is applicable with 4-HCCA, THAP and less frequently with SA.

4. **Nitrocellulose as additive:** Three 10 μ l aliquots of a 1:1 solution (40 g/l) of nitrocellulose and 4-HCCA in acetone are placed on the target and spin-dried. Then the analyte is added and allowed to air dry, followed by addition of 0.6 μ l 4-HCCA (20 g/l) in 70% acetonitrile. If the target cannot be spun, the preparation can be performed on a piece of scotch tape which is then glued on the target.

RESULTS

Choice of matrix: The choice of matrix must be matched with the type of analyte. Briefly the preferred matrices are 4-HCCA for peptide mapping and DHB/DHBs for proteins and glycoproteins. The matrix choice may also influence the sequence coverage in peptide mapping.

Importance of pH: Acidification to a pH below 2.0 is essential for samples containing considerable amounts of salts, buffers and detergents (2).

The sandwich method: Frequently the sandwich technique gives better results than the dried droplet method. For instance, in the case of a 40 kDa glycoprotein (the urokinase plasminogen activator receptor) a two times improvement in sensitivity was achieved. The protein was dissolved in 50mM Tris/HCl, 100mM NaCl, 0.0005% detergent (P20). Without acidification no spectra could be obtained from this sample. Moreover, the sandwich method results in less oxidation of Met and Trp than the thin layer preparation.

On-target protein chemistry: After a first sample analysis, reduction of disulfide bonds can be performed by placing a drop of DTT solution (150 mM DTT in 100 mM ammonium bicarbonate pH 7.8) on top of the matrix/sample layer. After 10 min. the sample was dried and an additional matrix layer applied according to the sandwich technique. On target digestion of proteins after a first sample preparation with SA and the dried droplet method is performed by adding the enzyme (e.g. trypsin) in an appropriate buffer. After 30 min. reaction in a moist environment, the droplet is removed with a pipette and used in a subsequent sandwich sample preparation.

DHB for glycoproteins: DHB or DHBs are our preferred matrices for glycopeptides/proteins. Microscopic observation of the matrix/sample crystals revealed, that the large rim crystals preferentially yield MH⁺ ions, whereas the small central crystals showed alkali adduct ions. Sometimes 4-HCCA and the sandwich preparation technique yielded better results with glycopeptides and were therefore used as a second choice.

Use of additives: Inclusion of nitrocellulose in the matrix results in dramatically improved spectra for samples contaminated with salts and polymer material of unknown origin. Nitrocellulose removes alkali metal adducts and additives, e.g. polyethylene glycol. No subsequent washing steps are needed. Addition of nitrocellulose is particularly advantageous for analysis of peptides and proteins from electrophoretic gels. Improved coverage in peptide mapping can also be obtained by inclusion of 5mM octylglycoside in the matrix.

Micropurification: When contaminants prevent recording of spectra even using all the tricks mentioned above, a micropurification is performed. This can be achieved with a micro LC system containing a 1 to 2 μ l volume plastic capillary filled with RP-column material.

CONCLUSIONS

No single sample preparation method yields optimal results in all cases. According to our experience, a number of alternatives must be available. These include a variety of matrix compounds as well as sample preparation techniques. However, based on previous knowledge of the sample it is possible to select a good first try, but often different attempts are needed to optimize the results.

Adjustment of the pH of the sample/matrix mixture to below 2-3, depending on the matrix, is essential and allows direct analysis of buffer containing samples. On target reactions and digestions are possible, especially when followed by a sandwich preparation. This technique also reduces oxidation of Met and Trp. The use of a nitrocellulose/matrix layer often eliminates problems caused by contaminants such as salts and a variety of polymers, e.g. PEG. Micro purification is sometimes needed and can easily be performed with a simple microchromatographic device.

Several of our observations agree with or complement those described in a recent report by Cohen and Chait (3).

MALDI-TOF has become a common technique in the mass spectral analysis of biological compounds. Because of its relative ease of operation, theoretically unlimited mass range, and ability to analyze femtomolar quantities of peptides and picomolar quantities of oligonucleotides, the technique is fast becoming the method of choice in the detection and analysis of peptides, proteins, and oligonucleotides. Sample preparation is the most important factor to the analysis of peptides and oligonucleotides by MALDI-TOF. Salts, glycerol, and other impurities detract significantly from desorption/ionization efficiency, and hence from the mass range and resolution of mass spectra.

We describe a novel means of purifying peptide, protein, and oligonucleotide samples for MALDI-TOF analysis. By spotting samples directly onto activated synthetic membranes, impurities are easily washed from the membrane, leaving biological samples intact. Upon the addition of the appropriate matrix, the mass resolution in spectra of both washed peptide and oligonucleotide samples was enhanced significantly. Using this purification technique, glycerol, salts, and other impurities samples were removed efficiently from peptides, proteins, and oligonucleotides, leaving the biopolymers intact.

Figure 1 is of parathyroid hormone [PTH], hen egg lysozyme [HEG], and bovine serum albumin [BSA] desorbed directly from the synthetic membrane. High molecular weight samples are desorbed with high efficiency and without appreciable peak suppression. Further, neither mass accuracy nor mass resolution are reduced as a result of desorption from a membrane instead of a probe tip. Figure 2 shows products of a carboxypeptidase digest containing glycerol and salts. Contaminants were removed without laborious methods such as dialysis and chromatography, and biological compounds were desorbed efficiently. Figure 3 shows a phosphodiesterase I digest of a glycerol and salt contaminated single stranded oligonucleotide. Again, glycerol and salts did not have a detrimental effect on resolution or mass range of the mass spectrum.

The use of synthetic membranes for peptide and oligonucleotide purification does not involve sample losses characteristic of more conventional purification techniques such as column chromatography and equilibrium dialysis. It is less time consuming than more conventional techniques since samples can be spotted and washed on a membrane mounted directly on the probe tip. By using activated synthetic membranes for purification, MALDI of both impure biological samples and enzymatic reactions is much more routine, consistent, and useful in a wide variety of applications.

Glycoproteins are large, complex molecules with cellular, regulatory, developmental, immunological, and other biological functions. The complexity of glycoprotein structures presents a dual analytical challenge: both the molecule's protein and carbohydrate components must be characterized. Typically, each carbohydrate attachment site has variability in the sequence and branching pattern of carbohydrate side-chains leading to "glycoform microheterogeneity" which is intrinsic to how these biomolecules function. The proper characterization of a glycoprotein requires analytical methods that can differentiate, identify, and quantify the relative amounts of each set of glycoforms. The methods must be sensitive and selective as the structural variations among glycoforms at each site are subtle and each variation is only a small fraction of the total glycoform population.

In the work reported here, the use of two relatively new analytical techniques, capillary electrophoresis (CE) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI TOF-MS) are investigated for their utility in glycoprotein characterization. CE, where separation is based on electrophoretic mobility, is orthogonal to HPLC, where separation is based on hydrophobicity, and often provides an additional level of information regarding a complex glycoprotein. CE separations can be performed which fractionate some of the various glycoforms of a glycoprotein sample. MALDI-TOF-MS is well suited to the analysis of large biomolecules and provides sensitive (fmol range) detection of collected CE fractions while being quite tolerant towards most CE buffers and salts. In addition, MALDI TOF-MS is used to observe the molecular ion pattern of the native, unfractionated glycoprotein.

Results from the analysis of a single-chain plasminogen activator (DSPA α 1) which contains two N-linked and four O-linked carbohydrate sites are presented on the next page. The CE electropherograms were optimal with a BSA coated 50 μ m i.d. capillary, l_{eff} 41 cm, 500V/cm, and 100 mM phosphate buffer (pH 3.0). Figure 1 shows the electropherograms generated at two different initial sample concentrations (upper trace, 1 mg/mL, lower trace 10 mg/mL). These complex electropherograms are consistent with the large population of glycoforms expected. Fraction collection was performed by controlled application of pressure (50 mbar) for zone elution. Figure 2 and 3 illustrate the results from fractions 1 and 2, with detected masses of 54,200 and 53,822 Da, respectively (sinapinic acid matrix). By contrast, the initial starting material gave a MALDI mass spectrum indicating a mass of 53,432 Da. The first two fractions collected have a higher molecular mass than the average mass of the unfractionated starting material due to these fraction's lower mobility.

The mechanism of separation of glycoforms is not totally characterized at this time. It appears to be not just electrophoretically mediated, but moreover a result of additional protein/surface interactions resulting in subtle but significant chromatographic selectivity. In the examples above, one fraction is not attributed to a single glycoform, but rather a mixture of glycoforms. However, the ability to perform off-line MALDI-TOF MS of all the fractions of the complex profile will be a powerful tool to demonstrate product consistency and equivalence with a reference material.

Examination of Approaches for Application of MALDI as an On-Line Biological Detection Technique

Jhobe A. Steadman,¹ Dennis C. Roser,¹ and S. Randolph Long²

¹GeoCenters, Inc, Aberdeen Proving Gd, MD, 21010-0068

²Edgewood RDE Center, Aberdeen Proving Ground, MD 21010-5423

The application of a next-generation mass spectrometric technique such as ESI or MALDI in a fieldable role for the detection and identification of materials of biological nature will require implementation in a fully on-line system. Unlike ESI, which utilizes a fluid interface for sample introduction and ionization, MALDI and related techniques are not routinely implementable in an on-line fashion. We have recently undertaken an examination of approaches which may facilitate on-line application of MALDI with fluid sample sources.

In this report, two approaches for the incorporation of fluid sample sources with MALDI are addressed: continuous flow MALDI and electrospray deposition sample preparation for conventional MALDI. CF-MALDI involves the laser irradiation of the analyte-containing solution at the end of a capillary in the mass spectrometer ion source region. Small molecule examples are provided. Preparation of samples by electrospray deposition is shown to provide enhanced homogeneity compared to routine dried drop sample preparation approaches while facilitating interface with a fluid sample source.

In the continuous flow MALDI approach we have explored for this report, a liquid solution of the analyte and matrix in a suitable solvent system is passed through a capillary tube into the mass spectrometer and laser-irradiated at the end of the capillary. The microcapillary tube inserts into the mass spectrometer via a specially fabricated stainless steel/macor probe and terminates at the center of the ionization region of the time-of-flight mass spectrometer. For the studies to date, the solution containing solvent, matrix, trifluoroacetic acid, and analyte is injected into the microcapillary tube using a syringe pump at the flow rate of approximately 0.5 microliter/min. A pulsed laser (266 or 355 nm) is focused at the apex of the droplet which forms at the outlet of the microcapillary tube. Ions ejected from the solution surface are pulse extracted into the mass spectrometer flight tube and detected using a microchannel plate detector. Flow rates are adjusted to balance effusion from the capillary tube and evaporation into the vacuum. To demonstrate the capability to detect and observe ions ejected from solution, we have conducted experiments examining ionization of anisole in liquid methanol from the tip of the microcapillary tube. The spectrum of an anisole/methanol solution irradiated with 266 nm laser pulses is dominated by the anisole molecular ion (Figure 1). We have also demonstrated the CF MALDI ionization of the amino acid tryptophan in an aqueous solution containing methanol, glycerol, TFA, and 3-NBA as matrix (Figure 2). Studies continue to optimize and extend to higher mass analytes.

Figure 1

Figure 2

To explore the potential of alternative means of sample preparation for conventional MALDI, we have assembled an electrospray system that allows us to produce a uniform film of sample/matrix on a MALDI probe tip from a liquid flow interface. The system consists of a high voltage power supply, syringe pump, and μ L volume syringes with interchangeable needles. Spectra have been recorded for electrospray-deposited samples of model polypeptides. These spectra demonstrate that the electrospray (ES) deposition approach permits recording of mass spectra on each single laser shot regardless of laser position on sample. Figure 3 displays spectra recorded at three of thirty positions across a 1 cm² sample spot, all thirty of which spectra are dominated by the pseudomolecular ion (An FTMS system was used for these studies. The peak at M/Z ca 530 is due to monitor noise). The sample homogeneity achieved by this approach is much greater than with the standard "dried droplet" approach. SEM photographs of samples prepared by this method and the standard dried droplet method demonstrate that the ES deposition approach produces a smooth film of microcrystals ca 100X smaller than those generated by the dried droplet approach.

TLC/MALDI: principles and applications

Arkady I. Gusev, John T. Mehl, William R. Wilkinson, Anthony J. Nicola, Olivier J. Vasseur, David M. Hercules, Department of Chemistry, Vanderbilt University, Nashville, TN 37235.

Thin layer chromatography (TLC) and other planar separation methods can be combined with mass spectrometry (MS) using *direct* and *indirect* coupling [1]. Indirect coupling usually involves analyte elution followed by MS analysis of the eluted fractions. Direct coupling with MS involves introduction of the TLC plate into the mass spectrometer for measurement of the separated analytes *in situ*. A major advantage of direct coupling is its suitability for one and two dimensional scanning (imaging) [1].

Recently we reported a direct coupling of TLC with matrix assisted laser desorption/ionization (MALDI) MS [2, 3]. Minor fragmentation, high sensitivity, broad utility, and suitability for imaging with minimal analyte spreading are the attractive features of the TLC/MALDI combination.

The direct TLC/MALDI coupling protocol has been described in detail elsewhere [3]. Briefly, this involves matrix deposition/crystallization on a separate substrate from the TLC plate, and subsequent matrix layer transport to the TLC surface. The major advantage of the proposed method is that analyte spreading is reduced. Direct imaging of silica gel TLC plates with high spatial resolution (250-500 μm) and high sensitivity (nanogram range) was demonstrated for various compounds including several synthetic dyes and small peptides.

Figure 1 shows an image and a contour plot of bradykinin obtained from silica gel TLC plates. Similar results have been obtained from reverse phase and cellulose plates.

Various MALDI matrices were evaluated for use with silica gel, cellulose, and reverse phase TLC plates, focusing on surface coverage, signal intensity and repeatability. Matrix selection was based on suitability for fast evaporation methods of crystallization [4]. The best detection limits were obtained for α -cyano-4-hydroxycinnamic acid (α -CHCA) matrix. These matrices also showed high sodium and potassium salt tolerance. Figure 2 shows mass spectra of cocaine separated on silica gel TLC plates. The detection limit for cocaine was found to be ca. 50 pg. Detection limits for the some other compounds tested on silica gel plates were: angiotensin and its derivatives - 200 pg; rhodamine B - 40pg; guinea green B - 60pg; bradykinin and its derivatives - 150pg; enkephalin derivatives - 250 pg; cyclosporin (A,D,G) - 200-300pg; cocaine metabolites - 200pg. Similar detections limits were obtained with reverse phase and cellulose plates.

Another issue studied was separation and analysis of oligonucleotides directly on TLC plates. Spectra obtained directly on silica gel plate exhibits more alkaline ion adducts compared to standard MALDI analysis. Thorough plate pretreatment and matrix selection can compensate for this problem. These results show that TLC/MALDI is a sensitive, non destructive method of analysis, suitable for direct TLC plate imaging and broad range of applications.

Figure 1. Image and contour plot of bradykinin (100 ng) on silica gel TLC plate. The image was collected using a 0.5 mm step.

Figure 2. Mass spectra of cocaine (100 ng) obtained on reverse phase (A) and silica gel (B) TLC plates.

route de Saint-Cyr, F-78026 Versailles Cedex

Pheromone binding proteins "PBP's" are involved in odor reception in insects by specific binding of pheromonal compounds. This specificity is encoded by the primary structure of isoforms of ~ 16000 Da proteins [1]. We purified and characterized three isoforms of PBP's from antennal extracts of the moth *Mamestra brassicae* by HPLC and native-PAGE electrophoresis [2]. Only MALDI-TOFMS of proteins electroblotted onto PVDF membranes after native-PAGE gave unambiguous information on the different molecular weights of apparent similar proteins [3]. This study has been extended to search for isoforms of PBP's in other moth species: *Spodoptera descoinsis* and *S. latifascia*.

Candidates proteins were localized in antennal extracts by western-blot with monoclonal antibodies against *M. brassicae* PBP's. MALDI-TOFMS analysis on a home-built linear TOF system allowed the localization of proteins of ~ 16000 Da in fractions obtained by HPLC separation from antennal proteins (see figure 1). However, the insufficient separation of the HPLC procedure did not allow to state definitely on the mass of the proteins responsible for the antibodies labelling. Thus, further checking of the antennal extracts by native-PAGE with MALDI-TOFMS analysis of fractionated proteins electroblotted onto PVDF membranes has been carried out. The methodology used has been described previously [3]. Briefly, small strips of membranes were cut according to the band of interest; after applying the calibrant and the matrix, the membranes were mounted on the probe tip using silver Electrodag (Acheson). Such analysis have shown the presence of proteins of ~ 16000 Da into the bands labelled by the monoclonal antibodies for both female and male species although the detection sensitivity was poor (see figure 2). N-terminal microsequences allowed to unambiguous identification of PBP's in such bands since N-terminal is highly conserved within this family of proteins. Thus, the presence of PBP's of ~ 16000 Da in the antennae of these moth species has been established.

This work points out that a multi-technical approach is necessary for studying proteins isoforms. The high sensitivity of MALDI-TOFMS allows detection of proteins present at the picomole level in moth antennae. Further MALDI-TOF developments should give more accurate molecular weights of these proteins

Semi-Automated Sample Analysis Using Liquid Chromatography/Matrix-Assisted Laser Desorption Ionization Mass Spectrometry.

Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company,
Ann Arbor, MI 48105

INTRODUCTION

Liquid chromatography is recognized as a powerful and reliable separation tool; however, for unknown compounds little information is obtained from HPLC alone. For example, the retention time of a peak observed in a reversed-phase chromatogram gives the analyst information regarding purity and hydrophobicity, but no information about molecular weight or structure is provided. Mass spectrometry, on the other hand, gives the analyst information about structure and molecular weight. Large peptides and proteins are most amenable to the mass spectrometry ionization techniques of electrospray ionization (ES) and matrix-assisted laser desorption ionization (MALDI). Interfacing the high separation efficiency of HPLC with the high sensitivity, mass accuracy and ease of interpretation of MALDI-MS combines the most attractive features of both techniques for analysis of large peptide or protein mixtures. Furthermore, additional structural information can be provided from the same sample spot by post-digestion and subsequent mass analysis.

Development of a methodology to interface microbore HPLC (off-line) to MALDI for semi-automated analysis of peptide and protein mixtures and applications will be presented. The interface consists of an HP 7550A pen plotter programmed to apply the HPLC peaks directly to a MALDI sample target substrate membrane. The membrane substrate can vary, but polyethylene is the membrane typically used for our experiments. The volume of sample deposited depends on the HPLC run time and sampling rate and varies from 0.5-2.0 μ L per sample spot. The size of the sample target, spot size and flow rate currently limits HPLC run times. An appropriate matrix (i.e., α -cyano-4-hydroxycinnamic acid for small peptides and digests or sinapinic acid for large peptides and proteins) can be applied manually or by using the plotter automation. The HPLC effluent is then analyzed using an automated MALDI-MS routine. Data obtained for a mixture of angiotensin peptides shows chromatographic resolution is retained by this interface and chromatographic peaks separated by less than 0.3 minutes can be resolved and molecular weights determined with only 2 pmol sample loadings. Peptide sequence information can be provided by either PSD fragmentation spectra or further proteolytic digestion of each spot. Sample spots can be subjected to "in-situ" enzymatic digestion and the digest products analyzed to obtain further structural information. Trypsin digestion of a sample spot containing myoglobin was performed "in-situ" and tryptic fragments determined using MALDI-MS.

RESULTS AND DISCUSSION

Since the introduction of matrix-assisted laser desorption/ionization mass spectrometry³, MALDI has been used to analyze peptides and large proteins (>300,000 Da) with picomole sensitivity or better. This sensitivity has been of great benefit for low level analysis of digest products resulting from various enzymatic or chemical cleavages. Typically, the sample of interest is digested, followed by reversed-phase HPLC separation and subsequent fraction collection. The HPLC fractions are then mass analyzed using standard MALDI techniques. For unknown compounds, the masses of the digest products can then be used to search available protein databases for identification.

To reduce sample loss due to handling or transfer, we have designed a semi-automated "off-line" HPLC/MALDI-MS interface comprised of a microbore HPLC, an HP 7550A plotter and a Vestec MALDI mass spectrometer. This semi-automated system applies the effluent from the microbore HPLC via a plotter pen modified to hold a PEEK μ -capillary (51 μ m I.D.) exiting the UV flow cell onto a membrane attached to plotter paper. The plotter applies the HPLC effluent in a precise 100 spot pattern matching the instrument's standard sample plate. Afterwards, matrix is applied to the membrane in the same 100 spot pattern via syringe pump and plotter. The HPLC peaks are correlated to their sample spot locations on the membrane through the use of an Excel spreadsheet which calculates location based on retention time.

An HPLC chromatogram was obtained from an injection (5 μ L) of a mixture containing five angiotensin peptide analogs (0.1 μ g each peptide). This mixture was used to determine how much resolution loss (band broadening) occurred for this system. The peak widths at baseline were determined to be 0.3-0.4 minutes (18-24 seconds) for each peak. The effluent from this chromatographic run, following a 1:1 split (post-detector), was spotted onto a PE membrane by the HP plotter over a five minute period of time corresponding to one spot every 3 seconds. After automated acquisition of mass spectra, each spectrum was inspected for the peptide components. It was determined that no loss of chromatographic resolution had occurred; each component was observed on only three or four consecutive spots corresponding to the original 18-24 second peak widths. Also, no sample carry-over was observed. The MALDI spectra for each peptide component (~2 - 5 pmols) from the mixture have the sensitivity and resolution expected for MALDI in this mass range. An injection of a mixture containing bradykinin, angiotensin I, bovine insulin, bovine cytochrome c, and bovine serum albumin was made. The corresponding MALDI spectra obtained from the semi-automated HPLC/MALDI-MS acquisition of this mixture shows the flexibility and efficiency of this system for analyzing a wide range of molecular weight peptides and proteins from an HPLC analysis.

This approach also gives us the capability to perform further structural studies on any of the components found in the HPLC/MALDI-MS analysis. The sample spot obtained from the HPLC/MALDI-MS analysis of a protein mixture containing bovine insulin was subjected to disulfide reduction by applying tris(2-carboxyethyl)phosphine (TCEP) directly to the spot on the PE membrane corresponding to the bovine insulin peak (allowed to react for 30 minutes). Matrix was then reapplied to this spot and the sample re-analyzed. The a-chain and b-chain of bovine insulin were observed as well as some remaining non-reduced bovine insulin. A mass spectrum was obtained from an "on-membrane" tryptic digest of cytochrome c after HPLC/MALDI-MS analysis of a mixture containing bovine insulin, bovine cytochrome c, equine cytochrome c, and equine heart myoglobin. Although the digest was incomplete, some structural information was obtained. The matrix may hinder the digestion process. Sample co-crystallized with the matrix may not re-dissolve sufficiently prior to application of the enzyme. A post-source decay (PSD) fragmentation spectrum was obtained following HPLC/MALDI-MS analysis of an angiotensin peptide mixture. Once the angiotensin I sample was found by semi-automated HPLC/MALDI-MS, a post-source decay experiment was performed on the spot which obtained nearly complete sequence information for the sample.

CONCLUSION

We have found that HPLC can be effectively interfaced to MALDI-MS for semi-automated analysis of peptide and protein mixtures. HPLC/MALDI-MS can be used to separate low level (1-10 pmols) peptide and protein mixtures which can then be mass analyzed. This technique has proven to work well for samples ranging in molecular weights up to ~ 66,000 Da. We have observed little or no loss of the original chromatographic resolution. Also, we have demonstrated that additional structural information can be obtained by chemically or enzymatically digesting chromatographic peaks which were originally auto-spotted onto the membrane substrate. Furthermore, we have shown that further structural information from post-source decay (PSD) spectra can be obtained from these membrane-bound samples. We feel that this system saves time and helps minimize or eliminate the sample loss that can occur during normal fraction collection and sample preparation. The addition of a more intelligent peak recognition and spotting interface, should improve the efficiency of the HPLC/MALDI-MS system.

Hyphenation between HPLC and Liquid MALDI in an Ion trap/TOF

Mass Spectrometer

Ling He, Xin Chen, Xuhui Li, David M. Lubman.

Chemistry Dept. The University of Michigan, Ann Arbor, MI 48109-1055

MALDI as an ionization method has been extensively studied in the static mode with solid matrices. There has been limited research work to explore the MALDI in the liquid and continuous modes. The possibility to combine the advantages of MALDI with the on-line separation techniques is the major driving force for this project.

A novel ion trap/ReTOF mass spectrometer is used as the interface to perform on-line analysis of peptides with liquid MALDI in the continuous mode (Figure 1). Samples are injected using a 4-port Reodyne injection valve with 5 μ l internal loop. The carrier solvent (H₂O: 1-propanol(or dioxane) = 80:20 v/v, containing 0.1%TFA) flows through a reverse phase capillary C-18 (250 μ m i d) column. The capillary-HPLC separation is performed in the isocratic mode. The separated peptides from the capillary column are mixed with the matrix solution (3-NBA:H₂O: isopropanol:Ethylene glycol = 2.5:25:20:2.5 v/v, containing 0.1% TFA) through a mixing tee and the flow rate after mixing is approximately 2 μ l/min. The matrix solution was split before it enters a pressure restriction column (packed capillary column) and the high splitting ratio (larger than 120:1) is critical for maintaining the liquid surface while reducing the pressure inside the ion trap. The flow rate of matrix solution after separation is about 0.3-0.5 μ l/min. A flow probe transmits the sample/matrix mixture into a hole on the ring electrode of the ion trap. The laser (266 nm) enters from the counter position and ionizes the sample eluted from the flow probe tip. After ions from 25-50 laser shots are stored and accumulated in the ion trap, a DC pulse is applied to the end cap to extract all the ions out of the ion trap and accelerated into the ReTOF mass analyzer to measure the m/z . It is demonstrated that this configuration can be used for the analysis of neurotensin (Mw 1672.9) and gramicidin (Mw 1140) and bradykine. The pressure inside the ion trap is found to be the most important factor that influences both the resolution and the sensitivity. Several typical organic solvents have been tried for the reverse phase capillary HPLC - MALDI and it has been observed that those solvents whose b.p. are near 100°C (such as 1-propanol, 1,4-dioxane) have improved performance when maintaining a liquid surface on the probe tip. The laser power has an optimal range of for generating ions of peptides with low background.

In conclusion, an on-line Liquid MALDI analysis system has been setup by coupling reverse phase capillary HPLC column with an Ion Trap/ReTOF mass analyzer. The mass spectra collected of several consecutive injections of neurotensin are presented in Figure 2. On-line separations of several peptides has been performed on this system and efforts are undertaken to reduce the memory effect and improve sensitivity.

MASS SPECTROMETRIC CHARACTERIZATION OF GLYCOPROTEINS SEPARATED BY GEL ELECTROPHORESIS.

Thomas N. Krogh, Ejvind Mørtz, Peter Højrup and Peter Roepstorff.

Dept. of Molecular Biology, Odense University, Campusvej 55, DK-5230 Odense M, Denmark.

INTRODUCTION

Mass spectrometry has today become an important tool for identification of proteins separated by gel electrophoresis. In this study, we investigate the possibilities for further characterization of glycosylated proteins after separation by 1-D gel electrophoresis. The glycoproteins are enzymatically cleaved in the gel^{1,2}, the peptides extracted and the unfractionated peptide mixture analyzed directly by MALDI MS. The glycosylated peptides are characterized using MALDI MS in combination with specific glycosidase digestions.

The aims of the study can be summarized as follows:

- Detection of the glycosylated peptides in the peptide mixture extracted from the gel.
- Identification of the glycosylated peptides and the glycosylation sites.
- Differentiation between N and O-linked glycans.
- Elucidation and verification of the glycan structures.

PROCEDURES

Reduced and alkylated proteins (fetuin^{3,4} and bovine α_1 acid protein, 5-10 μ g) were purified by 1-D SDS gel-electrophoresis, the gel pieces cut out and the proteins digested with trypsin. The extracted peptides were digested with glycosidases². MALDI mass spectra were acquired on a Perseptive Biosystems Voyager Elite mass spectrometer, equipped with delayed extraction.

RESULTS

Identification and localization of N- and O-linked glycosylations on bovine fetuin.

Fetuin was purified by 1-D SDS PAGE followed by *in situ* digestion with trypsin and MALDI analysis of the extracted peptide mixture. The determined masses were correlated with the protein sequence, and found to cover 52% of the sequence.

Treatment of the fetuin peptide mixture with neuraminidase, and analysis by MALDI-MS (Fig. 1A) resulted in the appearance of new peaks, corresponding to glycosylated peptides.

To verify the identity of the N- and O-glycosylated peptides, the peptide mixture was treated with PNGase F (Fig. 1B) or O-glycosidase (Fig. 1C). Upon PNGase F digestion three peaks appeared, corresponding to non-glycosylated peptides. Due to the mass difference of 1987.3 Da could the glycans be identified as triantennary complex type structures.

O-glycosidase digestion of the peptide mixture (Fig. 1C) resulted in the appearance of one new peak (6068.9), showing only one peptide to be glycosylated with one to four O-glycans.

Combining the MALDI spectra, resulted in a sequence coverage of 95%.

Structure elucidation of the N-linked glycans on bovine α_1 acid protein.

Bovine α_1 acid protein was purified by 1-D SDS PAGE followed by *in situ* digestion with trypsin. Sequential treatment of the α_1 -acid protein peptide mixture with neuraminidase, β -galactosidase and N-acetylglucosaminidase, reduced the molecular mass of these peptides, corresponding to two neuraminic acids, two galactose and two N-acetylglucosamine residues respectively, indicating that sialobiantennary structures were present on the major glycopeptides of bovine α_1 -acid protein.

Fig. 1A-C MALDI spectra of glycosidase digestions of peptides from tryptic digestion of fetuin.

CONCLUSIONS.

The Results presented show that it is possible to obtain complete characterization of glycoproteins separated by gel-electrophoresis.

We have so far applied these methods successfully on five glycoproteins:

bovine and humane α_1 -acid protein, fetal antigen 1, fetuin and interferon- γ .

ACKNOWLEDGEMENTS

Perseptive Biosystems is greatly acknowledged for setting a Voyager Elite MALDI-tof mass spectrometer equipped with delayed extraction to our disposal.

We also appreciate the excellent technical assistance given by Eva Nielsen

This study was supported by the Danish Biotechnology Program.

A Novel Laser Microprobe QITMS for Imaging Drug Compounds in Intact Biological Tissue

*Christopher D. Reddick, Matthew M. Booth, and Richard A. Yost
University of Florida, Department of Chemistry, Gainesville, FL 32611

The goal of our research is to develop a laser microprobe quadrupole ion trap mass spectrometer (QITMS) for trace-level analysis of drug compounds and other metabolites in biological tissues. Currently, there are several laser microprobe time-of-flight (TOF) mass spectrometers commercially available. These instruments are limited to a single stage of mass analysis of limited resolving power and are largely restricted to elemental imaging. The laser microprobe ion trap instrument we are currently developing promises much higher resolving power and the ability to perform multiple stages of mass analysis or tandem mass spectrometry (MSⁿ) for structure elucidation. We believe the combination of laser desorption/ionization and tandem mass spectrometry is the most promising approach for achieving a highly sensitive and selective trace-level microprobe technique for imaging molecular and macromolecular species in intact biological tissues.

In our initial experiments, matrix-assisted laser desorption/ionization (MALDI) was investigated as a method to enhance the detection of the anti-cancer drug taxol (MW 853) from rat liver tissue. Samples were prepared by incubating thin sections of tissue (~1 mg) in 1.0 mL solutions containing 100 ng of taxol for approximately one hour. For these experiments, a MALDI-ion trap instrument built in our laboratory was used for mass analysis. With only one stage of MS, the taxol [M+K]⁺ signal was lost in the background signal from the liver tissue (Figure 1A). Using the MS/MS capabilities of the ion trap, the taxol [M+K]⁺ ion was fragmented after mass isolating that region of the spectrum, producing the daughter ion spectrum seen in Figure 1B. By comparing this spectrum with the spectrum of a taxol standard, the presence of taxol in the incubated liver tissue was confirmed.

While MALDI was able to enhance the sensitivity for detecting taxol in liver tissue, it proved less useful for applications involving imaging of drug compounds in tissue. This is because the MALDI matrix solution disturbed the spatial distribution of the analytes in the tissue. An attractive alternative to MALDI for imaging drug compounds in tissue is laser desorption/ionization (LD/CI). Previous work in our laboratory, using a triple quadrupole mass spectrometer, demonstrated the utility of LD/CI for detecting drug compounds in tissue [1]. In this work, the anti-epileptic drug phenytoin (MW 252) was detected in rat liver tissue obtained from a male Sprague-Dawley rat which had been injected with a loading (150 mg/kg) of phenytoin one hour before being sacrificed.

The laser microprobe instrument we are currently developing consists of a Finnigan MAT 4500 ion source modified for LD/CI, a DC quadrupole deflector, an ion trap mass analyzer, and an electron multiplier detector (Figure 2). For microscopy, an x,y,z-manipulator will be adapted to the outside of the ion source flange to allow for micrometer manipulation of the sample probe. In addition, a CCD camera and microscope objective will be added so that samples can be viewed under magnification. For analysis of drug compounds in tissue, laser light from a pulsed nitrogen laser (337 nm) is directed and focused through the DC quadrupole deflector onto the tip of a stainless steel sample probe inserted inside the ion source. Neutrals desorbed from the sample probe are chemically ionized by methane reagent ions formed in the ion source prior to the laser desorption event. The ions formed by LD/CI are then directed into the DC quadrupole deflector using a series of accelerating lenses, and turned 90° into the ion trap for mass analysis. The DC quadrupole deflector used for this work was constructed of four quarter round stainless steel rods [2]. For stability, the rods were bolted to two anodized aluminum mounting blocks. With this design we were able to mount the ion trap directly to the DC quadrupole deflector assembly (Figure 3). SIMION 3D v6.0 was used to study the function and utility of the DC quadrupole deflector and to optimize the voltages of the ion injection system [3]. Simulations of ion trajectories for taxol are shown in Figure 4.

The authors would like to thank Dr. Dean Fetterolf at the Forensic Science Research & Training Center (FBI Academy) and Finnigan MAT for donating much of the instrumentation used for the laser microprobe instrument. Also, we would like to recognize Bristol-Myers Squibb for their continued support and funding of this project.

Inclusion complexes *versus* electrostatic adducts in electrospray and capillary zone electrophoresis.

Carlo Kanz, Marc J.-F. Suter*, Hans-Peter E. Kohler and Walter Giger
Swiss Federal Institute for Environmental Science and Technology, EAWAG
CH-8600 Dübendorf, Switzerland

Introduction

Non-covalent interaction is of interest in protein chemistry, when e.g. looking at entire enzyme complexes. It has also been thoroughly investigated in regard to metal binding by various ligands. Chiral recognition by way of host-guest complexes, using cyclodextrines (CD) as chiral selectors, has a great potential. However, there is a risk of mistaking electrostatic adducts for true inclusion complexes (1).

Biodegradation of optically active compounds very often follows different pathways for each enantiomer (2). We are investigating the biodegradation of linear alkylbenzene sulphonates (LAS), which are widely used as anionic surfactants. In a first step, they are transformed to sulphonated phenylcarboxylates in waste water treatment plants.

Capillary zone electrophoresis (CZE) was used to separate enantiomers of p-sulphophenyl-3 butyric acid (SP3BA), using α -CD as chiral selector. Using the same conditions, we analyzed the SP3BA • α -CD complex with electrospray mass spectrometry (ESI-MS).

Methods

Mass spectra were acquired on a Fisons AutoSpec-Q, using a Fisons ESI-interface. Aqueous samples were directly infused at flow rates of 5 - 10 μ l/min. Acceleration voltage: 4 kV, needle voltage: 8 kV, scan range: 850-1450 at 1 s/decade.

CZE experiments were run on a Hewlett Packard HP3D capillary electrophoresis system with on-column UV-detection. The fused silica columns used were coated with PVA (length: 50 cm to detector, 50 μ m I.D., 375 μ m O.D., bubble factor 3). Samples were diluted in water and injected hydrodynamically. Buffer: 20 mM citrate, pH 4.0, 20 mM α -CD; voltage applied: 600 V/cm (18 μ A); temperature: 15 °C; concentration of SP3BA: 0.1 mM; UV-detection at 223 nm.

SP3BA was synthesized by reacting 40 ml conc. sulphuric acid with 10 g phenylcarboxylic acid at 60 °C for 24 h.

Results and Discussion

Capillary zone electrophoresis clearly shows that chiral interactions between α -CD and SP3BA take place. ESI experiments showed a signal at m/z 1215, corresponding to the SP3BA • α -CD complex. However, no significant difference in signal intensities for the enantiomers of SP3BA could be measured. It could be argued that the chemical structure of SP3BA prevented the compound from entering the hydrophobic cavity of α -CD. This points to an electrostatic adduct, generated under ESI conditions. 3-Phenylbutyric acid (3PBA) on the other hand only has one negatively charged site and thus should be able to form a true inclusion complex with α -CD (3). However, the enantiomers again showed no significant difference in signal intensities for the formation of 3PBA • α -CD. Varying the concentration of α -CD, or changing the interface voltage (sampling cone) to increase the collision energy did not affect these findings even though higher collision energies are expected to favor the more strongly bound inclusion complex over the electrostatic adduct.

Figure 1: Negative ESI spectrum of an aqueous solution of 1 mM R-p-sulphophenyl-3-butyric acid, 20 mM citrate at pH 4.0 and 20 mM α -CD.

Figure 2: Negative ESI spectrum of an aqueous solution of 1 mM S-3-phenylbutyric acid, 20 mM citrate at pH 6 and 20 mM α -CD.

Conclusion

The cluster formation of sulphonated *versus* unsulphonated phenylbutyric acid (SP3BA vs 3PBA) showed no difference in signal intensities. However, because 3PBA is able to enter the cavity of α -CD, it should produce higher response. Also, there should be a difference between the two enantiomers, provided that complex formation is reasonably slow and the difference of the respective binding constants higher than the uncertainty of the experimental setup. Moreover, this suggests that one can not distinguish between electrostatic adducts and inclusion complexes using ESI-MS.

An Investigation of Cyclodextrin-Drug Complexes: True Complexes or Electrostatic Adducts?

J. Visentini¹, M.J. Bertrand², H. Gagnon^{1,2}, C. Rousseau¹ and C. Winters¹

¹Merck Frosst Centre for Therapeutic Research, P.O. Box 1005, Pointe-Claire-Dorval, Quebec H9R 4P8 Canada

Optimization of drug bioavailability and stability is essential in the development of pharmaceutical products which provide efficacious and safe treatment of medical conditions. In cases where low bioavailability of a drug is a result of its limited aqueous solubility, a number of techniques are available to improve the drug solubility. One such technique is non-covalent complexation with cyclodextrins. Cyclodextrins (CD) are cyclic oligosaccharides in which the number of glucose units increases from 6 to 7 to 8 for α -, β -, and γ -cyclodextrin respectively. The cavity diameter increases from 5.1 Å (α -CD) to 6.3 Å (β -CD) to 8.0 Å (γ -CD) and it is believed that the cavity size is a key factor in determining the degree to which CDs can form inclusion complexes with different molecules. It has been previously shown that it is possible to detect ions of solution complexes by mass spectrometry^{1,2}. Phase solubility experiments were conducted to determine whether the relative ion intensities (complexed CD to free CD) observed by LC/MS were indicative of non-covalent complexation or electrostatic adducts generated in the IonSpray ionization process. Inclusion complexes were prepared by adding known amounts of CD to saturated solutions of drug. These samples were stirred at 30 °C for 48 hours and then filtered using 0.22 μ m filters. From these mixtures, phase solubility diagrams were constructed using uv-visible absorbance data according to the method described by Higuchi and Connors³. Aliquots of the complex solutions were taken and diluted with water to concentrations which fell on the appropriate drug calibration curve. Another aliquot of the filtrate solution was diluted, if necessary, using water to keep CD quantities constant for comparison purposes and analyzed by flow injection HPLC on a Hewlett Packard HP1090 coupled to a PE/Sciex API III+ mass spectrometer.

Comparison of results obtained from phase solubility and LC/MS experiments for individual α -, β -, and γ -CD complexes with ASA are shown in Table 1. The relative ion intensities obtained from mass spectra for individual CD complexes correlate well with those obtained from a competition experiment of α -, β -, and γ -CD with ASA¹. The stability constants (K values) would have been expected to follow the same trend as relative ion intensities if mass spectral results were true representations of the complexation behaviour. The relative ion intensity measured for the α -CD+ASA system, however, was found to be much higher than that expected based on the results from phase solubility experiments. A proposed explanation for the discrepancy between stability constants and relative ion intensities observed by LC/MS is illustrated in Figure 1. Comparison of the ASA dimensions with cavity size indicate that the drug molecule can be included only partially in the α -CD cavity. The ionizable group (carboxylic acid in this case) would be completely exposed for ionization during the IonSpray process thus generating a relatively intense signal. The larger dimension of the β -CD cavity can better include the phenyl ring and the side groups which rest outside the cavity can also hydrogen bond with the hydroxyl groups on the CD ring. The greater interaction within the cavity causes an increase in the stability constant value and the exposed carboxylic acid group is also readily ionized. Since the γ -CD diameter is about the same dimensions as the largest axis of the ASA molecule, the drug could fit almost completely into the cavity. In this conformation, the carboxylic group would be shielded from being ionized as efficiently as it could be in the α - and β -cyclodextrin complexes.

It is well known that ASA is easily hydrolyzed to form salicylic acid (SA) and acetic acid⁴. It has been shown that inclusion of drugs in CDs can sometimes serve to protect drugs from reacting under stress conditions. The model of ASA+ γ -CD illustrated in Figure 1 suggests that the ASA molecule may be protected by the γ -CD from hydrolysis in aqueous solution. To support this hypothesis, the effect of α -, β -, and γ -CD complexation on the degree of hydrolysis of ASA to SA was monitored by uv-vis spectrophotometry (Figure 2) and HPLC (not shown). Both methods showed that there is less SA produced for the complexation of ASA at concentrations greater than 20 mM γ -CD with the effect being more pronounced at the higher γ -CD concentrations. This trend suggests that the ASA molecules are being protected from hydrolysis by their interaction with γ -CD. Undiluted solutions of ASA in 10 mM and 50mM γ -CD were analyzed in order to determine whether the protection effect could be detected by LC/MS. The mass spectra showed that the ion intensities for SA+ γ -CD complexes were significantly higher in the 10 mM γ -CD solution than in the 50 mM γ -CD sample. Although the mass spectral data are not quantitative, they are nonetheless consistent with trends observed by the alternate techniques.

Characterisation of Water Soluble Rotaxanes by Electrospray Ionisation Mass Spectrometry.

Harry Anderson, Sally Anderson and Robin Aplin, The Dyson Perrins Laboratory, Oxford University, South Parks Road, Oxford, OX1 3QY, UK

A rotaxane is a dumbbell shaped molecule with a macrocycle clasped around its waist. There is no chemical bond between the two components. Our goal is to synthesise long conjugated polymer "wires" which are isolated from each other and the external environment by the formation of poly-rotaxanes. We have synthesised two rotaxanes using the hydrophobic effect to direct rotaxane formation, **Scheme 1**. These hexa- and octa-cationic rotaxanes and their building blocks, the dicationic stopper and cyclophane and the by-product the tetra cationic dumbbell were characterised by ESI mass spectral analysis of their PF_6^- salts from acetonitrile solutions. The ESI mass spectra of the two rotaxanes are very simple, the major ions corresponding to the hexa- and octa-cations respectively together with M^{4+} and M^{2+} ions due to the dumbbell and cyclophane. Two additional abundant ions correspond to the sequential loss of one and two protons to produce $[\text{M}-\text{H}^+]^{5+}$, $[\text{M}-2\text{H}^+]^{4+}$ and $[\text{M}-\text{H}^+]^{7+}$, $[\text{M}-2\text{H}^+]^{6+}$ species. ESI mass spectral analysis of the PF_6^- salts from water:acetonitrile, 97:3, produced very different spectra to those obtained from acetonitrile solutions. The spectra while showing the ions due to M^{6+} and M^{8+} for the rotaxanes and M^{2+} for the dumbbell showed an abundant second series of ions corresponding to "ion pairs":-
 [2]rotaxane:- $[\text{M}+\text{PF}_6^-]^{5+}$; $[\text{M}+2\text{PF}_6^-]^{4+}$ and $[\text{M}+3\text{PF}_6^-]^{3+}$
 [3]rotaxane:- $[\text{M}+\text{PF}_6^-]^{7+}$; $[\text{M}+\text{PF}_6^-]^{6+}$; $[\text{M}+3\text{PF}_6^-]^{5+}$; $[\text{M}+4\text{PF}_6^-]^{4+}$
 "Ion pair" were also observed for the cyclophane and dumbbell PF_6^- salts when these were analysed from water:acetonitrile, 97:3

solutions. The charge state and elemental compositions were confirmed by high resolution ESI MS analysis.

Modification of the synthesis, **Scheme 1**, by the addition of 1,4-diethynyl benzene resulted in the formation of extended rotaxanes. ESI mass spectral analysis of the rotaxane fraction from the reaction showed the incorporation of one 1,4-diethynyl benzene unit into the [2]rotaxane and the incorporation of two 1,4-diethynyl benzene units into the [3]rotaxane, "a step towards sheathed molecular wires".

Synthesis of Dumbbell, [2]Rotaxane and [3]Rotaxane

CHARACTERIZATION AND FORMATION STUDIES OF SYNTHETIC SUPRAMOLECULAR COMPLEXES BY ESMS

Emmanuelle LEIZE,^{1*} Annick DUPONT-GERVAIS,¹ Annie MARQUIS-RIGAUT,² Paul BAXTER,² Jean-Marie LEHN,² Alain VAN DORSELAER¹

1. Laboratoire de Spectrométrie de Masse Bio-Organique, URA 31 CNRS 2. Laboratoire de Chimie Supramoléculaire, URA 422 CNRS, Université Louis Pasteur, Strasbourg, France

Introduction

Supramolecular chemistry may be defined as chemistry beyond the molecule, bearing on the organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular forces. [1] The formation studies (thermodynamics and kinetics) of these architectures are important in order to understand the basic principles of their self-assembly and to design new systems of higher complexity. The analytical techniques such as UV-visible spectrophotometry and NMR, usually used for such studies lead often to data difficult to interpret. It is thus necessary to develop techniques allowing the characterization and the quantization of species obtained in solution during these formation studies. Today, ESMS is considered as the method of choice for the characterization of synthetic supramolecular complexes [2], due to its ability to control fragmentation and to analyze diluted solutions (10^{-4} M- 10^{-6} M). Recently, studies have demonstrated that under some conditions, the ES mass spectrum gives the image of the species present in solution, which allows the use of ESMS data for quantization. [3] Thus ESMS could appear as a powerful method to study the formation of supramolecular complexes in solution.

In this work, we first present the **thermodynamic study of the formation of the cylindrical complex 1** (Figure 1), composed of 11 entities (T, L and copper(I) ions) self-assembled through non-covalent bonding. ESMS and UV-visible spectrophotometric titrations have been simultaneously conducted. In a second part, we show the possibilities of ESMS for **kinetics investigations**. This study has been performed on the pentanuclear helicate **Ha** (Figure 2), which is formed within hours by self-assembly of two ligand strands **La** in helicoidal fashion around copper(I) ions. The ESMS data were obtained as a function of time.

Results

Thermodynamic study :

Titration ($2T + 3Cu$) by L The ES mass spectra (recorded in CH_3CN/CH_2Cl_2 (5/95) at $V_c = 20V$, with a concentration of the sample of 10^{-4} M) corresponding to the three stoichiometries in L : 0.5, 1 and 2 equivalents were interpreted assuming that ionization occurs by the loss of BF_4^- (data not shown). With 0.5 equivalents of L, the complex 1 is already the major species present in the solution, but coexists with the complexes 2 and 3, while it is the only species when one equivalent of L has been added to the solution. In presence of an excess of L, four new species coexist with 1.

Possible mechanism for the formation of 1 : From ESMS data, [4] the thermodynamic intermediates present in solution have been determined, allowing to propose a possible mechanism for the formation of 1 (Figure 3). Moreover, thanks the ESMS data, the association constants of the complex 1 and the other species could be calculated from the UV-spectrophotometric data (data not shown). It was found that this assembling process occurs with positive cooperativity.

Kinetic study

The ES mass spectra of a solution containing 2 eq. $Cu(CH_3CN)_4BF_4$ measured 1 minute, 60 minutes and 60 hours after mixing (recorded in CH_3CN/CH_2Cl_2 (50/50) at $V_c = 20V$, with a concentration of the sample of 10^{-3} M) were interpreted assuming that ionization occurs by the loss of BF_4^- (data not shown). Apart from the peaks corresponding to the final helicate **Ha**, already formed after 1 minute, the spectra showed the presence of several well defined peaks, which could be attributed to $LaCu_2$ and to $LaCu_3$. The two kinetic intermediates $LaCu_2$ and $LaCu_3$ diminished progressively : after 60 minutes they had considerably decreased, and after 60 hours, the ES mass spectrum showed the presence of the only final complex **Ha**. **Possible mechanism for the formation of Ha** : From ESMS data, the kinetic intermediates have been determined, allowing to propose a new possible mechanism (> 1 minute) for the formation of **Ha** (mechanism 2, Figure 8). According to previous results obtained by other analytical techniques, [5] the formation of **Ha** could also follow the mechanism 1 (< 1 minute).

Conclusion

According to these promising results, ESMS appears as a necessary technique to determine the thermodynamic and kinetic intermediates of formation and to provide crucial information on :
- the mechanisms of the self-assembly of complex supramolecular architectures in solution,
- their thermodynamic and kinetic parameters, such as their stability constants.

One may expect that ESMS becomes also a powerful tool to provide thermodynamic and kinetic informations on the large biological non-covalent complexes, particularly when self-assembly is involved.

ESI/TOF MS is a powerful and reliable tool for the study of large non-covalent complexes at close to physiological conditions [1]. This makes the technique very attractive for solving some biochemical problems. Here we present the results of a study of the influence of NADH concentration on the conformational structure of citrate synthase.

Citrate synthase is the enzyme responsible for initiation of the citric acid cycle, so it plays a key role in cellular metabolism. The *E. coli* citrate synthase is strongly inhibited by NADH, suggesting that the cycle in this organism is at least partially controlled by allosteric end-product inhibition by NADH. Although there is evidence that the mechanism for this inhibition is allosteric, how NADH affects citrate synthase structure is unknown.

Citrate synthase was produced from a cloned gene expressed in *E. coli* and purified by ion exchange and gel filtration in the standard buffer (20 mM TRIS, 1 mM EDTA, 50 mM KCl, pH 7.8). Then the buffer was replaced with 20 mM ammonium acetate (pH 6.5). An aliquot of NADH in 20 mM ammonium acetate was added to the citrate synthase solution to obtain the desired molar ratio of the components. Finally the mixture was diluted, and 10 μ M solution of citrate synthase in 5 mM ammonium acetate (pH 6) was used for the mass spectrometric analysis.

The enzyme has been examined in our ESI/TOF spectrometer [2]. At pH ~3 only the monomer is observed (mass 47,887 u, $\langle m/z \rangle \sim 1200$). Under conditions closer to physiological ones (pH 6), both dimer and hexamer appear in the mass spectra at $\langle m/z \rangle$ values ~4,500 and 8,500 respectively. The results are shown in the figure. When NADH is added, a complex with the hexamer is observed, with a corresponding reduction in the dimer concentration. As the NADH concentration is raised, the hexamer/dimer ratio increases. The mass of the hexamer increases by an amount of bound NADH; the numbers in the deconvoluted spectra indicate the number of NADH molecules bound to citrate synthase. The mass of the dimer remains the same, indicating that NADH does not bind to the dimer.

We explain the findings in terms of two conformational states for citrate synthase: an active state, which is a mixture of dimers and hexamers, and an inactive state, which is the hexamer only and binds NADH.

Analysis of Trypsin-Inhibitor Complexes by Electrospray/Mass Spectrometry

Baiwei Lin[†], Joe Traina, Amy Liang, and David Light
Berlex Biosciences, Richmond, CA

Introduction

Bovine trypsin is a model of protease which involved in a wide variety of physiological processes, including blood coagulation, processing of hormones, and activation of digestive enzymes. Guanidinobenzoyl esters are commonly used inhibitors and their enzyme-inhibitor complexes were previously studied as active site titrants. Ester hydrolysis has been followed by UV or fluorescence for monitor the formation of enzyme-inhibitor complexes [1,2]. In this study, we choose several guanidinobenzoyl esters and an aminomethylimidazoyl ester as trypsin inhibitors and demonstrate trypsin-inhibitor complexes by using ESI-MS. The biochemical properties, such as the complex structure, binding stoichiometry, complex stability can be characterized using ESI-MS method. Thus, ESI-MS is a simple and direct measurement of enzyme-inhibitor complex and can be used to rapidly screen a variety of inhibitors.

Experiment

(1) Materials and sample preparation: Table 1 listed trypsin inhibitors used for this study. Trypsin-inhibitor complex solutions were prepared by mixing enzyme solution with inhibitors at a molar ratio of 1:1. These solutions were adjusted to different pH condition (pH3-pH6) by addition of acetic acid.
(2) Mass Spectrometry: A SCIEX triple quadrupole mass spectrometer with electrospray was used for this study. Trypsin and trypsin-inhibitor solutions were continuously infused to the needle tip at 4 μ l/min. The electrospray high voltage was optimized at 3.3-3.5 kV, the orifice voltage was 90v and interface was 50 $^{\circ}$ C.

Results and Discussions

(1) Formation of trypsin-inhibitor complex Figure 1 shows the electrospray measurement from trypsin and trypsin-inhibitor mixtures, where 10 μ M trypsin was mixed with inhibitor (1:1 molar ratio) in deionized water (pH $\approx$ 6). Results are summarized here:

(a) trypsin,	o.b. 23,296	mass increment=0
(b) trypsin+APGB,	o.b. 23,296 and 23,456	mass increment =160 $\pm$ 1
(c) trypsin+FUT-175,	o.b. 23,296 and 23,456	mass increment =160 $\pm$ 1
(d) trypsin+comp.44,	o.b. 23,296 and 23,497.	mass increment =200 $\pm$ 1

Based on the observed mass increment, a fragment of each inhibitor(not the whole inhibitor) was bonded to the enzyme. In the mixtures of trypsin/APGB and trypsin/FUT-175, a mass increment of 160 $\pm$ 1amu was observed, consistent with attachment of the guanidinobenzoyl moiety. Therefore, both inhibitors generate the same fragment bonded to trypsin. In the mixture of trypsin/comp.44, the observed adduct was 201 $\pm$ 1amu, which matched the fragment of imidazylaminolbenzoyl moiety. Similar complexes were still observed under lower pH condition, which often denatures protein and leads to loss of noncovalently bond inhibitors. Therefore, the complexes are covalently bonded and their formation involves a reaction between trypsin and each inhibitor. Published kinetic studies performed by UV and fluorescence show that when ethyl p-guanidinobenzoate interacts with trypsin active sites, a stable acyl-enzyme derivative is formed[4]. Its mechanism involves an enzymatic cleavage of the ester bond by trypsin and a formation of a covalently bonded acyl-trypsin complex. Thus, Trypsin hydrolyzes the ester bond of inhibitor resulting the formation of acyl-enzyme complex according to the reaction sequence:

Where: E - enzyme, I - inhibitor, EI - non-covalent complex, EI' - acyl-trypsin complex, and P1,P2 - alcohol and acid. In the present study, ESI-MS was able to detect the acyl-enzyme complex in a simple and direct method.

(2)Partial Protection by a Reversible Trypsin Inhibitor DX-9085[8] is a published potent reversible inhibitor of factor Xa, however, it also binds bovine trypsin quite tightly with a K_i of 85 nM. DX-9065a was coincubated with trypsin before the introduction of MUGB, in order to determine of a reversible inhibitor can partially protect against covalent modification of trypsin. As shown in figure 2, DX-9065a slows the rate of acylation by about 50% in the early time points, however, trypsin eventually is acylated to nearly the same extent.

Conclusions

This study characterizes a covalent protein-inhibitor complex as observed by ESI-MS. In the mixture of trypsin and ester type of inhibitors, the observed complex MW suggests an acyl-trypsin complex formation, confirming that when this type of inhibitor interacts with trypsin, the protein is readily acylated. Although, in the initial studies with ethyl p-guanidinobenzoate, it was observed that the p-amidinobenzoyl adduct is rapidly deacylated[4], we show here that the 4-aminomethyl-4,5-dihydro-midazylaminolbenzoyl adduct is stable enough to be detected in the time scale of the ESI-MS experiment. ESI-MS had been demonstrated to be a simple and direct way to detect enzyme-inhibitor complexes. It can be used to monitor the rate of formation of enzyme-inhibitor complex and to provide information in support of kinetic studies. The ratio of free enzyme and complex in the enzyme-inhibitor mixture can be easily obtained from ESI-MS measurements, which can be used to study the stability of the complex in variety of buffers and pH conditions.

ESI-MS Characterization of Zinc Ejection from HIV-1 Nucleocapsid Protein by Disulfide Benzamides

Joseph A. Loo, David Mack, Rocco Gogliotti, Joseph Sanchez,
 Tod Holler, Lisa Maloney, and Michael Reilly
 Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company
 Ann Arbor, MI 48105

Mass spectrometry (MS) can play a major role in the drug discovery process for the pharmaceutical industry. With the development of methods such as electrospray ionization (ESI), MS can be used to assess the activity of potential drug molecules on targeted proteins. The zinc finger protein, nucleocapsid protein (NCp7), is involved in encapsulation and packaging of genomic RNA during human immunodeficiency virus (HIV) particle assembly. The interaction with metal ions is essential for function and structural stability for many proteins. The 55-residue NCp7 (6.4 kDa) contains two zinc finger motifs characterized by the sequence Cys-X₂-Cys-X₄-His-X₄-Cys (X, any amino acid residue) which functions as the zinc-binding domain. The mass spectrum of a zinc-containing acidic solution of NCp7 (pH 2.5) showed a measured mass consistent for the apoprotein. At pH 6.9, the expected protein-Zn₂ species was detected as the major species (Figure 1).

Certain aromatic 2,2'-dithiobisbenzamides and benzisothiazolone compounds induce extraction of zinc from the peptide and possess anti-HIV activity. A common structural feature of these agents is the presence of electron-poor sulfur atom(s), making it likely that the first step in zinc ejection is nucleophilic attack of the 2,2'-dithiobisbenzamide or benzisothiazolone sulfur by a Zn-coordinated Cys sulfur atom. The solution behavior of these compounds and the mechanistic events leading to removal of zinc from HIV nucleocapsid protein *in vitro* was studied by electrospray ionization mass spectrometry.

ESI-MS experiments were performed to monitor reaction products from the interaction of NCp7-Zn₂ with disulfide benzamide compounds that show anti-HIV activity. Covalent complexation of these drugs results in zinc ejection (Figure 2). For example, two minutes after addition of 4 mol equivalents of disulfide A₂, the major products were the (NCp7+2Zn) and (NCp7+Zn+A) molecules, where A represents half of the disulfide drug molecule. At later time periods, the apo-protein and its various covalently-modified forms are the major products. The sites of these covalent modifications during the early reaction stages were identified by analyzing fragments resulting from trypsin digestion. From ESI-MS and MS/MS results, the C-terminal zinc finger is more reactive to the disulfides than the N-terminal finger. The C-terminal finger Cys residues were found to be covalently modified with the drug. High resolution ESI mass measurements indicate that up to 3 intramolecular Cys-Cys bonds are formed upon complete zinc ejection.

Complexation of ψ -RNA with NCp7 was also studied. NCp7 is thought to be responsible for packaging viral RNA by recognizing the ψ packaging site on the viral RNA genome. ESI-MS experiments demonstrated a greater affinity for complex formation between NCp7/Zn₂ and loop 1 of ψ -RNA (believed to be involved with specific interactions with the zinc-finger protein) compared to loop 2. Addition of disulfide drug to the NCp7-Zn₂/ ψ -RNA loop 1 complex yielded some dissociation of the complex to the apo-protein form in addition to covalent modification of the protein with the drug.

NCp7 - Zinc-Binding Protein

FOLDING OF PROTEINS STUDIED BY ION SPRAY MASS SPECTROMETRY: DEPENDENCE ON THE STRUCTURE OF COFACTOR

Yu-Ting Wang and Jentaie Shiea*

Dept. of Chemistry, National Sun Yat-sen Univ., Kaohsiung, Taiwan

Ion spray (IS) mass spectrometer was used as a tool to study the effect of porphyrin structure to the folding of myoglobin (Mb) and apomyoglobin (ApoMb). The idea behind the study is during folding, the cofactors (e.g. heme or porphyrin) in the solution will be incorporated into the folded protein to stabilize the structure. If the solution contains two different types of porphyrins, the chance for incorporating the one which give more stable protein structure will be higher. Such kind of competition for porphyrins to bind to Mb was understood either by monitoring the variation of (1) the porphyrins' signals or (2) the native myoglobin signal before and after protein folding. In this study, the conformation change of Mb was controlled by varying the pH in the solution. The sample solution (0.8 mg/ml) was continuously introduced at 2 μ l/min at ambient temperature by an infusion pump for ion spray mass spectrometry (Sciex API 1) experiments.

It is crucial to obtain the signals from both heme and porphyrin in the solutions. However, the signal from free heme (m/z 616) could not be detected even at pH 2.8 where Mb is known to be denatured. This is because heme is insoluble in water. To obtain the signal, certain amount of methanol has to be added. It has to be cautious that the presence of MeOH in the solution only allowed part of the Mb molecules to be renatured at pH 5.4.

To understand the competition for porphyrins (without metal ion) and heme to bind to Mb, the following experiments were proceeded and the signals of porphyrin and heme were monitored by IS/MS: (a) MeOH (50 %) was added into the Mb solution at pH 2.8. (Figure 1a). (b) Hematoporphyrin (HP) was gradually added into the solution until the signal of HP was the same as that of Heme (Figure 1b). (c) The pH of the solution was then increased rapidly to 5.4 by adding NH_4OH . It was found that the signal of Heme decreased with the formation of native Mb (Figure 1c). The results shows that the interaction of Mb-Heme is stronger than that of Mb-HP. This is not surprising since the metal ion (Fe) in Heme will greatly increase the interaction between Mb and Heme. Four different metal-less porphyrins were tested and the results showed that the interaction of Heme-Mb was always stronger than porphyrin-Mb.

The interaction between different metal-less porphyrins and Mb can be studied by mixing apomyoglobin (ApoMb) with different porphyrins individually (at neutral pH). Since there is no heme group in ApoMb and in the solution, during refolding, some of the porphyrin molecules will be incorporated into the protein. The degree of incorporation depends on how strong the interaction between the two molecules. Since the presence of MeOH in the solution will denature ApoMb, 50% pyridine solution was used instead. Figure 2 shows IS mass spectra from the solutions which

contained ApoMb and (a) mesoporphyrin (MP), (b) protoporphyrin (PP), and (c) hematoporphyrin (HP) individually. By comparing the intensity of native Mb signals (m/z 1953 and 2203) on the mass spectra, it can be concluded that the order of interaction between Mb and the porphyrin is: $\text{MP} < \text{PP} < \text{HP}$. So far, there is no reasonable explanation for this and further studies is required. However, it seems the interaction between Mb and porphyrin increases with the solubility of the porphyrin in the solution.

Optimization of ESI Conditions for Detection of Non-Covalent Complexes of Calmodulin with Peptides

Oлга V. Nemirovskiy, Ragular Ramanathan, Michael L. Gross
Department of Chemistry, Washington University, St. Louis, MO 63130

Calmodulin is a small 16.7-kDa calcium-binding protein that is central to the regulation of a wide range of cellular responses. The binding of calcium to calmodulin is cooperative with respect to the two globular domains and has been proposed to promote a conformational change that exposes a hydrophobic surface to initiate binding of target proteins. Naturally occurring peptides, such as mellitin and mastoparan, that bind to calmodulin have the same structural features: clusters of basic residues, hydrophobic residues adjacent to the basic residues, and a predicted high α -helical content.

The goal of our work is to study the complexation of calmodulin with naturally occurring peptides (mellitin and mastoparan) by using electrospray ionization mass spectrometry.

instrumentation

ESI-MS analyses were performed with a ZAB-T, four-sector double focusing mass spectrometer interfaced to a VG ESI source. The interface contained a spray chamber with a "pepperpot" counter electrode, a stainless steel spray needle, and a hexapole lens. The mobile phase was delivered via an infusion syringe pump with a flow rate of 10 mL/min. Samples were injected into the buffer solution through a 20-mL stainless steel loop of the injector. The spray was stabilized with a coaxial nitrogen stream of 12 L/h for a solution containing 20:80 methanol:water. Desolvation was supported by heated (40–80 °C) nitrogen gas at a flow rate 300 L/h.

analyses of calmodulin peptides complexes

In the absence of Ca^{2+} , calmodulin does not bind to mellitin or mastoparan. Only noninteracting compounds are observed in ESI-MS spectra (MW of mastoparan 1476, of mellitin 2844, and of calmodulin 16792).

In the presence of Ca^{2+} , association of calmodulin with peptides has been observed in both positive and negative ion modes. In the negative ion mode (Fig. 1 and 2), the charge state envelope for the calmodulin-mellitin complex moved to higher m/z values. This suggests that upon association, conformational changes have occurred, and some acidic residues are not accessible for deprotonation.

effect of concentration ratio on complexation

When the ratio of concentrations of calmodulin to peptide in the presence of 1 mM solution of calcium acetate was 1:1, the binding stoichiometry was determined to be 1:1 (actual conc. 3 pM/mL). When the amount of peptide was increased so that the ratio of protein to peptide was 1:5, only unbound peptide ions were detected. When a solution containing a 2:1 ratio of calmodulin to peptide was sprayed, however, no complexes were observed.

effect of heating

To desolvate electrosprayed species, a flow of heated nitrogen gas (80 °C) was employed. Under such conditions, non-covalent associations of calmodulin with peptides were observed; lowering the temperature of the nitrogen gas to 40 °C resulted in solvent molecules attachment to the complexes owing to the incomplete desolvation.

effect of sampling cone voltage

Protein-peptide complexes did not survive at high sampling cone voltages ($\Delta\text{SC} = 100 \text{ V}$). By decreasing the sampling cone to $\Delta\text{SC} = 10 - 15 \text{ V}$, non-covalent complexes were detected. Changes in the flow rate of drying nitrogen gas from 300 L/h to lower or higher values resulted only in poorer quality of ESI mass spectra.

Analyses of Coenzyme B₁₂ Derivatives and Complexes with Non-Covalent Bondings using ESI-MS

Bernhard C. Pellascio, Michael J. Pfammatter and Urs P. Schlunegger
Institute of Organic Chemistry, University of Berne, Berne, Switzerland

INTRODUCTION: The vitamin B₁₂ is one of the rare organometallic compounds in the nature. The biologically active substances of the vitamin B₁₂ are necessary for more than ten biologically important rearrangements. One of them is the methylmalonyl-CoA-succinyl-CoA rearrangement which takes also place in the human body. For a better comprehension of this rearrangement and its molecule recognition several new coenzyme B₁₂ derivatives had been prepared. Up to day coenzyme B₁₂ derivatives were usually analyzed with Fast Atom Bombardment (FAB) or Liquid Secondary Ion Mass Spectrometry (LSIMS). But these spectra had a relatively poor quality. For this reason we were analyzing them with Electrospray Ionization Mass Spectrometry (ESI-MS). Electrospray data of coenzyme B₁₂ derivatives and complexes with non-covalent bondings are presented.

RESULTS: Data of coenzyme B₁₂ derivatives (positive mode): Five different coenzyme B₁₂ derivatives were dissolved in acetonitrile:water (1:1, v/v, 2% formic acid) and subjected to ESI-MS in the positive mode. The obtained spectra showed two peaks, one at the mass of the protonated coenzyme B₁₂ derivative minus one ligand (m/z 1'409 $[MH-CN]^+$), the second corresponds to the protonated double charged ion (m/z 705 $[MH-CN]^{2+}$). No further fragments or molecule peaks were found (cf. FIG. 1).

FIG. 1 Coenzyme B₁₂ derivative measured with ESI-MS in the positive mode

Data of coenzyme B₁₂ derivatives (negative mode): The five coenzyme B₁₂ derivatives were also measured with ESI-MS in the negative mode under the same conditions as described above except the composition of the diluting solvent (cf. FIG. 2). Instead of 2% of formic acid 2% of triethylamine were used.

The second inset presents the enlargement of the signal at m/z 1'291.66 with a factor of 15. This is the only signal between m/z 500 and 1'500. This signal corresponds to the unfragmented coenzyme B₁₂ derivative. It was the first time that it was possible to analyze an entire derivative with mass spectrometric methods.

FIG. 2 Coenzyme B₁₂ derivative measured with ESI-MS in the positive mode

ESI-MS data of a complex with non-covalent bondings: The next aim was the examination of a complex with a coenzyme B₁₂ derivative and a substratum with ESI-MS. The two subunits of the complex hold together because of two hydrogen bondings between the organic bases thymine and adenine. In FIG. 3 the ESI-MS spectrum of this complex is shown. As carrier solvent chloroform:methanol:water (4:4:1, v/v/v) was used. The expected signals for the protonated substratum (m/z 460), the single charged (m/z 1'257) and the double charged (m/z 629) coenzyme B₁₂ derivative were found. By taking a closer look at the region between m/z 1'650 and 1'850 one will find a peak at m/z 1'742.55 which corresponds perfectly to the mass of the complex.

CONCLUSIONS: With ESI-MS (negative mode) it was possible for the first time to analyze coenzyme B₁₂ derivatives with mass spectrometric methods without any fragmentation. The analysis of the derivatives with ESI-MS (positive mode) gives always the same peaks: $[MH-X-Y]^+$ and $[MH-X-Y]^{2+}$ (MH = protonated molecule, X = a ligand, Y = possibly a counterion). For the first time a very hydrophobic and sensitive coenzyme B₁₂ derivative complex with two hydrogen bondings between the organic bases thymine and adenine was analyzed. We were able to show that with the right carrier solvent it is possible to measure hydrophobic molecules with ESI-MS. Up to day coenzyme B₁₂ derivatives were measured only with FAB or LSIMS. We were now able to show that the obtained ESI-MS data had a better performance.

Metal Ion Flux in Metallothionein-Drug Reactions

Joseph Zaia, Daniele Fabris and Catherine Fenselau
Structural Biochemistry Center, University of Maryland Baltimore County
5401 Wilkens Ave, Baltimore MD 21228

Introduction. Metallothionein (MT) is a highly conserved zinc binding protein which contains 61 or 62 amino acid residues. The twenty cysteines in the MT sequence chelate seven divalent zinc ions in two domains *in vivo*. MT is known to sequester electrophilic alkylating agents at cysteines 33 and 48^{1,2}. Zinc bound to MT is thermodynamically stable but kinetically labile. This combination may allow MT to act as a flexible mediator of zinc ion transfer in the cell³. Functional assays have been used to show that zinc is transferred *in vitro* from MT to apo-metalloproteins⁴. Such exchange reactions are believed to be part of the mechanism whereby MT mediates cellular zinc ion distribution, particularly in times of stress.

ESI-MS can be used to measure metalloprotein metal binding so long as aqueous, neutral pH solutions are used⁵. The present work shows that metal ion transfer reactions can be monitored using ESI-MS on-line. By continuously monitoring the reaction in progress, data on the reaction time course and structure of reaction intermediates is generated at the same time.

Method. Mass spectrometry: Electrospray mass spectra were collected using the first mass spectrometer of the JEOL HX110/HX110 instrument fitted with a thermally assisted electrospray source. Solvent: 10 mM NH₄OAc (pH 7.0), 1 μ L/min via syringe pump; interfacing capillary: 120 °C; resolution: set to 500; mass accuracy was found to be 0.06% or better.

Metal exchange: MT-EDTA zinc ion exchange, [MT] = 50 μ M; carbonic anhydrase (CA)-MT zinc ion exchange, [apo-CA] = 4.5 μ M, [Zn₇-MT] = 1.5 μ M; Apo-CA⁶, Zn₇-MT⁷ were prepared according to published methods.

Chlorambucil (CHB) modified Zn₇-MT was prepared by reacting 2:1 CHB:MT at pH 7.0, 30 min, 37 °C ([MT] = 1 mg/mL). The metal ion transfer reaction was monitored continuously by ESI-MS at room temperature.

Results. Figure 1 Shows the ESI spectrum of 4.5 μ M apo-CA in the presence of 1.5 μ M Zn₇-MT at (a) time = 3.5 min and (b) time = 43.5 min. The resolution (set to 500) is sufficient to allow apo-CA and holo-CA (apo-CA + Zn + H₂O) to be resolved (apo-CA molec. wt. = 29,023.7). The expanded insets show the CA 9⁺ ion and that the addition of a zinc ion is clearly resolved in Figure 1b. The increase in relative abundance of holo-CA can be followed continuously and the data used to generate a reaction time course (not shown). This time course shows that Zn ions are transferred more rapidly from CHB modified Zn₇-MT than unmodified Zn₇-MT.

Conclusions. ESI-MS on-line monitoring is useful for studying metal ion transfer reactions of biological interest. The technique requires an ESI source that is capable of maintaining a stable electrospray, over a time period of 30 min. or more, in a 100% aqueous solution. The data shown here illustrate the dynamic nature of MT-metal binding.

TERNARY COMPLEXES OF TRIPEPTIDES WITH COPPER AND DIIMINES IN THE GAS PHASE

Christine L. Gatlin, František Tureček, and Tomas Vaisar
Department of Chemistry, University of Washington, Seattle, WA 98195-1700,
and Molecumetics, Inc., Bellevue, WA 98005

Dissociations of gas-phase peptide-transition metal complexes have been studied extensively as an alternative means of peptide structure elucidation and sequencing (1). To make transition metal-cation assisted fragmentations practically useful, new methods are needed to ensure efficient formation of peptide-metal complexes in the gas phase and to suppress side reactions in their dissociations, such as dehydrogenation and metal insertions.

In our approach we moderate the electronic properties of the transition metal ion by an auxiliary bidentate ligand, e.g., 2,2'-bipyridine or 1,10-phenanthroline, which occupies two binding sites at the metal ion (2). This leaves a limited number of binding sites for the peptide molecule and affects its bonding and the charge state of the resulting complex ion. In particular, Cu-bpy-peptide complexes show formation constants in solution on the order of 10^8 and are efficiently electrosprayed to produce gas-phase ions. Singly charged ions of the $[\text{Cu}(\text{peptide} - \text{H})\text{bpy}]^{+}$ type and doubly charged $[\text{Cu}(\text{peptide})\text{bpy}]^{2+}$ ions were obtained by electrospray ionization of solutions containing CuSO_4 , bpy and tripeptides LGF, GLF, GFL, GGF, FGG, GGA, AGG, GGI, GGL, LGG, GAY, GYA, GGH, GFHG, AHK, and GHK (3).

$[\text{Cu}(\text{GFL})\text{bpy}]^{2+}$. The ternary Cu-peptide ions are formed in competition with simple protonation to $[\text{peptide} + \text{H}]^+$, as shown for GFL in Figure 1. The ratio of doubly and singly charged ions depends on the conditions in the electrospray ionizer. The doubly charged ions are more susceptible to collision-induced dissociation and deprotonation and so their relative abundance decreases at higher skimmer potentials.

Figure 1. ESI mass spectrum of 10^{-3} M solution of GFL, CuSO_4 , and bpy in 50/50 aqueous methanol.

Collision-induced dissociation of singly charged ions at 10-30 eV E_{LAB} commences with decarboxylation. Peptides with *Leu* or *Ile* at the C-terminus further undergo β -fission of the side chain and loss of an alkyl radical that identifies the amino acid. C-terminal *Phe* and *Gly* do not undergo specific fragmentations. The Cu(bpy) residue, which is originally bound at the C-terminus, migrates along the peptide chain upon collisional activation and causes backbone cleavages that provide sequence information. Sequence ions of an *a* type are observed that correspond to imine-Cu(bpy)⁺ complexes. The relative abundance of the *a*_n ion increases with the imine affinity to Cu, e.g., *Leu* > *Phe* > *Gly*, which roughly correlates with its basicity.

Dissociations of doubly charged $[\text{Cu}(\text{tripeptide})\text{bpy}]^{2+}$ ions show three series of fragments. First, ions of *a* and *b*-type series do not contain the Cu(bpy) residue, and are formed by dissociations originating at or propagating from the N-terminus. These dissociations can be viewed as proton-initiated, and the relative abundances of the *a* and *b* ions increase with the N-terminal amino acid basicity. Second, elimination of the N-terminal *Gly* residue gives rise to doubly charged $[\text{Cu}(\text{dipeptide})\text{bpy}]^{2+}$ ions. This dissociation is specific for *Gly* and is not observed for more basic N-terminal amino acids. Third, protonated N-residues are eliminated on CAD to form singly charged $[\text{Cu}(\text{peptide} - \text{H})\text{bpy}]^{+}$ fragment ions, denoted as *y*(Cu) (Scheme 1). The relative abundance of these *y* ions depends on the basicity of the amino acid or peptide eliminated with the N-terminal residue. Weakly basic residues (*Gly*) tend to remain in the *y* ions, whereas *Leu* and *Phe* are eliminated to form *b* and *a* type ions. A further study of larger peptides of various amino acid compositions and sequences is in progress to establish the full utility of peptide-Cu ternary complexes for analytical sequencing.

Introduction. 4-Oxalocrotonate tautomerase is an enzyme used by certain soil bacteria to help convert aromatic hydrocarbons to intermediates in the Krebs cycle. The wild type enzyme is a hexamer of 62 amino acid subunits and contains no cysteine residues. We have established access to 4OT by total chemical synthesis, and the synthetic enzyme was used to show that the noncovalent hexamer can be readily detected by ESI-TOF mass spectrometry at m/z values between 3000 and 3500 (1). We have also used ESI-TOF to assess the oligomeric state of several 4OT analogues including: (*desPro1*)4OT, a truncated construct in which the N-terminal proline was deleted; (*Cpc1*)4OT, a derivative where the N-terminal proline was replaced with cyclopentane carboxylate (*Cpc*); and, the D-enantiomer of the enzyme (2). Here we report ESI-TOF results obtained with two additional 4OT analogues: a derivative [Met(O)45]4OT, in which Met45 was oxidized to the sulfoxide; and an analogue (Nle45)4OT in which Met45 was replaced with norleucine. Our purpose in studying [Met(O)45]4OT was to determine what effects the oxidation of the single Met residue in 4OT had on the enzyme's structure. The (Nle45)4OT construct was designed to eliminate the possible oxidation of the enzyme during sample handling.

Methods. Mass spectra were acquired using an ESI-TOF mass spectrometer constructed at the University of Manitoba (3). Samples were normally electrosprayed from a stainless steel needle (I.D. 120 μ m) using flow rates of 250 nL/min; in nanospray mode a small conical glass capillary (I.D. 1-3 μ m) was used with flow rates of 10-25 nL/min. ESI-TOF measurements were performed under native solution conditions (5 mM ammonium bicarbonate buffer, pH 7.5). Samples were typically prepared and analyzed at concentrations of approximately 60 μ M (based on total amount of monomer). In nanospray mode the sample concentrations used were approximately 6 μ M (based on total amount of monomer).

Results. The ESI-TOF results obtained for (Nle45)4OT and [Met(O)45]4OT under native conditions are shown in Fig. 1 (a spectrum of wild-type 4OT acquired under identical conditions is also shown for comparison). The native mass spectrum obtained for (Nle45)4OT was similar to that obtained for 4OT suggesting that in solution this analogue forms a hexameric protein complex resembling that of the wild-type enzyme. Analysis of [Met(O)45]4OT yielded predominantly monomer ions and only very weak hexamer signals (Fig. 1C) suggesting that noncovalent, intersubunit interactions defining the hexameric, [Met(O)45]4OT complex are weaker than those in 4OT. Our measurements of the apparent solution phase dissociation constants (K_D) for 4OT, (Nle45)4OT, and [Met(O)45]4OT (approximately 0.04, 0.4 and 40 μ M, respectively) also support this finding, as the K_D of the hexameric [Met(O)45]4OT complex was increased 1000 fold over that of the wild-type enzyme.

In an effort to reduce possible dissociation of the hexamer during the electrospray process we also analyzed 4OT and [Met(O)45]4OT by nanospray, which was expected to be milder than normal electrospray conditions. The native ESI-TOF mass spectrum of 4OT acquired by nanospray is shown in Fig. 2. Under these conditions the hexamer was the only species observed with the 4OT sample, suggesting that the enzyme was nearly all hexamer in solution prior to ESI. The hexamer signals in Fig. 2 are broader than those in Fig. 1A presumably due to salt adduction and/or incomplete desolvation of the complex. These adducts are not detected at higher declustering potentials. Analysis of [Met(O)45] under nanospray conditions still yielded spectra with relatively small amounts of hexamer detected.

Conclusions. The two 4OT analogues characterized in this study contained very subtle differences in their covalent structure: (Nle45)4OT and [Met(O)45]4OT each differ from wild type 4OT by a single atom. Despite these small changes, however, there were clear differences in the ESI-TOF spectra: intense hexamer signals were detected for 4OT and (Nle45)4OT but not for [Met(O)45]4OT. The correlation of these results with solution phase K_D measurements provides strong evidence for the relevance of the protein-protein complexes detected in our ESI-TOF experiments to the solution phase behavior of this enzyme molecule.

Detection of Glycosylated and Phosphorylated Peptides by LC-MS Using API-CID and In-Source CID

Seipelt, C. Thomas, Caldwell, Brenda E., Pound, Vickie L.
Abbott Laboratories, Ross Products Division, 3300 Stelzer Road, Columbus, OH 43219

INTRODUCTION

Selective detection of modified peptides has been reported in the literature based on generation of characteristic fragment ions using collisional excitation scanning. [1] This technique relies on the ability to control the potential on the skimmer to generate fragmentation in the high pressure region of the API source. Conditions apply to both glycopeptides and phosphopeptides. [1-4] In the Finnigan electrospray source the skimmer is held at ground potential, prohibiting the ability to perform collisional excitation scanning. However, other source components may be used to generate fragments specific for the detection of post-translational modifications.

The Finnigan electrospray source contains three separate source components under electrical control. In API-CID, the potential on the octapole in the post-skimmer region may be varied to induce fragmentation. Alternatively, fragmentation may be induced by varying the potential on the tube lens and heated capillary. We have termed this in-source CID.

DISCUSSION

It was found that fragmentation could be induced by varying the capillary and tube lens voltages simultaneously. The tune tables for both components could be adjusted at the low mass range to mimic collisional excitation scanning reported by Huddleston, et. al. [1] Examples of spectra obtained using in-source CID with stepped voltage scanning and API-CID for a glycopeptide isolated from the tryptic digest of reduced and alkylated bovine fetuin are shown in Figure 1. While the in-source CID scanning procedure sacrifices some of the sensitivity for carbohydrate marker ions versus the API-CID procedure, it gives the advantage of simultaneous molecular weight determination.

The positive ion tune conditions were inverted for operation in the negative ion mode. Under these conditions, API-CID was found to generate unacceptable S/N for the phosphate marker ion at m/z 79 while infusing the synthetic phosphopeptide LKRApSLG-amide obtained from the Protein and Carbohydrate Structure Facility at the University of Michigan (see Figure 2). By using in-source CID, the marker ion could be generated at the same intensity without the concomitant increase in noise. Simultaneous use of in-source CID and API-CID with stepped voltage scanning allowed detection of phosphopeptides while also obtaining molecular weight information. This appears to be analyte dependent, however. Analysis of bovine β -casein, a model phosphoprotein, under these conditions did not yield any molecular weight information for the tryptic peptides. Under SIM conditions the two predicted phosphopeptides (tetraphosphorylated Arg¹-Arg²⁵ and monophosphorylated Phe³³-Lys⁴⁵) from bovine β -casein were both detected.

CONCLUSIONS

Characteristic marker ions for PTM peptides can be generated in the Finnigan electrospray source with both in-source CID and API-CID. In-source CID using stepped voltage scanning allows specific glycopeptide detection without loss of molecular weight information. Combined API-CID and in-source CID under SIM conditions is optimal for phosphorylation

screening. Stepped voltage scanning in negative ion mode is possible but is analyte specific and requires additional optimization to be more universally applicable.

Another Approach to Enhance Fragmentation of Proteins and Peptides; Data Analysis by MaxEnt. **X. Kate Zhang**¹, Robert C. Dutky¹, Rita Derua¹, Anthony G. Ferrige² and **Henry M. Fales**¹.¹ National Heart, Lung, and Blood Institute, NIH, Bethesda, MD. ² MaxEnt Solutions Ltd., Isleham, Ely, Cambs., UK.

How to partially sequence an unknown protein in a simple and robust manner? Inducing fragmentation in the skimmer region (Smith, R.D., *et al*, *JASMS*, **1990**, *1*, 53-65, Viswanatham, K.V., *et al*, *Anal. Chem.*, **1991**, *63*(2), 174-8; Mordehai, A. V., *RCMS*, **1992**, *6*(8), 508-16) can be used, where one needs to increase the voltage of the skimmer or the voltage between nozzle and skimmer electrodes up to 250-350 V so that CAD of ions occurs in the atmosphere-vacuum interface. However, such high voltage operation is not feasible in Finnigan-type instruments. Here, we report another approach—introducing dry air in the spray interface—to collisionally activate droplet-desorbed ions in order to enhance dissociation in the skimmer-tube lens region.

The experiments were carried out on a TSQ-700 triple-quadrupole MS. Dry air is introduced through the auxiliary gas inlet and flows with the drift of droplets and their desorbed ions. The ESI mass spectrum of melittin (Fig. 1) shows extensive fragmentation of the multiply protonated peptide ions. The most prominent fragments (y_{13}^{2+} at 812.0 and y_{13}^{3+} at 541.7) are generated by cleavage of the pro-leu bond. In general, the higher the charge state, the more extensive the fragmentation. By lowering the voltage on the tube lens, the fragmentation can be effectively avoided; conversely, increasing the tube lens voltage causes more fragmentation. This observation suggests: 1) the actual decomposition occurs in the skimmer-tube lens region; and 2) ions entering the skimmer region must have much more internal energy than those generated without dry air. It is conceivable that with dry air in the spray region the desorbing ions experience many more collisions with neutral gas molecules. Such collisions activated the ions so effectively that when the ions are later accelerated in the skimmer-tube lens region the normal voltage is enough to induce their decomposition.

It is also interesting to note that the absolute intensity of $[M+2H]^{2+}$ actually increases in spite of the general decrease in intensity of ions in the higher charge states. When the flow rate of dry air is very low, the expected slight shift of ion charge distribution to a higher charge state is observed. However, further shift is masked by the extensive fragmentation of the ions in these higher charge states as well as the increase of population of the ions in the lower charge states. Because the flow rate of the dry air adds to the velocity of the ion-desorbing droplet eventually they will have less time to evaporate. As a consequence, the ion distribution will be expected to shift to lower charge states, and this is what we observe.

Tandem mass spectrometry of y_{13}^{2+} at 812.0 and y_{13}^{3+} at 541.7 was then performed to further confirm the sequence information. The technique was then applied to larger molecules such as superoxide dismutase and apomyoglobin (Fig.2a). With the assistance of the MaxEnt technique, partial sequences were obtained.

As a conclusion, dry air-assisted ESI breaks bonds efficiently and MS/MS/MS is available on a triple-quadrupole ms via combination of dry air (spray interface) and CID (Q_2). The technique can be used to obtain complete sequence information of peptide such as melittin (2846) and also can be used to partially sequencing large molecules such as superoxide dismutase and apomyoglobin. It is demonstrated also that MaxEnt technique can successfully generate the zero-charge spectrum for a complicated mixture of fragments even when only 2-3 charge states are detected.

Figure 2. A fraction of dry air-assisted ESI ms and the zero-charge spectrum obtained by MaxEnt technique (a) for superoxide dismutase (M_r :15590.6Da) and (b) for apomyoglobin (M_r :16590.6Da).

The determination of protein modifications by precursor ion scans of proteolytic digest mixtures.

James H. Bourell, Beth L. Gillece-Castro, Chris Nelson, and John T. Stults
Protein Chemistry Dept., Genentech, Inc., 460 Point San Bruno Blvd.
South San Francisco, CA 94080

The determination of the sites of protein modification, both those naturally-occurring and those induced by chemical treatment, is an important analytical question in structure-function studies. It is a problem for which mass spectrometry is proven to be well-suited. We find microelectrospray in combination with precursor ion scans, originally proposed by Wilm, Neubauer, and Mann [Anal. Chem., 68, 527-533 (1996)], to be particularly useful for these analyses due to the speed with which the results can be obtained. The microelectrospray spectrum of a proteolytic digest of the protein of interest shows peaks for many, if not all, of the component peptides, even for large proteins that display complex digests. This spectrum is frequently quite complex and interpretation is time-consuming. In some cases in which the sample level is low or high levels of contaminants are present, the peptides of interest may not even be evident in the spectrum. In order to identify only those peptides that contain the modification, a fragment ion that is characteristic of the modified amino acid, usually an immonium ion, is used for the precursor ion scan in a triple quadrupole mass spectrometer. In some cases, the precursor mass may be sufficient for identification of the peptide and the tentative site of modification. For greater specificity, the precursor masses are used subsequently for CID fragment ion spectra to identify the peptide conclusively and show the site of modification. The prolonged ion current and high sensitivity produced by microelectrospray permits all these experiments to be performed on a single sample in rapid succession.

This method is applied to the identification of sites of protein modification by the protease inhibitor, 4-(2-aminoethyl)benzene sulfonyl fluoride (AEBSF). The tryptic digests of AEBSF-modified proteins were analyzed by precursor ion scans and MS/MS. The data show the sites of modification to be on tyrosine and lysine residues, with a lack of histidine modification. Fig. 1 shows the precursor scan for m/z 319, the immonium of AEBSF-modified tyrosine, that was performed on the tryptic digest of AEBSF-modified human growth hormone. Those peaks marked with an asterisk correspond to the modified peptides. These identities were confirmed by MS/MS. Figure 2 shows the CID fragment ion spectrum of T*14 which matches with the predicted sequence.

A second application of this approach is to identify peptides that have been modified for lysyl-iodination by reaction with the Bolton-Hunter reagent [N-succinimidyl-3-(4-hydroxyphenyl)propionate. This reagent attaches a tyrosine-like group to lysine and/or N-terminal amino groups, for subsequent iodination. Figure 3 shows the Q1 scan for the tryptic digest of Bolton-Hunter-modified *ob* protein. The major peaks in the spectrum correspond to oligomers of Tris-HCl (MW=156.7), the buffer used for the digestion. No peaks that correspond to the modified peptides are observed. Nevertheless, the precursor ion scan for the modified lysine immonium ion (m/z 231.9) using the same sample clearly shows the modified peptide masses. CID fragment ion spectra for these peaks, not surprisingly, were entirely dominated by peaks from Tris, giving no sequence information. Additional data by LC-MS were used to confirm the peptide identities.

Since its development, the polymerase chain reaction (PCR), has become widely used in biological research¹. It provides a means to specifically target a length of DNA or RNA, and amplify it millions of times requiring only a few hours to complete. The ability to target sequences of interest, and quickly amplify them, has made PCR an attractive tool for diagnostic methodologies. This approach has been used for the study of human genomic regions important to diverse areas of research. Regions known to contain mutations important in human genetic diseases² have been targeted for amplification so that the appropriate deletion, addition, or substitutions could be detected. The detection of microorganisms has been another blossoming area of research which has widely employed PCR. These studies generally use a unique region, such as a toxin gene, or a universally found, but highly variable region of the genome³. Polymorphic regions of a bacterial genome, such as the spacer region between the 16S and 23S rRNA genes, have also been used to provide taxonomic information. The *Bacilli* have demonstrated variability in this region between the economically significant *B. cereus* group (*B. cereus*, *B. anthracis*, and *B. thuringiensis*), and the common organism *B. subtilis*.⁴

The commonly used method for the detection of PCR products involves the use of gel electrophoresis. This typically allows only limited mass resolution, and requires several hours to complete. Even higher resolution gels possibly allowing determination of size (resolution of single base pairs), require several hours and are difficult to prepare.⁵ Detection of single substitutions, requires sequencing, which involves laborious manipulations and several more hours to days for completion. Mass spectrometry provides the potential to rapidly analyze nucleic acids and provide information on size and sequence variation in an automated fashion. Recently PCR products have successfully been analyzed. However, the mass accuracy has been limited in many cases⁶, and lengthy purification schemes, requiring several days, have been employed⁷.

Focusing on the variable 3' end of the 16S/23S rRNA, PCR products have been generated for the 89 and 114 base pair regions in the *B. cereus* group and *B. subtilis* species respectively. These products were amplified directly from the genomic DNA using *Pfu* DNA polymerase which contains 3'-5' proofreading ability⁸. A brief set of cleanup steps were employed to eliminate the reaction components and assure that no residual metal ion adduction remained. The reaction volume was first combined with a vast molar excess of chaotropic salts and then applied to a immobilized silica resin in a single centrifugation of one minute. Steps of equal length were used to wash the salts out with 100% ethanol and two times with 70% ethanol. A final step was used to elute the sample in on fifth the volume using a 1 mM TEA/ 5 mM CDTA elution buffer by centrifugation for one minute. Microdialysis was performed on the sample to further remove metal ions. A 13K molecular weight cutoff tubing was used to carry the analyte through a counter current flow of 2.5 mM ammonium acetate requiring 10 minutes. The sample (80% acetonitrile and 25 mM each of piperidine and imidazole) was infused into the electrospray source at 0.3 μ l/min. A 2.3 kV source potential was used with a 10 second accumulation time on a 7 T Fourier transform ion cyclotron resonance mass spectrometer.

The PCR products were observed with no residual metal ion adduction or additional residues

attached. This was evidenced by the accurate mass measurements that were obtained for each product. For each 89 base pair product, the measured values fell within one mass unit of the predicted masses. Likewise, the 114 base pair product gave a mass that differed from the theoretical by only 1.2 mass units. The amount of error for each measurement was below 20 parts per million. Furthermore, the production of single strands from the double stranded product was noted in two cases including the 114 base pair product. The spectrum below contains charge states 16 to 22 for each strand of the 114 base pair product from *B. subtilis* strain W23. This demonstrates that single stranded DNA over 100 nucleotides in length remains sufficiently stable for analysis.

The level of accuracy demonstrated in the analysis clearly demonstrates that the differentiation of the products could easily be achieved. Furthermore, differences down to a single base pair, which is ca. 620 Daltons, could be detected based on these mass measurements. Even more significant is the ability to obtain highly accurate measurements on the individual strands to within 1.2 mass units. Because the smallest difference in mass between any two nucleotides is nine mass units, this finding illustrates the ability to detect single base substitutions. The few minutes required for cleanup and analysis indicates that rapid analysis of genomic regions for specific variations is possible. Further investigation is proceeding to determine what size of product is amenable to this type of analysis. Commercially available alternatives for mass spectrometers which are more facile will also be investigated for directly studying PCR products.

Analysis of Cobalt Coordinated High Mannose Oligomers using Ion Trap Mass Spectrometry

David C. Gale,[#] Martin Kohler,* and Julie A. Leary*

[#]Finnigan MAT, San Jose CA 95134

*Department of Chemistry, University of California at Berkeley, Berkeley CA 94720

Oligosaccharides are important biopolymers which are found throughout living systems. However, unlike proteins and nucleic acids which are linked together in a linear fashion, oligosaccharides can form linkages in several locations. Due to the nature of the linkage between adjacent carbohydrate units, the structural diversity displayed by these molecules is quite large. The complicated structures and diversity of these molecules has presented analytical chemists with a challenging problem in attempting to obtain useful linkage and structural information.

Positive electrospray ionization coupled with ion trap mass spectrometry was used to analyze several cobalt coordinated oligosaccharides. Initial experiments were performed on the α 1,6; α 1,3 mannose trimer as well as the di-N-acetyl pentamer, conserved tri-mannose core. Collision induced dissociation experiments were also performed on a more complex oligosaccharide, Man10GlcNAc, obtained from endo H digestion of a glycoprotein isolated from *Saccharomyces cerevisiae*. The concentration of carbohydrate and cobalt for each sample was 20 pmol/ μ L and 100 pmol/ μ L respectively. Solutions of carbohydrate and cobalt were prepared in a 50:50 mixture of water and acetonitrile. The doubly protonated Man10GlcNAc sample was prepared in a 50:50 mixture of water and acetonitrile with 2% formic acid.

Generally, MS and MS^N experiments on the ion trap provided molecular weight, linkage information, and some structural information. The ability to perform MS^N experiments did enable the characterization of certain fragmentation pathways. Fragment ions observed in the MS³ experiment of the α 1,6; α 1,3 mannose trimer indicate the presence of a 1,6 linkage due to the observation of two, three, and four carbon neutral losses. An MS⁴ experiment on the most abundant ion (m/z 400) confirmed the presence of a 1,6 linkage.^{1,2} Sequential MS of the singly charged C_n³ series glycosidic ions observed from the conserved tri-mannose core pentamer (m/z 968.1 and 765.1) indicate cross ring cleavages which are specific for 1,4 linkages at the reducing and penultimate rings. MS^N on the B_n series does not provide cross ring cleavages and thus no linkage information is obtained. MS/MS of the doubly protonated Man10GlcNAc oligosaccharide provides information indicating glycosidic cleavage only. A number of ions are observed for the MS/MS of the cobalt coordinated Man10GlcNAc oligosaccharide, several of which are indicative of cross ring cleavages. MS^N experiments on ion trap instrumentation clearly indicates differences in pathways, which can provide specific information on the sequence of cross ring cleavages.

Electrospray mass spectrometry coupled to high performance liquid chromatography (HPLC) or capillary zone electrophoresis (CZE) is a powerful analytical technique for the analyses of polar mixtures. Although the hyphenation causes additional problems related to buffer composition and flow-rate of the mobile phase, an extra dimension in sample analysis is provided when different components in a sample have to be estimated.

In this abstract we report on the analysis of adenosine 3',5'-cyclic monophosphate (3',5'-cAMP), adenosine 2',3'-cyclic monophosphate (2',3'-cAMP), guanosine 3',5'-cyclic monophosphate (3',5'-cGMP), cytidine 3',5'-cyclic monophosphate (3',5'-cCMP) and inosine 3',5'-cyclic monophosphate (3',5'-cIMP) using LC coupled electrospray tandem mass spectrometry (ES-MS). For the study of cyclic nucleotides in extracted biological samples 3',5'-cAMP was chosen as the lead compound due to the controversy in the literature which surrounds its reported natural occurrence.¹

Since nucleotides in general require nearly 100% aqueous mobile phases to allow reversed phase chromatography, additional problems like corona discharge in (-)ES and other difficulties related to high surface tension were inspected. Optimizing the electrospray process along with chromatographic conditions involved tuning on pH, bulk ion concentration and organic solvent composition. Initially various on-line HPLC conditions were tested using different flow-rates, mobile phases and narrow-bore columns. Subsequently electrolyte composition and pH were optimized according to the molecular-ion response model based on the Langmuir isotherm² For optimal ion suppression conditions resulting in subpicomole detection of 3',5'-cAMP in biological samples a C18 reverse-phase column (250mm x 2.1mm I.D., 3µm, Adsorbosphere) using methanol/water/acetic acid in a ratio 9/90.75/0.25 (pH 3.5) at a flow-rate of 200µL/min. These conditions in combination with (-)ES resulted in the detection of 3',5'-

cAMP in biological samples at the subpicomole level using multiple reaction monitoring (MRM) (VG Quattro II instrument)

Quantitation of cyclic nucleotides was carried out in MRM mode using the appropriate diagnostic transition ions. Together with the extra selection- and identification criteria, the MRM mode also gave the benefit of a reduced signal to noise ratio and hence an improved detection limit. Quantitation of the compounds in biological samples was achieved through interpolation of external standard response curves since no ²H-, ¹⁵N- or ¹³C- labelled heavy tracers for cyclic nucleotides were readily available. A tritiated isotope was used as an internal standard for calculation of recoveries and subpicomole determinations in plant and animal tissue were realized with 100 femtomoles as a detection limit.

Implementation of a capillary system (150mm x 0.3mm I.D., 60nL internal loop injections, flow-rate 7µL/min) and applying analogous chromatographic conditions gave a detection limit as low as 6 femtomoles [(-)ES, MRM]. Since ion pair HPLC generally is a better method for nucleotide separation, experiments were done to investigate its compatibility with the ES interface. Therefore the ion pair reagent tetrabutylammonium bromide (TBA-Br) was added to the mobile phase described above in an increasing concentration ranging from 50nM to 500µM. It was found that using 50µM of TBA-Br resulted in a five to tenfold lowered sensitivity. Introducing a coaxial 2-propanol sheath-flow to the source improved the sensitivity to the same level as with ion suppression conditions. Furthermore the chromatographic efficiency was drastically enhanced. We also want to emphasize that, especially in the case of capillary LC/(-)ESMS the presence of the ion pairing reagent does not interfere with cyclic-nucleotide analysis and that no adverse effect on the sensitivity over a long period of time was observed. This is mainly due to the limited pollution by TBA-Br of the source at low µL/min flow-rates.

The methods presented are of wide ranging potential use for example in biomedical and pharmacokinetic studies concerning cancer cell proliferation where small tissue samples could be evaluated for cyclic nucleotide content. However it is in plant research, with the controversy of the physiological relevance for cyclic nucleotides, that this new method of quantitation is anticipated to have the greatest impact. For the first time endogenous subpicomole cAMP levels in chloroplast samples could be detected using mass spectrometry as a detection device. In addition to determining endogenous cyclic nucleotide concentrations it now becomes feasible to study the kinetics of cyclic nucleotide-synthesising and degrading enzymes in higher plants utilising µL aliquots of protoplast or chloroplast preparations.

Purity Analysis of Polysulfated Materials by ESI/MS in the Negative Ion Mode

Marshall M. Siegel, Keiko Tabei, Michael Z. Kagan
Wyeth-Ayerst Research, Lederle Laboratories, Pearl River, NY 10965 and Princeton, NJ 08543

INTRODUCTION Polysulfated synthetic and natural products, generally prepared as salts, acids or as mixtures of both, are difficult to characterize by most mass spectrometric ionization techniques because of the lability of the sulfate groups which readily fragment losing the elements SO₃. Because of this fragmentation, the precise number of sulfate groups associated with the molecule of interest is lost, thereby, preventing the determination of the purity and distribution of polysulfated materials. This is most noticeably the case in studies of polysulfated materials by positive or negative ionization FAB where degradation and multiple losses of SO₃ groups are observed. To overcome this problem, a very gentle electrospray ionization mass spectrometry (ESI/MS) method in the negative ion mode was developed and optimized for determining the purity and distribution of polysulfated materials without fragmentation of the labile sulfate groups.

RESULTS The experimental results for the variables studied are summarized below:

1. Effect of Net Relative Charge and Molar Ratio Between Polysulfate and Peptide for Complex Formation SOS, a disaccharide with eight sulfate groups, when analyzed by ESI/MS in the negative ion mode produced a very complex spectrum due to multiple negatively charged molecular ions with multiple additions of sodium ions and multiple losses of SO₃ groups. The ESI negative ion mass spectrum is not diagnostic for SOS. In addition, no mass spectrum of SOS can be generated in the ESI positive ion mode. However, when SOS is mixed with a variety of peptides containing basic amino acid residues, viz., lysine and arginine, the ESI negative ion mass spectra in a number of cases exhibited multiply charged negative ions consistent with 1:1 molar complexes (as indicated in the last column of Table 1) without nearly any evidence for the presence of sodium counter ions. A feature of all the observed 1:1 SOS:peptide ion-paired complexes is that the number of negative sites in the polysulfate exceed the number of positive sites in the peptide by 2 to 4 negative charge sites. When the polysulfate (SOS or SHS) and peptide were mixed with molar ratios of 1:5, ESI negative ion mass spectra were generated containing exclusively the 1:1 complexes with optimum sensitivity and no fragmentation (losses of SO₃). Figures 1A and 1B illustrate the transformed ESI negative ion mass spectra for 1:1 complexes of SOS:A-8186 and SHS:A-8186, respectively, demonstrating the purity of these polysulfates. Figure 1C is the transformed ESI negative ion mass spectrum for a 1:1 molar ratio mixture of SOS:SHS each complexed in a 1:1 ratio with a peptide (A-8186), demonstrating the relative responses of the two materials and that the ion-pairing complexation method can be used to determine the relative purity of this class of polysulfated disaccharides.

Under similar negative ion ESI/MS conditions, principally 1:0, 1:1 and 1:2 polysulfated cyclodextrin:peptide (A-8186) complexes were observed each exhibiting a distribution for the sulfates present in polysulfated α -, β - and γ -cyclodextrins (See Table 2).

2. Effect of Nozzle-Skimmer Voltage on Polysulfate Fragmentation in 1:1 Polysulfate:Peptide Complexes Low nozzle-skimmer voltages (10-12 V) were used to produce ESI negative ion mass spectra containing essentially single peaks demonstrating the high purity of the SOS and SHS samples (Figures 1A and 1B, respectively). When the nozzle-skimmer voltage is elevated to ≥ 20 V, a series of fragment ions appear in the ESI negative ion mass spectra, 80 daltons apart, originating from multiple losses of SO₃ from the sulfate groups (Figure 1D for the pure SOS sample). These negative ion ESI/MS data demonstrate the stability of the 1:1 polysulfate:peptide complexes and the ability to control the lability of the sulfate groups by adjusting the nozzle-skimmer voltage.

3. Effect of ESI Source Temperature and Solvent Composition on Sensitivity of 1:1 Polysulfate:Peptide Complexes When the ESI source temperature is lowered from 80 °C to 60 °C, the sensitivity for 1:1 polysulfate:peptide complex increases approximately by two fold with a concurrent dramatic decrease in sulfate fragmentation. Likewise, when the solvent volume ratio for water:acetonitrile is changed from 50:50 (or 10:90) to 25:75, the sensitivity for the 1:1 polysulfate:peptide complex increases approximately two fold. Optimum sensitivity is achieved with this 25:75 solvent volume ratio.

4. Formation of 1:1 Polysulfate:Protein Complexes and Characterization by Negative Ion ESI/MS 1:1 complexes of ubiquitin with SOS, SHS and polysulfated α -cyclodextrin were observed in ESI negative ion

mass spectra (with natriated adducts of low abundance). Optimized spectra were obtained when the complex is prepared from a 1:2 molar ratio mixture of polysulfate and ubiquitin, the capillary voltage is set to a relatively low value of 2.4 kV and the nozzle-skimmer voltage set in the range of 20-50 V. The transformed ESI negative ion mass spectra for 1:1 complexes of sulfated α -cyclodextrin with ubiquitin and A-8186, respectively, exhibited nearly identical sulfate distributions. The similarity in these results for significantly different complexes validates this ESI/MS negative ion method for polysulfate analysis.

Similar samples, prepared as described in the paragraph above, in the ESI/MS positive ion mode produced spectra consistent with the presence of poly-natriated ubiquitin and the absence of the polysulfate:ubiquitin complex. Polysulfate:horse heart myoglobin complexes were not observed in both negative and positive ion ESI mass spectra.

5. Formation of Polysulfate:Amine Complexes Preliminary experiments in the ESI/MS negative ion mode failed to produce abundant polysulfate:amine complexes with spermine and spermidine.

6. +/- IR- and UV-MALDI/MS of Polysulfate:

Peptide Mixtures The MALDI mass spectra exhibited poly-peptide adducts to a single polysulfate unit with multiple SO₃ losses from the polysulfate. These preliminary results demonstrate that the laser induced multiple sulfate fragmentations. MALDI/MS does not appear to be suited for quantitative sulfate distribution analysis but is useful as a qualitative tool for sulfate analysis as demonstrated by P. Juhasz and K. Biemann for the analysis of heparin components [Proc. Natl. Acad. Sci. USA 91, 4333-4337 (1994)].

CONCLUSIONS Ion-pair complexes can be readily formed in the ESI/MS negative ion mode between acidic polysulfates and basic peptides and proteins for quantitating the distributions of the sulfate groups. The major limitation in the technique is that the formation of the complex is highly dependent upon the nature of the chemical structures and the number of charges present in them. To form stable complexes, the choice of best peptides or proteins for complexation for a given polysulfate must be determined by trial and error.

ACKNOWLEDGMENTS

The authors greatly appreciate the assistance of Robert J. Linhardt, University of Iowa, Iowa City, Iowa for kindly providing the SOS and SHS, the American Maize-Products Co., Hammond, Ind. for kindly providing the polysulfated cyclodextrins and S. Berkenkamp and F. Hillenkamp, University of Münster, Germany for kindly obtaining the MALDI mass spectra.

NEGATIVE ION ELECTROSPRAY MASS SPECTRA OF FULLERENE DERIVATIVES

* I. Haller, U. A. Mirza and B. T. Chait, The Rockefeller University, New York, NY 10021, and H. Tokuyama, R. M. Strongin, and A. B. Smith, III, University of Pennsylvania, Philadelphia, PA 19104.

Mass spectrometry has played a major role in the structure verification of recently synthesized methylene- and oxo-linked fullerene dimers, I and II (Ref. 1). Although electrospray ionization is frequently thought of as a tool predominantly suited for the creation of ions by acid-base equilibria in polar and/or protic solvents, the technique can be used to ionize molecules by redox processes (Ref. 2). We show here that structural identification of low level components in mixtures can be achieved with negative ion ESI spectra obtained from fullerene derivatives by a redox process in toluene solution.

ESI mass spectra were obtained by infusing ~100 μ M solutions of the fullerene derivatives in the presence of N,N,N',N'-tetramethyl-p-phenylenediamine electron donor at 3 mM concentration, with the addition of sulfur hexafluoride arc-suppressant (Ref. 3) to the atmosphere of the spray chamber. Singly and doubly negatively charged ions of the compounds C₁₂₀X, and singly charged ions of the fragmentation products C₆₀ and C₆₀X are observed (see Fig. 1. for compound II). The fragmentation of these labile compounds under these conditions, however, is much less extensive than in APCI. Satellite peaks separated by 16u are also seen. High enough signal/noise ratios were obtained to operate the triple quadrupole at a resolution sufficient to observe half mass-unit isotopic peak separations in the m/z 727 peak in I (Fig. 2) and in 728 in II, confirming the presence of doubly charged ions. Similar half mass-unit isotopic peak separation, as well CID spectra (Fig. 3) of an impurity peak at m/z=1094 identifies it as the doubly charged ion of a tr fullerene with 2 bridging groups.

In Fig. 4 we compare experimental spectra to theoretical isotopic peak distributions (bar graphs) calculated, as appropriate, for C₆₀ and C₁₂₁. Singly charged C₁₂₁H₂⁻ (Frame A) shows a substantial elevation of all component with mass $\geq$ M+2 over theoretical indicating the presence of oxo- analog impurities. An even larger elevation is observed (Frame B) in the intensity of the same components in the doubly charged ion, pointing to preferential ionization of solution-phase impurities (due to their higher electron affinity) and to oxygen pick-up in the electrospray process.

Direct Quantitation Of Methyl Succinate By Electrospray Negative Ion Tandem Mass Spectrometry; Marcia M. Ketcha and Robert J. Strife, Procter & Gamble Co., Miami Valley Laboratories, P.O. Box 538707, Cincinnati, OH 45253

Applications of electrospray mass spectrometry tend to focus on larger molecular species like proteins, peptides, oligonucleotides, etc. However, some of the first demonstrations of electrospray by Fenn et. al.[1] concerned smaller molecules, e.g., species less than 500 daltons in molecular weight. Over the last four years, several determinations of small polar molecules (i.e., < 200 daltons) have been done in our laboratory. Chemical background is reduced by using tandem mass spectrometry in these experiments.

While "small" molecules are often analyzed by GC/MS, direct analysis by electrospray is attractive because it eliminates the need for derivatization, especially of polar molecules. In this case the stability of dimethyl succinate in product formulations was evaluated by analysis of one of the hydrolysis products, mono-methyl succinate (MES).

Internal Standard: Stable-isotope-labeled MES was synthesized by methanolysis of succinic anhydride with CD₃OH, to be used as the internal standard. The purity of the d₃-MES was checked by preparing the TMS ester derivative using BSTFA for 30 min. at 60 °C. The analysis was done on a HP 5890 Series II GC interfaced to a Finnigan MAT ITMS. The column used for separation was a RTX-1 (Restex) 15m x 0.25mm with a film thickness of 0.25µm. Conditions for the GC were an initial temperature of 35 °C with a 5 °C/min ramp to 150 °C. The isotopic purity of the deuterated MES was confirmed to be > 99.5%.

Sample Preparation: To prepare calibration standards, 2 ml of 63.3 µg/ml d₃-methyl succinate was added to an aliquot of d₀ methyl succinate solution (0-50ul). A make-up volume of 0-50 ul was added to give a total volume for each standard of 2.050 ml. The standards were diluted by a factor of 10 before analysis by flow injection.

For comparison, a standard curve using the product matrix was prepared. Samples containing 20 mg of product matrix were spiked with known amounts of methyl succinate. To these samples 2 ml of d₃ methyl succinate was added. The samples were vortexed and centrifuged. The supernatant then was diluted by a factor of 10 before analysis. All product samples were prepared in a similar manner.

Ion Spray and Flow injection Analysis: Negative electrospray of unlabelled and labelled MES in 50/50 acetonitrile/water was performed on an SCEIX API III. The base peak in the negative ion electrospray mass spectrum for both species was the [M-H]⁻ ion. When subjected to collision-induced-dissociation, the base peak ions fragment by loss of methanol and d₃-methanol, respectively, to m/z 99⁻, which is suggested to be the "enolate" form of succinic anhydride. This specific fragmentation provided the basis for the selective detection and quantitation of MES in crude extracts of product formulations, by multiple-reaction monitoring.

The samples were analyzed by flow injection using a Waters 600/MS pump at 50µl/min through a 50 µm ID fused silica line interfaced to the SCEIX. The mobile phase consisted of 50/50

acetonitrile/water and the sample injection volume was 2 µl. The fragmentation of the precursor ion (131 or 134) to the product ion (99) was obtained using a 2.3 V center-of-mass energy and orifice setting of -60 V. The collision gas, argon, was set to a collision gas threshold of 200. The multiple reaction monitoring parameters were a 25 ms dwell time with a 250 ms pause.

Results: Standard curves produced with the product matrix had similar slopes and intercepts to those obtained from standards which were prepared in solution. Regression analysis from 0.51 ng to 51 ng (two orders of magnitude) gave linear coefficients $r^2 > 0.9995$ on curves derived by both methods. The slope of the curves ranged from 0.91 to 0.96 (theoretical = 1.00).

Both fresh and aged product samples were analyzed. The aged samples were found to have an 100 fold increase in the concentration of methyl succinate in comparison to the fresh samples. The level of methyl succinate in the aged samples was 1% by weight. This level corresponds to a 0.2% level of methanol.

ADDITIVE ENHANCEMENT FOR ESI OF NITRATED EXPLOSIVES

Mark L. Miller*, Jeff Leibowitz, & Roger Martz

Federal Bureau of Investigation, FSRTC, FBI Academy, Quantico, VA 22135

PURPOSE Find additives to enhance response of nitrated explosives in electrospray ionization for LC/MS

METHOD Try anions (A) that can add to explosives to form (M+A)⁻ adducts

RESULTS Ammonium nitrate additive enhances ESI response ~1000X for RDX. Trifluoroacetic acid and chloroacetonitrile give a ~6-40X lower response as nitrate

INTRODUCTION

Nitrated explosives give poor response by electrospray ionization mass spectrometry under conditions typically used for ESI. Common LC solvent systems such as methanol/water and acetonitrile/water can require microgram size injections in order to detect these explosives. An additional experimental problem is the inconsistency in the spectra of the explosives. Adduct ions such as chloride have been observed in the spectra at times even though chlorinated compounds were not intentionally added to the solvent systems. The ESI detection of explosives in "real world" samples has been further complicated because of omnipresent interferants which add to the spectral inconsistencies. Alternatives to GC/MS are needed for the trace analysis of explosives because many are thermally labile and/or give indistinguishable spectra. Some of the nitrated explosives exhibit nitrate adduct ions in their ESI mass spectra. Presumably, these adduct ions come from the explosives themselves. The goal of this research was to find mobile phase additives to enhance ESI intensities and spectral consistencies for nitrated organic explosives detection.

Chemicals investigated are listed below.

Nitramines: cyclo-1,3,5-trimethylene-2,4,6-trinitramine (RDX); trinitro-2,4,6-phenylmethylnitramine (tetryl); cyclotetramethylene tetranitramine (HMX)

Nitroaromatics: 2,4-dinitrotoluene (DNT); 4-amino-2,6-dinitrotoluene (ADNT), 2,4,6-trinitrotoluene (TNT)

Nitroesters: ethyleneglycol dinitrate (EGDN); nitroglycerin (NG); pentaerythritol tetranitrate (PETN)

METHODS

MS INSTRUMENT: Finnigan TSQ 700

INTERFACE: Finnigan API electrospray at a spray voltage of 4.5 kV

CHROMATOGRAPH: Hewlett Packard HP 1090 ternary pump

STANDARDS: explosives obtained from AccuStandard (New Haven, CT) and Radian Corp. (Austin, TX)

MOBILE PHASE: HPLC grade methanol, acetonitrile, and water used were 50:50 organic/water

ADDITIVES: were individually added to the aqueous portion of the mobile phase at 1, 5, & 10 mM for NH₄NO₃, 0.01 & 0.1% for TFA, and 0.1 & 1% for CH₂ClCN

COLUMN: Alltech Inertsil ODS 2 or Alltima ODS, 5 micron 2.1x150 mm at a flow rate of 0.3 mL/min
Procedure: Plastic explosives (50 mg) were extracted twice with 1 mL of hexane by mechanical agitation and vortexing. The hexane insoluble portion was dissolved in 2 mL of acetone and filtered with a 13 mm nylon HPLC syringe filter. The filtrate was diluted 10X with acetonitrile and 1 or 2 microliter injections were made on the LC/MS.

RESULTS

Several of the explosives gave nitrate adduct ions in the negative mode with the 1 mM ammonium nitrate mobile phase (aq. pH 5.5). Higher concentrations of ammonium nitrate (5 mM & 10 mM) did not

give higher adduct ion intensities but did result in excessive spray currents and salt residues on the interface. Nitrate adduct ions were generally 6-40X more intense than trifluoroacetate (TFA) or chloride (chloroacetonitrile) adduct ions. Some of the compounds did not give nitrate adduct ions or were only observed when large injections were made. No signal was observed for DNT even for 500 ng injections. However, a background ion at mass 244 at the same location the nitrate adduct ion of DNT would appear may have prevented the observance of a weak signal. EGDN and TNT exhibited nitrate adduct ions but only for 500 ng sample sizes. TNT's base peak was 226 (M-H)⁻ and the nitrate adduct ion (289) had a relative intensity of 5% at 500 ng. NG's base peak was 289 (M+NO₃)⁻ but it also had a 226 (M-H)⁻ ion at 35% int. All of the other compounds had (M+NO₃)⁻ as the base peak. The lowest molecular weight explosives were observed to be the weakest signals overall.

CONCLUSIONS

Nitramines and nitroesters show enhanced response for ammonium nitrate additive by forming (M+NO₃)⁻ adduct ions. Nitroaromatics exhibited weak nitrate adduct ions due to the high electron density in their rings. The strong inductive field effect (electron with-drawing) of nitro groups on nitramines and nitroesters is sufficient for the attachment of nucleophilic nitrate anions on sites of low electron density. It appeared some mass discrimination occurs by ESI as the compounds with the weakest response were the lower molecular weight compounds. The nitramines RDX and HMX showed the greatest enhancement in response of the explosives. Methanol/water mobile phases gave similar results to acetonitrile/water combinations when used with 1 mM ammonium nitrate except methanol resolved peaks better at the expense of analysis time. Application of this system was demonstrated on "real world" samples of plastic explosives extracts and bomb residue. Trace detection of RDX from a bombing site was possible with the ammonium nitrate additive even though it was not observed when analyzed in an acetonitrile/water with ammonia additive mobile phase ESI system. The use of ammonium nitrate makes it possible to obtain consistent and interpretable LC/MS spectra at the nanogram level of some of the most difficult to analyze organic explosives.

ELECTROSPRAY IONIZATION MASS SPECTRA OF CARBOCYANINE DYES USED AS MOLECULAR PROBES

Michael C. Melnyk, Michael Bartlett and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400; Dept. of Medicinal Chemistry, University of Georgia, Athens, GA

Carbocyanine dyes used as molecular probes [1] are symmetric ring compounds with long alkyl chains on each ring. Since these dyes exist as precharged compounds, they provide high quality positive ion LSIMS and ESI mass spectra in which the intact cation is the dominant ion in the mass spectrum.

The intact cation of a carbocyanine dye undergoes charge-remote fragmentation (CRF), evident in the LSIMS mass spectra. Charge-remote fragmentation has also been observed in collision-induced dissociation (CID) and surface-induced dissociation (SID) of the mass-selected intact cation. The structural feature that allows CRF fragmentation to occur in these molecules is the presence of the two long alkyl chains proximate to a resonance stabilized charge site.

Progressive fragmentation along each of the chains can be monitored as experimental parameters in CID and SID are varied. The energetics of the successive CRF processes has been explored. In this work, the ESI mass spectra and MS/MS spectra for this class of compounds are investigated, with particular emphasis on the extent of CRF process in the mass spectra and in the CID MS/MS spectra.

We begin with a brief summary of the positive ion LSIMS of these compounds, concentrating on the CRF process. DiOC₁₈ (see molecular probes catalog for structure) was chosen as a representative example of this class of compounds. The intact cation of the dye appears at m/z 782, and fragments to form the ion at m/z 528, the most intense ion within this mass range, by complete loss of the first alkyl chain. The ion at m/z 766 corresponds to the loss of CH₄ from the intact cation, followed by a series of ions separated by 14 Da, terminating at m/z 528. The final alkyl fragment loss of the first alkyl chain (m/z 573 to m/z 560) corresponds to a loss of 13 Da, which is a CH group rather than a methylene group. There is a small contribution from background noise from the mNBA matrix, but the majority of the signal is genuinely associated with the CRF fragment ions. This is seen in the reproducible pattern observed for the cluster of ions observed around each CRF product ion. This pattern suggests a series of common mechanisms involving hydrogen transfer reactions that accompany each CRF loss of methylene unit. Excellent pattern reproducibility is seen in the cluster of ions around the CRF fragment ions at m/z 738, m/z 724, m/z 710, and m/z 696. These CRF losses correspond to a C_nH_{2n+2} and/or C_nH_{2n+1} series as suggested by Adams and Gross [2], and Wysocki and Ross [3], respectively.

The next step in this study was to document the low-energy CID process for these compounds. DiOC₁₆ was chosen as a representative example for this discussion. Figure 1 shows a portion of the low-energy CID MS/MS spectrum of DiOC₁₆ recorded on a VG70-SEQ mass spectrometer at a laboratory collision energy of 150 eV. The precursor ion is the intact cation at m/z 726. The CRF ions corresponding to losses from within the first alkyl chain are absent. Some of the product ions corresponding to second chain CRF dissociation are present in the spectrum, but only a few of the CR product ions corresponding to C_nH_{2n+2} series were observed.

High-Energy CID was recorded for DiSC₁₈ on a JEOL HX110/HX110 mass spectrometer. The collision energy in the laboratory frame of reference was 7.0 keV. As in LSIMS data, the MS/MS spectrum includes initial loss of CH₄ from the cation, followed by a series of product ions separated by 14 Da, with the charge-remote losses of the first alkyl chain terminating in the ion at m/z 560. At laboratory collision energies greater than 3.0 keV, CRF losses in both alkyl (alkenyl) chains are observed in the CID MS/MS spectra of the carbocyanine compounds analyzed. In general, as the collision energy drops below 3.0 keV, CRF losses were not observed for the second alkyl chain. However, the collision energy at which the second chain CRF losses were not observed was compound dependent.

Surface-induced dissociation (SID) is an alternative method for ion dissociation. The advantages of SID include high internal energy deposition, and fine control of internal energy deposition [4,5]. The collision energy for these experiments was 100 eV, and the collision surface was perfluoropolyether-coated brass. At this

surface collision energy, charge-remote fragmentation product ions were observed for the entire second alkyl chain for the carbocyanine dyes examined. However, only a few of the product ions corresponding to CRF in the first alkyl chain were observed. For SID, the relative intensities of the product ions corresponding to CRF for both the first and second alkyl (or alkenyl) chains are much different than the relative intensities of the same product ions obtained in the high-energy CID experiments. High-energy CID produces CRF ions of a higher relative intensity for the first alkyl chain dissociation. The opposite is true under SID conditions; the relative intensities of the CRF product ions corresponding to second alkyl chain dissociation are much greater than those corresponding to dissociations along the first alkyl chain.

We have shown that charge-remote fragmentation initially occurs for the second alkyl chain in the carbocyanine dyes examined in LSIMS MS/MS under different collision energy conditions. We would expect to see no evidence of charge-remote fragmentation in the ESI mass spectra due to the fact that ESI is a softer ionization method than LSIMS. As expected, in ESI, no charge-remote fragmentation is evident for either the first or second alkyl chain. DiOC₁₆ was then analyzed by low-energy CID MS/MS using a VG Quattro II triple quadrupole mass spectrometer at a laboratory collision energy of 50 eV. The precursor ion is the intact cation at m/z 726. As in LSIMS MS/MS, the CRF ions corresponding to losses from the first alkyl chain are absent. However, the product ions corresponding to second chain CRF dissociation are present in the spectrum. It is important to note that the charge remote fragmentation process did not occur for any of the carbocyanine dyes examined by ESI until the collision energy approached 50 eV.

Charge-remote fragmentation is observed in LSIMS mass spectra as well as in CID MS/MS and SID MS/MS of carbocyanine dyes. Successive charge-remote fragmentation for the two alkyl chains can occur, but the extent of the fragmentation is different for each of the alkyl side chains, and appears to be related to the stability of the charge site and the amount of internal energy present in the dissociation precursor ion. The fact that CRF occurs in the LSIMS mass spectra, in a pattern that resembles the CID-induced process, suggests that at least some fraction of sputtered parent cations have a high internal energy. The carbocyanine compounds discussed here may prove to be valuable in assessing the relative energetics of LSIMS, low-energy CID, high-energy CID, SID, and ESI mass spectrometry. The absence of first chain CRF product ions in the low-energy CID MS/MS and CID ESI MS/MS spectra suggest that the first chain CRF process occurs at a higher relative energy compared to the second chain CRF process.

DETERMINATION OF UNSTABLE INTERMEDIATES FROM ORGANIC REACTIONS BY LOW-TEMPERATURE ESI/MS AND LSIMS

Chin-Hsiung Wang, Hsing-Long Chei, and Jentaie Shiea*
Dept. of Chemistry, National Sun Yat-sen Univ., Kaohsiung, Taiwan

Some of the intermediates in organic reactions are thermally unstable and can be trapped only at very low temperature. The structure of such intermediate can only be determined by low temperature NMR. Recently, we have reported that thermally unstable and volatile organic compounds can be detected by ESI/MS and LSIMS at very low temperature^{1,2}. In this study, a temperature-controlled ESI source connected to a low temperature reactor was built to detect very unstable intermediate from Wittig Reaction (scheme 1). The same intermediate was also detected by low-temperature LSIMS. An interface was built so LSIMS could be operated at low temperature.

Figures 1 and 2 are the schematic diagrams of temperature-controlled ESI source and low-temperature LSIMS interface. In this study, the temperature of the reactor was kept at -78°C or 0°C . This was done by immersing the reactor into the MeOH/dry ice solution or ice water. The temperature in the ESI source was adjusted and controlled by a nitrogen gas flow, heating wire, thermocouple, and temperature controller. The operating temperature of the source is between -100°C and $+100^\circ\text{C}$. The intermediate of the reaction was monitoring continuously by transferring the solution from the reactor to the ESI source. A Sciex API 1 mass spectrometer was used as the detector. The LSIMS probe was cooled by flowing nitrogen gas through the probe and although through heat conduction by a copper block immersed in the liquid nitrogen. The temperature of the probe reached to -120°C ten minutes after cooling. A VG QUATTRO mass spectrometer equipped with a cesium ion gun was used as the detector.

The intermediate (oxaphosphonium; MH^+ , m/z 391) from Wittig Reaction was only detected by ESI/MS at low temperature (reactor temperature: -78°C ; ESI source temperature: -40°C) (Figure 3). When the temperature of the ESI source was higher than -40°C , the signal of the intermediate disappeared. Similar low temperature conditions are also required to detect the intermediate by low-temperature LSIMS (Figure 4).

Regulation of Multimer Formation in API-MS

Morgan Stefansson, Per Sjöberg, and Karin Markides

Inst. of Analytical Chemistry, Uppsala University, P.O. Box 531,
75121 Uppsala, Sweden

Atmospheric pressure ionization (API) mass spectrometry is a sensitive analytical sampling technique that continuously finds wider applications. The two main ionization methods used are electrospray or pneumatically assisted electrospray and atmospheric pressure chemical ionization.

One limitation severely affecting quantitative work is the tendency for certain analytes (e.g. small and neutral compounds) to form multimers as exemplified by artemisinin (an antimalaria drug) as sodium complexes in Figure 1. Variation of the drift potential of curtain gas temperature proved unsuccessful in the suppression of these multimers which were present down into the nanomolar range and resulted in highly non-linear calibration curves. It has recently been shown (1) that addition of organic primary amines can be used to fully suppress multimer formation (Figure 2) resulting in linear calibration curves and up to a sevenfold improvement in the signal-to-noise ratio. For ammonium additives with different degrees of substitution this effect increased in the order; quaternary << tertiary < secondary < primary, respectively. Furthermore, an increase in hydrophobicity was favourable as demonstrated through increment of the carbon chain length on the amine. The presence of hydrophilic groups, however, (amino, guanidino or hydroxy) decreased the complex stability.

**MALDI/time-of-flight MS analyses of antigens
after immunoaffinity extraction from whole cell lysates**

Identification of proteins recognized by antibodies is often difficult using classical protein chemistry. This is particularly true when the individual proteins are present in small quantities within the structure, when the cells cannot be cultured easily, or when epitopes incorporate post-translational modification. Several mass spectrometric procedures have been recently described for epitope mapping in relatively simple systems^{1,2,3}

We present here the development of the first immunoaffinity-based mass spectrometric epitope analysis method for use in complex biological systems, such as whole cells, identifying protein antigens at physiologically relevant levels. The system used here for development of the method is the well-characterised Ty1 retrotransposon present in the yeast *S. cerevisiae*⁴. We have used a magnetic bead-conjugated monoclonal antibody BB2 with a known epitope (residues 27-32) to specifically precipitate the Ty1 structural protein or protein fragment from whole and protease-digested yeast cell lysates. We have then analysed the affinity extracted protein/peptide reacting with BB2 by MALDI-TOF-MS. We have demonstrated the sensitivity of the system by successful extraction of the antigen from yeast cell lysates containing only the wild-type, low levels of Ty1 structural protein. Moreover, partial sequence information of the extracted antigen has been obtained by ESI-MS/MS.

The MALDI/TOF MS analysis of pure Ty1 protein derived by dissociation of virus-like particles indicated a molecular mass of 43224, in satisfactory agreement with the expected value of 43001. Identification of Ty1 protein was substantiated by SDS-PAGE and western blotting using anti-Ty1 C-terminal TYG3 and anti-Ty1 N-terminal BB2 antibodies. The mass spectrum of the intact Ty1 recovered by immunoaffinity extraction from a lysate of overexpressing yeast cells (OGS40) gave a molecular mass at 42969 which was also in satisfactory agreement with expected molecular mass.

An immunoaffinity extract of a tryptic digest of the OGS 40 cell lysate contained a single component (as judged by MALDI/TOF MS) corresponding to the T2 fragment (residues 25-39) incorporating the known epitope. When the OGS40 cell lysate digest was diluted with lysate from wild-type cells, partial tryptic hydrolysis products were detected in the immunoaffinity extract, suggesting the detection of products of Ty1 present at wild-type levels. MALDI/TOF MS analysis of an immunoaffinity extract of a tryptic digest of wild-type (MC2) cell lysate confirmed successful detection at wild-type levels (Fig.1)

Finally, the ESI-MS analysis of the wild-type digest extract yielded confirmatory data. Furthermore, the ESI MS/MS of the wild-type digest extract provided partial sequence data consistent the expected structure(Fig 2)

Protein Epitope Identification Using Limited Proteolysis of Immune Complexes and Mass Spectrometry

M. Macht¹, K. Kürzinger², M. Przybylski¹

Introduction. Nearly all biochemical reactions involve steps with supramolecular complexes. For the understanding of the mechanisms the knowledge of the three-dimensional structure of these complexes is essential.

Antigen-antibody complexes are well suited model systems for studying such intermolecular interactions. For this reason the characterization of epitope binding sites in immune complexes is a major aim of biochemical and biomolecular research. There are few examples using limited proteolysis of proteins bound to immobilized antibodies and mass spectrometric analysis after dissociation of the complex to study epitope binding sites [1-4].

The separation of non-epitope peptides presents the major difficulty in these experiments. In this work we present a method for characterization of the epitope sequences without prior immobilization of the monoclonal antibody. As model system a synthetic 32 amino acid peptide derived from heart muscle protein Troponin T and a monoclonal antibody IgG-M7, which was raised against the whole proteins were used. We have applied a) proteolysis of the intact immune complex and removal of non-bound fragments followed by detachment of the antigenic peptides (epitope excision) and b) catching the peptides after enzymatic digest and detachment of antigenic peptides after removal of non-binding fragments (epitope extraction).

Materials: The 32 amino acid peptide bc-TnT(118-149) [5] was synthesized by Fmoc solid phase peptide synthesis followed by HPLC-purification. Monoclonal antibody IgG-M7 was a gift of Boehringer Mannheim, Germany. Trypsin was pretreated with TPCK (Tosyl-(phenylalanyl)-chloromethyl-ketone) to avoid chymotryptic activity.

Methods: For epitope excision antibody (200 µg) and antigen (10 µg) were mixed and incubated for 15 min. Proteolytic enzymes were added in a ratio of 1:50(w/w) regarding to antigen. Digests took place within 30 min and were stopped with 0.5 µl DFP in abs. DMSO. For removal of unbound peptides the mixture was centrifuged through 30 kD Ultrafiltration membranes (Amicon, USA). Releasing of the epitope-peptides was achieved by adding 400 µl 0.1% TFA and the solution was centrifuged again. For epitope extraction digestion of antigen was carried out prior to antibody addition.

Results. Epitope excision with trypsin delivered ion signals for peptides (1-10) and (1-14) (Fig. a), epitope extraction yielded peptide (1-10) (Fig. b). Epitope excision with S.A.-V8 protease gave peptide (1-16), in epitope extraction peptides (1-13) and (1-16) were obtained. By endoprotease Lys-C digestion it was shown, that K⁹ is shielded from proteolytic degradation by the antibody. Peptide sequence (1-10) was the

shortest sequence which was found in agreement with each other and can therefore be assigned as epitope sequence. Modelling of this sequence using secondary structure prediction and circular dichroism (CD) measurements deliver an α -helical structure of the epitope peptide of which one side of the helix is recognized and shielded by the antibody. This assumption agrees well with the discrimination of skeletal muscle protein relative to heart muscle protein, which has four mutations in the region detected by the antibody.

Epitope identification of bc-TnT by epitope excision (a) and epitope extraction (b) with trypsin. Left hand side shows the non-epitope peptides (non-epitope fraction), while on the right hand side spectra of the epitope fractions (which contain the TFA released peptides) are shown.

Selective Detection of Aldehyde/Peptide Adducts Using Affinity Extraction and Tandem MS Screening

Mark S. Bolgar and Simon J. Gaskell

The Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, U.K.

Structural changes that accompany oxidation of low density lipoprotein (LDL) are believed to be responsible for the increased atherogenicity of oxidized LDL. The modifications that are considered to occur include the adduction to protein amino acids by lipid peroxidation products. One of the lipid peroxidation products implicated in the modification of LDL is 4-hydroxynonenal (HNE). Thus, the unequivocal characterization of HNE-modified LDL in atherosclerotic plaques would clarify the role of lipid/protein in the progression of atherosclerosis. Towards this goal we have implemented tandem mass spectrometric procedures which allow for the specific

detection of HNE-modified peptides derived from enzymatic hydrolysis of modified proteins (1). As a complement to selective mass spectrometric detection we have developed an affinity extraction approach to the prior concentration of enzymatic hydrolysate components incorporating lipid modification. This method exploits the observation of the incorporation of a free aldehyde moiety into proteins modified by reaction with HNE. The aldehyde function is reacted with a solid-phase coupled hydrazide reagent resulting in the selective immobilization of the HNE-modified peptides (as well as other modified peptides which have incorporated an aldehyde or ketone moiety) (Figure 1). The covalent bond established between the aldehyde-containing peptide and the immobilized reagent is stable at neutral pH allowing the use of thorough rinsing procedures to remove unbound peptides.

Figure 1. Affinity extraction procedure using a solid-phase coupled hydrazide reagent.

Recovery of the bound peptides is achieved by lowering the pH to 2.5 and heating to 37°C for 90 minutes which induces hydrolysis of the linkage between the immobilized reagent and the aldehyde-containing peptide.

This affinity extraction procedure was applied to the concentration of HNE-adducted peptides derived from the tryptic digestion of HNE-adducted apomyoglobin. The sample consisted of 20 µg of HNE-adducted protein digest in 2 mg of native protein digest. The ESI spectrum of the material recovered by affinity extraction was dominated by the ions from the native tryptic peptide T16 but some HNE-adducted peptides were apparent (Figure 2a). T16 is the most hydrophobic of the 21 native tryptic peptides (as measured by its Bull and Breese index), suggesting that hydrophobic interaction was responsible for the recovery of this peptide. The selectivity of this analysis was further enhanced through scanning for precursors of m/z 266 which corresponds to the HNE-adducted histidine immonium ion. Six HNE-adducted peptides are clearly visible in the precursors of m/z 266 spectrum (Figure 2b); and only one ion due to a native peptide is observed. The HNE-adducted peptides represented a maximum of 1% of the total sample (20 µg adducted hydrolysate/2000 µg native). The actual concentration was certainly lower because the adducted-hydrolysate contains a mixture of native and adducted peptides.

Figure 2. Solid-phase coupled hydrazide extraction of 2 mg of apomyoglobin tryptic hydrolysate containing 20 µg of HNE-adducted hydrolysate (a) ESI spectrum (b) precursors of m/z 266 spectrum

Continuous Epitope Mapping by On-line Capillary Electrophoresis ESI Mass Spectrometry.

Yelena Lyubarskaya*, Yuriy M. Dunayevskiy*, Paul Vouros, Barry L. Karger.

Department of Chemistry, Barnett Institute, Northeastern University, Boston MA 02115.

Epitope mapping has been widely used for deciphering structure-function relationship of proteins and for rational drug design. Traditional strategies for linear epitope mapping involve proteolysis of an antigen followed by immunoprecipitation or immunoblotting and MW and/or sequence determination of the epitope.^{1,2} Mapping of antigenic determinants of proteins has been facilitated by automated synthesis of selected peptides and combinatorial libraries.^{3,4} Other strategies of epitope mapping involve recombinant DNA technologies⁵ and site directed mutagenesis.⁶ We propose linear epitope determination in solution by on-line CE-MS. This method utilizes high resolution of CE and the ability to determine molecular weight and structure by MS. The methodology is demonstrated using human β -endorphin (Fig. 1) and its monoclonal antibody as a model system. The experimental strategy is the following. The antigen is subjected to proteolysis and the resulting digest is analyzed by CE-MS. Then the digest and the antibody are analyzed individually by CE-UV/MS under binding conditions. When the mixture of the digest with excess amount of the antibody is run under the same conditions, an immunoreactive peptide (if present) is expected to disappear from its original place in the electropherogram.

CE-UV experiments were performed using a P/ACE 2100. CE capillaries were covalently coated with polyvinylalcohol (PVA). The MS experiments were performed on a Finnigan TSQ 700 triple quadrupole mass spectrometer. The CE capillary was 50 μ m ID and 35-40 cm in length. The liquid sheath was 1:3 mixture of the running buffer: MeOH at a flow rate of 1.5-2.5 μ L/min. The applied voltage was 20-25 kV, current 5-10 μ A. The analytes were injected hydrodynamically with injection volumes of 2-30 nL. Tryptic digestion was optimized by changing the reaction time, temperature and protein:enzyme ratio. The tryptic digest was obtained in 1 min at 37°C using trypsin: β -endorphin ratio of 1:100. It consisted of 6 specifically hydrolyzed peptides as was determined by CE-MS. Human β -endorphin (8 μ g/mL) and the monoclonal antibody ($\approx$ 0.5 mg/mL) were analyzed individually by CE-UV, at pH 6.2. Binding experiments were done as follows: the analytes were sequentially ("plug-plug") injected into a capillary, where they were electrophoretically mixed and incubated for 10 min under low voltage (1 or 2 kV). The injection of the antibody plugs of different length was followed by a constant 5 sec injection of β -endorphin in order for the latter to migrate through the plug of the antibody while interacting with it. The peak of β -endorphin disappeared from the electropherogram when sufficient amount of the antibody was added. "Plug-plug" experiments without on-line preincubation produced identical results, since the binding affinity of β -endorphin to its monoclonal antibody is very high ($K_d \sim 10^{-9}$ M) and the complex was formed almost instantaneously. Binding of the β -endorphin tryptic digest with its antibody was first performed at pH 5. Analytes were separated as cations and only five peptides of the digest were detected. Figures 2a and 2b represent extracted ion electropherograms of the peptides without and with the antibody injected, respectively (Fragments 1 and 2 were detected as doubly charged ions). Upon the injection of excess amount of the antibody (25 sec), peptide 1 disappeared from the electropherogram. For more acidic peptides that could be separated as anions similar set of experiments was performed using 20 mM TRIS/acetate buffer, pH 8.0. The peptides were detected in the negative ion ESI mode.

A new strategy for linear epitope mapping using on-line CE-ESI-MS is proposed. This technique can be applied to a high affinity system when the antibody-antigen complex is stable during the course of the CE experiment. The proposed solution phase methodology has the following advantages: nonspecific interactions with the absorbent surface are eliminated, steric hindrance is avoided, binding kinetics in

solution are fast. The technique is rapid, involves minimum manual labor and can be automated. The method is economical, as little as 10 μ L of the 0.7 μ g/ μ L AB solution were required for the complete set of experiments, and only 0.2 μ g of a digest was needed. With the proposed "plug-plug" injection procedure, only nanoliters of sample were consumed in each run. This technique can potentially serve as a useful approach for assaying small combinatorial libraries for tight binding affinity to biological targets.

New Chemistries for Probe Affinity-Mass Spectrometry

Adam H. Brockman, Ron Orlando

Complex Carbohydrate Research Center, and the Departments of Chemistry, Biochemistry and Molecular Biology

Introduction

Probe Affinity Mass Spectrometry (PAMS) is a technique which we developed in our lab to couple matrix assisted laser desorption/ionization (MALDI) mass spectrometry to affinity separations.[1] A drawback of the previous surface synthesis, however, was that only a relatively small number of analyte molecules could be covalently attached to a modified probe. Specifically, our previous coupling chemistry was based on forming a monolayer of antibodies. If one assumes that this process is 100% efficient, steric effects will only permit immobilization of ~80 femtomoles of a given binding moiety. This limitation has lead us to investigate new coupling chemistries for PAMS that will alleviate the need for monolayer limited binding, and thus permit more receptors to be attached. We discuss here the use of modified dextrans to chemically bind antibodies to the MALDI probe. The surface we have synthesized overcomes limitations of direct surface adsorption by creating a solvation friendly environment and by increasing the number of potential ligand binding sites. These functionalized surfaces can be used in a wide range of applications, especially in the area of biospecific interaction analysis.

Methods

- ◆ Dextran Monolayers were constructed using conventional means. Antibody immobilization was achieved by oxidizing the carbohydrate overlayer such that a surface rich in amine-reactive aldehydes was obtained. Binding of antibodies to this surface was achieved with an appropriate catalyst. Suitable buffers were employed in the ensuing separations to block unwanted binding from electrostatic interactions. In this experiment, a solution of 3 μ M egg albumin, 8 μ M cytochrome C, and 312 nanomolar (nM) gamma interferon, (γ INF), is applied to a probe tip functionalized with anti- γ INF mAb.
- ◆ The mass spectra shown here were acquired on a Hewlett Packard LDI 1700XP MALDI TOF mass spectrometer, using ethanolic sinapinic acid as a matrix. The instrument was operated at an accelerating voltage of 30 kV and an extractor potential of 9 kV.
- ◆ Gamma interferon was purchased from R&D systems and mAb was obtained from Dr. Tarleton of the University of Georgia. T500 dextran was purchased from Pharmacia and all other reagents were purchased from Fluka.

Results

The results of an experiment in which the cytokine γ INF was isolated from a mixture of 3 μ M egg albumin and 8 μ M cytochrome C using a dextran/antibody surface are shown in figure 1. The molecular weight of γ INF is 16kD. In figure 2 the results of a PAMS experiment using a typical DSP/antibody monolayer are presented for comparison in Figure 2. Figure 2 demonstrates that electrostatically bound antibody can obfuscate the cytokine signal on DSP/Antibody surfaces.

Conclusions

- ◆ Buffer salts are important to maintain protein activity.
- ◆ Buffer salts can suppress ion yield in MALDI.
- ◆ Too much washing/desalting can deplete the surface bound analyte.
- ◆ Charge-carrying surfaces should be avoided.
- ◆ A Good PAMS separation must be carefully optimized.

Introduction

The BIAcore (Biomolecular Interaction Analysis) instrument enables real time functional interaction studies of molecules. One interacting partner is covalently immobilised on a carboxymethyl-dextrane gold surface (sensor chip) and the other partner is passed over the surface via a flow injection system. The interaction is monitored directly on the chip in real time with a surface plasmon resonance detector (SPR). The quantities bound to the chip are the same order of magnitude as those necessary for mass spectrometric (MS) analysis. Therefore combining BIAcore and mass spectrometry is obvious. This can be done in two ways: 1. MS identification of the eluted molecules. 2. MS analysis of the compounds bound to the chip directly, as recently demonstrated by J R Krone¹. The purpose of this work is to establish the characterisation of molecules by nanoESI and MALDI-MS, eluted after specific interaction analysis by preparative BIA. The analytes used are human myoglobin (17 kDa) and theophyllinamine (308 Da)

Methods

Instrumentation: Esquire quadrupole iontrap (Bruker) coupled to a nanoESI source; Voyager Elite Mass Spectrometer (PerSeptive Biosystems), BIAcore 1000 (Pharmacia Biosensor). Materials and Samples: CN-stabilized human myoglobin, Anti-myoglobin antibody (monoclonal, 2F9.1); Theophyllinamine, Anti-theophyllinamine antibody; Buffer during immobilisation BIA HBS pH 7.4; Coupling buffer: 10 mM ammonium acetate pH 4.7; Buffer during elution. 10 mM ammonium acetate buffer pH 7; Desorption solution. 1% formic acid pH 2.1, MALDI-matrices: 2,5-dihydroxybenzoic acid (DHB) and α -cyano-4-hydroxycinnamic acid (4-HCCA). BIA Methods Antibody: 10-20 ng/mm immobilised on chip by amine kit, Analytes: Bounded with 40 μ l and 35 μ l for myoglobin (2 fM) and theophyllinamine (20 μ M); desorbed with 24 μ l desorption solution. A control for the theophyllinamine test made as the normal recovery test except that a blank chip is used instead of one with immobilised antibody. MS Methods: Myog-lobin sample preparation for MALDI: Samples were pooled, dried and desalted on a nanoscale RP-column² from c. 60 BIAcore cycles. Myoglobin was eluted from this column by 2 μ l 80% methanol / 5% formic acid directly into a DHB matrix droplet on the target and subsequently analysed in delayed extraction mode with a low mass gate set at 3800 Da. Theophyllinamine sample preparation for MALDI and nanoESI: Samples eluted from 5 and 10 BIAcore cycles were pooled, dried and dissolved in 2 μ l 0.1 % TFA; 1 μ l was used for MALDI analysis; 4-HCCA in acetone served as matrix. The same

¹Jennifer R Krone et al., BIA journal, vol 3, No 1, p 16-17, 1996

² Mathias Wilm and M. Mann, Anal. Chem. vol 68, p 1-8, 1996

amount of sample was dissolved in 2 μ l water and used for nanoESI iontrap analysis with isolation of the molecular ion at m/z 309.

Results

Mass spectra of myoglobin and theophyllinamine recovered from 60 and 5 BIAcore cycles respectively were obtained. The possibility for isolation and fragmentation of the theophyllinamine-MH⁺ ion gave further confirmation of the analyte identity. Mass spectra of the negative-control runs for theophyllinamine (recovered from 5 and 10 BIAcore cycles) showed no memory effects after 5 cycles but an intensive peak after 10. The corresponding BIA sensograms did not show binding to the chip.

Diskussion

Our experiments show that considerable losses take place during elution. In the case of myoglobin 1 ng per cycle is bound to the chip. The 60 cycles collected should thus contain 60 ng = 3.5 pmol myoglobin in a volume of 750 μ l. Comparison of the MALDI spectra of a reference myoglobin sample with that of the eluted myoglobin shows that only a small fraction of the eluted myoglobin is available for analysis. Although MALDI-MS cannot be considered quantitative, a rough estimate indicates c. 200 femtomole. The reasons for the losses are yet not clear. Dilution in the elution process, partially due to dead volumes in the system, as well as losses in the nanopurification procedure certainly play a role. Other factors contributing to the losses might be non-specific adsorption to surfaces. In the case of theophyllinamine it is currently unclear whether the analysed molecules are related solely to the antibody binding or also to memory effects. Nevertheless, the spectra show that mass spectrometry and surface plasmon resonance are equivalent in sensitivity to low mw molecules.

The BIAcore 2000 instrument with multi-channel facilities seems to offer an improvement because the eluates are more concentrated thus reducing losses due to non-specific adsorption. Another improvement could be a flow-system with reduced volumes, e. g. a shorter outlet for the elution. The mass spectra of the theophyllinamine control show memory effects in the BIAcore flow-system. The corresponding sensogram shows that no binding to the chip was detectable and that the carry-over must be elsewhere in the flow-system. These memory effects do not influence the BIAcore results, but can influence mass spectrometric analysis of the eluate

Conclusion

It is possible to analyse molecules by mass spectrometry after recovery from a BIAcore instrument. The number of cycles on the BIAcore necessary for subsequent mass spectrometric analysis increases with increasing molecular weight. In this case 60 cycles were necessary for a 17 kDa and 5 cycles for a 0.3 kDa analyte. On-line coupling of surface plasmon resonance requires optimisation of the BIAcore equipment. The origin of the memory effects for theophyllinamine is unclear and must be further investigated

STRUCTURAL IMMUNOLOGY BY MALDI/MS: EPITOPE DETERMINATION ON AIDS RELATED PROTEINS

Carol E. Parker, Sonja Trojak, and Kenneth B. Tomer

National Institute of Environmental Health Sciences
P.O. Box 12233
Research Triangle Park, NC 27709

There are a variety of approaches that have been used for the determination of the epitope on a protein recognized by a particular antibody, including X-ray crystallography (the most definitive methodology), NMR, immunoprecipitation of peptide fragments or combinatorial libraries of peptides, site-directed mutagenesis and antibody protection assays. We have incorporated mass spectrometric determination with antibody protection assays for the determination of epitopes on AIDS related proteins, in their natural conformation, recognized by monoclonal antibodies. Epitopes on proteins in their native conformation are called B-cell epitopes. They typically consist of 15 to 25 residues and are usually associated with immunoglobulin based antibodies (1). This is in contrast to T-cell epitopes which are linear sequences from unfolded peptides, such as the epitopes associated with MHC Class I and II molecules. In the protection assay approach to epitope determination (2), the protein is allowed to interact with an immobilized antibody. The affinity-bound protein is then subjected to a series of enzymatic digests, either in parallel or in series (3). The reaction product(s) still affinity-bound are determined using direct analysis by MALDI (4).

We have applied this approach to the determination of an epitope on the recombinant HIV proteins p24 and p26. Using a combination of Lys-C and/or trypsin digestions with carboxypeptidase or aminopeptidase digestions, the fine structure of the epitope can be determined. The figure shows the results of a carboxypeptidase cleavage after successive Lys-C and trypsin cleavages in A) and an aminopeptidase M digest of a tryptic digest. Only analytes that remain affinity-bound to the antibody are detected. In addition to the structure of the major antigenic determinant, information about the wider contact area between the antigen and the antibody and/or information about the nature of discontinuous epitopes can be obtained using this combination of techniques. For example, in the determination of the epitope on p26 recognized by the monoclonal antibody 13-102-100, residues 102-112 (HPVHAGPIAPG) were found to be the primary antigenic determinant. In addition two other sequences, residues 150-158, and residues 189-200, showed weaker affinity for the antibody. These latter sequences may either contain short sequences of a discontinuous epitope or be involved in the wider contact area. The results of these experiments also shed light on the results of a gene-deletion study involving the same antibody in which the epitope could not be determined (5).

MALDI Mass Tracer Methods Based on the Avidin-Biotin Interaction

David C. Schriemer, Liang Li
University of Alberta, Chemistry Department
Edmonton, Alberta, Canada

The avidin-biotin interaction is incorporated into a great number of areas in biology and biochemistry. The usefulness of this system lies in the extremely strong interaction between the avidin glycoprotein and biotin ($K_d \sim 10^{-15}$). A wide variety of avidin-related products and biotinylation reagents are commercially available, geared to the many different applications of this system.

This work incorporates the existing avidin-biotin chemistry into a mass spectrometric technique that can be used to monitor the activity of biotinylated biomolecules in complex systems with minimal sample handling (mass tracer method). Avidin products immobilized on small agarose beads can be used to extract biotinylated species from a mixture. The resulting bound complex can be incorporated into a MALDI experiment for a fast identification of the biotinylated species [1-3]. Samples can be eluted from the beads onto the MALDI probe tip in the following way:

1. A matrix layer is deposited on the probe from an acetone solution.
2. A small amount of the beads/complex is deposited on this layer.
3. An optional second matrix solution is applied to improve the MALDI preparation and possibly aid in elution.
4. After drying, the beads are removed.

Upon removal of the beads, the probe tip can be presented for analysis. Various biotinylation reagents were investigated for their applicability to this technique, using the neuropeptide bradykinin (MW 1060.23 amu) as a test compound. This peptide was biotinylated with three different biotinylation reagents, each with a different spacer arm length (between biotin and the peptide). Purification of the biotinylated peptide from the free peptide was undertaken with immobilized tetrameric avidin/agarose. It was found that long spacer arms are necessary to ensure strong binding with the avidin. Figures 1A,B demonstrate the purification of biotinylated bradykinin with a long-chain spacer arm of 29 angstroms.

Figure 1

This spacer arm contains a disulfide, which can be cleaved on the probe with the application of dithiothreitol to the bead slurry. This generates a characteristic mass shift (Figure 1C) that can be used to confirm the identity of the peptide.

Other biotin extraction products in addition to tetrameric avidin/agarose beads were applied to the purification of a sample of biotinylated bovine insulin (Figure 2A). The results are displayed in Figure 2B (tetrameric avidin/agarose), Figure 2C (biotin/agarose) and Figure 2D (monomeric avidin/agarose). Both the tetrameric avidin/agarose and the conjugated avidin:biotin/agarose approaches were very successful in the purification of this sample. The monomeric product proved to be more sensitive to washing conditions, demonstrating a variation in the binding constants for the various forms of biotinylated insulin.

Figure 2

This procedure is capable of isolating and analysing low femtomoles of a biotinylated species from complex solutions (i.e. from tryptic digestions). Furthermore, it is applicable to a wide range of MALDI matrices and matrix preparations, and does not require harsh elution conditions incompatible with MALDI.

Epitope mappings of Maillard reaction products using LC/ESIMS

Kazuo Hirayama,¹ Uno Tagami,¹ Naoyuki Yamada,¹ Reiko Yuji,¹ Kazuyoshi Noguchi¹ and Toshimitsu Niwa²

¹ Central Research Laboratories, Ajinomoto Co., Inc., 1-1 Suzuki-cho, Kawasaki-ku, Kawasaki 210, JAPAN

² Department of Internal Medicine, The Branch Hospital, Nagoya University School of Medicine, 1-1-20 Daiko-minami, Higashi-ku, Nagoya 461, JAPAN

Introduction

Epitope mapping by mass spectrometry is very promising for the determination of the epitopes in antigens and characterization of antibodies. This paper reports the epitope mapping of the Maillard reaction products of lysozyme and glucose using LC/ESIMS.

The reaction between reducing sugars and amino groups in amino acids or proteins is called Maillard reaction. This reaction in foods caused by heating has long been studied. Maillard reaction occurs also in living bodies, and it has come to be studied with a correlation between the age and the severity of diabetes. Reaction pathway of Maillard reaction is very complicated, and it produces a complex mixture of a large number of compounds. First, a Schiff base is produced by the adduct of the aldehyde group in sugars to the amino group in amino acids or proteins, then it rearranges to a more stable ketoamine, called Amadori product. Reactive intermediates are formed by enolization, dehydration, cyclization, fragmentation, and oxidation. Ultimately, these intermediates are led to stable advanced glycation end products (AGE).

The AGE produced by amino acids and sugar have been investigated for a long time. As a result, some of these structures have been determined. However, the structure of AGE derived from proteins have not been determined, because these structures have been considered to be very complicated. We characterized the structure of AGE of lysozyme and glucose using anti-AGE antibody column chromatography, LC/ESIMS, and ion trap mass spectrometry.

Methods

- 1) Hen egg lysozyme is incubated with glucose at 50 °C for 50 days.
- 2) Glycated lysozyme is reduced and carboxymethylated, and then digested with chymotrypsin.
- 3) Monoclonal antibody against AGE-hemocyanin is produced by the immunological method.
- 4) Only the peptides with AGE moiety are isolated from the digests by the affinity column chromatography using its monoclonal antibody.
- 5) The isolated peptides are then subjected into LC/ESIMS, and molecular weights of AGE-peptides are determined.
- 6) Structure of AGE moiety is investigated by MSⁿ study.

Results

Table 1 shows the antibody-binding peptides produced by chymotryptic digestion of RCM-AGE lysozyme observed by LC/ESIMS. All the peptides bound to the anti-AGE antibody contain glycated arginine residue. It was revealed that the monoclonal anti-AGE-hemocyanine antibody recognizes the glycated arginine residue in AGE moiety. It was also revealed that all the arginine residues were glycated and that glycation on arginine residue occurred with two molar dehydroxylation. Protonated molecular ions of

the AGE peptide were subjected to MSⁿ experiments.

In order to determine the structure of the AGE moiety, we compared MSⁿ spectra to those of S12, a product by the reaction of N α -benzoylarginine amide (BzArgNH₂) and 3-deoxyglucosone, whose structure already has been determined.¹⁾ Figure 1 (a) and (c) show MS/MS spectra of S12 and glycated peptide R*GY from these (M+H)⁺. In these two spectra, the same product ion was observed at *m/z* 256.1. Figure 1 (b) and (d) show MS³ spectra of S12 and glycated peptide R*GY from a product ion at *m/z* 256.1. It can be concluded that the structure of glycated arginine residue in R*GY is the same as in S12. This is considered to be the epitope of AGE recognized by the antibody.

Determination of Beta-Agonists in Bovine Urine by Immunoaffinity Extraction-LC/LC/MS/MS

Jenny Cai and Jack Henion

Analytical Toxicology, Cornell University, 927 Warren Dr., Ithaca, NY 14850

Introduction

Several beta-agonist drugs have been found to be illegally used as growth promoters in livestock. Incidences of human food poisoning where beta-agonists were implicated have been reported (1-3). The concentrations of beta-agonists in the urine of treated animals usually drop to part per billion levels shortly after the cessation of administration (4,5). Highly sensitive analytical methods are required for reliable determination of these compounds present in complex matrices (6-9). This presentation demonstrates the potential of on-line immunoaffinity extraction (IAE) and coupled-column packed-capillary liquid chromatography-ion spray tandem mass spectrometry for multiresidue determination of beta-agonists in bovine urine using an automated column switching approach.

Experimental

The instruments used in this study include a Sciex API-300 triple quadrupole mass spectrometer, an automated column-switching system (Integral™ microanalytical workstation, PerSeptive Biosystems) in combination with an external pump (ABI 140A solvent delivery system, Applied Biosystems, Inc.) to deliver the HPLC mobile phases for gradient elution. The mass spectrometer was operated in the selected reaction monitoring (SRM) mode. Three columns were involved. The immunoaffinity extraction (IAE) column was a 2.0-mm-i.d. self-packed guard column cartridge from Upchurch Scientific packed with protein G packing from PerSeptive Biosystems. Antibodies specific for clenbuterol (Central Veterinary Laboratory, UK) were noncovalently bound to the protein G column. The trapping column was a self-packed 1.0-mm-i.d. guard column packed with 30-40-μm Pellicular Cg (Upchurch Scientific). The analytical column was a 320-μm-i.d. packed-capillary HPLC column packed with 3-μm Spherisorb C₁₈ (LC Packings) with the flow rate maintained at 4 μL/min flow rate. The automatic sample preparation and analysis processes can be divided into three steps: priming the protein G antibody column by noncovalently immobilizing antibodies followed by loading PBS-diluted bovine urine onto the IAE column; desorbing bound analytes from the IAE column and transferring onto the trapping column; and finally SRM-LC/MS of the preconcentrated beta-agonists.

Results and Discussion

Bovine urine spiked with clenbuterol, mabuterol, mapenterol, methyl-clenbuterol, and tolbuterol was diluted with phosphate-buffered saline and was analyzed using the on-line SRM/IAE/LC/LC/MS approach. Figure 1 shows the corresponding chromatograms of a bovine urine spiked with the five beta-agonists at 50 ppt levels. Calibration curves were constructed for clenbuterol, mabuterol, methyl-clenbuterol, and mapenterol using tolbuterol as the internal standard. The quantitative data showed good linear response within the concentration ranges studied (Figures 2 and 3). Lower levels of quantitation were 50 part per trillion (ppt) for clenbuterol and methyl-clenbuterol, 20 ppt for mabuterol, and 10 ppt for mapenterol. The bovine renal clearance is described for clenbuterol. Figure 4 shows the semi-log plot for the urinary elimination of clenbuterol in a calf treated orally with clenbuterol at 20 μg/kg daily for three days as indicated by arrows. The urinary half-life of clenbuterol in the calf was determined to be 42.2 hours. The concentration of clenbuterol dropped to 81 ppt 15 days after the cessation of the administration. Ten random slaughterhouse calf urine samples were analyzed using the described system. All of them tested negative for the targeted beta-agonists.

Acknowledgments

We acknowledge Advanced Bioanalytical Services, Inc. for the financial support, PE Sciex for the loan of the API-300 triple quadrupole mass spectrometer, PerSeptive Biosystems for the loan of the Integral™ microanalytical workstation, LC Packings for the donation of packed capillary columns, Dr. J. Hurley and A. Vonderchek of the College of Veterinary Medicine at Cornell for the assistance with the clenbuterol administration and renal clearance study, Dr. M.-P. Montrade of Ministère de l-

Agriculture, France, Dr. J. van der Greef of the Center for Bio-Pharmaceutical Sciences, The Netherlands, and Dr. L. Leyssens of the Dr. L. Willems-Instituut, Belgium for the donation of several beta-agonist standards, Dr. M.J. Sauer of Biochemistry Discipline, UK for the donation of some of the clenbuterol antibodies used in this study, and Dr. A. Chaudhry at the USDA for the slaughterhouse random calf urine samples. We thank Dr. Tim Wachs for the invaluable technical support.

Bioaffinity Characterization Mass Spectrometry (BACMS) of the Human src SH2 Domain Protein

James E. Bruce,¹ Ljiljana Pasa-Tolic,¹ Paula Lei,¹ Richard D. Smith,¹ Steven A. Carr,² Damien Dunnington,² William Prichett,² Dennis Yamashita,² Jack Yen,² Ed Applebaum,² and Seth Fisher²

The developments and applications of electrospray ionization-Fourier transform ion cyclotron resonance mass spectrometry (ESI-FTICR-MS) for the characterization of noncovalent complexes of target biomolecules and combinatorial type libraries, an approach which we call bioaffinity characterization mass spectrometry (BACMS), have been previously reported. This approach relies on the ultrahigh resolution and mass measurement accuracy of FTICR-MS and high sensitivity attainable with selected-ion accumulation techniques to directly detect noncovalent complexes from mixture solutions. Previous work has demonstrated a direct correlation of observed peak intensities with solution phase complex stability, under appropriately gentle interface conditions. This work examines the use of this technique with a model system of significant biological relevance, the SH2 - phosphoprotein system. Several phosphopeptides are combined with the SH2 domain of the human src protein and the resulting solutions directly analyzed by ESI-FTICR-MS. In addition to the comparison with known solution phase binding constants, several interesting features of the SH2 system are presented. The enhanced capabilities of FTICR-MS produce ultrahigh resolution and mass measurement accuracy on the complexes and individual components and reveal the existence of two proteins that differ by only 13 Da and yet vary substantially in binding affinities.

Figure 1 illustrates the ESI-FTICR mass spectrum of the SH2 domain of the human src protein under noncompetitive binding conditions with two phosphopeptide ligands. The high resolution data presented by the ESI-FTICR-MS allows the observation of the two species with masses differing by only 13 Da. This 13 Da heavier species is most likely an artifact of the expression system used for protein synthesis, however this observation demonstrates the specificity that can be observed, since both ligands preferentially bind with the lower m/z species. Also discussed as part of this presentation are some potential complications that can arise from the mass spectral bioaffinity analysis by comparison of ligand intensities resulting from dissociation of the complexes. Variations in proton and sodium cation affinity among the various peptides illustrates some interesting chemistry, but prevents direct correlation between dissociated ligand intensity and binding constants. The effect observed on the relative complex peak heights with variation in the concentration ratio of the protein and ligands is also presented. Good agreement between the observed relative complex peak heights obtained under competitive binding conditions and the known relative binding constant is observed, as is shown in Table 1. Finally, the present results again show that biologically relevant non-covalent associations can effectively be studied using ESI-MS under appropriate solution and ESI interface conditions.

2. Department of Chemistry, Harvard University, Cambridge, MA 02138

It is now well established that, given proper experimental technique, a wide range of non-covalent complexes in solution can be transferred into gas phase using electrospray ionization (ESI) and studied by mass spectrometric (MS) methods. Last year our laboratory first reported a method of screening combinatorial libraries by detecting protein-ligand complexes based solely upon the use of ESI-MS, i.e. Bioaffinity Characterization Mass Spectrometry (BACMS)^{1,2}. The initial work demonstrated a good correlation between solution binding constants with gas phase ion intensity for bovine carbonic anhydrase II (BCAII) and libraries of benzenesulfonamide inhibitors.

In this work, we compare the binding constants (K_b) in solution with the dissociation energy (E) in gas phase for BCAII and a library of eight benzenesulfonamides with para-substituted amino acid residues. K_b was obtained by standard Scatchard method and E was determined by SORI-CID using a 7 Tesla FTICR-MS with an external ESI source. Under the CID conditions, the noncovalent complex (10+ charge state) was dissociated into BCAII (10+) and an inhibitor molecule. The binding constants of these inhibitors in solution differ by over two orders of magnitudes. No direct correlation between the binding constants and the gas phase dissociation energy (Figure 1A). However, the dissociation barriers were found to be related to the length of the amino acid tail of the inhibitors (Figure 1B). This was supported by a linear relationship between E and the number of glycine residues for poly-glycine inhibitor ladders. Interestingly, E was inversely related to the calculated total hydrophobicity (see Figure 1B) of the amino acid tail (within a group of inhibitors having the same number of amino acid residues). These observations indicate that the interactions *in vacuo* are related to the contact surface area between the protein and the ligand, which should increase as the length of an inhibitor tail increases. It can be expected that when the solvent is removed, the hydrophilic regions of the protein and the ligand should also contribute to the binding affinity as well as the hydrophobic portions. Our observations thus reflect subtle changes in the noncovalent interactions of enzyme-inhibitor complexes from the solution to the gas phase.

If the various complexes have significant differences in stability *in vacuo*, proper conditions would be required to transfer these complexes into gas phase. This is generally important when mass spectrometry is used in studying competitive binding in solution, such as in the case of BACMS, where significant differences in transfer efficiency of the intact non-covalent complexes into the gas phase would be problematic. Figure 2 was obtained by electrospraying a 35 μ M of BCAII solution with 10 μ M (each) of six of the inhibitors in 10 mM NH_4OAc using a triple quadrupole mass spectrometer (Finnigan MAT, TSQ 7000) equipped with a heated capillary interface. At a capillary temperature of 90 °C (Figure 2A and its inset), the complex of BCAII with three of the stronger binding inhibitors appear correspondingly as peaks of higher intensities in mass spectra. However, a much different pattern was obtained when the capillary temperature was increased to 110 °C (Figure 2B and its inset). The ion intensities for the complexes were greatly decreased with respect to those for BCAII, and a new peak at 2962 m/z became evident, corresponding to the most stable complex from the inhibitor with four amino acid residues (see Figure 1), in a good agreement with the CID experiments. These experiments contribute to the understanding of the bioaffinity characterization mass spectrometry method, and provide fundamental insights to the difference in interactions between proteins and ligands in the gas phase and in solution.

Studying Drug Binding to the Noncovalent Tat Peptide-TAR RNA Complex by ESI-MS

Kristin A. Sannes*, Joseph A. Loo, Peifeng Hu, Hsiung-Yau Mei and David Mack

Division of Warner-Lambert Company
2800 Plymouth Road
Ann Arbor, MI 48105

Electrospray ionization mass spectrometry (ESI-MS) has shown promise for investigating noncovalently-bound biological complexes. To assess the usefulness of ESI-MS for studying noncovalent interactions, we have examined the complexation of Tat peptide with TAR RNA and the effect of targeted drug inhibitors of this complex.

Replication of the human immunodeficiency virus (HIV) requires the complexation of the viral transactivator protein, Tat, to the transactivation responsive element (TAR), which is located at the 5'-end of mRNA. TAR is a small RNA hairpin consisting of a stem-loop structure with a pyrimidine bulge. Tat protein contains an arginine-rich region that is believed to interact specifically with the TAR RNA pyrimidine bulge. Nonspecific binding of Tat protein can occur at other places on the TAR RNA. Because the complexation of Tat protein to TAR RNA is critical to the HIV replication, drugs that interfere with this complexation might inhibit HIV replication.

ESI-MS provides an ideal method to determine drug binding stoichiometry and potentially, binding constants, for biochemical systems. ESI-MS has been used to examine the action of various compounds on the Tat peptide (40 amino acid residues, M_r 4644)-TAR RNA (31-mer, M_r 9941) complex. The aminoglycoside antibiotics, neomycin and streptomycin, are known to specifically bind to RNA molecules and might interfere with the complexation of Tat with TAR RNA. It has been proposed that a stem-loop structure like that found in TAR RNA is necessary for binding of the antibiotics.[1] Calnan et al. showed that Arg₉ binds TAR with the same affinity and specificity as the Tat peptide.[2] Thus, Arg₁₁ might effectively compete with the Tat peptide for binding TAR.

Titration of the Tat peptide-TAR RNA complex with these three compounds showed that all three bind to the complex as well as to TAR RNA itself. Neomycin and Arg₁₁ were effective in inhibiting the complexation of Tat/TAR. Streptomycin did not appear to dissociate the Tat/TAR complex at the concentrations studied.

Positive and negative ion mode ESI-MS give different results for the titration of the Tat/TAR complex with the drugs. The negative ion mode results for the titration of Tat/TAR complex with Neomycin and the titration of TAR with Neomycin agree with gel shift assay studies.[3] Both studies indicate that Neomycin binds to the Tat/TAR complex and then the Neomycin/Tat/TAR complex dissociates to form the 1:1 Neomycin/TAR complex. In addition, both the gel shift assays and the ESI-MS results indicate that multiple Neomycin molecules can bind to TAR.

Further studies are planned to determine why the ESI-MS results depend on the polarity. The action of other compounds on the complexation of Tat peptide and TAR RNA will be studied as well.

Figure 1. Representative ESI mass spectrum of the titration of a 1:1 Tat/TAR complex with Arg₁₁ (positive ion mode). At a 2:1 ratio of Arg₁₁ to complex, the 1:1 Arg₁₁/TAR complex dominates the 1:1 Tat/TAR complex. A 2:1 Tat/TAR complex is observed as well even though only the 1:1 Tat/TAR complex is present initially.

Figure 2. Plot of the titration of a 1:1 Tat/TAR complex with Arg₁₁ (positive ion mode).

Determination of the sites of interaction between the formyl peptide receptor and its ligand formyl-met-leu-phe. John S. Mills, Heini M. Miettinen, Edward Dratz, David Barnidge, and Algirdas J. Jesaitis. Department of Chemistry and Biochemistry, and Department of Microbiology, Montana State University, Bozeman MT, 59717.

Membrane receptors are involved in a number of critical functions of cells, especially signal transduction. However, X-ray crystallography and NMR have generally failed with very few exceptions to determine the structures of integral membrane proteins. As such, the understanding of the structure and function of these proteins remains a major unsolved problem in biochemistry. Thus, new alternative methods which provide structural information on these proteins are needed. We are developing a method which we call site directed photoaffinity scanning.

G protein-coupled receptors belong to a receptor super family based on conserved amino acids and a conserved pattern of hydrophobic residues which are thought to be responsible for their unique transmembrane topology of seven membrane-spanning domains. The phagocyte chemotactic receptors, the formyl peptide receptor (FPR), C5a receptor (C5aR), platelet-activating factor receptor (PAF-R), and interleukin-8 receptor (IL8-R) are all G protein-coupled receptors. The best characterized of these is neutrophil FPR which binds *N*-formyl peptides, such as *N*-formyl-met-leu-phe (fMLF). We have synthesized several photoaffinity analogues of fMLF which will place photoaffinity labels at different positions on the molecule.

1. Phenylalanine was substituted with the photoaffinity analogue benzoylphenylalanine.
 2. The leucine was replaced with benzoylphenylalanine.
 3. The formyl group was replaced by a diazopyruvyl group.
- The analogues were derivatives of fMLFYK (1 or 2) or fMLFNleYC (3). The lysine was tagged with fluorescein hexanoate and the cysteine with fluorescein iodoacetamide.

All three analogues bind to FPR with high affinity and are displaced by fMLF (figure 1).

Figure 1. Binding of 10 nM Fluorescein labeled fMLF analogues to FPR expressed in CHO cells was determined in the presence or absence of 10 μ M fMLF using FACSscan analysis. % bound represents specific binding displaced by fMLF. Binding to fNleLFNleYC-Fluor was set as 100%.

fMBenzoylPheYK-Fluorescein can be specifically photocrosslinked to a protein in CHO cells expressing wild type FPR that elutes just before rhodopsin on a HPLC gel filtration column. Labeling is inhibited in the presence of 10 μ M fMLF. Tandem anion exchange (AX500) with the gel filtration column provides a much cleaner preparation of the fMBenzoylPheYK-fluorescein labeled protein and the peak fractions immunoblot with anti-FPR antibodies. Approximately 80 pMoles of photocrosslinked FPR was obtained from 2×10^6 CHO transfectants. This should be sufficient for determining the site of photocrosslinking of proteolytic or CNBr cleavage fragments of FPR by MALDI mass spectroscopy. Placing 16 pMoles of fMBenzoylPheYK-fluorescein bound to anti-fluorescein Sepharose directly in the mass spectrometer has allowed MALDI mass spectroscopy. Analysis of this peptide in the reflectron mode allowed a "fingerprint" of this peptide to be obtained with *m/z*'s of 930.5 (FYK-hexanoyl fluorescein), 783.3 (YK-hexanoyl fluorescein), 620.0 (K-hexanoyl fluorescein) and 557.5 (FYK-hexanoate) (figure 2). The peptide was cleaved with CNBr in 80% TFA at concentrations of 0.4, 2, and 10 mM. Maximal cleavage required 10mM CNBr, with the major observed mass of 1180, the expected mass of BenzoylPheYK-fluorescein. Thus it should be possible to use these antibodies to isolate the crosslinked proteolytic or CNBr fragments of FPR followed by direct analysis of these fragments bound to anti-fluorescein Sepharose.

Supported by the Rocky Mountain Chapter of the Arthritis Foundation and the Harmon Foundation.

Reflectron Analysis of fMBpaFYK-hexanoyl Fluorescein bound to Anti-FITC Sepharose

Figure 2. 16 pMoles of fMBpaFYK-hexanoyl Fluorescein bound to Anti-FITC Sepharose was applied to the sample plate and saturated α -Cyano-4-hydroxy cinnamic acid in 0.1% TFA, 50% Acetonitrile was applied directly to the Sepharose beads and the sample was analyzed by MALDI-TOF mass spectrometry.

Study of non-covalent enzyme-cofactor and enzyme-inhibitors complexes by ESMS

Alain Van Dorsselaer¹, Noelle Potier¹, Patrick Barth², Denis Trisch² and Jean-François Biellmann²

¹ Laboratoire de spectrométrie de masse bio-organique, URA 31 CNRS-Université Louis Pasteur, Strasbourg, France. ² Laboratoire de chimie organique biologique, URA 31 CNRS-Université Louis Pasteur, Strasbourg, France.

Introduction : Recent publications have reported the use of electrospray mass spectrometry for the characterization of noncovalently-bound complexes. If several parameters are carefully controlled (buffers, pH, pressure and collisional activation in the atmosphere/vacuum interface), non-covalent interactions can be preserved during the ionization-desorption process. We have used ESMS for the study of non-covalent complexes formed between an enzyme, the aldose reductase (AR), its NADP⁺ cofactor and five inhibitors, in order to detect possible differences in their affinities or specificities.

Experimental : All studies were performed on a VG Bio-Q (Fisons, Manchester, UK) triple quadrupole upgraded by the manufacturer so that the source and the first quadrupole had Quattro II performances (mass to charge range 4000) and the second quadrupole had an m/z range up to 8000. The extraction cone voltage (Vc), which controls the kinetic energy of the ions in the first stage of the atmosphere-vacuum interface, ranged from 20V to 120V depending on the application. Samples were dissolved in a 25 mM AcONH₄ buffer, pH 7 at a final concentration of 10 pmol/μl and were continuously infused into the ion source at a flow rate of 4 μl/min.

Results : ESMS was used to investigate the AR molecularity in diluted solution (10⁻⁵ M) and to study AR-NADP⁺ and AR-NADP⁺-inhibitor non-covalent complexes. Yeast alcohol dehydrogenase, which is known to form homotetramer in solution, was used as a reference protein in order to verify that our experimental conditions were compatible with the detection of intact protein-protein interactions if they existed in solution. Valuable information concerning the AR molecularity, the specificity, affinity or interaction mechanism of AR inhibitors was deduced from the obtained mass spectra. 1) A monomer/dimer equilibrium was observed for the AR apoenzyme while the holoenzyme appeared as a monomer. These results were consistent with crystallographic data revealing that local structural changes were induced by the binding of the cofactor to AR which destabilize the dimer. 2) the stoichiometry of the ternary AR-NADP⁺-inhibitor non-covalent complexes was shown to be 1:1:1. A single specific site has been detected for the cofactor and for the inhibitors. 3) Structural information was obtained for the AR-NADP⁺ complex. CID-MS-MS experiment revealed the high stability of the complex in the gas phase since fragmentations of covalent bonds occurred before the dissociation of the non-covalent complex. These fragmentations revealed that the adenosine diphosphate part of the NADP⁺ interacts more strongly with AR than the nicotinamide moiety. 4) the five inhibitors studied bind to the enzyme only if the cofactor first bound to its site. The AR apoenzyme has no affinity for these inhibitors. 5) The stability of the AR-NADP⁺-inhibitors complexes in the gas phase was also determined and correlated with their stability in solution. 6) Finally, the specificity of the five inhibitors was evaluated in order to compare their ESMS data with their known side effects.

Three parameters were shown to be important to obtain good results : an optimal pressure value in the first stage of the atmosphere/vacuum interface, an optimal Vc and an appropriate m/z range. Vc had in particular to be high enough to strip away solvent molecules and to enable the detection of low charge states but not too high in order to maintain the weak non-covalent interactions.

Conclusion : These results have shown that specific non-covalent interactions between an enzyme (AR), its cofactor and its inhibitors can be characterized by ESMS, indicating that a protein can be desorbed and maintained in the gas phase in a form very close to its native conformation. The use of ESMS for the study of non-covalent interactions in solution is still difficult and requires very cautious interpretation. But the potential of the method is very attractive and ESMS might provide a rapid and sensitive method for the screening of potential drugs or for the identification of candidate compounds displaying high binding affinity to a target biomolecule.

left: ES multiply charged ion mass spectra showing the molecularity of non-covalent complexes in solution. (a): for yeast alcohol dehydrogenase, only five ions are detected corresponding to a mass of 147523 Da (tetramer); (b): for AR apoenzyme, two series of ions are detected (measured masses : 35775 and 71549 Da). No NADP⁺ has been added and a dimer is clearly detected. (c): for AR holoenzyme reconstructed by addition of 1 eq. of NADP⁺ to the apoenzyme (measured mass : 36512 Da). No dimer observed. **Right :** (a) : ES mass spectra showing ion with 12 charges for a 10 μM AR apoenzyme solution. (b) : The 12⁺ ion remains unchanged after addition of 1 eq. of an inhibitor (the tolrestat). (c) : The addition of 1 eq. of NADP⁺ to the previous solution leads to the detection of the ternary non-covalent AR-NADP⁺-tolrestat complex.

Study of Non-Covalent Interactions and H-D Exchange using Micro Electrospray

Carol Robinson, Stuart Jarvis, Evonne Chung, Christopher Hughes and Brian Green,
Oxford Centre for Molecular Sciences, South Parks Road Oxford OX1 3QT and
Micromass Ltd.,
3 Tudor Road, Altrincham, Cheshire, WA14 5RZ.

Introduction

Low flow rate electrospray sources have been described previously^{1,2} in particular for the sequence analysis of peptides. In this study we investigate the use of micro electrospray for studying the non-covalent interactions of intact proteins from their native state. These studies are often complicated by dissociation of protein-ligand complexes in the gas phase and 'gentle' interface conditions are required for their observation. The low voltages applied to the micro electrospray capillary, the reduction in drying gas pressure and absence of nebuliser gas suggest that the micro electrospray source provides a much 'gentler' environment for their study.

Hydrogen exchange of proteins is generally carried out by continuous flow injection over several hours but suffers from large sample requirements and assumes no change in the conditions of the electrospray interface during measurement. The stability of the ion beam derived from the electrospray needle enables measurements to be carried out over several hours without changing the sample capillary.

Method

The micro electrospray interface used in this work was a Micromass NanoflowTM probe fitted to either a Quattro II or Platform II mass spectrometer. This probe, used in place of the standard electrospray probe and counter electrode, was positioned to spray directly at the sample cone. Protein samples were introduced from borosilicate glass capillaries which were pre-pulled to give a tip internal diameter of either 1 or 2 μm and gold coated for electrical conductivity. Between 1 and 5 μL of protein sample was loaded into a fresh capillary which was then inserted into the NanoflowTM probe. The tip was maintained at a potential of 1.5 kV and a constant pressure of up to 20 psi nitrogen applied to achieve a stable flow in the range 10 nL/min to 30 nL/min.

Results

SH2 domains are thought to have a role in signal transduction from cell surface receptors. Their interactions are dependent upon tyrosine phosphorylation of ligands. Using micro electrospray the interaction between an equimolar solution of phosphorylated peptide EPQpY EEPIP YI and SH2 measured K_D $4 \times 10^{-6} \text{M}$ was investigated. Despite the relatively high dissociation constant measured for this system the SH2 domain remained completely bound to the peptide, figure 1. No free SH2 protein was detected under these conditions. This is in contrast to results obtained from conventional electrospray where equimolar solutions yield a mixture of free and bound protein in the electrospray mass spectrum.

The use of hydrogen exchange measurements in mass spectrometry represents an important breakthrough in obtaining 3D structural information from proteins. The bovine milk protein α -lactalbumin binds both Ca^{++} and Na^+ and is stabilised by metal binding. The

micro electrospray probe enables the hydrogen exchange properties of protein samples placed in the to be measured directly without sampling the exchanging solution. Using this technique 2 μL of 10 pmole/ μL solution of bovine α -lactalbumin was analysed from H_2O for 2 hours from the same borosilicate capillary. Results from micro electrospray measurement of hydrogen exchange were found to be consistent with those measured previously³.

Figure 1: Micro electrospray spectrum of *Fyn* SH2 with its specific binding peptide showing the molecular weight of the intact protein-peptide complex without dissociation

Conclusions

The micro electrospray technique demonstrates three major advantages for hydrogen exchange measurements and for the study of non-covalent protein-ligand interactions. Reduction in sample consumption - one hundredth of the sample required for micro electrospray hydrogen exchange measurements compared with conventional electrospray. The technique was found to be less sensitive to the presence of salts and buffers in the sample solution. Increased quantities of protein-ligand complexes were detected using the micro electrospray technique compared with those obtained by conventional electrospray suggesting that micro electrospray provides a gentler environment for their study.

Probing non-covalent complexes of tyrosyl phosphopeptides and an SH2 domain by ESI MS

Evonne W. Chung, Craig J. Morton, Terry D. Mulhern and Carol V. Robinson.
Oxford Centre for Molecular Sciences, South Parks Road, Oxford OX1 3QT.

Introduction

Electrospray ionization mass spectrometry (ESI MS) has developed into a powerful technique in its applications to structural biological and, more recently, molecular recognition processes. This gentle ionization method has allowed the study of non-covalent systems such as receptor-ligand, enzyme-substrate, DNA oligonucleotide and DNA-drug complexes.

In this work, the formation of high-affinity non-covalent complexes between *fyn*-SH2 and its two tyrosyl phosphopeptides was studied by ESI MS. The *fyn*-SH2 domain has an ionic pocket which recognises phospho-tyrosine (*pY*) residue and a hydrophobic pocket for the insertion of an isoleucine residue^{2,3}. It forms complexes with a specific binding peptide (SBP) (EPQpYEEIPIYL) with $K_d = 4\mu\text{M}$ and a tail peptide (TP) (ATEPQpYQPGEN), $K_d = 40\mu\text{M}$. Complexation with a dephosphorylated form of the specific binding peptide was also investigated.

Results and Discussion

All three peptides were shown by ESI MS to form complexes in their equimolar solutions with *fyn*-SH2. Consistent with their solution binding affinities, the highest amount of intact complex was observed for SBP (Fig. 1). This qualitative agreement with solution binding constants was further demonstrated by a competitive binding experiment between SBP and TP for *fyn*-SH2. It was shown that *fyn*-SH2 binds selectively to SBP (Fig. 2). A similar competitive experiment was also carried out between SBP and the dephosphorylated SBP. In the resulting mass spectrum, SBP-bound complex was detected as the only complex observed in the gas phase (Fig. 3). These results imply that both the *pY* residue and the I residue three residues apart are important for the formation of high-affinity complexes.

pY and I were used to examine the binding of amino acids to the binding pocket of *fyn*-SH2 compared with those of the peptides. Equimolar solutions of the individual amino acids with *fyn*-SH2 has shown a very small amount of the *pY*-bound complex, but no binding between the protein and I. With a 10-fold excess of the amino acids, no I-bound complex was detected, but a stronger signal for the *pY*-bound complex was observed, together with a small amount of the non-specific doubly-bound complex. When SBP was added to the *pY*-bound complex in the equimolar solution, displacement of the *pY* together with binding of SBP to *fyn*-SH2 was observed. The absence or low intensity of complexes with amino acids alone and results of the displacement reaction indicate that for high-affinity binding *fyn*-SH2 requires interactions with the phosphopeptides in sites other than the binding pockets. Ionic interactions are also better preserved than hydrophobic interactions in this system.

Introduction

Ras protein is a regulatory guanine nucleotide binding protein that serves as a signal transducer controlling cell proliferation and differentiation. Ras protein has GTPase activity. It can exist in two interconvertible states in the cell; GDP-bound form (Ras-GDP; inactive) and GTP-bound form (Ras-GTP; active). Only the active form, Ras-GTP, can bind with a targeting protein, such as Raf.

This paper reports the mass spectrometric characterization of Ras protein in both states by the combination of chemical modification with the sample amount of less than 1 nmol. A slowly hydrolyzing GTP analogue, guanosine-5'-(β,γ -imido)-triphosphate (GppNp) was used instead of GTP in this study.

Methods

1. Chemical modifications (glycinamidation of carboxyl groups, amidation of amino groups, acetylation and iodination of Tyr residues) of Ras protein both in the active and inactive forms were performed in mild conditions, avoiding denaturation, with less than 1 nmol of the sample.
2. Molecular weights of the modified proteins were determined by MALDI-TOFMS.
3. Peptide mappings of the proteins were carried out by MALDI-TOFMS and LC/ESIMS.
4. The results on the active and inactive forms were compared (with/without Raf).

Results

Amidation and glycinamidation were selectively carried out on amino and carboxyl groups, respectively, with less than 1 nmol of sample. It was observed that a reaction with acetylimidazole caused acetylation also on amino groups. Remarkable side reactions by iodination, especially on Cys and Met residues, were recognized and peptide-maps of iodinated Ras proteins were too complicated to interpret. In this paper, glycinamidation of Ras is discussed as an example.

Figure 1 shows MALDI-TOF mass spectra of the tryptic digest of glycinamidated Ras-GDP (a) and Ras-GppNp (b). Molecular ions of the glycinamidated peptide 17-41 and 17-42, which contain the effector region of Ras, were observed as shown in the insets. There are three Asp and two Glu residues in the sequence of the peptide 17-41 or 17-42. It was observed that 0 to 5 carboxyl groups were glycinamidated in these peptides. Peptide mappings by LC/ESIMS of Ras-GDP and Ras-GppNp gave similar results to those by MALDI-TOFMS. Only a slight difference in the extent of modification between the active and inactive form could be recognized in glycinamidation. Ras-GppNp was a little more glycinamidated than Ras-GDP. It was suggested that a conformational change in Ras protein is possible to be detected by chemical modification.

Glycinamidation of Ras was reduced in the presence of Raf, both in the active and inactive forms. In the presence of Raf, glycinamidation suggested that Ras-GppNp was less modified than Ras-GDP. Figure 2 shows MALDI-TOF mass spectra of the tryptic digest of

glycinamidated Ras-GDP (a) and Ras-GppNp (b) in the presence of Raf. It was estimated that 0 to 3 carboxyl groups were glycinamidated in these peptides. Peptide mappings by LC/ESIMS of Ras-GDP and Ras-GppNp gave similar results to those by MALDI-TOFMS. The most intense peak in the inset of Fig 2(a) was $[M+H]^+$ of the peptide 17-42 with one glycinamidated carboxyl group, while that in the inset of Fig 2(b) was $[M+H]^+$ of the peptide 17-42 with no glycinamidation. It was estimated that only the active form can bind with Raf and its effector region was covered with Raf molecule, while the effector region of the inactive form was exposed to the outside.

It is suggested that the combination of chemical modification and mass spectrometry is effective for the investigation of protein-protein interaction, with small amount of sample.

and Christopher M Dobson,
Oxford Centre for Molecular Sciences, South Parks Road Oxford OX1 3QT

Introduction

Acyl CoA binding protein is an 86 residue protein present in a wide range of eukaryotic organisms. The protein binds long chain acyl CoAs with high affinity, with a maximum binding affinity for C₁₆ acyl CoA, has a weak interaction with free CoA and is thought to have a role in transport and storage of acyl CoAs in the cell. The protein adopts a four helix bundle structure which forms a bowl shape with a highly polar rim and a predominantly apolar core. The presence of a number of well defined interactions, a range of acyl CoA ligands with differing dissociation constants and the existence of mutant proteins known to form less stable CoA protein complexes make this an ideal system for assessing the role of different interactions in preserving protein-ligand complexes and their hydrogen exchange information in the gas phase of mass spectrometric experiments.

Methods

Proteins and Ligands: ACBP, protein mutants and CoA ligands were a kind gift from Prof. J. Knudsen, Odense University. All protein samples and ligands were at a concentration of 20 μ molar (measured optically).

H-exchange experiments: Samples were prepared by dissolving apo and ligated protein in D₂O at pH5 using 2 steps of lyophilisation. The proteins were then re-suspended in D₂O and diluted 100 fold into water to initiate H-exchange.

Mass Spectrometry: ESI mass spectra were obtained on the Platform (Micromass Ltd.,) using 100% water, pH5 adjusted with formic acid, no source heating and with a nozzle to skimmer offset of 5V.

Results

Variation of Chain Length

A range of solution binding constants from 10⁻⁶ M for C₈ acyl CoA, 10⁻⁸ M for C₁₂ acyl CoA and 10⁻¹⁰ M for C₁₆ acyl CoA have been measured for the different acyl CoA complexes. To investigate the effect of solution binding constant of the ligand an equimolar mixture of these acyl CoA ligands was added to protein such that the total concentration ratio of ligand to protein was 1:3. The ESI mass spectrum recorded for this protein-ligand mixture showed complexes involving all three ligands within the same spectrum despite. This result suggests that in the gas phase the presence of the fatty acid chain does not increase the stability of the gas phase complex, in contrast to the solution dissociation constants. Furthermore, free CoA ligand (C₀) does not show a strong interaction with ACBP in solution but forms a gas phase complex in the ESI mass spectrum when an equimolar quantity is added to ACBP.

Mutation of Protein Binding Site

CoA ligand binding to ACBP involves stacking and ionic interactions. A mutant, Y31N, removes the stacking interaction between the Y31 and the adenine ring of the CoA ligand. The C₁₆CoA-Y31N complex has a dissociation constant reduced by a factor of 40 compared

to wild-type. A competition experiment in which a molar equivalent of C₁₆CoA was added to wild type and Y31N ACBP shows complex formation mainly for wild-type protein. Mutant proteins Y28N and Y73F, involved in a network of H-bonds to the CoA ligand, were also examined in competitive binding experiments with wild type protein and CoA ligand. Reduced complex formation was observed in all mass spectra for mutant proteins when in competition with wild-type protein, consistent with measurements in solution.

H-exchange Measurements

The apo protein, and CoA ligand bound proteins were solvent exchanged with D₂O and the exchange of D for H was measured with time. The results demonstrate greater protection for the protein when bound to acyl CoA ligands than for free CoA bound protein and for apo protein, consistent with solution phase hydrogen exchange measurements.

Figure 1 Measurement of hydrogen exchange protection of ACBP bound to acyl CoAs (■), free CoA bound protein (○) and apo protein (●).

Conclusions

The correlation between solution and gas phase binding constants for mutant protein in competition with wild type implies some interactions are similar in solution and gas phases. However, absence of correlation for ligands differing only in their chain length suggests the nature of the protein-ligand is critical for their study by MS. Moreover, in this protein-ligand system the interactions stabilising the gas phase complex are located in the CoA region of the molecule.

Identification of a Non-covalent Trimer of *Silurus asotus* (catfish) Roe Lectin (SAL) in Solution by Analytical Ultracentrifugation and Electrospray (ESI) Mass Spectrometry

Murayama, K.; Taka, H.; Kaga, N.; Shindo, N.; Hosono, M.*; Nitta, K.*

Cent. Lab. of Med. Sci. Juntendo Univ. Sch. of Med. Tokyo, Japan; Cancer Res. Inst. Tohoku College of Pharm. Sci. Sendai, Miyagi, Japan*

Animal lectins have been widespread among prokaryotes and eukaryotes and many of their specific biological functions have also become clear, such as the cell-cell interaction, protein trafficking, primitive defense reaction, and immunoglobulin superfamily etc. (1-3). Recent structural information of animal lectins makes it possible to organize the known lectins into several categories, i.e. C-type (Ca^{2+} -dependent), S-type (thiol-dependent) and others (3).

The fish roe lectins have been found in many fish families. Their physiological significance seems to associate with fertilization mechanism. They are classified into three groups for the carbohydrate-binding property; (I) L-rhamnose binding lectins, (II) D-glucose/L-fucose binding lectins, and (III) sialoglycoconjugate binding lectins (4).

Silurus asotus (catfish) roe lectin (SAL) has a high affinity for L-rhamnose in common with some other fish lectins. Neither divalent cations or SH groups are required for SAL binding to carbohydrates. The molecular weight of SAL was found to be 38,000 by size exclusion chromatography and 32,000 by SDS polyacrylamide gel electrophoresis in a previous study (4). Furthermore we determined its molecular weight and trimer structure using analytical ultracentrifugation and mass spectrometry.

SAL was prepared from an acetone powder preparation of *S. asotus* roe as described previously (4). We determined the molecular weight of native SAL dissolved in 0.5% acetic acid:methanol (1:1v/v) by ESI mass spectrometry (Finnigan SSQ 7000; capillary temperature, 150°C; scan range, m/z 200-2,500; final conc., 10 pmol/ μl). The main peak was at 31,750 and there were some minor peaks at 31,580, 31,910 and 32,080, which we attributed to binding to carbohydrates. In order to purify native SAL, further it was loaded onto a C_8 ODS reverse-phase column and subjected to HPLC. There were three peaks on the chromatogram; SAL1 (9.5%), SAL2 (28.0%) and SAL3 (62.5%), the ESI mass spectra and amino acid compositions of which were identical to those of native SAL. We used a MALDI mass spectrometer (Finnigan Vision 2000; matrix, 2,5-dihydroxybenzoic acid), which showed that the maximal peak intensity of each of these SALs was 31,830(M). However, dimer was observed in SAL2 but dimer and traces of trimer were found in SAL3. And also all were found in native SAL. However, SAL2 converted easily into a mixture of SAL2 and SAL3 on a rechromatogram. They appeared to be interconvertible and SAL3 also seemed to be the most stable form.

A Hitachi analytical ultracentrifuge (CP 100 α attached with ABS-8) was used to determine the sedimentation coefficient (S) of native SAL, which was dissolved in ultrapure water, to produce a final concentration of 31 μM and ultracentrifuged at 50,000 rpm for 7 min at 20 °C and then monitored at 230 nm with an UV detector. The $S_{20,w}$ value, calculated by the Hitachi program for analytical ultracentrifugation, was 5.58. The molecular weight of native SAL (final conc. 14 μM) was determined by the sedimentation equilibrium method (8,000 rpm for 24 h at 20 °C) and also calculated using the above software program. The molecular weight was 95,200 when the partial specific volume (v) was 0.763, which corresponded to the trimer (3M) in the MALDI mass spectrum, indicating that SAL in water must have existed as a non-covalent trimer without the monomer or dimer. The $S_{20,w}$

must have existed as a non-covalent trimer without the monomer or dimer. The $S_{20,w}$ values of SAL1, SAL2, and SAL3 were the same as that of native SAL which was confirmed that neither the monomer nor dimer were present.

Finally we tried to identify the non-covalent trimer (3M) of SAL using ESI mass spectrometry (Finnigan TSQ700). Native SAL was dissolved in 0.5% acetic acid (20 pmol/ μl), methanol was used as the sheath liquid, the capillary temperature was 75 °C and the scan range was m/z 1,500-3,800. Biphasic patterns with charge distributions from 16+ (m/z 1,986) to 10+ (m/z 3,176) and from 27+ (m/z 3,533) to 26+ (m/z 3,669) were observed. The molecular weights of the deconvoluted spectra from both distributions were 31,754 and 95,362 as the monomer and trimer, respectively. Methanol was better than ethanol and acetonitrile as a sheath liquid, acetic acid was more effective than trifluoroacetic acid, and a low capillary temperature was preferable to find out non-covalent trimer of SAL.

We have demonstrated, by analytical ultracentrifugation and ESI mass spectrometry (TSQ-700), that native SAL in water exists as a non-covalent 5.58S trimer with a MW of 95,362. Monomer (SAL1) and dimer (SAL2) appeared on a RP-HPLC chromatogram but they interchanged trimer (SAL3) in water. MALDI mass spectra yielded some information on non-covalent binding proteins, but did not confirm the presence of the non-covalent trimer. The scan range of the SSQ 7000 (m/z 1-2,500) instrument used was too narrow to demonstrate the trimer of SAL by ESI mass spectrometry.

INTRODUCTION

Aerolysin is a virulence factor secreted by *Aeromonas hydrophila* as an inactive precursor that is activated by the proteolytic removal of about 40 amino acids from the C-terminus. The toxin is representative of a group of β -sheet toxins that must form stable homooligomers to be able to insert into biological membranes and generate channels.

Despite numerous efforts¹, the molecularity of the oligomer remained unsure : 5, 6 or 7 subunits ?

Taking advantage of the high stability of the complex, we decided to address the question by MALDI-TOF mass spectrometry and tried to get some informations on its mechanism of formation.

The known molecularity of the less stable α -toxin complex has also been studied by this technique.

RESULTS

Molecularity of aerolysin oligomer².

The spectrum displayed on fig 1 shows the best result which can be obtained after carefully adapting the dilution of the sample. Two series of multiply charged ions can clearly be observed. One, labelled M, is corresponding to the monomer (MH^+ 47480 Da, calculated mass: 47471 Da) and the second, labelled 7M, to an heptamer of aerolysin (M^+ 333850 Da, calculated mass: 332300 Da).

No ions corresponding to alternative association degrees of aerolysin were detectable. The complex is specific and heptameric.

Mechanism of formation of aerolysin.

The mechanism of formation of aerolysin oligomer has been investigated by monitoring the generation of the oligomer from proaerolysin upon trypsin digestion. Spectra could be obtained by directly analysing diluted crude aliquots of the reaction medium with our sample preparation (fig 2). Alternative oligomers could only be observed at the end of the reaction (2 hours). Fig 3 shows an enlargement of the last reaction time. In addition to the monomer and the heptamer, only a trimer and a tetramer could be detected whatever the dilution was. No penta or hexamer were detectable. The peak at 225 kDa corresponds to the triply charged dimer of aerolysin heptamer.

Regardless to possible unspecific multimerisations (which are always possible³ but were minimized by the dilution), the association of monomers and dimers in partially oligomerized trimers and tetramers which associates to give the heptamer could be a mechanism of formation of the active form of aerolysin.

Molecularity of α -toxin oligomer.

To determine whether less stable complexes could be observed by MALDI-TOF MS, we applied the same sample preparation to the α -toxin (a toxin closely related to aerolysin, known to be heptameric⁴). Despite the fact that the conditions are more critical than for aerolysin, the careful adjustment of the dilution allowed the observation of the heptamer of α -toxin (fig 3) with good mass accuracy (M^+ 234900 Da, expected mass: 232890 Da).

CONCLUSION

In this study, we have demonstrated that it is possible to observe specific non-covalent interactions using MALDI-TOF mass spectrometry.

The really unusual molecularity of both aerolysin and α -toxin could unambiguously be confirmed: they are heptameric.

Finally, we could obtain some preliminary informations on the aerolysin assembly process: partial oligomerization in trimers and tetramers leading to the heptamer might occur.

Of note, only the more stable structures can be observed by MALDI-TOF MS. Less stable complexes might be observable by optimizing the sample preparation and adjusting the dilution.

FT ICR INVESTIGATION OF CHIRAL SUPRAMOLECULAR PROPELLERS OF DIALKYL TARTRATE TRIMERS

Introduction. Gas-phase chiral discriminations in protonated dimers of dialkyltartrates M have been studied since several years by chemical ionization (CI) mass spectrometry [1] and Fourier transform ion cyclotron resonance (FTICR) mass spectrometry [2]. Recently, chiral effects in multi-component clusters of M have also been observed [3]. Under CI with water (but not alcohol), ammonia, and primary (but not secondary and tertiary) amines as reagent A, the dialkyltartrates M show the formation of protonated mixed quaternary clusters $M_3 \cdot A \cdot H^+$. This process is strongly directed by the chirality of the R and S antipodes of M. The homochiral clusters $RRR \cdot AH^+$ and $SSS \cdot AH^+$ are unusually stable species, whereas the heterochiral clusters $RRS \cdot AH^+$ and $RSS \cdot AH^+$ are less stable [3]. This was explained by a chiral supramolecular propeller structure (see below) which also allowed experiments for molecular and chiral recognition [3]. In this paper, we report related FT ICR studies

Experimental. The antipodes of dimethyltartrate (DMT) and diisopropyltartrate (DIPT) have been distinguished by 2H -labeling of the alkyl groups of one antipode, to give the pairs of *S*-DMT and *R*-[2H_6]DMT (*s* and *r*), and *S*-DIPT and *R*-[$^2H_{14}$]DIPT (*S* and *R*), respectively. The reagent A applied here was methylamine as ethanolic solution. A Spectrospin AG CMS-47 instrument was used to produce the different protonated species by self CI, and to study the cluster formation kinetics

MeNH $_3^+$ coordinated propellers [4] In the first study, DMT and methylamine were used. The kinetics of the $M_3 \cdot AH^+$ formation was observed for preselected adducts *s*· AH^+ and *r*· AH^+ with ligands *s* and *r* ($1.6 \cdot 10^{-5}$ mbar, 20 °C). Figure 1 shows the spectrum at a reaction time of 5 sec. The four diastereomeric products $sss \cdot AH^+$, $ssr \cdot AH^+$, $srr \cdot AH^+$, $rrr \cdot AH^+$ yield about 40% of the ion sum. They do not show the binominal abundance distribution 1:3:3:1, but one of ca. 15:1:1:15. Thus, the chirality effect of the clusters $M_3 \cdot AH^+$ in the ICR cell is much greater than that found under CI, with a distribution of ca. 5:3:3:5 [3].

In an ICR study with DIPT, the homochiral propellers $RRR \cdot AH^+$ and $SSS \cdot AH^+$ gave the base peaks of the spectrum obtained after 4.5 sec ($p = 6.0 \cdot 10^{-6}$ mbar, $t = 19$ °C). The nonstatistical distribution of the series $SSS \cdot AH^+$, $SSR \cdot AH^+$, $SRR \cdot AH^+$, $RRR \cdot AH^+$ was near 10:1:1:10. The kinetics study for the initial ions *R*· AH^+ and *S*· AH^+ over 5 sec clearly showed two successive steps of cluster growth as expected.

Semi-empirical calculations (AM1) predict three-blade propeller structures for the homochiral clusters $rrr \cdot AH^+$ and $sss \cdot AH^+$ [3]. The DMT ligands form an H-bond crown ether, and solvate the nitrogen H's of the central ion $MeNH_3^+$. The loss of one H bond in the heterochiral clusters changes the solvation enthalpy from -69.8 to -67.8 kcal/mol for the anticipated conformers. The heterochiral destabilization by 2.0 kcal/mol is relatively low compared with the strong chiral discrimination in the experiments

Figure 1 ICR spectrum of chiral propeller clusters $(DMT)_3 \cdot CH_3NH_3^+$

Chiral recognition on the basis of ligand exchange. The chiral assignment for M homologs and related compounds by the propeller species in the ICR cell could be demonstrated. A chiral reagent system of A and *s* + *r* was used for competitive binding. In Figure 1, residual traces of DIPT illustrate this principle. *S* and *R* are bound in mixed homochiral clusters $ss \cdot AH^+$ and $rr \cdot AH^+$. This behavior is a type of host-guest chemistry. Chiral guests *R* and *S* fit into the chiral cleft of self-assembled hosts $ss \cdot AH^+$ and $rr \cdot AH^+$.

Figure 2 exemplifies the chiral recognition of an "unknown" antipode, *S,S*-1,4-dimethoxybutane-2,3-diol (*S*). The mixed propellers $ss \cdot AH^+$, $sr \cdot AH^+$, $rs \cdot AH^+$ do not give the statistics 1:2:1, but a pattern near 1:1:2. In the geometry-related *D,L* notation, the ions are stated $dd \cdot AH^+$, $dL \cdot AH^+$, $LL \cdot AH^+$. Thus, the unusually stable cluster $LL \cdot AH^+$ is homochiral, and correctly assigns the chirality of *S*. Further studies on chiral recognition applying the concept of self-assembling hosts are in progress

Figure 2 Chiral recognition of *S* as homochiral $(DMT)_2 \cdot S \cdot AH^+$

Detection of the specific binding site between nm23-H2 and human c-myc oncogene by LC/MS

Yajuan Chen, Mark G. Qian, Xiaoli Liang, Kefei Zheng,

University of Michigan, Ann Arbor, MI 48109-1055

Mass spectrometry has been emerging as one of the most important techniques to solve the problems encountered in biological, medical and pharmaceutical fields, because it can provide fast, direct and accurate molecular and structural information of biomolecules. In our case, we used LC/MS to determine the interaction sites between proteins and DNA.

DNA binding proteins play a central role in fundamental cellular processes involved in transcription, DNA replication, transposition, restriction, recombination, and DNA repair. One of the largest and most diverse classes of DNA-binding proteins is the transcription factors which regulate cell development, differentiation, and growth by binding to a specific DNA site(s) and regulating gene expression.

Protein nm23-H2, also known as NDP kinase B, has been found to a candidate suppressor for tumor metastasis. Numerous studies have indicated that the metastatic process can be regulated to a significant degree by various genetic events (activation or deactivation of specific genes, mutations, etc.). Recent reports demonstrated that nm23-H2 has DNA binding capability. It binds to a domain within the promoter of the c-myc oncogene, and activates c-myc transcription. The determination of the site of nm23-H2 binding c-myc oncogene will improve our understanding of the molecular mechanism involved in repression and activation of gene expression. It may also open up possibilities of using active recombinant proteins in cancer diagnosis and gene therapy.

The complex between protein nm23-H2 and c-myc oncogene is formed by non-covalent bond. Direct analysis of these complexes is extremely difficult even with soft ionization methods, such as ESI. However, ultraviolet(UV) light-induced photochemical cross-linking of nm23-H2 to c-myc can "freeze" the interaction between these two biopolymers since only proximal amino acid residues of DNA-bound proteins can form covalent bond with reactive radicals of DNA which are generated by UV irradiation.

We used 5-Iodothyrimine-Substituted c-myc in order to enhance photosensitivity. In this case, longer wavelength UV light can be used for photocross-linking, which causes less degradation and also increased yield of cross-linked complex.

The UV source we used is UV lamp of bulk light with wavelength of ~300nm. C-myc was γ -³²P labeled, in order to identify and locate the formation of its complex with nm23-H2. Nm23-H2 and c-myc had a ratio of 40:1 in the binding reaction. A time course of 0min, 10min, 30min, 1hr, 1.5hr, and 2hr under UV ~300nm was applied to the samples. Then we ran 15% SDS-PAGE of these samples. From the film developed, see figure(1), we found that besides the free c-myc band which was below mw. 14k, there were two bands, one a little bit below mw.30k, the other a little bit below mw. 46k, in each sample except the one with 0min UV irradiation time. And the longer the UV irradiation time, the stronger these two bands. We therefore came to the conclusion that we have the covalent complex of c-myc and nm23-H2. The band near mw. 30k may be due to the complex between c-myc and monomer nm23-H2 and the band near mw. 46k may be due to the complex between c-myc and dimer nm23-H2. Figure(2) shows γ -³²P labeled c-myc under the same experimental condition as that in figure(1), but without protein nm23-H2. We can see that no band shows above that of free c-myc. The bands above mw.14k shown in figure(1) must be due to the covalent complex formed by UV cross-linking between nm23-H2 and c-myc. Figure(3) further proves this by using antibody detection of nm23-H2 and its complex from PVDF membrane which was Western-blotted from 15% SDS-PAGE with samples under the same binding and UV cross-linking conditions as those in figure(1), except that c-myc was not γ -³²P labeled. Also, the band just below mw.30k is due to the covalent complex of monomer nm23-H2 with c-myc.

Next, we can use on-line LC/MS to perform the peptide mapping of both c-myc binding nm23-H2 and free nm23-H2 which are cut from the membrane. A comparison of the peptide mapping patterns could reveal the binding sites of nm23-H2 to c-myc oncogene. This means any peptide fragment missing from mapping compared with that of free protein will determine that it is the binding domain of protein to DNA. By changing the enzymes for digestion, we can narrow down the binding sites of nm23-H2 to c-myc oncogene. Figure(4) shows the TIC of peptide mapping of free nm23-H2. Figure(5) shows mass spectrum of the fraction eluted at 23.3min. The amount of covalent complex formed is limited, also we found there is a small amount of impurity(GST) inside the protein, which was cleaved from GST-nm23-H2 fusion protein in order to get nm23-H2 and had not been totally eliminated. GST stayed at the same place as that of the complex after we ran the gel. We can not just cut the band of complex from the membrane to do the digestion and must purify the protein first. It was also found that nm23-H2 can form a complex with single strand c-myc about 40 times more efficiently than that with double strand c-myc which we used in the former experiments. We expect to obtain more complex, cut it from the membrane, and do the digestion to obtain the result.

COVALENT MODIFICATION OF RHO PROTEIN BY THE ANTIBIOTIC, BICYCLOMYCIN

Riba, Isabel, *Gaskell, Simon J; Park, Hyeung-geun; Zhang, Xiangdong; Widger, William R;
**Kohn, Harold;

*Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, U.K.,

**Department of Chemistry, University of Houston, Houston, TX

Bicyclomycin (Fig. 1) is a relatively new antibiotic with a broad spectrum of antimicrobial activity against a variety of Gram-negative bacteria¹. Bicyclomycin (BCM) interacts with nucleophilic compounds at near neutral pH, which gives it a great importance in the therapeutic field. In *E. coli*, the primary site of BCM binding is rho transcription termination factor². Rho protein has 419 amino acids and is active as a hexamer of six identical monomers. When BCM binds to rho protein, protein synthesis is halted. The interaction is not completely understood; however, studies with model peptides have suggested Michael addition to the exomethylene group^{3,4}. We report here studies of covalent binding of BCM to rho protein, to model peptides and to apomyoglobin.

When rho protein was incubated with BCM, the presence of two adducts corresponding to the addition of 1 and 2 molecules of BCM was observed (Fig 2). A mutant rho protein containing Gly in place of the single Cys at position 202, showed similar proportions of adducts as native rho. This finding may suggest that the Cys residue is not involved in the covalent binding of BCM to the protein. Furthermore the mass increments are not consistent with the previously observed⁴ rearrangement reaction of BCM with thiols, which involved the loss of ammonia.

Incubation of BCM with model peptides containing His and Lys residues yielded multiple products, incorporating intact BCM or BCM fragments. Tandem MS analyses confirmed the His and Lys residues as the site of modification, but further work is required to elucidate the precise structures of the adducts.

Incubation of BCM with apomyoglobin showed the incorporation of 1 to 3 molecules of BCM per molecule of protein, together with adducts corresponding to addition of 144 Da. The location of modification were studied by tryptic digestion and electrospray-tandem MS analyses of HPLC fractions. All the tryptic fragments containing His residues showed adduction to BCM, except for those containing His-48. In general, modified and unmodified fragments coeluted.

Further work is required to elucidate the sites of BCM covalent modification of rho protein, since preliminary analyses of tryptic digests of the native and adducted rho protein have failed to reveal individual sites of adduction, possibly suggesting a lack of specificity with respect to covalent binding under the conditions used.

Investigation of Binding of SSB to DNA by Competitive Labeling and Mass Spectrometry

Jiwen Chen, Mark A. Griep and David L. Smith

Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

Escherichia coli single stranded DNA binding protein (SSB) is essential for DNA replication, repair and homologous recombination. Electrostatic interactions are believed to be important for binding, probably involving various lysine residues in SSB, the identities of which have not been determined. The goal of this study was to identify the lysine groups in SSB responsible for its binding to DNA. The reactivity of the ϵ -nitrogen of lysine with acetic anhydride is sensitive to its environment, and may therefore, be used to detect changes in the micro-environments around lysine residues (1, 2). If certain lysine residues are directly involved with electrostatic binding of SSB to DNA, their reactivity with acetic anhydride is expected to be diminished.

The principal reaction between acetic anhydride and proteins is acetylation of the N-terminus and ϵ -nitrogen of lysine residues. The reactivity of these nucleophiles can be determined following proteolytic fragmentation of the protein into peptides, which are analyzed by directly-coupled HPLC ESIMS. Isotopically labeled acetic anhydride was used to increase the accuracy of the measurements. The general procedure used to study binding of SSB to DNA is illustrated in Fig. 1.

The change in reactivity of the N-terminus and four lysine residues of SSB as it binds to DNA is illustrated in Fig. 2. The reactivity of the N-terminus and Lys residues 43, 62 and 73 were substantially lower when SSB was bound to DNA. These four residues are likely to be directly involved with binding of SSB to DNA. Interestingly, acetylation at Lys 87 decreased by only 14%, indicating that this residue is not involved with binding. Reactivity of Lys 7 was too low to be detected, suggesting that it plays a minimal role in the binding of SSB to DNA.

Whether the reduced reactivity found in this study might be attributed to non-specific interaction between a polypeptide and DNA was investigated using substance P which does not bind to DNA. The level of acetylation of substance P was the same in the presence and absence of DNA.

Haemophilus ducreyi is the gram-negative bacterium that causes the sexually transmitted disease chancroid. Chancroid is common in developing countries and has been shown to be an independent risk factor in the transmission of the human immunodeficiency virus [1]. Although chancroid is still treatable with antibiotic regimens, resistant strains of *H. ducreyi* have been increasing. Lipooligosaccharides (LOS) present in the outer membrane of *H. ducreyi* have been shown to be a virulence factor. Recently, we have shown that many *H. ducreyi* strains synthesize LOS-glycoforms that contain a terminal N-acetyllactosamine which further undergoes the addition of sialic acid [2]. Sialic acid plays important roles in cellular recognition and the masking of epitopes, especially terminal galactose residues, and has been found to protect pathogenic organisms from host defenses [3-4].

Considering the role of sialic acid containing molecules as virulence and/or adhesion factors, enzymes involved in the biosynthesis of sialylated LOS may be attractive targets for therapeutic intervention. We have isolated the CMP-N-acetylneuraminic acid (NeuAc or sialic acid) synthetase from *H. ducreyi*, cloned its gene, and expressed the enzyme in *E. coli* using a T7lac promoter system [5]. CMP-NeuAc synthetase catalyzes the formation of the nucleotide-sugar of sialic acid according to the following reaction: CTP + NeuAc → CMP-NeuAc + PP_i. The product CMP-NeuAc is then the substrate for the bacterial sialyltransferase that adds sialic acid (i.e. NeuAc) onto the terminal lactosamine disaccharide contained in the bacteria's surface lipooligosaccharides. The recombinant enzyme has been purified to homogeneity and found to have a molecular mass of 25439.9 ± 1.4 Da by ESI-MS, within 1 Da of the expected mass based on the DNA sequence (Fig. 1). We have observed an interesting gas phase fragmentation of the intact enzyme under ESI-MS conditions with relatively low orifice potentials at an unusual labile proline residue in the intact enzyme that leads to two gas phase products (approx 9 kDa and 16.4 kDa).

Based on sequence analysis of CMP-NeuAc synthetases that reveals a number of conserved residues (including 2 lysines and 4 arginines) and domains, we are attempting to identify which residues are involved in binding its substrates, CTP and NeuAc. Currently, we are using the substrate analog, 2',3'-dialdehyde CTP (oxCTP), which is capable of covalently modifying lysine residues, to label the enzyme. We have been able to make covalent adducts of oxCTP with the expressed enzyme using MALDI-TOF to assay the extent of reaction (Fig. 2). Secondly, we have shown using ESI-MS techniques that the reaction with oxCTP can proceed via β-elimination of the triphosphate moiety. Proteolytic digestion of the covalently labeled enzyme followed by ESI-MS and MALDI analysis was carried out to identify the site of covalent addition of oxCTP. We have isolated a labeled peptide from a Glu-C digest and identified it as the N-terminal peptide (residues 1-58, MH⁺ (avg) = 6078 Da), which contains six lysine residues. Further digestion and mass spectrometric analysis of this peptide will be required to identify the modified residue(s).

Fig. 1. Electrospray mass spectrum of recombinant CMP-NeuAc synthetase. The mass of the enzyme (25439.9 ± 1.4 Da) was within experimental error of the predicted molecular weight (25440.6 Da). In addition to the intact protein, two fragments (16440.1 + 8997.7 = 25437.8 Da) were detected. These species arose from a gas-phase fragmentation between residues Ile¹⁵⁰ and Pro¹⁵¹ and not chemical hydrolysis i.e., no addition of H₂O was found in the N-terminal fragment and the percentage of fragmentation was highly dependent on the cone voltage. Addition of H₂O would have been easily detected with the accuracy obtained.

Fig. 2. MALDI mass spectrum of labeled and unmodified CMP-NeuAc synthetase. Desalted enzyme (~5 mg/ml, 0.2 mM), was diluted 10-fold with H₂O and 1 μl (~20 pmol) was mixed with 1 μl of a saturated solution of α-cyano-4-hydroxycinnamic acid in 70% CH₃CN 0.08% TFA and then spotted on the MALDI sample plate. Several charge states are seen when using α-cyano-4-hydroxycinnamic acid as the matrix. (A) Unmodified enzyme. (B) Enzyme labeled with the reactive substrate analog, oxCTP. An increase of approx. 200 Da is observed.

Investigation of the Interactions Between 4-Hydroxy-2-Nonenal and Lysine Residues of Proteins

Mark S. Bolgar and Simon J. Gaskell

The Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, U.K.

The detection of the conjugates formed between lipid peroxidation products and protein is of increasing interest as a method for determining oxidative stress and because the formation of lipid modified-protein has been implicated in several disease states, including atherosclerosis. 4-hydroxy-2-nonenal (HNE) has been identified as a product of *in vitro* oxidation of low density lipoprotein (LDL) and has been shown to covalently modify LDL and other proteins. It has been suggested that lysine residues are a major site of HNE modification to LDL and two mechanisms for conjugate formation have been proposed, namely, Schiff base (imine) formation and Michael addition. The propensity of imines to hydrolysis makes necessary their reduction to the corresponding secondary amines prior to analysis. When NaBH₃CN was added at the start of an HNE/N α -acetyllysine incubation (to effect reduction of imines immediately upon formation) a high proportion of the imine conjugate (relative to the Michael addition product) was observed. When NaBH₄ was added at the conclusion of the incubation, only minor proportions of imine adducts were evident. We suggest that incubation in the presence of reducing agent leads to over-estimation of the significance of the imine product under physiological conditions by displacing the equilibrium between primary amine and imine adduct.

Investigations into the stability of HNE-peptide adducts revealed that the non-reduced Michael addition product with lysine residues readily decompose at neutral and slightly alkaline pH. Neurotensin which incorporated a non-reduced HNE adducted lysine residue (formed by Michael addition) showed 45 and 39% decomposition to the native peptide following a 90 min incubation at 37° C in potassium phosphate buffer pH 7.4 or Tris pH 8.4, respectively (Figure 1a & b). At pH 2.5 the adduct had not decomposed after 12 hrs (data not shown). HNE adducts with histidine residues were found to be significantly more stable yielding only 6% decomposition after 90 min in Tris pH 8.4. The rapid decomposition of non-reduced lysine adducts under conditions typically employed for trypsin digestion (Tris, pH 8.4) may explain why lysine modifications were not detected during previous analyses of digested HNE-modified protein (1).

In order to assess the significance of HNE adduction to lysine residues of protein, apomyoglobin was incubated with HNE, followed by NaBH₄ reduction, digestion with endoproteinase Glu-C and HPLC fractionation. HPLC fraction 10 contained a peptide with MW 980.2 Da (Fig. 2a), consistent with the addition of 158 Da to the expected Glu-C product containing residues 142-148. The 158 Da mass increase is the expected value for adduction with HNE by Michael addition followed by reduction of the aldehyde to an alcohol. As this protein fragment contains no histidine residues, modification of one of the two lysine residues seems certain. The product ion spectrum of the (M+2H)²⁺ ion (Fig. 2b) contained a series of amino-acylium internal fragment ions which indicated that the HNE modification is on Lys¹⁴⁵ rather than Lys¹⁴⁷. This was confirmed by the masses of y₂, y₃ and b₄ ions.

Application of on-line CE-ESI-IT/TOF in the analysis of Variant Hemoglobin

Michael X. Li, Jingtao Wu, Lin Liu, Ling He, David M. Lubman
Department of Chemistry, The University of Michigan
Ann Arbor, MI 48109

Since the first discovery of its variant in 1956, hemoglobin (Hb) has been an important subject for biological research and clinical practice. The conventional detection of the Hemoglobinopathies relies on electrophoresis and isoelectrofocusing, while further characterization is made possible by application of reverse-phase high-performance liquid chromatography (RP-HPLC), capillary electrophoresis (CE) and confirmation by mass spectrometry (MS).

The separation step requires a fast and high resolution method that can identify the minute difference between the normal and abnormal Hbs. CE meets these challenges quite well, where for example tryptic digests of Hb β chain were analyzed by Ferranti¹ and also the whole globin chains were separated by C. N. Ong² in order to identify the abnormal chain. The mass analysis provides unambiguous information for the fragments and confirms the variant sites inside the specific chains.

In this work, both of the Hb variants were collected and purified from the crude blood samples directly from patients and chain-separated by C₁₈ RP-HPLC. Sequentially, the β chains of both the normal and variant Hbs were digested by trypsin with a substrate to enzyme ratio (50:1). CE separation was monitored by on-column UV detection and on-line coupled with the MS system to characterize the different fragments resulting from digestion. A sheathless interface was used so that the sensitivity and resolution could be improved accordingly. Due to the non-scanning characteristics of the TOF, the data acquisition time for the whole mass spectrum can be as low as 0.1 s per spectrum in the current data system. However, 0.5 s was chosen in order to compromise between preserving the CE resolution and the mass sensitivity.

As shown in figure 1, the different Hb chains were efficiently separated by HPLC, where the slight variation in migration times can be noticed over the several tested samples. Basically, 20 μ g Hb protein was subjected to separation, and the α and β chains were collected separately. Figure 2 shows the UV detection of the Hb A, S, E β chain digests in the CE system. The chain variations in S, E are $\beta 6$ (Glu $\rightarrow$ Val) and $\beta 26$ (Glu $\rightarrow$ Lys), respectively. Due to the negative charge on the Glutamate amino acid, the migration time of the indicated peak by arrow varies in these three proteins. It is suspected that these are the substitution sites of abnormal Hbs.

Figure 3 shows the TIC obtained by CE-MS results, where A, B are for the Hb S and E β chain respectively. It was clearly observed that most peaks correspond to the UV results very closely, but small differences exist in terms of peak widths and migration times. The latter is due to the fact that the UV window is 5cm away from the capillary anode end. In the Hb E TIC figure, there are several additional peaks than in the Hb S, as the substitution of the Glutamate group by Lysine might result in more tryptic fragments. The TIC data somewhat confirm the abnormality existence and provide the mass and migration time shift in these specific fragments for both the Hb S and E. However, it demands further investigation.

These crude data show the possibility of applying the on-line CE-MS system to obtain structural information and rapid screening of the mutation positions inside proteins. The fast data

system could handle even extremely narrow CE peaks which is important in complicated fragment patterns

ELECTROSPRAY MASS SPECTROMETRY OF THE HUMAN S100 PROTEINS CALGRANULIN A and B.

Mark J. Raftery and Carolyn L. Geczy.

Immunology Group, The Heart Research Institute, 145 Missenden Road, Camperdown, Sydney, 2050, Australia.

Introduction.

CAGA and CAGB, also known as MRP8/14, p8/14, L1 light/heavy chain and S100A8/A9 are small acidic Ca^{2+} -binding proteins belonging to the S100 protein family. They are isolated from human peripheral blood mononuclear cells, monocytes and HL60 cells as a non-covalent complex [1]. The sequence of each protein was determined from the derived cDNA sequence. MALDI TOF MS of CAGB indicated it was post translationally (PT) modified and comprised of two forms. The precise function of these proteins is unknown [1]. Two S100 proteins have been isolated from activated murine spleen cells; CP10 (Chemotactic protein, 10 kDa), and mMRP14. CP10 has 59% amino acid identity with hCAGA, and is a potent chemotactic agent for neutrophils and macrophages [2] and mMRP14 has 59% amino acid identity with CAGB. The amino acid sequence of mMRP14 was deduced from the cDNA sequence [3] and the PT modifications determined by ESI/MS and Edman degradation. mMRP14 contains an unusual 1-methylation of His₁₀₆ [4].

We have used ESI/MS to determine the average mass of the calgranulins and compared them with the theoretical mass of proteins derived from cDNA sequences. The post translational modifications were deduced from these masses and compared with the reported PT modifications of the murine proteins.

Experimental.

Proteins were isolated from human neutrophils or activated murine spleen cell supernatant using reported procedures [1][4].

Mass spectra were acquired using a single quadrupole mass spectrometer equipped with an electrospray ionisation source (Platform, VG-Fisons Instruments, Manchester, UK). Spectra were calibrated with horse heart myoglobin (Sigma). Samples collected from C4 RP-HPLC were concentrated to approx 20 pmol/ μl (Speedvac) and injected (10 μl) into a moving solvent (10 $\mu\text{l}/\text{min}$; 50:50 water:acetonitrile, 0.05% TFA) coupled directly to the ionisation source via a fused silica capillary interface (50 μm x 40 cm). The source temperature was 50°C. Sample droplets were ionised at a positive potential of approx 3kV and transferred to the mass spectrometer with a cone voltage of 50 V. Spectra were scanned over the mass range of 700 to 1800 Da in 5 sec.

Results and Discussion.

The C4 RP-HPLC chromatograms of S100 proteins isolated from activated murine spleen cell supernatant and lysed human neutrophils are shown in Fig 1. The S100 proteins isolated were mMRP14 and CP10 from spleen cells and CAGA, CAGB' and CAGB'' from neutrophils. The ESI mass spectrum of each protein contained one series of multiply charged ions. A comparison of their theoretical masses (derived from the published cDNA sequences [1]) with the experimental masses (by ESI/MS) and with the calculated masses (after inclusion of post translational modifications) is shown in Table 1. All S100 proteins analysed were PT modified because the ESI mass and theoretical mass were different, except CAGA where the

two masses were identical (CAGA retains the initiator Met). PT modifications previously determined for mMRP14 include removal of the initiator Met, N-terminal acetylation, an internal disulfide bond and an unusual 1-methylation of His₁₀₆. The C-terminal domains of both mMRP14 and CAGB contain a number of His residues and a His residue of CAGB could potentially be methylated.

Figure 1. C4 RP HPLC chromatogram of A) Mouse spleen cell supernatant after heparin affinity chromatography and B) Human neutrophil lysate after Mono S chromatography.

Analysis of the masses (Table 1) indicates that both forms of CAGB are PT modified by removal of the initiator Met and N-terminally acetylated. The truncated protein is formed after translation from an alternate start codon, resulting in a protein with 3 fewer amino acids. No protein with a mass 14 Da higher, corresponding to a protein containing an N-methylated His was observed in ESI mass spectra of CAGB' or CAGB''.

Table 1. Comparison of C4 RP-HPLC, theoretical mass, the ESI mass and the calculated mass after inclusion of PT modifications of murine and human S100 proteins.

Locating Hemes in the Integral Membrane Protein cytochrome b_{558} from Human Neutrophils using MALDI-TOF MS

David Barnidge, Ed Dratz, and Jan Sunner

Dept. of Chemistry and Biochemistry

Al Jesaitis

Dept. of Microbiology

Montana State University, Bozeman, MT 59717

email: UCHJS@EARTH.OSCS.MONTANA.EDU

The protein, cytochrome b_{558} , is the flavocytochrome responsible for the transfer of high energy electrons from NADPH to molecular oxygen to produce superoxide anion (O_2^-). It is a heterodimeric, integral membrane, glycoprotein composed of a glycosylated large subunit and a non-glycosylated small subunit with primary sequence M_r of 65,204Da and 20,827Da respectively. Stimulated human neutrophils (leukocytes of the immune system) rely on superoxide during the respiratory burst as a microbicidal agent. Deletion of the gene coding for cytochrome b_{558} results in chronic granulomatous disease. This X-linked disorder manifests itself by chronic infection and eventually death due to the inability of neutrophils to adequately destroy invading bacteria.

Cytochrome b_{558} is a hydrophobic integral membrane protein and detergent is needed to solubilize the protein during purification. Because of its hydrophobic nature, a crystal structure does not exist for the enzyme. Cytochrome b_{558} contains heme groups that give the protein its name as determined by its spectral properties (the reduced form's α -band is at 558nm). The non-covalently linked hemes play a principal role in the redox chemistry involved in generating superoxide anion. Knowing their location and the exact number of hemes is critical for determining the mechanism involved in producing superoxide anion.

In this study we present a method using mass spectrometry to provide structural information on the location of the non-covalently bound heme prosthetic groups in cytochrome b_{558} . By combining gel filtration chromatography, partial digestion, and antibody specificity, we have isolated a heme containing fragment located between amino acids 158-327 in the central region of the protein.

ISOLATION of CYTOCHROME b_{558}

Cytochrome b_{558} was purified from whole blood using the method of Parkos et. al. (1) Heparin extracts were split into two fractions containing cytochrome b_{558} solubilized in the detergent Triton X-100. Fractions were run on a HPLC gel filtration column (TSK gel, G3000SW) to exchange the protein into a 1% solution of the detergent octyl- β -glucoside (OG) in 5mM HEPES pH 7.4 and 60mM ammonium acetate. The detergent exchange was carried out to eliminate difficulties associated with analysis of samples containing 0.1% or greater Triton X-100. Also, due to its large micelle size, Triton X-100 cannot be concentrated with centricon style concentrators used in this study. Fractions were monitored for heme absorbance at 414nm and fractions eluting at the proper time for the mass of cytochrome b_{558} (~14 min. at 0.8ml/min.) were used.

PARTIAL DIGESTION OF CYTOCHROME b_{558}

Approximately 100 μ g of cytochrome b_{558} (determined by heme absorbance at 414nm) was used for partial digestion. Sequencing grade trypsin at an enzyme to substrate ratio of 1:20 was allowed to react with the samples for 60 minutes at 37 C. Samples were removed and tumbled with immobilized soybean trypsin inhibitor for 15 minutes to remove trypsin. The serine protease inhibitor PMSF was then added to eliminate any residual protease activity. Samples were reinjected onto the gel filtration column (buffer=1% OG in 5mM HEPES pH 7.4 and 60mM ammonium acetate) and monitored for heme absorbance at 414nm.

MALDI-TOF MASS SPECTROMETRY

Fractions having heme activity from partially digested cytochrome b_{558} were isolated by gel filtration chromatography and analyzed by MALDI-TOF mass spectrometry. Samples used for MALDI-TOF were mixed 1:1 with a 50:50 solution of acetonitrile:water containing 0.5% TFA before mixing with a saturated solution of α -cyano-4-hydroxycinnamic acid (ACHCA) on the sample stage. Mass spectra were acquired on a PerSeptive Biosystems Voyager RP time-of-flight mass spectrometer. The instrument is equipped with a 337nm nitrogen laser, a dual stage source, and a 1.3m linear flight path. Samples were run in linear mode with 30kV accelerating voltage, 21kV secondary grid voltage, and 45V guidewire voltage. Trypsin ($MH^+=23,304$ Da) was used as an internal standard along with the ACHCA dimer.

The heme containing tryptic fragments that were identified using MALDI-TOF mass spectrometry are from the large subunit of cytochrome b_{558} consisting of amino acid residues 158-327. This region of the protein fits with the current model of cytochrome b_{558} having the histidyl residues coordinating the heme within a hydrophobic region. The MALDI-TOF mass spectra shown below is from one of duplicate partial digests that was done on cytochrome b_{558} . The amino acids that are labeled were identified by matching the possible tryptic fragments with the western blot analysis from specific regions of the protein. Without positive identification of the heme containing fragments by western blots, there is still the possibility that the fragments are from a contaminant. However, the fact that the fragments had heme absorbance, coupled with the mass accuracy of the mass spectrometer (0.2% error), makes this less possible but still a concern.

Finally, without Edman sequence information and antibody recognition, the identification of these fragments is still not complete. We are currently pursuing the production of polyclonal antibodies to a peptide within the region of the heme containing fragments in addition to direct sequencing of the heme containing fragments.

Characterization of Low Molecular Weight Chromium Binding Substance by Matrix-Assisted Laser Desorption Ionization FT-ICR Mass Spectrometry

Bryan A. Vining*, Guo-Zhong Li, Touradj Solouki, Sheng Guan*, Alan G. Marshall*, and John B. Vincent†

Low Molecular Weight Chromium Binding Substance (LMWCr) is an anionic oligopeptide that is the only known naturally occurring binding agent for chromium (III) in mammals. It consists primarily of glycine, cysteine, glutamic acid, and aspartic acid, and its exact composition varies from species to species and even from organ to organ. Although its exact role in the body is still not fully clear, LMWCr, when bound to chromium (III), potentiates the action of insulin in rat epididymal cells and shows similar activity in other systems. Moreover, chromium deficiency in humans causes an onset of symptoms similar to those brought about by diabetes. Isolation of milligram quantities of material has recently been achieved; however, the presence of the chromium ions in LMWCr renders many traditional peptide characterization techniques (e.g., NMR, Edman degradation) difficult or impossible. Mass spectrometry may provide for partial characterization of LMWCr. Here we present preliminary characterization of LMWCr by matrix-assisted laser desorption/ionization (MALDI) FT-ICR mass spectrometry.

We produce the apo-peptide (i.e., peptide minus the chromium complex), by incubation with EDTA and a catalytic amount of sodium borohydride for 12 h, followed by gel filtration chromatography (G-15 Sephadex), to yield a solution with a chromium:peptide ratio of 0.1-0.3:1. This solution is still sufficiently salty after the gel filtration chromatography to make ionization difficult. Additional reversed-phase HPLC purification yielded a chromatogram (Figure 1) showing several small peaks, including three that yielded significant mass spectrometric signals.

All of the various HPLC fractions show a MALDI FT-ICR mass spectral signal at m/z 719.44 u (see Figure 2). Fraction 4 shows signals only at m/z 719 and 735, and Fraction 5 shows a signal only at m/z 719. Fractions 1, 3, and 6 did not yield significant MALDI mass spectral signals.

The origin of the multiple chromatographic peaks may be an unusually high affinity for C18 on the part of ApoLMWCr (the chromium-bound material does not elute from a reversed phase column). The origin of the multiple species seen in the mass spectra of the earlier-eluting chromatographic peaks is less clear. Prospects for interpretation should improve, once a better chromatographic procedure has been developed and larger amounts of material can be isolated. In particular, collision-induced dissociation should help to determine the primary amino acid sequence of the apo-peptide, which, in turn, should make possible fuller characterization of the chromium-bound material. Inhibition Mechanisms and Kinetics of Human Cytomegalovirus Protease Inhibitors Analyzed by ESI/MS

Marshall M. Siegel, Keiko Tabei, Geraldine A. Beberitz, Jeff Hulmes, Wei-Dong Ding, Ellen Z. Baum
Wyeth-Ayerst Research, Lederle Laboratories, Pearl River, NY 10965

INTRODUCTION Human cytomegalovirus (HCMV) is a virulent pathogen often found in immunocompromised patients. The virus could be suppressed if the HCMV protease associated with it is inhibited. Using random screening methods, a number of chemical agents were found which inhibit the HCMV protease. To better understand the nature of the chemical reactions between the protease and different inhibitors, electrospray ionization mass spectrometry (ESI/MS) was used to both characterize and quantitate reaction products of the protease and inhibitors. Methods were developed which allowed the identification of three distinct mechanisms of inhibition: (I) covalent adduct formation between protease and inhibitor, (II) inhibitor-induced disulfide bond formation within the protease, and, (III) tight binding of the inhibitor to the protease. The kinetics of mechanism I was also monitored so as to provide information on the reaction rates of the different reaction sites of the protease with the inhibitor.

RESULTS The experimental results for the various mechanistic and kinetic studies are summarized below:

1. Reaction Kinetics and Inhibition Mechanism Type I: Covalent Adduct Formation Between Protease and Inhibitor and Formation of a Protease Intramolecular Disulfide Bond Wild type HCMV protease contains five cysteine residues (C84, C87, C138, C161 and C202). Since CL13933 contains a disulfide, the inhibition mechanism was thought to involve disulfide chemistry between the inhibitor and cysteines of the protease. Previous data (Baum *et al.*, Biochemistry (1996)) indicated that disulfide bond formation between C138 and C161 inhibits the enzyme. The reaction and kinetics of inhibitor CL13933 with HCMV protease was monitored, using mutated recombinant HCMV protease C84S/C87S/C202A (MW 27,976). This mutant protease contains only the cysteine residues C138 and C161 (the others were mutated and retain enzymatic activity). The first 10 minutes in the reaction between this protease and inhibitor CL13933 (MW 568) is illustrated in Figure 1. Initially, at 0 time, the transformed ESI mass spectrum for the protease exhibits a molecular mass (MW 27,975) consistent with the proposed structure (AA's 1-256) as well as two autodigestion products with MW's 15,487 and 12,507, referred to as the N-terminal fragment (MW 15,487, AA's 1-143) and the C-terminal fragment (MW 12,507, AA's 144-256), respectively. The protease reaction products as well as the autodigestion products were monitored during the reaction. The autodigestion products give structural details for the reaction because the protease reaction sites for the inhibitor are consistent with the only available cysteines at AA's 138 (found in the N-terminal fragment) and 161 (found in the C-terminal fragment). At 5 minutes into the reaction, half of a CL13933 molecule reacted rapidly with the protease (MW 28,259) at C138 while C161 was unreactive. As the reaction proceeded, at 10 minutes, the protease reacted further with a total of one molecule (2 half molecules) of CL13933 (MW 28,542) at sites C138 and C161, the molecule with MW 28,259 disappeared and two forms of the protease appeared (MW's 27,974 and 27,995) consistent with the formation of an intramolecular disulfide linkage within the intact protease (between C138 and C161, MW 27,974) and the disulfide linked complex of the N- and C-terminal autodigestion products (MW 27,995). The difference in mass between these two molecules is 18 daltons, corresponding to the mass of a water molecule. With increasing reaction times, the abundances of these reaction products increase. These ESI/MS results demonstrate that the inhibition mechanism is consistent with covalent disulfide formation within the protease and between the protease and inhibitor.

2. Inhibition Mechanism Type II: No Covalent Adduct Formation Between Protease and Inhibitor and Formation of an Intramolecular Protease Disulfide Bond The reaction products of inhibitor CL384188 (MW 177) with HCMV proteases was monitored by ESI/MS. The mass spectral data indicated that no protease-inhibitor conjugate was formed, the protease was oxidized (intramolecular disulfide bonds were formed between C84-C87 and C138-C161 and C202 did not react) and that the inhibitor was reduced (MW 179). ESI/MS data of the HCMV protease A144L (MW 28,083) before and after reaction with CL384188 produced similar spectra consistent with the predicted MW for the protease. However, when the respective materials were further reacted with iodoacetamide (IAM) to determine the number of free cysteines, the observed MW's 28,370 and 28,137 corresponded to the respective addition of 5 and 1 IAM equivalents. (Each IAM equivalent contributes a mass increment of 57 daltons.) The difference in mass between the two samples corresponds to the formation of two disulfide bonds in the protease formed after reaction with

CL384188. This oxidation is confirmed by the reduction of CL384188 to CL277439 (MW 179) as indicated in Figure 2. Hence, the analysis of low and high mass products by ESI/MS enabled the elucidation of Mechanism II.

3. Inhibition Mechanism Type III: Only Non-Covalent Tight Binding Between Inhibitor and Protease

A general method was developed for quantitating the extent of non-covalent binding between a protein (protease) and inhibitor using ESI/MS. The assay is performed in the following manner. The reaction products of the protease and inhibitor are passed through a GPC column, referred to as a spin column, which selectively passes high MW proteins and traps low

MW inhibitors. If the inhibitor binds tightly to the protein, both the inhibitor and protein pass through the spin column. ESI/MS is used to assay the effluent and to quantitate the amounts of protein and inhibitor based on known standards. Figure 3 illustrates a qualitative assay demonstrating that the inhibitor does not

pass through the spin column when alone or in the presence of HCMV protease S132A, but the inhibitor does pass through the spin column in the presence of HCMV proteases A144L and E122V/A144G. This ESI/MS non-covalent binding assay methodology is useful for screening a variety of inhibitors in the presence of different proteases.

DEDICATION This presentation is dedicated to the fond memory of our beloved colleague and friend Yakov "Yasha" Gluzman who inspired us to achieve in our technical fields.

Use of Data-Controlled Microflow LC-MS/MS to Identify a Host Cell Protein Interacting with the Internal Ribosome Entry Site of Poliovirus RNA

Kristine M. Swiderek^{*1}, Lawrence B. Blyn² & Douglas C. Stahl¹

Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010, ¹ and

Department of Molecular Biology and Biochemistry, University of California, Irvine, CA 92717, ²

Introduction

Using a combination of microcapillary LC-MS (1), automated, tandem mass spectrometry (2, 3) and post acquisition correlation of spectral data with protein sequence databases (4), the data obtained in a single analysis was sufficient to identify a protein that specifically interacts with polio virus RNA. It has been shown that polio virus translation occurs via internal ribosome binding by the interaction of host cell proteins with the 5' noncoding region of the viral RNA. Domain IV of this region is of particular interest for possible interaction due to the reduced translational efficiency resulting from sequential or structural alteration of this domain (5). A host cell protein, binding specifically to domain IV was isolated, digested with trypsin in situ and identified by data controlled LC-MS/MS analysis. Based on the mass spectral results, the cDNA was cloned. Expression of the protein with specific domain-IV binding activity proved that the correct protein had been unambiguously identified (6).

Materials and Methods

Stem-loop IV binding proteins were isolated from HeLa cells according to procedures previously described (5, 6). The protein was separated by SDS-page and stained with Coomassie-Blue. The excised protein band was digested in situ with trypsin according to the protocol of Hellman et al. (7). Ultra low flow LC/ESI/MS and LC/ESI/MS/MS analyses were performed using a microscale HPLC system developed by the authors (1, 8, 9) using linear gradients from 2% to 92% B (A, 0.1% TFA in water; B, 90% acetonitrile, 0.07% TFA in water, v:v) at 100-200 nL/min. On column UV detection was performed at 200 nm using an ABI 759A UV/VIS spectrophotometer equipped with a capillary flowcell holder. Mass spectrometry was performed on a Finnigan TSQ700 triple sector quadrupole mass spectrometer equipped with an electrospray ion source. The TSQ was controlled using the ICIS data system version 7.2. Programs for data acquisition and instrument control were developed by the authors using Instrument Control Language (ICL, version 7.27) (2, 3). Correlation of all MS/MS spectra was performed using the SEQUEST program (4) and by manual interpretation.

Results and Discussion

1% of the sample digestion mixture was utilized for the analysis. Based on the UV-absorbance, this represented approximately 500 - 1000 fmole of peptide material. Over 55% of the complete protein sequence of PCBP2 could be positively identified by MS/MS analysis (Fig. 1). Several modified cysteine and methionine residues were observed. Cysteine residues 54 and 99 were identified as acrylamide adducts. Cysteine residue 54 was also found as the mercapto-ethanol adduct. Both modifications can occur during SDS polyacrylamide gel electrophoresis (SDS-PAGE). Peptides with the methionine sulfoxide in position 20, 74 and 87 were also found. Methionine residue 74 and 87 are located within one fragment and this peptide eluted at three different retention times. MS/MS data revealed that peak # 21 corresponded to the peptide carrying oxidized Met-87. Peak #23 contained the same fragment with methionine sulfoxide in position 74. Unexpectedly, this peptide eluted later than the non-oxidized form of the peptide (#22). Met-251 and Met-258 are positioned within the same fragment as well, however, MS/MS analysis of this peptide did not reveal which of the two methionine residues was oxidized.

Figure 1: Alignment of peptides obtained by LC-MS/MS analysis with PCBP2 and PCBP1

The sequences are presented using the single letter code. The numbers to the right designate the residue numbers of the amino acids at the end of each line. The identified peptide sequences are indicated in black. Peptide sequences labeled with more than one number were found more than once in the chromatogram due to various amino acid modifications.

Based on the mass spectral results, the cDNA was cloned. PCBP2 is 90% homologous to PCBP1 (Fig. 1). Although LC-MS/MS analysis did not indicate the presence of PCBP1, both cDNAs were cloned and both proteins expressed. Only the expressed PCBP2 protein showed specific domain-IV binding activity proving that the correct protein had been unambiguously identified.

Structure Studies of HIV Related Proteins Using MALDI/MS

Xiao-Hong Qian, Carol E. Parker, Rachelle Bienstock, Shanthini Jeyarajah and Kenneth B. Tomer
National Institute of Environmental Health Sciences
Research Triangle Park, NC 27709

There is considerable interest in structural studies of HIV related proteins because this information should be useful in unraveling the functions of these proteins, and in understanding the mechanisms of the functions of these proteins. With recent instrumental advances, mass spectrometry combined with chemical and biochemical reactions is playing an increasingly important role in the structure determination of proteins. In this presentation, we both determined an error in the primary structure and obtained information about the tertiary structure of truncated p24, a commercial recombinant HIV protein. In addition, using this structure information and the information we have obtained relating to antigenic determinants of HIV p24, we improved the molecular model of HIV p24.

The primary structure of truncated p24 was determined by molecular weight determination, proteolysis reaction and MALDI/MS identification. The MALDI/MS analyses were carried out on a PerSpective Biosystems Voyager RP instrument. The matrix used in this experiment was α -cyano-4-hydroxycinnamic acid. The tertiary structure of the truncated p24 was probed by chemical modification followed by proteolysis reaction combined with MALDI/MS. Chemical modification was carried out with glycnamide hydrochloride by stirring the reaction solution at room temperature for 1 hour and dialyzing against 0.1% TFA H_2O for 8 hours.

The expected proteolysis fragments from truncated p24 were observed except those arising from the N-terminus. Major fragments were observed, however, which corresponded to the N-terminus with eleven of the initial twelve amino acids in the leader sequence missing. The molecular weight calculated for this sequence is 21264 which compares very well with the determination molecular weight 21266 (Fig. 1). The MS spectra of the first fragment from the N-terminus with the deletion of eleven amino acid confirmed this observation (Fig. 2).

The tertiary structure of truncated p24 was probed by the reaction of the carboxyl group on Asp and Glu. The molecular weight of the fragment that has been modified by glycnamidation increases by 56 u. Relative reactivities were estimated from the relative abundance of the $[M+H]^+$ ions of the modified and unmodified fragment (Fig. 3). The results showed a selective modification of Asp-94, -165, -176 or -116 and Glu-188, -141, -172 or -111 while other Asp and Glu residues in truncated p24 did not react at a level detectable by MALDI/MS. The modification of Asp-94 was identified by $[M+H]^+$ ions 1681 (94-109) and 3336 (94-124) which is consistent with the results obtained by our epitope mapping experiments on HIV p26 which showed that residues 102-112 (HPVHAGDIAPG) recognized by a monoclonal antibody and therefore must be on the surface of the molecule.

Characterization of Covalent Modifications in a Viral Protease

by ESI-MS and MALDI-TOFMS

Douglas Sheeley¹, Lois Wright², Eric Furfine², and Mary Moyer¹

Depts. of ¹Chemistry and ²Biochemistry, Glaxo Wellcome Inc., 5 Moore Drive, RTP, NC 27709

The genomes of many viruses encode proteases which are required for the formation of infectious virions (1), and these viral proteases are excellent targets for rational drug design (2). An essential step in the design of a potent inhibitor of a viral protease is the characterization of the amino acids that define the enzyme active site, and the interactions of these amino acids and inhibitors. One useful technique for characterizing active site functional groups is to make covalent modifications to them and then locate these modifications in the protein sequence. Mass spectrometry has been applied to these problems previously (3). In this case, mass spectrometry has been used in conjunction with proteolysis and amino-terminal sequencing to characterize a protease from human cytomegalovirus (HCMV).

HCMV protease was modified with an inhibitor intended to bind covalently to an active-site histidine. The potency of this inhibitor was characterized by enzyme kinetics. Subsequent analysis of the intact protein by LC-MS determined the extent of protein modification, which was compared with kinetic data describing the degree of inhibition. LC-MS of the intact protein provided a rapid and effective method for correlation of kinetic data and the extent of covalent modification of the protease.

The modifications in HCMV protease have been mapped by a combination of LC-MS, nanoelectrospray MS/MS, MALDI-TOFMS, and amino-terminal sequencing. It was determined that the protein was modified not at a histidine residue, but at two cysteines. The unexpected result that these modifications occurred at cysteine residues points out the importance of full characterization of covalent modifications to proteins.

HPLC fractions containing modified and unmodified peptides were analyzed by nanoelectrospray, using a source of the design of Wilm and Mann (4), on a Sciex API III. The nanospray MS/MS spectrum of a 20 residue tryptic peptide containing a modified cysteine residue is shown in Figure 1. Only the singly charged Y ion series is labeled. Analysis of the observed fragment ions localizes the modification to the first three residues of the peptide. This agrees with amino-terminal sequence analysis and LC-MS, which indicate that the cysteine is the modified residue.

Tryptic digestion using a PoroszymeTM column was used in conjunction with MALDI in order to characterize sub-digests of HPLC fractions. A PoroszymeTM immobilized trypsin column packed in-house was equilibrated in ammonium bicarbonate, pH 8. Samples were loaded onto this column using a syringe pump, and eluted with 30 μ l of buffer at 3 μ l/min, according to the method of Blackburn and Anderegg (5). 1 μ l of the column eluent was applied directly to a MALDI target, dried, and overspotted with 1 μ l of a 10 mg/ml solution of α -cyano-4-hydroxycinnamic acid (ACH). Samples were analyzed using a Tofspec SE (VG Micromass) operating in the reflectron mode. Figure 2 shows MALDI-MS mass maps from subdigestion of an unmodified and modified Lys-C peptide. The ion at m/z 1047 corresponding to one cyst-containing fragment is consistent between spectra. However, the ion at m/z 1487, corresponding to the second cyst-containing fragment, is significantly diminished in the second spectrum, indicating that this site is modified. LC-MS analysis of tryptic subdigests performed in solution confirms this result. MALDI-TOFMS combined with immobilized trypsin columns permits the rapid generation and comparison of proteolytic maps (< 15 min) using less than 10 pmol of protein.

Characterization of BSA based immunogens by MALDI and ESI mass spectrometry

John C. Gebler, Maciej Adamczyk, and Philip G. Mattingly
ADD Divisional Organic Chemistry Research (9NM)
Abbott Laboratories
Abbott Park IL 60064

Immunogens are structurally complex materials which are used for eliciting antibodies. In order to obtain antibodies against small molecular weight compounds (haptens), immunogens are prepared by conjugating the hapten to a carrier protein such as BSA. A fundamental and important characteristic of a conjugate is the number of hapten covalently attached. Despite various methods available (UV-VIS, colorimetric titrations, radiolabelled hapten, or gel electrophoresis), our experience has shown that accurate characterization of BSA-hapten conjugates is very challenging.

The goal of this study was to explore the extent of chemical posttranslational modifications and analytical purity of selected BSA based immunogens by electrophoresis (SDS-PAGE), MALDI and ESI mass spectrometry. Fifteen immunogens were prepared using five different haptens (mol. wt. range of 227 to 473) coupling under three different ratios (5:1, 15:1, 30:1, hapten:BSA). The resulting conjugates were purified by dialysis and/or size exclusion chromatography. The results of analysis for one hapten series (biotin labeled BSA) is illustrated here (the other conjugates gave similar results).

Electrophoresis (SDS-PAGE, not illustrated) for all of the conjugates showed an increase in the apparent molecular weight which paralleled the increase of hapten to protein coupling ratio. In addition, none of the gels revealed crosslinked BSA. However, some of the conjugates gave apparent molecular weights that were below or equal to that of unmodified BSA. This may be due to the fact that the molecular weight standards employed are not appropriate for such modified proteins.

MALDI-MS spectra were obtained using sinapinic acid as the matrix. Experimentation with different concentrations of the conjugate were found to be an important factor for successful spectra generation. In addition, an enhancement of the ion generated signal was observed by washing the sample-matrix crystals with a dilute solution of trifluoroacetic acid just prior to analysis. The resulting spectra have broad peaks, presumably due to the heterogeneous nature of the investigated conjugates. Nevertheless, the spectra were useful for average molecular weight determinations.

Spectra from ESI-MS were recorded employing a HPLC (PLRP-S 2.1 x 50 mm column) interfaced to a heated pneumatically-assisted ionization source of a single quad instrument (Sciex API 100 with Turbo Ionspray ion source). In contrast to MALDI-MS, high resolution spectra were generated using the ESI-MS system. In each case the observed increase in protein mass corresponded to the molecular weight of an attached hapten. BY ESI-MS we observed up to 25 hapten covalently bound on a protein of ~66,430 which is ~40% of the available sites for modification. In addition, ESI-MS allowed us to also monitor a low molecular weight window for the presence of unbound coupling reagents. During the coupling reaction both hapten and BSA were observed. After completion and purification by dialysis or size-exclusion chromatography no residual coupling materials were detected.

ESI-MS appears to be the best single method for characterization of BSA based bioconjugates. In addition, ESI-MS was useful for monitoring the course of conjugation, purification procedures, and hapten integrity. MALDI-MS provided more qualitative information about the modified protein, but not with enough detail to differentiate between small changes. SDS-PAGE usefulness was limited to detecting crosslinked proteins which is a possible side reaction during the coupling process.

Formation and Stabilization of MHC Class II-Peptide Complexes: Results of a MALDI Study

Ilan Vidavsky¹, Andy B. Whitehill¹, Michael L. Gross¹, Chris A. Nelson² and Emil R. Unanue²

¹Department of Chemistry, Washington University, St. Louis, MO 63130

²Department of Pathology, Washington University, St. Louis, MO 63110

Efforts are under way to understand immunological problems by mass spectrometry. One of the problems is the immuno response of T cells to antigens on the cell surface. Extracellular proteins enter the cell via endosomes to be degraded by proteases. The endosome and its content eventually find their way to the cell surface. When an MHC class II molecule enters an endosome, a complex process occurs. The CLIPs (class-II associated invariant chain peptides) are removed by DM (MHC class-II related molecule) and, the MHC-II molecules take up antigenic peptides. The mechanism of unloading CLIP and loading an antigenic peptide is unknown. One hypothesis is that DM open the MHC-II molecule groove area so it can form a complex with a protein chain. This chain, except the part that is bound to the MHC is then degraded by exopeptidases present in the endosome. Thus, the MHC-peptide complex is protected from further degradation.

To test this hypothesis, we studied the peptides presented on the surface of APC (antigen presenting cells) in complexes with MHC-II molecules, after treatment with HEL (hen egg lysozyme). Previous results showed that after treatment with HEL and extracting the MHC class II complexes, the major HEL components are HEL 48-63, 48-62, 48-61 for I-A^k type APC. These results and the subsequent ones were obtained by MALDI-TOF analysis of HPLC-separated extracts from MHC-peptide complexes. PSD analysis was used to confirm peptide sequences.

To probe the processing mechanism, a series of mutated HEL proteins was prepared. These HELs were engineered by oligonucleotide-directed cDNA mutagenesis that encodes the HEL, and produced by expression of HEL (or mutated HEL) genes in the APC. Previous results (1) showed that an APC type I-A^k cell encoded with wild type HEL, a 14 amino-acid linker and approx. a 30 amino acid transmembrane segment (mHEL) presented mostly the HEL 48-63 and 48-62 peptides. Examination of a series of mutated mHEL encoded APC, by deleting amino acids, shows that the length of the amino side of the peptide is an important factor in determining which peptides will be eventually presented by the MHC-peptide complex. For each deletion, the major presented peptides conserved their length. Another important factor is the presence of an acidic amino acid like (e.g., Asp) in the fourth position. The peptide chain is probably also stabilized by a pocket in the MHC molecule under the major groove. These results are consistent with computer modeling and stability constants for peptides/MHC complexes. Prolin mutation of several sites on the HEL protein chain shows that if the mutation site is far from position 48 (e.g., positions 42 and 45) the MHC will present the same peptides as the wild type, but if the mutation site is nearby (e.g., positions 46 and 48), the chain length of the extended peptide becomes longer.

These results suggest that the processing of the peptide involves degradation of the long peptide chain by exopeptidases. The part of the chain in the groove is stabilized by the MHC molecule and is protected from further degradation. These results show also that not only extra-cellular but also endogenous proteins are sampled and presented by MHC Class

II complexes. The processing is probably taking place in early endosomes and not in lysosome vesicles.

MALDI-TOF MASS SPECTROMETRY AS THE SECOND DIMENSION IN 2D-PAGE EXPERIMENTS FOR THE STUDY OF BIOLOGICALLY DERIVED SAMPLES.

Nigel J. Clarke¹, Andy J. Tomlinson¹ and Stephen Naylor^{1,2}

¹ Biomedical Mass Spectrometry Facility and Dept. of Biochemistry and Molecular Biology, ² Dept. of Pharmacology and Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN 55905, USA

Introduction

Two dimensional polyacrylamide gel electrophoresis (2D-PAGE) is a well established separation technique that allows the user to resolve complex biological mixtures into their constituent parts. This separation is carried out in two stages:- dimension one separates on the basis of the compounds isoelectric point (pI), dimension two by the compounds molecular mass.

The use of mass spectrometry as a replacement to the isoelectric focusing stage is of great value allowing faster, easier and more accurate mass determination plus the ability to gain important structural information about the sample. The mass spectrometer of choice is the Matrix Assisted Laser Desorption Time of Flight (MALDI-TOF) instrument due to its simplicity of operation and large dynamic range.

Description of the study

This study took the form of an evaluation of the techniques available for sample preparation when combining PAGE with MALDI-TOF. To this end a series of experiments were completed examining the advantages and disadvantages of several possible methods of sample handling.

The results shown document the systematic evaluation of:

1. Direct laser ablation from the polyacrylamide gel.
2. Laser ablation from several types of electroblotted membranes.
3. The use of a novel microelution chamber combined with membrane preconcentration techniques developed in house (Figs. 1 and 2).

The power of a 2D-PAGE/MALDI-TOF system to examine possible diagnostic markers of disease state can be immediately recognised and the experience gained during this study will be of extreme value when examining complex samples such as cell lysates.

Conclusions

This investigation highlighted the difficulties inherent within a seemingly simple idea. The major problems do not appear to be due to either the PAGE experiments nor the mass spectrometry, both mature disciplines, but rather the method of extraction of the protein from the gel once separated

From the experience gained microelution appears to be the most appropriate procedure, allowing swift, efficient removal of the target proteins from the gel media and providing an automatic concentration step. The next stage will be to take this procedure on-line and incorporate the system into the more standard membrane pre-concentration capillary electrophoresis routinely carried out in this laboratory.

Mass spectrometry is contributing to a revolution in our understanding of cellular immunology. Specifically the identification and sequence determination of peptide antigens bound to major histocompatibility complex (MHC) class I and class II molecules has been impacted by micro-LC electrospray ionization tandem mass spectrometry. (1) MHC class II molecules bind peptides derived from proteins (or peptides) found in vesicles of the endosomal pathway. Subsequently, peptide-MHC class II complexes are displayed on the cell surface for recognition by CD4 T cells, where foreign antigens are recognized and an immunological response is initiated. Recent research has shown that many bound peptides originate from endogenous proteins. This mixture may play a role in the positive selection of CD4 T cell populations in the thymus. (2) In an effort to characterize the endogenous peptide mixture presented by murine MHC class II I-A^b, we are sequencing peptides using automated micro-LC-ESI-MS/MS and the database searching algorithm, SEQUEST. (3) We have synthesized several peptides and have assayed their binding to I-A^b. Here we show the data from these efforts.

Methods

Single cell suspensions were derived from B6 mouse spleens. The suspensions (3-5 x 10⁶/mL) were incubated with LPS (Sigma), 10 µg/mL, for 60 hrs at 37°C, 5-7% CO₂. Lymphocyte separation medium (Organon Teknica, Durham NC), ficoll, was used to separate B cells from the dead cellular material by centrifuging for 15 min at 2000 rpm (20°C). The B cells were washed and resuspended with PBS and frozen in dry ice. Cells were washed 2-3 times with phosphate buffer at 4°C. Cells (1 x 10⁶/mL) were lysed by resuspending in lysis buffer (1% NP-40, 25 mM iodoacetamide, PMSF, TLCK, in PBS) pH 7.4 and rocking gently for 1-2 hr at 4°C. Lysate was clarified by centrifugation (20000 x g) for 45 minutes. Lysate was passed over two columns in series, IgG-Sepharose (nonspecific) and Y3P-Sepharose (anti-I-A^b). (4) Class II molecules were eluted with DEA buffer (25mM diethylamine, 1% octyl-B-D-glucopyranoside, 150 mM NaCl, PMSF, TLCK, pH10.5). Peptides were dissociated from MHC molecules using 2.5 M acetic acid. (4) The mixture was passed through a Centricon 10 membrane filter to isolate the peptides. The peptides were further purified using reverse phase HPLC. Peptides were synthesized using f-MOC chemistry and purified using reverse phase HPLC. Competitive binding of synthesized peptides to MHC class II I-A^b molecules was assayed using a modified version of the procedure described by Jensen. (5) The endogenous peptide used for competition was Eα52-68. (4,6) Micro-column high performance liquid chromatography was performed as previously described. (3) using 75 µm i.d. fused silica columns packed with Perseptive Biosystems (Boston, MA) POROS 10 R2, a 10 µm reversed-phase packing material, to a length of 10-15 cm. Mass spectra were recorded on a Finnigan MAT (San Jose, CA) TSQ700 equipped with an electrospray ionization source as described before. (3) Automated tandem mass spectra were acquired using Instrument Control Language (ICL). (3) Amino acid sequence databases were searched directly with MS/MS spectra using a computer algorithm, SEQUEST, previously described (3) using the OWL database, version 26.2. Each sequence was verified by manually interpreting the corresponding spectrum.

Results

We are investigating the role endogenous peptides play in the positive selection of CD4 T cells. The first step was to determine the sequences of many of the peptides presented by MHC class II molecules using automated micro-LC electrospray ionization tandem mass spectrometry in combination with our database searching algorithm, SEQUEST. We have isolated peptides presented by murine MHC class II I-A^b molecules from LPS stimulated B cells. Of 44 HPLC fractions, 30 were analyzed by automated micro-LC tandem mass spectrometry. Each spectrum was used to directly search several databases, including the nonredundant OWL

database and the mouse subset of the OWL database. Eighteen peptide sequences were determined, Table 1. The majority of peptides were derived from immunological proteins. The next step was to determine if these peptides bind to MHC class II I-A^b molecules. Several peptides were synthesized. Competitive binding assays, with the peptide Eα52-68, were used to determine if the synthesized peptides could bind to I-A^b, *in vitro*. Several of the peptides did bind, Table 1.

We will continue to characterize the peptides presented by MHC class II I-A^b molecules using automated micro-LC-ESI-MS/MS and the database searching algorithm, SEQUEST. New peptides will be synthesized and we will test for binding to I-A^b molecules. In addition these peptides will be used to determine if a single peptide or a mixture of peptides can rescue CD4 T cell development in mice which have deficient CD4 T cell development.

IDENTIFICATION OF A HUMAN ALLOANTIGEN BY MASS SPECTROMETRY

Pamela H. Gulden, Wei Wang, Victor H. Engelhard, Jeffrey Shabanowitz and Donald F. Hunt
University of Virginia, Charlottesville, VA 22901

Introduction

T cells of the immune system are restricted by self-MHC. However, a large fraction of T cells from unimmunized animals have been found to respond to allogeneic stimulator cells, and are termed alloreactive T cells. An alloreactive response is when stimulator cells that express a certain MHC allele are recognized and killed by T cells from an individual that does not express that MHC allele. These strong cellular responses are thought to be the basis of allograft rejection. Understanding alloreactivity is a challenge that may shed light on the physiological responsiveness to self-MHC molecules in complex with foreign peptide.

Identification of the peptides that reconstitute epitopes recognized by alloreactive T cells is an important step in defining the molecular events involved in the alloreactive response. Here, we have combined mass spectrometry with ^{51}Cr release assay to identify an alloantigen presented by human A2.1 MHC class I molecules and recognized by A2.1 negative T cells.

Experimental and Results

A2.1 bound peptides were isolated using immunoaffinity purification followed by acid extraction, as described previously¹. Peptides were subjected to two dimensions of reversed-phase HPLC using different organic modifiers. Aliquots of these peptides were assayed for their ability to reconstitute the epitope recognized by the alloreactive T cell clone, MHN24, using ^{51}Cr release assay.

50% of second dimension bioactive fractions were separately analyzed using a post-column effluent splitting device. As the peptides were eluted off a microcapillary HPLC column, five sixths of the effluent was directed into the electrospray source of a triple quadrupole mass spectrometer (TSQ-700: a TSQ-70 (Finnigan-MAT, San Jose, CA) mass spectrometer upgraded with the electronics of a TSQ-700 and equipped with a Finnigan API ESI/CI source), while one fifth of the effluent was directed into the wells of a microtiter plate for subsequent ^{51}Cr release assay. Lytic activity of the MHN24 T cells could then be correlated with ion abundance of different ions present in the portion of the mass spectrum corresponding to the active wells. Although many ions were still present in the active wells, only two ions matched the lysis profile well: m/z 532²⁺ and m/z 921¹⁺ (See figure 1).

Using a TSQ-7000 (Finnigan-MAT, San Jose, CA) triple quadrupole mass spectrometer, approximately 10 fmols of m/z 921¹⁺ and of m/z 532²⁺ were used to sequence these ions. The sequence of m/z 532 was shown to be YXDPAQX (See figure 2), where X is either Leu or Ile. YXDPAQXN was able to reconstitute the MHN24 CTL epitope when tested by ^{51}Cr assay. Coelution experiments showed that the alloreactive peptide was actually YLDPAQQNL.

Discussion

Using mass spectrometry, we have identified a human alloantigen presented by A2.1 MHC molecules and recognized by the A2.1 negative CTL clone, MHN24. Because allogeneic responses are very strong, it has been proposed that alloreactive T cells with low reactivity are stimulated by a subset of class I-associated peptides that are expressed at the highest relative densities on the cell surface². However, we found that YLDPAQQNL was presented at levels

similar to other T cell antigens^{3,4,5}. This finding questions the validity of the low reactivity CTL/high density alloantigen theory of alloreactivity.

Graphs of Ion Abundance Versus % Lysis for Best Candidate Peptides

Figure 1:

Candidate peptides were chosen by comparing ion abundance to CTL activity, following a post-column effluent split of the second RP-HPLC purified fractions 17 and 18. Results of the Cr release assays are shown. The only ions matched the % lysis profile in both splits were ions 532 and 921.

Figure 2:

CAD spectra of (M+2H)²⁺ ions with m/z 532 were recorded on a TSQ-7000 (Finnigan-MAT, San Jose, CA). Predicted masses for fragment types b and y are shown above and below the deduced amino acid sequence. Ions observed in the spectrum are underlined.

Introduction

A very promising area in cancer immunotherapy is the prospect of developing effective tumor vaccines. In order to be able to do this, we need to understand the molecular events involved in a T cell response against tumors. Central to this response is the structure that the T cell recognizes as foreign, initiating the first step leading ultimately to the death of the tumor cell. We know that CTL recognize peptidic tumor antigens in complex with self-MHC class I molecules. Since MHC molecules present many more peptides derived from normal cellular proteins than antigenic peptides, identifying tumor antigens is a difficult task. Using irradiated murine colorectal tumor cells (CT26) transduced to secrete GM-CSF (CT26/GM-CSF) as a vaccine, anti-CT26 CTL were produced. Using these anti-CT26 CTL in ^{51}Cr release assay combined with triple quadrupole mass spectrometry, we were able to identify and characterize an immunodominant colorectal tumor antigen.

Experimental and Results

Immunoaffinity purified peptides were subjected to two dimensions of HPLC fractionation, using a different organic modifier in each fractionation, and aliquots were test by ^{51}Cr release CTL assay. The second dimension fractionation produced two bioactive fractions (fr. 20 and 21), each still containing more than 100 distinct peptide species.

To determine which of these peptides was the active CT26 tumor antigen, second dimension HPLC fractions 20 and 21 were separately rechromatographed by microcapillary HPLC. Using an on-line splitter, five-sixths of the effluent was directed into the source of a TSQ-70u (a TSQ-70 (Finnigan-MAT, San Jose, CA) upgraded with the electronics of a TSQ-700 and a Finnigan API ESI/CI source), while one-sixth was simultaneously collected into a 96-well microtiter plate for subsequent ^{51}Cr release assay. This allowed us to correlate reconstitution activity with ion abundance for individual peptides observed in the mass spectrum. Although, many peptides were present in the active wells (Figure 1A and B), the relative ion abundance of only one of these peptides (with mass to charge ratio (m/z) of 564) matched the activity profile of CT26WT-specific CTL sensitizing activity (Figure 1, inserts of A and B).

Free acid collision-activated dissociation (CAD) spectra of candidate peptide ions were recorded on a TSQ 7000 triple-quadrupole mass spectrometer (Finnigan-MAT, San Jose, CA). Approximately 10 fmols of m/z 564 was used to obtain CAD spectra of this peptide. Analysis of the mass spectrum produced (Figure 2), showed that its amino acid sequence was SPSYVYHQF. The identity of SPSYVYHQF as the bioactive peptide recognized by CT26-specific CTL was confirmed by demonstrating that synthetic peptide corresponding to the deduced sequence sensitized the surrogate target for lysis by an anti-CT26 CTL line.

Discussion

Using triple quadrupole mass spectrometry, we were able to identify and structurally characterize an immunodominant murine colorectal tumor antigen from the chemically induced

tumor, CT26. This peptide, which shows 100% homology to a portion of the MuLV envelope protein, gp70, is being used to test different tumor vaccine strategies. Preliminary data show mixed results. Adoptive transfer of anti-SPSYVYHQF CTL into mice protects them from challenge with CT26 tumors. Additionally, established CT26 tumors are irradiated upon adoptive transfer of anti-SPSYVYHQF CTL. However, when dendritic cells are pulsed with SPSYVYHQF and injected into mice, CT26 tumors still grow upon challenge. This could be due to the lack of a CD4 positive T cell epitope, which would be presented by MHC class II molecules. This possibility is under investigation.

Figure 1: Summation of mass spectra recorded on peptides deposited in active wells for fraction 20 and 21 is shown in (A) and (B), respectively. Results of the ^{51}Cr release assays are shown as percent specific release in inserts of (A) and (B) from fraction 20 and 21, respectively. Peptide ion abundance is shown for the peptide with m/z value of 564 for fraction 20 and 21 in inserts of (A) and (B), respectively.

Figure 2: Free acid collision-activated dissociation (CAD) spectra of approximately 10 fmol of m/z 564 were recorded on a TSQ-7000 triple quadrupole mass spectrometer (Finnigan-MAT, San Jose, CA).

The Identification of a human Male-Specific Histocompatibility Antigen H-Y

Leslie R. Meadows, Nicholas E Sherman, Jeffrey Shabanowitz, and Donald Hunt
University of Virginia, Dept. of Chemistry, McCormick Road, Charlottesville, Va 22901

Joke M.M. den Haan, and Els Goulmy
Dept. of Immunohematology and Bloodbank, University Hospital, Bldg. 1 E3-Q, Rijsburgerweg 10, 2333 AA, Leiden, The Netherlands

Wei Wang, Victor Engelhard
University of Virginia, Dept. of Microbiology, MR-4 Bldg. 4072C, Charlottesville, Va 22901

H-Y is a transplantation antigen that can lead to the rejection of HLA-matched male organ and bone marrow in female transplantation patients. However, the origin and function of H-Y antigens has eluded researchers for 40 years. The H-Y antigens are peptides derived from cellular proteins that are associated with MHC-class I molecules on the cell surface and recognized as antigens by T lymphocyte cells. As with other minor antigens, the recognition of H-Y by T lymphocytes is MHC restricted. By combining microcapillary liquid chromatography-electrospray ionization mass spectrometry with T cell epitope reconstitution assays we have identified a peptide antigen recognized by a human cytotoxic T lymphocyte (CTL) clone that is H-Y specific and restricted by the class I MHC molecule HLA-B7.¹

HLA-B7 restricted peptides were purified by affinity chromatography from a B lymphoblastoid cell line, JY. The peptides were separated by reverse-phase HPLC, and aliquots of each fraction were assayed with the H-Y specific CTL clone for H-Y activity. The active peaks were then applied separately to a microcapillary HPLC column and the effluent was split following separation.² Four-fifths of the effluent was directed into an electrospray ionization mass spectrometer for analysis, while one-fifth was simultaneously directed into a 96-well microtiter plate for subsequent epitope reconstitution assay. By correlating the assay data with ion abundance from the mass spectrometer, we were able to identify an $(M+3H)^{3+}$ ion at a m/z ratio of 391, whose abundance correlated with the amount of H-Y epitope reconstituting activity. A CAD mass spectrum of peptide 1171 was recorded at the femtomole level on a Finnigan-MAT TSQ-7000 (Figure 1). Assignment of a complete amino acid sequence proved difficult due to the absence of high mass fragment ions containing the amine terminus (b-type ions). A CAD mass spectrum was also recorded on the naturally processed material after conversion of the R residue to ornithine (Figure 2). From these CAD spectra and derivitization data the amino acid sequence was determined to be SPSVDKARAEI. This peptide is derived from a protein called SMCY, an evolutionarily conserved Y chromosome protein expressed in all male tissue tested. Half maximal lysis for the synthetic of this peptide was achieved at 10pM. There is a homologous SMCY protein located on the X chromosome called SMCX. The corresponding SMCX peptide SPAVDKAQAEI was also present in the naturally processed peptide extract of HLA-B7, but its abundance was only 25% of the SMCY peptide. The SMCX peptide achieved half-maximal lysis at 10,000-fold higher peptide concentration. The concentration of the SMCY peptide that inhibited the binding of an iodinated standard peptide to purified HLA-B7 by 50% (IC_{50}) was 34 nM, whereas the IC_{50} for the SMCX peptide was 140 nM. This HLA-B7 H-Y minor antigen and other H-Y specific peptides are candidates for immunomodulatory approaches in bone marrow transplantation.

HLA-A2.1 and HLA-A1 restricted H-Y minor antigens are currently being investigated. Genetic mapping of the mouse Y chromosome has suggested at least two and up to five distinct loci encoding H-Y antigens. It will be interesting to determine whether the HLA-A2.1 and the HLA-A1 restricted H-Y antigens are also derived from the SMCY protein or arise from other proteins located on the Y chromosome.

Identification of Class II Target Antigens in Multiple Sclerosis

Carthene Bazemore Walker*, Bob Settlage*, Jeffrey Shabanowitz*, and Donald Hunt*[^]
Departments of *Chemistry and ^Pathology, University of Virginia, Charlottesville, VA 22901;

Ken Snoke, and Alex Sette
Cytel Corporation, San Diego, CA 92121

Recent immunological studies have implicated the central nervous systems proteins, myelin basic protein (MBP) and proteolipid protein (PLP), as the principal sources of target antigens for MHC class II autoreactive T-lymphocytes.¹ The self-reactive lymphocytes destroy the myelin sheath, leaving the nerve fibers unprotected and susceptible to many neurological dysfunctions. However, the role of autoreactive T-cells has been difficult to prove although the encephalitogenicity of both MBP and PLP has been widely established.¹ Therefore, the structural characterization of processed antigens from cells presenting fragments from the two proteins should aid in defining the mechanism of multiple sclerosis induction by MHC class II restricted autoaggressive lymphocytes.

DR2-associated peptides were obtained from human B-cell lymphomas cultured with crude preparations of bovine brain. An unpulsed B-cell lymphoma was used as a control. The peptides were subjected to reverse-phase HPLC and then a combination of microcapillary HPLC-ESI mass spectrometry. Although the mixtures were still complex, ions could be found in the pulsed cell lines that were not present in the control cells. The presence of these unique ions in the cultured cells suggests that the pulsed cells could endocytose the externally cultured proteins, process them, and present peptide fragments on the surface of their cells.

The identified candidate peptide ions were analyzed by tandem mass spectrometry on a Finnigan MAT TSQ 7000. Although sequence analysis of class I peptides in complex mixtures has been performed routinely in our laboratory, identification of these class II peptides has been a formidable task. The analysis of the larger class II peptides (15-25 amino acids vs. 8-11 residues for class I) is complicated by the higher charged states observed for the precursor ions. Under low energy conditions, incomplete fragmentation occurs along the peptide backbone. Also, peptide modifications such as acetylation, esterification, and arginine conversion² provided little additional information.

The viability of MSⁿ experiments using a quadrupole ion trap mass spectrometer (Finnigan MAT LCQ) was explored to facilitate sequence identification. A case study was conducted on a model class II synthetic peptide. Figures 1 and 2 show the MS/MS data for the (M+5H)⁵⁺ ion (m/z 550) of the model synthetic peptide, GRTQDENPVVHFFKNIVTPRTPPP, obtained on a TSQ 7000 and a LCQ, respectively. Qualitative inspection of the ion trap data clearly shows additional sequence information. Complete sequence identification of the peptide was accomplished by additional MSⁿ experiments.

Reverse phase HPLC and on-line microcapillary HPLC-ESI-MS were used in this study to identify and sequence putative target antigens in multiple sclerosis. Complete sequence information was not attainable using a triple quadrupole instrument. However, preliminary data suggest that MSⁿ experiments of multiply protonated peptides will yield additional information (at the least) or nearly complete structural information (at best). Future experiments will be conducted on the unknown class II peptides using an LCQ. Obtaining sequence information

about peptides associated with this disease will provide insight into the mechanism of antigen processing and presentation. Moreover, it will further the understanding of the pathogenesis of multiple sclerosis and eventually lead to useful therapies and treatments.

Proteolytic Processing of a 44-mer Ovalbumin Peptide by the Murine Proteasome

Gina M. King, Jeffrey Shabanowitz, and Donald F. Hunt
University of Virginia, Charlottesville, VA 22901

Gabi Niedermann and Klaus Eichmann
Max-Planck-Institute for Immunology, Freiburg, Germany

A complex mixture of more than 10,000 peptide fragments derived from cellular proteins is displayed on the surface of nucleated mammalian cells by class I molecules of the major histocompatibility complex (MHC). Cytotoxic T lymphocytes (CTL), killer cells, bind to class I molecules, sample the peptides presented, and lyse those cells that display peptides derived from viral infection or other disease states. One mechanism for peptide presentation involves proteolysis of cellular proteins in the cytoplasm, followed by transport of peptides into the endoplasmic reticulum, a compartment where peptide-MHC I complexes are assembled. Once peptides become associated with class I molecules, the resulting complex moves to the cell surface. The initial degradation of proteins in the cytoplasm is thought to occur by a 700 kDa multi-component enzyme complex called a proteasome. The specificity of the enzymes in this complex determine, in part, which peptide fragments are generated from a particular protein and presented to the immune system. Here we describe the use of mass spectrometry to follow the production of peptides from a portion of a 44 kDa glycoprotein, ovalbumin, by a murine proteasome.

Two synthetic peptides, a 22-mer and a 44-mer, both found in the ovalbumin amino acid sequence, were subjected to proteolytic degradation by the proteasome and sampled at various time points (30 minutes, 1 hour, 5 hours, 10 hours, 15 hours, 20 hours and 25 hours). Digests were carried out *in vitro* with 20mM HEPES buffer, 5mM magnesium chloride, 1mM EGTA, 300 fmol of purified murine proteasome, and 5 nmol of peptide at pH=7.8. All degradation products were analyzed directly by a Finnigan TSQ 70 mass spectrometer equipped with an on-line microcapillary HPLC and electrospray ionization source. Peptide products were collisionally dissociated and sequenced. Relative abundances of peptides produced by the proteasome were determined by spiking known amounts of several peptide standards into the product mixture and performing co-elution experiments. The immunodominant peptide, SIINFEKL, generated from both the 22-mer containing SIINFEKL and the 44-mer containing SIINFEKL, and was identified as the most abundant peptide in both preparations at all time points. This finding is consistent with other studies performed with ovalbumin derived peptides and proteasomes (1) (2). The SIINFEKL peptide binds with high affinity to the class I molecule and elicits a strong CTL response *in vivo* (1).

We conclude from these studies that the proteasome plays a role in antigen processing. We found that the 20S murine proteasome cleaves virtually every peptide bond on the peptide substrate, but peptide products are generated with different efficiencies. The SIINFEKL peptide is produced after 30 minutes of digestion and the concentration of this peptide increases up to 20 hours and then levels out up to 25 hours. In general, most other peptides are created and subsequently destroyed over the time course.

The studies of targeting signals of protein which imports into peroxisomes are significant since human diseases such as Zellweger's syndrome and infantile Fefsum's disease, which result in severe neurological impairment, are due to peroximal disorders. It is found that an SKL-like tripeptide sequence at Carboxyl-terminus of the peroxisomal protein is one of the targeting signals involved in direct transport of passenger proteins to peroxisomes. In order to identify other internal targeting signals in the peroximal proteins such as isocitrate lyase, a derivative of isocitrate lyase lacking the C-terminal SRM tripeptide signal will be introduced into an *in vitro* import assay to see whether successful import can be achieved so that the targeting determinants can be defined.

The protein isocitrate lyase (IL) and its mutated protein which lacks the three C-terminal amino acids SRM (IL-3) were synthesized *in vitro*. The DNA construct, which encodes a truncated isocitrate lyase which lacks the carboxyl-terminal targeting signal is made by PCR reaction. Normally sequencing of whole DNA is required here to make sure that the altered DNA bears the correct sequence that will give rise to the designed mutated protein. *In vitro* transcription and translation were followed to make the isocitrate lyase (IL) and its mutated protein (IL-3).

Initially, we were planning to digest the proteins by trypsin. Though trypsin is the most commonly used enzyme to digest proteins, it is not a good choice in this case. First, the tripeptide SRM in which we are interested bears a cleavage site of trypsin, thus reduce the difference of molecular weights of the corresponding digested fragments of isocitrate lyase and its mutated protein. Moreover, there is an interesting observation when the radioactive-labeled proteins were run on a SDS-PAGE gel (figure 1). Several bands of smaller-sized proteins whose molecular weights ranging from 20 kDa to 50 kDa were observed as well as the isocitrate lyase proteins whose molecular weights are 64 kDa. This is due to the internal initiation of translation, that is, these proteins were translated starting from the internal methionine residues instead of the first methionine. The presence of the mixture of proteins generated in the process of *in vitro* translation will complicated the analysis.

To solve this problem, one method involving separating isocitrate lyase or its mutated protein from the mixture, for example by HPLC, and digesting them. This method, though simple and straightforward, requires long separation time and optimization of separation conditions. Another way to analyze the proteins is to digest the

mixture of proteins directly without separation using CNBr. Since CNBr cleaves proteins at the C-terminal of methionines, digestion of the mixture of proteins generated from *in vitro* translation gives rise to the same profile of peptide fragments as the intact isocitrate lyase, since all the proteins in the mixture begin with methionine residues. Furthermore, since we are interested in the C-terminal mutations, after the digestion of the mixture proteins by CNBr, the fragment that results from the C-terminal becomes the most abundant among all the fragments. This improves the sensitivity of detection.

Capillary electrophoresis can be used to separate these CNBr digests of isocitrate lyase and its mutated protein, where each fragment is subject to mass analysis. The fragments that carry different amino acid sequence for these two proteins have molecular weights of 1334.6 and 960.1, respectively. The difference of molecular weights is 374.5, and this can be easily detected on a mass spectrometer.

Mutation of proteins at specific sites have been widely and commonly used in the biological research to help to determine the active sites of proteins, and mutations of proteins can be easily implemented by the application of recombinant DNA techniques. Instead of sequencing the entire DNA encoding the altered proteins with radioactive labeling, mass analysis requires digestion of proteins and comparison of the molecular weights of the resulting fragments, the mutations and mutation sites can be easily determined by mass shift. Therefore, mass analysis of proteins provides an alternative, and more straightforward detection of mutations of recombinant proteins.

Capillary LC/MS for Structural Confirmation of Nucleoside Diphosphate Kinases

Mark G. Qian, Kefei Zheng, Yajuan Chen, Christina L. Chang¹, and David M. Lubman

Departments of Chemistry and ¹Pediatrics
The University of Michigan, Ann Arbor, MI 48109

Nucleoside Diphosphate Kinase (NDPK, E.C. 2.7.4.6) is a family of proteins functioning as the catalyst for conversion of diphosphate to its triphosphate counterpart. It has two major isoforms with high conservation among different species. Recent studies have shown that NDPK may be involved in tumor metastasis. In human carcinomas such as thyroid, pancreatic and squamous-cell lung, high protein and RNA levels of NDPK were detected in aggressive tumors. In order to better study the functions of the NDPK, three human NDPK isoforms, wild-type NDPK A, mutant NDPK A, and wild-type NDPK B, were recently cloned, expressed in *E. coli*, and purified to homogeneity, which was evidenced by 2-D gel electrophoresis followed by Western blotting using both polyclonal and monoclonal antibodies against the NDPK.^[1] All three isoforms have 152 amino acid residues, and this work has been focused on using capillary LC/MS combined with chemical/enzymatic cleavage to verify the primary structures of the three NDPK isoforms.

Packed-capillary HPLC was coupled with an ion trap storage/reflectron time-of-flight mass spectrometer (LC/IT/reTOF-MS) through an electrospray ionization interface for this application. Taking advantage of the total ion storage capabilities of the trap over an extended mass range and the high sensitivity from the packed capillary column with i.d. as small as 250 μ m, high sensitivity peptide mapping in the low picomole range was achieved for the three NDPK isoforms. This high sensitivity was achieved while also maintaining a mass resolution of nearly 1500 for high-fidelity mass identification. For the structural confirmation of the sequence of wild-type NDPK A and B (88% homology), two sets of chemical/proteolytic digestion (trypsin and CNBr/V8) were generated independently (see figures 1 and 2) followed by LC/MS analysis of the molecular weight of each protein fragment. The complementary information from the two chromatographic analyses allowed for the verification of 86% and 98% sequence of NDPK A and NDPK B, respectively. A strategy combining chemical/enzymatic digestions as well as collision induced dissociation (CID) in the electrospray source was successfully employed to infer the minor primary structural differences among the three recombinant proteins. A single mutation of serine 120 to glycine was verified between the wild-type NDPK A and its mutant ($\Delta m = 30$ amu) by both selective ion monitoring and ion source CID of the protein fragment containing the mutation site. The experiments clearly demonstrated that the high sensitivity of the capillary HPLC separation together with the advantages of the IT/reTOF-MS could provide a low cost, high performance means for protein structural analysis.

CHARACTERISATION OF THE PROTEOLYTIC SITES OF PROTEASES ISOLATED FROM *P. gingivalis* W50 USING MALDI-MS

Sally U and Chris Sutton

Thermo BioAnalysis Ltd., Paradise, Hemel Hempstead, HP2 4TG, UK

Minnie Rangarajan

MRC Molecular Pathogenesis Group, London Hospital Medical College, London E1, UK

P. gingivalis W50 is one of several organisms implicated in periodontal disease. There are many secretory products of which proteases are one of the most important virulence factors. An arginine specific cleaving protease has been isolated from the culture supernatant.

ArgI a hetero-dimer ($\alpha\beta$)

ArgIA a monomer (α)

ArgIB contains the α monomer with LPS covalently attached

All three enzymes have an optimum pH of 8.0 for activity, require thiol groups and are stabilised and slightly stimulated by calcium ions.

Previous work with inhibitors have shown that all three hydrolyse the arginyl-peptide bond.

Also, by using small peptides and proteins such as glucagon, melittin and insulin B chain, ArgI and ArgIA were found to cleave specifically at the carboxyl-side of L-arginine residues, as analysed by MALDI.

MALDI-MS is a well established technique in the characterisation of proteins and peptides due to its rapid analysis time and tolerance for buffer and detergents found in most samples. It is also a very useful technique in monitoring the progress of enzymatic reactions.

This presentation describes the determination of specific cleavage sites by ArgI and ArgIA of much larger naturally occurring substrates found in human blood, for example, haemoglobin and albumin. These substrates were digested both in the native and denatured states. By analysing aliquots of reaction mixtures at various time intervals, it is possible to monitor the progress of reaction and determine optimal conditions for digests. The digest was performed with an enzyme to substrate ratio of 1:1000 for 0 minutes, 30 minutes, 1, 2 and 4 hours.

No difference was observed in the digest patterns between the native and denatured forms of haemoglobin.

ArgIA seemed to digest haemoglobin more rapidly than ArgI.

After cleavage of the specific arginyl-peptide bonds, non-specific cleavages may occur, fragments observed corresponding to lysyl-peptide bonds as observed for the 2 and 4hrs digest with ArgI and the digest with ArgIA.

The peptide mass fragments spectrum from the native and denatured albumin digest are shown in figure 1.

Figure 1. Spectra obtained from a digest of both native and denatured albumin with ArgI for 1 hour.

It can be seen that more fragments were generated at the same time points, due to the proteolytic sites being more accessible from the denatured protein to the proteases for a larger substrate

Once again, it can be seen that upon prolonged digestion, especially in the case of the denatured albumin, the lysyl-peptide bonds were susceptible to cleavage after the arginyl-peptide bonds had been cleaved.

Using MALDI to accurately assign mass values to these fragments and a general protein analysis software, it was possible to rapidly identify the source and position of these peptides and hence determine the specificity of these proteases.

By further optimising digest conditions by MALDI, it should be possible to determine the rates of cleavage of preferential sites and also determine the adjacent residues and hence any sequence specificity of these cleavage sites. This is under current investigation.

MALDI-MS has proved to be a very valuable technique in the detailed characterisation of proteolytic sites of proteases.

Analysis of Purified Human Serum Albumin by Electrospray Ionization Mass Spectrometry.

email:tcyr@hpb.hwc.ca

Introduction: Human serum albumin (hsa) is the major protein in blood; its function is to preserve plasma osmotic pressure and assist in the transport of large organic anions. The electrospray ionization mass spectra of either hsa or albumin from other mammals has been reported several times. The mass of the major component of hsa has been fairly consistently reported as $66,438 \pm 20$ Da [ex. $66,440^5$, $66,444^4$, $66,460^2$ Da]. There have also been numerous references to the appearance of additional components, generally of higher mass to the parent. These are usually ascribed to: impurity adducts (sodium, sulfate or phosphate), glycosylation, aminoglycosylation, hydrolysis and reaction with the free cysteine. Our interest stemmed from the fact that hsa is used as a carrier molecule in the formulation of recombinant biotech products such as erythropoietin.

Methods: Instrument 1: AutoSpec-Q (EBE-qQ geometry). Electrospray ion source, spray housing @ 55° C; scan range 2300-1000 @ 100 sec/dec. Needle voltage = 8.0 kV, Sampling cone = 4.2 kV (36.8%), Skimmer lens = 4.2 kV (37.1%), Ring electrode = 4.0 kV (29.9%) and accelerating voltage = 4.0 kV. Source/analyzer/inlet vacuum = $3 \times 10^{-6}/6 \times 10^{-8}/0.2$ mbar.

Instrument 2: VG Quattro (Q-Q-Q), ESI source temperature @ 80° C; scan range 2000-1000 @ 10 sec/scan. Thanks to Dr. Frank Benoit, Environmental Health Directorate for the use and operation of instrument 2.

Human albumin samples were obtained from Pentex, Miles Inc. Sample purification: initial attempts, using instrument 1, to analyze the samples were not successful. The hsa was thought to contain minor amounts of interfering cations. Membrane dialysis from acidified water followed by lyophilization did not improve the spectra. Therefore, the hsa was denatured with urea then sequentially dialyzed against water, followed by lyophilization.

Sample preparation: The samples were dissolved in 5% acetic acid/purified water, diluted 1:1 with methanol or acetonitrile, then filtered ($0.45 \mu\text{m}$).

Results and Conclusions: The transform of the Maximum Entropy continuum spectrum from the ESI/MS analysis (instrument 2) of purified hsa is shown in Figures 1. The major component has a mass of $66,435 \pm 5$ Da, which is very close to the calculated² mass for hsa 66,438 Da. Additional components have mass differences of {possible modification}: +39 {acetylation +42, 2X proteolysis +36}, +115 {phosphate or sulfate +98, cysteinylolation +119}, +166 {hexosamine +161, hexose +162}, 201 {N-acetylhexosamine +203}, +272 {sialic acid +291}.

Mass Spectrometric Analysis of the Lens Membrane Protein MP26

K.L. Schey¹, J.G. Fowler¹, J. Dillon² and R.K. Crouch³

Departments of Pharmacology¹ and Ophthalmology³, Medical University of South Carolina, 171 Ashely Ave, Charleston, SC 29425

Department of Ophthalmology², Columbia University, 630 West 168th St., New York, NY 10032

Analysis of hydrophobic membrane proteins remains a great challenge to structural biochemistry. Recent advances in mass spectrometry of biomolecules provide attractive alternative methods to characterize membrane proteins. MP26 is the major intrinsic membrane protein in the lens having a predicted molecular weight of 28,224 Da. The function of this abundant protein remains unknown although it is likely to play a role in channel formation. MP26 has been reported to be phosphorylated in the vicinity of the C-terminus¹ and additional, uncharacterized, modifications have been reported for MP26 isolated from cataractous lenses². We have applied mass spectrometric methods to the analysis of bovine lens MP26 in an effort to map the protein sequence and identify sites of modification. The methodology developed will be used in the analysis of protein modification during cataract formation.

MP26 was isolated from bovine lenses by homogenizing lenses, pelleting the membranes, washing with 7M urea followed by sucrose gradient centrifugation. Membranes containing MP26 were cleaved with cyanogen bromide (CNBr) in 85% acetic acid followed by HPLC purification using a 2.1mm X 30mm C₄ column with a gradient from 98% aqueous TFA (0.1%) to 98% isopropanol/acetonitrile (2:1), 0.07% TFA. Purified fractions were analyzed by MALDI and electrospray (ESI). CNBr cleavage products were digested with trypsin (NH₄HCO₃ buffer, pH 8.5) and endoproteinase Glu-C ((NH₄)₂CO₃ buffer, pH 7.86) followed by MALDI and electrospray analysis. Tandem mass spectrometry (MS/MS) was carried out on tryptic peptides ionized from the digest mixtures.

HPLC fractionation of the CNBr digest revealed a large signal at 26 min. containing three C-terminal peptides 177-263, M_r 9511; 177-263(M¹⁸³ox), M_r 9558; and 184-263, M_r 8797 which were identified by ESI-MS (Figure 1). A signal 80 Da higher in mass was observed for each sequence which indicative of the predicted C-terminal phosphorylation. The entire C-terminal sequence was observed from the combined tryptic and Glu-C maps (Figure 2). Overlapping signals for phosphopeptides (underlined in Figure 3) identified a site of phosphorylation as Ser235. Tandem mass spectra confirmed some of the C-terminal sequence (outlined letters in Figure 3).

Successful mapping of this hydrophobic membrane protein has revealed a site of phosphorylation and confirmed a portion of the C-terminal sequence. Further confirmation of sequence and phosphorylation sites will be accomplished by MS/MS experiments.

Characterization of Insect Diuretic Hormone Proteolysis by RP-HPLC/ESI-MS

Hong Li, Kathy Schegg, Houle Wang, Robert Maxwell, and David Schooley
Department of Biochemistry, University of Nevada, Reno, NV 89557

Introduction

The diuretic hormone of tobacco hornworm, *Manduca sexta*, (Mas-DH) is an amidated peptide with 41 residues. It was the first isolated of a family of insect diuretic peptides that are related to corticotropin-releasing factor. We used microbore RP-HPLC coupled to ESI-MS to identify the metabolites of Mas-DH after *in vitro* incubation with Malpighian tubule (Mt), the target organ of Mas-DH. This technique allows identification of metabolites from Mas-DH added at ~1 μ M.

Methods

Mas-DH metabolism studies

1. Malpighian tubule (Mt) dissection; 2. Pre-incubate for 1 hr; 3. Incubate with synthetic hormone at 30 °C for 1 or 2 hr; 4. Stop the incubation by taking out the Mt, and adding 100 μ l of 2% TFA/CH₃CN; 5. Freeze samples in liquid N₂ and store in -20 °C; 6. RP-HPLC/ESI-MS (HPLC: UMA-Michrom BioResources. Mass Spec: Finnigan MAT SSQ 710); 7. Amino acid analysis/Edman degradation of major metabolites.

Mas-DH degrading endopeptidase purification

1. Substrate ALRAAA was synthesized; 2. coupling of 4-dimethylaminoazobenzene-4'-isothiocyanate to the N terminus of ALRAAA according to the methods of Norman and Chang (*JBC* vol. 260, pp2653-2656, 1985). DABTC-ALRAAA is a chromogenic substrate for endopeptidase assay; 3. peptidase activity partition assay (Fig. 1); 4. Endopeptidase purification: A. Mt dissections (300-500 animals), B. Extraction; C. Isoelectric focusing (BioRad Rotofor); D. Ion exchange chromatography (Mono Q); E. Reversed phase HPLC (PLRP).

Results

1. Mas-DH is cleaved and oxidized by Mt (Fig. 2). As determined by the agreement of calculated with measured M_r , the metabolites observed were R¹-L²⁹, R¹-R³⁰, Mas-DH plus two O atoms, and two different forms of Mas-DH plus one O atom (Fig. 3). The identification of the major metabolites indicates that the initial proteolytic sites are R³⁰-A³¹, L²⁹-R³⁰. Mas-DH is also oxidized at M² and M¹¹.

3. Partial purification of the endopeptidase. The isoelectric focusing purification of the endopeptidase by Rotofor indicated that its pI is ~6 (Fig. 4). Anion exchange chromatography by Mono Q column (FPLC) enabled further purification of this enzyme. Final RPLC purification was performed on a polymer column. However the protein concentration was too low for definitive MW determination by MS.

Conclusions

Mas-DH is metabolized via two overlapping pathways, proteolysis and oxidation (Fig. 5). An endopeptidase has been partially purified with the aid of a synthetic substrate-based partition assay. The protease has a pI at ~6.

Fig. 1

Peptidase Activity Partition Assay

Fig. 2 RP-HPLC separation of Mas-DH metabolites.

Expt cond: Incubation of Mt (1 cm) with Mas-DH (1 μ M) @ 30 °C for 1, 5, 60, 90 & 120 min. Reliasil C₁₈ column (0.5x150 mm) @ 20 μ l/min and 50 °C. Gradient: 20-40%B in 7 min, 40-45%B in 5 min & 45-65%B in 8 min. LC/MS was used to identify peaks. 1. Mas-DH + 2O, 2 & 3. Mas-DH + O, 4. R¹-R³⁰; 5. R¹-L²⁹.

Fig. 5 Mas-DH degradation pathways.

Fig. 4 Isoelectric focusing purification of Mas-DH degrading endopeptidase. Expt cond: BioRad Rotofor. Ampholyte pH range, 2-12.5. Protease activity is proportional to A₄₅₀ of the upper phase. The most active fractions are #6 and 7, indicating the pI of the protease is at about 6.

Location of Oxidized Residues in Bovine α -Crystallins by HPLC/ESI/MS and CF-FAB MS/MS

Xiangyu Jiang, Jean B. Smith, David L. Smith, E. C. Abraham*
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304 and Department of Biochemistry and Molecular Biology, Medical College of Georgia, Augusta, GA 30912-2100*

Cataract, the major cause of blindness worldwide, occurs when the lens proteins, called crystallins, become opaque due to aggregation and precipitation. Oxidation of lens crystallins is thought to be a major contributor to age-related cataractogenesis. Recent investigations have shown that in vitro oxidation decreases the α -crystallin chaperone activity that prevents aggregation and precipitation of other crystallins. Of the several oxidation reactions examined, the most effective in inhibiting chaperone activity was oxidation by Fe(III) chloride and hydrogen peroxide.

α -Crystallins were isolated from bovine lens extracts by gel filtration chromatography (Sephacryl S-300-HR) and oxidized by incubation with 0.1 mM FeCl₃ and 1 mM H₂O₂ for 24 hrs.

Oxidized and unoxidized α A- and α B-crystallins were separated by reversed phase HPLC on a Vydac C4 column. The molecular weights of both α A- and α B-crystallin, determined by ESIMS (Fisons VG Platform II), were each 32 Da higher than the calculated molecular weights of the unmodified proteins (Table 1).

Table 1. Molecular weights of α -crystallins

Protein	Unoxidized	Oxidized
α A-crystallin	19,832	19,864
α B-crystallin	20,079	20,111

To determine what regions of the proteins were oxidized, and consequently are implicated in the loss of chaperone activity, the oxidized α -crystallins were enzymatically digested into peptides. Initially, the digestion employed trypsin, which cleaves C-terminally to lysine and arginine. The molecular weights of peptides were determined by on-line reversed phase HPLC-ESIMS (Fisons VG Platform II). The HPLC system consisted of Gilson pumps, an Upchurch low volume mixing tee and a Rheodyne 8125 injector with a Vydac 50x1 mm C8 column. The flow rate was 50 μ l/min with a post-column splitter that allowed 5 μ l/min to enter the mass spectrometer and 45 μ l/min to be monitored by a UV detector and collected for further MS/MS analysis.

In α B-crystallin, two peptides, 1-11 and 57-69, were observed with molecular weights 16 u higher than their unmodified peptides. In α A-crystallin, only peptide 1-11 was observed with a 16 u higher molecular weight; but a peptide containing the other modification was not seen. Therefore, α A-crystallin was digested with endoproteinase Asp-N, which cleaves N-terminally to aspartic acid. In this digest, peptide 136-150 was observed with a molecular weight 16 u higher than the corresponding unmodified peptide.

Because the modified peptides included several residues that could be oxidized, i.e. Met, Trp, Cys, His, the exact location of the oxidation was determined by continuous flow-FAB MS/MS analysis. The flow rate for was 2 μ l/min; the solvent was 1:1 aqueous acetonitrile with 3% glycerol and 3% thioglycerol. The analysis used a Fisons VG Autospec equipped with an orthogonal acceleration TOF mass analyzer with Xe (1.1x10⁻⁶ mbar) as a collision gas. The MS/MS spectrum for peptide 136-150 from α A is shown in Fig.1. In addition to the expected b and y⁺ series, each b fragment containing an oxidized Met also gave a b-64 peak. This loss of 64 u, which has not been previously reported, can be attributed to the loss of neutral HSOCH₃ from the side chain as shown below:

The 64 u loss was also observed from MH⁺ (1457.9). The MS/MS spectrum of peptide 57-69 from α B shows y⁺-64 series because the oxidized Met is near the C-terminus. The MS/MS spectra of the peptides containing Met residues showed conclusively that all four Met residues of α -crystallins are oxidized with one oxygen attached to each Met. The loss of 64 u in the fragmentation pattern may be useful in detecting oxidized methionine residues in other proteins.

Fig. 1

Isolation and Structural Determination of Modified Human Alpha-crystallins by IEX, LC-MS and MS/MS

Peiping Lin, Jean B. Smith and David L. Smith
Department of Chemistry, University of Nebraska, Lincoln, NE 68588

Cataract, an opacity of the lens, is the major cause of blindness worldwide. Lens α -crystallins are not only structural proteins important to the maintenance of lens transparency, but also molecular chaperones that suppress the aggregation of other proteins. Post-translational modification of α -crystallins may result in opacification of the lens by disrupting the order of crystallin packing and/or by interfering with the chaperone activity. The water-soluble lens α -crystallins with post-translational modifications have been isolated and identified using a combination of chromatographic techniques including size exclusion, ion exchange and reversed phase HPLC, in conjunction with mass spectrometric techniques of LC-MS, MS/MS and exact mass determinations utilizing both electrospray and FAB instruments. These techniques enabled identification of modifications present at a level as low as 1 nmole per lens.

Each lens was homogenized in a buffer (0.5 M NaCl, 0.05 M Tris, 0.001 M EDTA, pH 7.4) and centrifuged at 15,000 g for 1 hr. The supernatant was fractionated by Sephadex G-200 size exclusion chromatography (SEC) to isolate the α -crystallins from the other lens crystallins. The α -crystallins were fractionated into α A and α B by reversed phase HPLC (RPHPLC). Each of these groups of proteins was further fractionated by anion exchange (IEX) HPLC on a Mono Q column using a buffer of 0.01 M Bis-tris, with 6 M urea, pH 6.2 for α A, and 0.01 M Tris, pH 7.5, 6 M urea for α B. The proteins were eluted and separated, based on the effective charges of modifications, with linear gradients of the above buffers plus 0.2 M NaCl.

The molecular weights of the modified α -crystallins, determined by ESIMS (Micromass Platform II) indicated the presence of phosphorylation of α A and α B, acetylation of α A in addition to the previously known N-terminal acetylation, oxidation of α A and α B, C-terminal degradation of α A and α B and unknown modification causing an increase of 72 u in the molecular weight of α B. Each isolated protein was digested with trypsin or Asp-N at a 1:50 enzyme: protein ratio in 50 μ l NH_4OAc buffer, pH 8.0. The peptides in the digests were fractionated and analyzed by on-line microbore (50 x 1 mm, C18) HPLC-ESIMS, using a gradient of 2-50% acetonitrile in water, both with 0.05% TFA, with a post-column splitter, dividing the effluent with 10% going to the ESIMS and 90% going to a UV detector and a fraction collector.

Each modified peptide was analyzed by MS/MS to determine the exact location of the modified residue. Both exact mass and MS/MS analyses were performed using a FAB source on a Micromass Autospec high resolution mass spectrometer equipped with an orthogonal acceleration TOF analyzer.

Separation of the modified α -crystallins by IEX allowed identification of minor components that could not be detected in complex mixtures. Modifications not previously reported included an additional site of phosphorylation, Ser 53 of α B; acetylation of Lys 70 of α A (Fig. 1) and an unknown addition of 72 u to the C-terminal Lys of α B. For this unknown modification, determination of the exact mass provided the elemental composition of $\text{C}_3\text{H}_5\text{O}_2$. Data from MS/MS analysis indicated that the modification was at the ϵ -amino group of the Lys, that it included a carbonyl group next to the ϵ -amino group, and that there was an additional OH group. These data are consistent with the unknown modification being lactylation of Lys 175 of α B-crystallin (Fig. 2)

Fig. 1 Location of acetylation site (Lys 70) of α A by MS/MS of Asp-N peptide 69-75 of α A.

Fig. 2 Strategy for determining the location and structure of unknown post-translational modification on human eye lens α B-crystallins.

Determination of oxidation sites in α -crystallin by ESI-MS/MS. M. Busman, E.L. Finley, J. Dillon, R.K. Crouch, K.L. Schey, Departments of Pharmacology and Ophthalmology, Medical University of South Carolina, Charleston, SC, Department of Ophthalmology, Columbia University, New York, NY

Introduction Cataract, a disorder resulting in opacification of the lens, most often occurs after the fifth decade of life. Oxidation is postulated to alter the structure of lens proteins, which results in aggregation leading to opaque regions in the lens. α -Crystallin is the major cytosolic lens protein comprising 40% of the protein in the lens. It is composed of two 20 kDa subunits, A and B, which form large aggregates of approximately 800 kDa in vivo. Many posttranslational modifications of α -crystallin have been reported including oxidation, phosphorylation, and glycation (1-3). In this study we have subjected bovine α -crystallin to a variety of oxidative insults. The protein has been reacted with UV light, UV light + uroporphyrin, and $H_2O_2 + FeCl_2$. We have developed MS methods for determining the extent of oxidation of peptides resulting from enzymatic cleavages of the protein. Furthermore, we have applied tandem mass spectrometry (MS/MS) in an effort to determine which amino acid residues are oxidized in each modified peptide.

Experimental **Isolation of α -crystallin.** Bovine lenses were dissected and the outer cortex was stirred under N_2 in 50 mM TRIS, 0.2 M NaCl, 1 mM EDTA, 10 mM 2-mercaptoethanol, pH 7.4 at 4 C. The suspension was homogenized and centrifuged, and the supernatant was loaded onto a gel filtration column where absorbance at 280 nm was monitored. The α -crystallin sample was dialyzed, lyophilized. **Oxidative Conditions.** UV: Protein (2 mg/mL) in 10 mM sodium phosphate, pH 7.4, was irradiated with a 450 W medium pressure mercury lamp using a filter system of 5% copper sulfate solution (>297 nm) for 12 hours. UV + uroporphyrin: UV irradiation was performed for 30 minutes under the same conditions as for UV alone in the presence of 1 μ M uroporphyrin. $H_2O_2 + FeCl_2$: Protein (2 mg/mL) in 10 mM sodium phosphate, 0.1 mM $FeCl_2$, and 0.3 mM EDTA, pH 7.4, was reacted with 0.15% H_2O_2 . **Digestion of α -Crystallin.** Reacted α -crystallin was dialyzed, lyophilized, and (10 nmol) digested with 100:1 (protein:enzyme) ratio of trypsin in 10 mM NH_4HCO_3 , pH 7.8 at 37 C for 18 hours and then lyophilized. **MS analysis.** Mass spectrometric analyses of the tryptic peptides was performed on a SCIEX API-III triple quadrupole mass spectrometer. The α -crystallin tryptic digests were resuspended in methanol/water/acetic acid (47/47/6) and this mixture was electrosprayed by direct infusion.

Results **MS of crude digests.** The tryptic digest of the control protein, as well as the digests of the proteins exposed to oxidative insult, were analyzed by ESI-MS without prior separation. The digests corresponding to the exposed proteins contain some peptides that appear at 16 Da, and in some cases multiples of 16 Da, higher than the sequence predicted molecular weights. For example, fragment 1-11 of α_A -crystallin (Ac-MDIAIQHPWFK, 1427.7 Da) appears at m/z 723 as well as at m/z 714 in the exposed protein digests. **MS/MS of selected peptides.** Figure 1 shows the MS/MS spectrum for the doubly charged ion ($(M+2H)^{2+}$) of the tryptic peptide α_A 1-11 from the control protein. Figure 2 shows the MS/MS spectrum for the doubly charged ion of α_A 1-11+16 Da. The peptide fragments in a similar manner to the unoxidized peptide. However, the series of small b-ions occurs 16 Da higher than for the unoxidized peptide. The appearance of the b_{1+16} ion, as well as a normal series of larger y-ions, facilitates identification of the site of oxidation as methionine. Figure 3 shows the MS/MS spectrum for the α_A 1-11+32 Da ion. Again a similar fragmentation pattern is seen. The series of b+16 ions indicates one site of oxidation at the N-terminal methionine. The series of large y+16, and/or

y+32 peaks, suggests a second oxidation near the C-terminus.

Conclusions We have demonstrated the ability of mass spectrometric methods to provide detailed structural information on oxidized peptides. Results of the analyses for the exposed proteins were compared to results for an unexposed control to determine the extent of oxidation to tryptic peptides as evidenced by increases of 16 Da in molecular masses from the sequence predicted molecular weight. Furthermore, ESI-MS/MS was utilized to obtain sequence information for the oxidized peptides. This information allowed identification of sites of oxidation within the oxidized peptides. Preliminary results not only identify expected oxidized amino acids, but assist in determining the order in which reactive sites are oxidized. Results of these preliminary experiments will, for example, be used for reference in the examination of α -crystallins obtained from cataractous lenses.

Identification of *in vivo* modifications of water insoluble human lens α -crystallins

Anders L. Lund, Jean B. Smith and David L. Smith

Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304

Cataract is the number one cause of blindness worldwide. In the United States the cost of cataract surgery is 12% of the Medicare budget. As a result, research leading to the cure or a delayed onset of cataract is a high priority. As the lens ages and cataract develops, an increasing portion of the lens proteins, called crystallins, become insoluble. The modifications that lead to crystallin insolubility are thought to be precursors of cataract. Specific modifications that may effect the chaperone activity of the α -crystallins are of particular interest. In this investigation mass spectrometry was used to compare the type, location, and amount of modification found in the water insoluble with previously determined modifications of the water soluble lens crystallins.

The crystallins from three 45 year old lenses, obtained from NDRI, were homogenized separately in buffer, and centrifuged at 15,000 x g for 30 min to separate the soluble from insoluble material. The insoluble fraction was dissolved in 6M urea, and the monomers were separated from the dimers and high molecular weight aggregates by size exclusion chromatography on a Sephacryl S-300 column. The monomers were fractionated on a Mono Q 5/5 ion exchange column. The gradient was 0% B for 5 min, 0-100% B over 30 min, 100% B for 5 min. Eluent A was 6.0 M urea, 0.01 M Tris, pH 7.45; eluent B was eluent A plus 0.1M NaCl. On-line LC-ESIMS was used to further isolate the crystallins from the ion exchange fractions and to determine the molecular weights of the intact crystallins. The effluent was split after the reversed phase microbore C4 column, 10% for ESIMS analysis and 90% collected for peptide mapping. The gradient was 25% B for 10 min followed by 25-50% B over 25 min. Eluent A contained 0.1% TFA in water and eluent B contained 0.1% TFA in acetonitrile.

To identify the crystallins and the location of the modifications, the fractions isolated from the reversed phase separation were digested with trypsin (0.01 M Tris, pH 7.8, 4-5 hours at 37°C with an enzyme to substrate ratio of 1:25), or with AspN (0.01M Tris, pH 7.4, 6 hours at 37°C with an enzyme to substrate ratio of 1:100). On-line LC-ESIMS fractionated the digest, and determined the molecular weights of the peptides. The gradient was 2% B for 3 min followed by 2-50% B over 25 min on a C18 RP-HPLC column. The sequence of the peptide, and/or the location of the modifications were confirmed by MS/MS analysis (micromass AutoSpec M with an oa-TOF detector) or by the molecular weights of the fragments produced by further digestions.

The modifications identified in the water insoluble fraction included deamidation, oxidation, disulfide bond formation, phosphorylation, and cleavage of several peptide bonds (Table 1). The extent of deamidation found in the water insoluble portion was much greater than had been previously found in the water soluble portion (Miesbauer 1994). The same amino acid residues in both the water insoluble and soluble fractions were found to be deamidated. Oxidation of the Met residues in the α -crystallins (Met 1 and 138 of α A and Met 1 and Met 68 of α B) were all confirmed by MS/MS analysis. The MS/MS spectrum of peptide 1-11 of α A with Met 1 oxidized is shown in Figure 1; the b and y series ions were most prevalent. Formation of an intramolecular disulfide bond between the two Cys residues in α A was found in both the water soluble and insoluble fraction. The amount of disulfide bond formation in the water soluble portion was below 5% (Miesbauer, 1994); however in the water insoluble portion, the two cysteines were completely disulfide bonded (greater than 95%). α A-crystallin with evidence of cleavages of peptide bonds in the C-terminal domain was found to coelute with intact α A. Truncations of the peptide sequence after Asn 101, Thr 168, and Ser 172 were evident from the mass spectra of the undigested crystallins. The sites of peptide bond cleavage were confirmed by analysis of the peptides isolated from the tryptic digest. Evidence for cleavage of a peptide bond in the N-terminal domain of α A was found in a fraction with a retention time much less than intact α A. A peptide with a molecular weight corresponding to residues 51-54, suggesting cleavage at Gln 50/Ser 51 was isolated and its identity confirmed by MS/MS. No peptides corresponding to 1-50 of α A were identified in this fraction while all of the expected C-terminal peptides were found. Loss of the N-terminal region which is hydrophobic is consistent with a reduced retention time on reversed phase HPLC. Residues 27-37 of the N-terminal region have been linked to the chaperone activity of α -crystallin. Cleavage of the peptide bond in the N-terminal domain of α B-crystallin between His 7/Pro 8 has been confirmed by MS/MS analysis (data not

shown) of the peptide 8-11 of α B and by Edman sequencing of the intact crystallin. The modified crystallin eluted with the intact α B-crystallin.

Among the modifications found in the water insoluble α -crystallins, three may be significant to the formation of insoluble crystallins through a change in the charge, conformation or effect on α -crystallin chaperone activity.

- **Increased Deamidation** The change in the overall charge of the crystallin may lead to change in conformation.
- **Disulfide Bond Formation** A conformational change, such as one caused by deamidation, may be "locked" in by the formation of a disulfide bond.
- **Specific Cleavage of Peptide Bonds** Both the C-terminus and N-terminus have been implicated in the α -crystallin chaperone activity. In addition, loss of hydrophilic portions from the C-terminus may cause the protein to become insoluble.

Table 1 *In vivo* modifications found in the α -crystallins isolated from the water insoluble monomers fraction of normal human lenses

Modification	Site of Modification	Confirmation
α A		
Oxidation	Met 1 and 138	MS/MS
Deamidation	Gln 50,90 and 147	MS/MS
Deamidation	Asn 6 and 101	AspN peptide 6-22, 101-24
Disulfide bond formation	Cys 131 to Cys 142	AspN peptide 125-35 bound to 136-50
Phosphorylation	Ser 45 and 122	Miesbauer, 1994
Peptide Bond Cleavage	Gln 50/Ser 51	MS/MS
Peptide Bond Cleavage	After 101,168,172	Spectrum of intact protein fragment
α B		
Oxidation	Met 1 and 68	MS/MS
Deamidation	Asn 108,146	MS/MS
Phosphorylation	Ser 19, 45 and 59	Miesbauer, 1994
Peptide Bond Cleavage	His 7/Pro 8	MS/MS

Protein function and structure is often moderated by both chemical and post-translational modifications. Therefore, structural characterization of sites of substrate adduction is vitally important. In the present study we report a strategy for rapidly identifying the number and position of sites such protein modifications. Initially, native and modified proteins and proteolytic digests of these samples are analyzed by MALDI-TOF-MS. Further evidence of the site of a covalent modification is obtained by membrane preconcentration-capillary electrophoresis-mass spectrometry (mPC-CE-MS) analysis of the protein digest mixture. This technology uses a piece of impregnated membrane (e.g. a 3M Empore™ styrene-divinyl benzene copolymer membrane) at the inlet of the CE capillary to preconcentrate analytes and enable on-line sample cleanup. Ultimately, the site of substrate adduction is unambiguously determined by mPC-CE-MS/MS analysis of the adducted peptide. This approach is demonstrated by determination of the site of acrylodan adduction for two proteins, intestinal fatty acid binding protein (IFABP) and FK506 binding protein (FKBP).

Acrylodan is a polarity sensitive dye that is used to probe protein structure by fluorescence and photoacoustic spectroscopy. It is known to selectively label thiol residues of cysteine via a Michael-type addition. However, in the absence of cysteine acrylodan can react with the amino side-chain of lysine under appropriate basic pH conditions. In the present studies acrylodan was reacted in molar excess separately with both IFABP and FKBP, after which the excess reagent was removed by extensive dialysis.

Following acrylodan adduction both native and adducted analogs of each protein were subjected to structural identification by MALDI-TOF-MS. From these studies, we were able to tentatively conclude that both IFABP and FKBP possessed only one label when reacted with acrylodan. Next, native and labeled forms of IFABP and FKBP proteins were individually subjected to enzymatic digestion (trypsin was used for the IFABP proteins and lys-C for the FKBP samples). The data obtained from MALDI-TOF-MS analysis of these samples were consistent with one acrylodan label and enabled tentative assignment of the site of adduction on both proteins. The enzyme digest samples were then analyzed by mPC-CE-MS to again detect the acrylodan labeled peptides. Ultimately, these were subjected to mPC-CE-MS/MS to unequivocally identify the modified amino acid residue. The mPC-CE-MS/MS spectra obtained from these studies are shown in Figure 1 for IFABP and Figure 2 for FKBP. From these data the site of acrylodan adduction on IFABP was clearly the lysine residue at position 27 (see Figure 3). The mPC-CE-MS/MS data acquired for labeled FKBP, when taken in

isolation was less conclusive (see Figure 2). This, in part, was due to the inefficient labeling of FKBP by acrylodan (typically 30 - 50 % of the protein was adducted). Therefore, the adducted peptide was a minor component of the protein digest mixture. Furthermore, while mPC-CE-MS enables analysis of large sample volumes, this peptide did not perform ideally in collision processes, resulting in incomplete y and b ion series. However, detection of the y₁₂ ion (m/z = 1250) in the mPC-CE-MS/MS spectrum indicated that the acrylodan label was on positions 1-5 of this peptide and from chemical considerations the only possible site of adduction was the cysteine at position 5 (amino acid 22 of the native protein, see Figure 4).

Identification of the Disulfide Bonds in the Circulins, a Group of Anti-HIV Circular Peptides

Rita Derua, Kirk Gustafson, Yali Hallock and Lewis Pannell

Laboratory of Analytical Chemistry, NIDDK, NIH, Bethesda MD 20892-0805

LDDR, NCI, FCRDC, Frederick MD 21702

INTRODUCTION AND AIM

The circulins are a family of macrocyclic peptides which were originally isolated from the tropical tree *Chassalia parvifolia* and have since been found in a number of other species. The interesting feature about these peptides is the fact that they display potent *in vitro* anti-HIV activity (Gustafson K.R. et al., 1994). Circulins consist of 29-31 amino acids arranged in a highly constrained three-dimensional structure. Three intramolecular disulfide bridges are present, which have been shown to be critical to the anti-HIV properties. In the present study, the disulfide pairing motif of the circulins was elucidated.

METHODS

Circulins were almost totally resistant to enzymatic degradation. Therefore, they were subjected to chemical degradation in dilute acid (0.5 N HCl, 3h, 110°C). This condition reduced disulfide scrambling to a minimum (Ryle et al., 1955). Separation of cleavage products was executed on a C18 reversed-phase HPLC column using a 60 min linear gradient (0.1 % aqueous TFA to 100% acetonitrile) at 1 ml/min. The cleavage products were very difficult to identify because of the non-selective nature of acid hydrolysis cutting and the large amount of homology within the circulin molecule. To solve this problem, a combined approach of FAB-MS and computer software ("ssia" program)* was adopted. FAB-MS analysis provided molecular weight information, while the "ssia" program identified disulfide bonded fragments of the circulin molecule that matched the given molecular weight. Only those ions with m/z greater than 400 (we were only interested in disulfide containing fragments and acid hydrolysis cleaves to dipeptide level or greater) that were present in the spectra from two FAB matrices, glycerol/thioglycerol and nitrobenzyl alcohol, were analyzed. B/E linked scanning was used to confirm sequence information and distinguish between possible alternatives (only for m/z smaller than 1000).

*The "ssia" program is part of a suite of programs used for peptide/protein work in our lab. The program finds all possible peptide/protein fragments containing one or more cysteine residues up to a given maximum mass. Then, for a given fragment mass, the program finds any combination of cysteine containing sequences that matches the given mass. It takes into account the change in mass resulting from the disulfide bonds linking the pieces together

RESULTS

Circulin cleavage products most often could not be uniquely identified and, as a result, they could be consistent with several of the fifteen theoretically possible disulfide arrangements. When the number of times each disulfide linkage was not consistent with a fragmentation product was assessed, it turned out that the [Cys4 - Cys20], [Cys11 - Cys27], [Cys15 - Cys29] linkage pattern for circulin A (Table 1) and the equivalent [Cys4 - Cys21], [Cys12 - Cys28], [Cys16 - Cys30] linkage pattern for circulin B (Table 2), was the only disulfide arrangement showing no mismatches. Other disulfide linkage patterns displaying a low number of mismatches were ruled out by using B/E linked scanning information (Table 3).

Table 1:

Possible disulfide linkages	4-20 11-15	4-20 11-27	4-20 11-29	4-11 15-20	4-11 15-27	4-11 15-29	4-15 11-20	4-15 11-27	4-15 11-29	4-27 11-15	4-27 11-20	4-27 11-29	4-29 11-15	4-29 11-20	4-29 11-27
Total Mis-matches	4	0	1	19	11	11	16	2	5	3	3	1	8	5	2

Table 2:

Possible disulfide linkages	4-21 12-16	4-21 12-28	4-21 12-30	4-12 16-21	4-12 16-28	4-12 16-30	4-16 12-21	4-16 12-28	4-16 12-30	4-28 12-16	4-28 12-21	4-28 12-30	4-30 12-16	4-30 12-21	4-30 12-28
Total Mis-matches	7	0	1	12	1	2	8	3	4	7	4	6	7	2	5

Table 3:

Circulin A fragment molecular weight (Da)	Circulin A fragment identification	Information from linked scanning	Disulfide link
581	[2-4]-[20-21]	N-term. Lys-Val	4-20
668	[2-4]-[20-22]	N-term. Lys-Val	4-20
791	[2-4]-[18-21]	N-term. Lys-Val and N-term. Leu/Ile-Pro	4-20
555	[15-16]-[28-30] or [14-16]-[29-30]	C-term. Val	15-29
642	[14-16]-[28-30]	C-term. Val	15-29

CONCLUSION

By making use of FAB-MS and the "ssia" computer program, we were able to unambiguously identify the disulfide linkage pattern in circulins as [Cys4 - Cys20], [Cys11 - Cys27], [Cys15 - Cys29] for circulin A and the equivalent [Cys4 - Cys21], [Cys12 - Cys28], [Cys16 - Cys30] for circulin B.

β -Endorphin-containing Proteins in Human Pituitary

Robert Becklin, Lin Yan, Jasper X. Chu, Jih-Lie Tseng, and Dominic M. Desiderio
Charles B. Stout Neuroscience Mass Spectrometry Laboratory, University of Tennessee at
Memphis, 800 Madison Avenue, Memphis, TN, 38163.

Introduction The opioid peptide β -endorphin (BE) is located at the C-terminus of its precursor: Proopiomelanocortin (POMC) (Scheme 1). BE-containing proteins are produced in the metabolic pathway from POMC to BE. That metabolic pathway, especially the characterization of BE-containing proteins in this pathway, have not been fully clarified. It has been hypothesized that metabolic defects in the above pathway could be involved in human anterior pituitary tumor formation. Therefore, it is necessary to detect BE-containing peptides and proteins in a pituitary.

The objective of this research was to establish an MS-based analytical system to detect BE-containing intermediate-sized precursor proteins in control human pituitaries to generate data that will provide a baseline for the study of metabolic defects in the production of BE and of BE-containing proteins in human pituitary tumors. Previous study methods mainly include cDNA and radioimmunoassay (RIA). DNA sequence data alone are inadequate to study the post-translational modification of proteins. RIA lacks molecular specificity. This system avoids the limits of cDNA and immune-based methods, and offers excellent detection sensitivity and optimum molecular specificity.

Methods The present study combines chromatography separation, enzyme digestion, MS, and MS/MS to detect BE-containing proteins. The peptides and proteins were extracted from human pituitaries and were purified by SPE chromatography and RP-HPLC. Each collected HPLC fraction was treated with trypsin, and was analyzed by MS to detect those selected tryptic peptides that are unique to BE and that served as a "marker" for the presence of BE in an HPLC fraction. For example, for BE-containing peptides and proteins, BE₂₀₋₂₄ (POMC₂₅₆₋₂₆₀, M.W. 557) and BE₁₀₋₁₉ (POMC₂₄₆₋₂₅₅, M.W. 1133) are two peptides that are unique for POMC and that have favorable LSIMS relative hydrophobicity and desorption-ionization properties. Based on a computer search of protein sequence databases, we find no other matches of those two amino acid sequences. The MS detection of the (M+H)⁺ ion of both marker peptides in the trypsin-digested HPLC fractions permits a rapid detection of all BE-containing peptides and proteins. MS/MS confirmed the amino acid sequence of BE₂₀₋₂₄. ESIMS was used to determine the M.W. of each BE-containing protein.

Results Figure 1(a) shows the LSIMS spectrum of the unseparated trypsin-digested HPLC fraction 47. The arrows at *m/z* 558 and 1134 indicate the (M+H)⁺ ions of those marker peptides. Figure 1(b) shows the ESI mass spectrum of HPLC fraction 47 (no trypsin treatment) obtained from human pituitary. Figure 2(a) shows the LSIMS spectrum of the unseparated trypsin-digested HPLC fraction 51. The arrows at *m/z* 558 and 1134 indicate the (M+H)⁺ ions of those marker peptides. Figure 2(b) shows the ESI mass spectrum of HPLC fraction 51 (no trypsin treatment) obtained from human pituitary. Figure 3 shows the isocratic RP-HPLC (4% CH₃CN) chromatograms of (a) the unseparated mixture of tryptic peptides corresponding to the data shown in Figure 1a (The arrow indicates the retention time of synthetic NAIK), and (b) synthetic NAIK. Figure 4 shows the LSIMS-MS/MS product ion spectrum of the precursor ion at *m/z* 558: (a) from the isocratic HPLC-purified NAIK fraction from human pituitary (see Figure 4a), and (b) from synthetic NAIK (see Figure 3b).

Conclusion Two new BE-containing proteins (MW=9764 and 9381) were discovered in the human pituitary. They derive from the C-terminal portion of POMC. The discovery of these two new BE-containing proteins are important for studies of neuropeptidergic processes in the human. The analytical method used in this study shows a higher molecular specificity than that provided by any other analytical method.

Sequencing of Glucokinase from *Bacillus stearothermophilus* by Tandem ESI-FTICRMS

Craig P. Dufresne and Troy D. Wood

State University of New York at Buffalo, Dept. of Chemistry, Buffalo, N.Y. 14260-3000

Glucokinase (GK, EC 2.7.1.1) is an enzyme which catalyzes the transfer of phosphate from ATP to glucose, to produce glucose 6-phosphate. Mutations in human glucokinase have been associated with Maturity Onset Diabetes of the Young (MODY).¹ While nucleotide and amino acid sequences are known for glucokinase from rat, human, and other species, a corresponding sequence for one of the most widely-available commercial varieties (from *Bacillus stearothermophilus*) is unknown. In addition to being commercially available, this variety is thermally stable, has only one known isozyme, and has a lower molecular weight (~ 32 kDa.) than most glucokinase varieties (~ 50 kDa.). Glucokinase from *Bacillus stearothermophilus* was isolated and characterized in 1973 by Hengartner and et al.² Their amino acid composition analysis indicated 330 residues with an average mass of 34,289 Daltons, while a molecular weight determination via SDS-PAGE was reported as 34,500 Daltons. The N-terminus was identified as phenylalanine and two disulfide bonds were reported.

Recently, McLafferty et al. have shown that electrospray ionization (ESI) coupled to Fourier transform ion cyclotron resonance mass spectrometry (FTICRMS) is an extremely powerful analytical tool for characterizing large proteins greater than 40 kDa.³⁻⁵ Recently, we have obtained ESI-FTICRMS data of intact, multiply, charged ions of glucokinase (Sigma, from *Bacillus stearothermophilus*); this data indicates a charge state distribution ranging from 20+ to 35+ (Fig. 1). Deconvolution of the charge state distribution indicates a molecular weight of 32,439 daltons, approximately 1850 Daltons less than the reported amino acid composition. Here, we exploit tandem ESI/FTICRMS to obtain amino acid sequence information of glucokinase from *Bacillus stearothermophilus*. Two approaches are used. First, intact GK is electrosprayed and the resultant (M+nH)⁺ ions are dissociated by nozzle/skimmer dissociation. Under low energy nozzle/skimmer conditions, small singly-charged fragment ions predominate. Unfortunately, even multiply-charged ions of such a large enzyme generate only a limited number of dissociations along the peptide backbone. Thus, a second approach is used by which GK is first enzymatically digested (e.g., with trypsin) to produce smaller peptides. These may be separated by HPLC prior to ESI, with each proteolytic "fragment" subjected to dissociation in the FTICRMS. HPLC of the tryptic digest fragments showed at least fifteen usable peaks for mass spectrometry (Fig. 2).

Future work will include obtaining a high-resolution molecular weight spectrum, showing the protein's isotopic distribution for accurate mass assignment. Comparison studies between high-resolution spectra sprayed from both normal solution conditions and dithiothreitol spiked solution conditions will be used to probe for the disulfide bonds. The tandem MS results will be compared to known sequences of other varieties of GK in an effort to ascertain the degree of sequence homology. This work is supported by the State University of New York at Buffalo.

Investigation of Lens Proteins with High Cysteine Content

Stacy R.A. Hanson, Jean B. Smith and David L. Smith
Department of Chemistry, University of Nebraska, Lincoln, NE 68588

The chemical processes associated with aging are of great interest to both the scientific and nonscientific communities. The lens proteins are particularly valuable for revealing clues as to the identities of these processes because they do not experience turnover. As the lens ages, many types of modifications can occur that alter the compact way in which the lens proteins, or crystallins, are folded. Disulfide bonding is one such modification and the human gamma crystallins contain a high proportion of cysteines that can take part in disulfide bond formation more readily than the rest of the lens crystallins. Disulfide bonding not only contributes to the general aging of the lens, but also can lead to its opacification, or cataract. The continued study of the gamma crystallins will give insight as to how the body ages and what modifications are directly related to aging.

Methods

The human lenses, obtained from NDRI or from Dr. Larry David at Oregon Health Sciences University, were homogenized in a 0.05 M TRIS buffer at pH 7.4 for one hour. After centrifugation at 15,000xg for one hour, the water soluble supernatant was removed and fractionated by Sephadex G-200-50 gel filtration chromatography. The individual α , β and γ fractions were pooled and stored. Further separation of the γ crystallins was obtained by high performance reversed phase liquid chromatography (HPLC) on a Vydac C4 column (Fig. 1). The gradient used for separation was 30% B for 5 minutes followed by 30-50% over 20 minutes. The molecular weights of the proteins isolated from HPLC were determined by direct injection electrospray ionization mass spectrometry (Fig. 2). The solvent used was 50:50 acetonitrile and water with a flow rate of 5 μ L/min. Calibration was performed with myoglobin and a 0.01% mass accuracy was achieved.

The insolubility of the γ crystallins from older donors presented many problems and after little success with other methods, the proteins were treated with iodoacetamide to derivatize the thiols of the cysteine residues. This method proved successful at solubilizing the proteins for analysis.

Fig. 1 Reversed Phase Separation of the Lens γ -Crystallins

Fig. 2 ESIMS Spectrum of Peak #2 of Fig 1

Reversed phase HPLC fractions containing γ_C and γ_D crystallins were enzymatically digested with trypsin and Asp-N endoproteases. To determine the molecular weights of the peptides after digestion, an on-line LC/ESIMS (Micromass Platform) system was used. The peptides were fractionated by reversed phase liquid chromatography on a Microbore C18 column with a gradient of 2-50% in 45 minutes. The effluent from the HPLC was split before the source with 10% for ESIMS analysis and 90% for collection and further analysis. Calibration was performed with NaI with a mass accuracy of 0.3%.

Results and Conclusions

The ESIMS determined molecular weight for γ_C agreed with the sequence which had previously been determined by cDNA (Meakin, *et al.*, 1987, *Mol. Cell. Biol.* 7, 2671) (Fig. 1). After enzymatic digestion, several peptides which were not consistent with the published amino acid sequence were found. The tryptic and Asp-N digests yielded peptides for all areas of the sequence except the regions 15-36 and 77-88. There were two peaks observed in the mass spectrum for region 15-36: one peak at 865 and another at 871. The peak at 865 corresponded to the triply charged species of peptide 15-36. The peak at 871 corresponded to the triply charged species of peptide 15-31 and peptide 32-36 disulfide bonded to each other through Cys 22 and Cys 32. Another disulfide bond was discovered within the peptide 77-88. The theoretical molecular weight of this peptide is 1342, but ESIMS data produced a doubly charged peak at 671 which corresponds to a peptide of molecular weight 1340. MS/MS data also confirmed the complete disulfide bonding within peptide 77-88 at Cys 78 and Cys 79.

To determine whether the disulfide bonding in the region of 15-36 had been induced by the experimental procedure, the peptide was incubated for an additional 5 hours at 37 degrees Celsius for a total incubation time of 10 hours. No increase or decrease in disulfide bonding was observed. All other areas, except a small region from 140-141, were found to agree with the current published sequence of γ_C .

The molecular weight for γ_D was not in agreement with the molecular weight of the most recently published sequence which yielded a calculated molecular weight of 20,575 (Meakin, *et al.*, 1987, *Mol. Cell. Biol.* 7, 2671). A molecular weight of 20,604 has been repeatedly obtained with a variety of lenses varying in age. This indicates that there is either a modification of the protein or that the published sequence contains an error. After performing both tryptic and Asp-N digests, the majority of the sequence was confirmed to be in agreement with the published sequence except the region of 37-58. The sequence of this region has not yet been determined and is suspected of containing errors or modifications. MS/MS and additional enzymatic digestions are currently being performed to determine the exact sequence. In addition, a disulfide bond was discovered between Cys 18 and Cys 32 of the γ_D sequence. Complete disulfide bonding at this position was observed.

The gamma crystallins have been linked to aging of the lens because of their high cysteine content and ability to disulfide bond. This study has proved the existence of such disulfide bonds and subsequent solubility problems. Lenses ranging in age from 0 days to 55 years in age have been studied and it has been found as the lens ages more and more modifications occur, the three γ -crystallins change in their proportions to one another and they are more difficult to keep in solution. The reasons for these observations have not yet been determined, but continued work on the crystallin sequences will give more insight into cataract formation and aging.

Direct Characterization of Proteins from Organisms with Small Genomes

Edwin Carmack, Lara Hays, Andrew J. Link and John R. Yates, III
University of Washington, Seattle, WA

Introduction

The integration of liquid chromatography with tandem mass spectrometry has created a powerful method for the analysis of biomolecules. In particular, application of this methodology to the analysis of the complex array of peptides presented by major histocompatibility molecules has led to new insights in cellular and tumor immunology. The large numbers of peptides present in these and other mixtures create a challenge for efficient and timely sequencing, a process that requires acquisition and interpretation of the tandem mass spectra. Recent developments in the use of automated data acquisition employing data dependent computer algorithms has significantly improved the efficiency for the acquisition of tandem mass spectra. Analysis of the larger volumes of data produced by automated data acquisition can best be performed by the computer algorithms designed to correlate tandem mass spectra to protein or nucleotide databases. The ability to acquire and then quickly analyze large numbers of tandem mass spectra by using the growing sequence databases has enabled the analysis of increasingly complex problems. The near completion of the *Escherichia coli* genome (85%) and the recent completion of the *Haemophilus influenzae* genome have made it feasible to use LC/MS/MS and database searching to identify the proteins present. This method can also help to confirm the expression of hypothetical proteins predicted from the nucleotide sequence.

We have developed a methodology for the analysis of complex mixtures that can be used to identify the proteins present based on peptides identified using LC/MS/MS. This methodology has been applied to the proteins present in the periplasmic space of *E. coli*. *E. coli* and other gram negative bacteria possess an inner and outer membrane. The space located between the cell wall and the plasma membrane is called the periplasmic space and is a staging and storage area for materials entering and leaving the cell. In order to pass molecules into or out of the cell, they must cross the periplasmic space. Consequently, a set of soluble proteins are localized in this space to assist in the translocation of molecules into and out of the cell. The same methodology as that used to study *E. coli* periplasmic proteins is being used to identify the cellular proteins of *H. influenzae*.

Methods

E. coli cell lysates were enriched for periplasmic proteins using the osmotic shock method of Neu and Hoppel. The enriched protein mixture was fractionated into 20 fractions using a strong anion exchange column (Mono Q HR 5/5) on a Pharmacia FPLC system. SDS-PAGE with silver staining was used to visualize an aliquot of each of the fractions. Following concentration and buffer exchange each fraction was digested overnight using the enzyme trypsin. The resulting peptides in each fraction were subjected to reverse phase micro-column LC/MS/MS. The peptides were eluted off a 15 cm reverse phase micro-column using a gradient of 0 - 40% B in 50 minutes followed by 40 - 80% B in 10 minutes (A:0.5% acetic acid in water; B:80:20 acetonitrile:water with 0.5% acetic acid). MS/MS were collected using a Finnigan MAT TSQ700 with an electrospray ionization source. Peptide spectra generated were searched against an *E. coli* subset of the OWL database (6,637 sequences) using SEQUEST software. This allowed for the identification of proteins in each fraction.

The above methodology has also been applied to the *H. influenzae* organism. Total cellular protein extracts were fractionated using a strong anion exchange column on an FPLC. This generated approximately 40 fractions. Four of these fractions have been digested as above and subjected to micro-column LC/MS/MS. Database searching against an *H. influenzae* database using SEQUEST software has resulted in the identification of proteins in the analyzed fractions. The *H. influenzae* database was obtained as an ASCII text file in the FASTA format from the TIGR *Haemophilus influenzae* Rd genome data server by anonymous ftp (ftp.tigr.org).

Conclusions

Silver stained SDS-PAGE visualized 159 proteins (above 20kDa) in the *E. coli* periplasm fractions. 80 proteins were identified using LC/MS/MS with database searching. Preliminary results from four fractions out of approximately 40 with *H. influenzae* has resulted in the identification of 53 proteins.

These results show that automated tandem mass spectrometry combined with database searching software can be used to rapidly survey the identities of proteins in mixtures. Furthermore, this method can be applied to a global survey of the proteins contained in subcellular spaces. This method does not, at this point, provide a comprehensive survey of the proteins present in the mixture. Methods to improve the data acquisition rate through improved chromatographic resolution or scan rates on mass spectrometers are under study.

A depiction of the procedure used to identify proteins present in the periplasmic space of *E. coli*.

Analysis of Proteins in the 80S Ribosome of *S. cerevisiae* by Tandem Mass Spectrometry

David M. Schieltz, Jimmy K. Eng and John R. Yates III
University of Washington, Box 357730, Seattle, WA 98195-7730

Introduction

One of the challenges in the study of biochemical processes is the identification of proteins involved in large multicomponent complexes. To explore this our laboratory has developed methods for identifying proteins using MS/MS analysis of peptides generated by enzymatic cleavage of the proteins. Using the Sequest program developed by Eng et al. [1], peptide tandem mass spectra are searched against possible sequences of amino acids in the protein databases, allowing for rapid identification of proteins. This experiment describes a methodology for identification of proteins in the multicomponent complex of the yeast 80S ribosome (~70 proteins [2]) which has been enriched from a yeast whole cell lysate.

Experimental

An *S. cerevisiae* (AAY1048) whole cell lysate was prepared and centrifuged at 10,000 g to remove cell debris. The supernatant was removed and centrifuged again at 150,000 g to pellet the crude ribosomes. The pellet was resuspended and the solution was loaded onto a 5%-20% discontinuous sucrose gradient [3]. The ribosomes were sedimented through the gradient by ultracentrifugation at 150,000g for 8 hours. The ribosome pellet was resuspended and the solution was centrifuged a final time at 10,000 g. The ribosome solution was denatured, carboxymethylated and digested with trypsin.

Ten μ L of the digest was loaded onto a 100 μ m i.d. microcapillary column packed with POROS 10 R2. The fritted end of the column was inserted into the needle of the electrospray ion source on a Finnigan TSQ-700. The HPLC pump was programmed to ramp the organic phase from 0% B to 30% B in 50 minutes and 30% B to 80% B in 40 minutes. Automated tandem mass spectra were acquired using a program written with the Finnigan Instrument Control Language (ICL). The program selects precursor ions for CID from the mass scan when the intensity and signal to noise ratio exceed specified values. A differential modification search was performed on the tandem mass spectra data, against the Stanford *Saccharomyces* Genome Database.

Results

Figure 1. shows the base peak ion chromatogram for the ribosome digest analysis by μ L C/ESI/MS/MS. The automated CID program recorded 266 tandem spectra over the course of 90 minutes. Duplicate spectra were filtered out and 156 tandem spectra were searched against the Stanford database. The search identified 30 ribosomal proteins. Identification of a greater number of ribosomal proteins was hampered by co-eluting peaks. Even though the gradient covered 90 minutes, up to ten peaks at a time would be

present in any given mass scan. The automated CID program would select only the most intense peak in each parent scan while other would not be selected, and thereby sequence information would be lost. Solutions to this problem are to improve the chromatography and the improve the automated cid program.

Conclusions

The objective of this experiment was to develop a new approach for rapid, accurate identification of proteins in a multicomponent complex. To demonstrate this approach, the 80S ribosome was enriched from a yeast whole cell lysate using a discontinuous sucrose gradient. After enrichment, the complex was denatured, carboxymethylated and digested with trypsin. 266 tandem spectra were recorded over a 90 minute gradient and 156 non-duplicate spectra were searched against the Stanford *Saccharomyces* Genome database. Approximately 45% of the proteins in the complex were identified. Further work will refine the methodology to identify all the proteins present in these large protein complexes.

Glutathione-S-Transferase Heterogeneity in Human Tissue Analyzed by ESI-MS.

E. Nieves*; J. D. Rowe and I. Listowsky
Albert Einstein College of Medicine; Bronx, NY 10461

The Glutathione-S-Transferases (GSTs) represent a major group of detoxification enzymes that function by utilizing glutathione (GSH) in the catalysis of conjugation and reductive reactions, and by acting as intracellular binding proteins for a variety of lipophilic agents. Mammalian GSTs are classified into multiple classes, including Alpha (A), Mu(M), Pi(P) and Theta (T). Within these classes there can be multiple isoforms. The expression of GST isoenzymes is known to vary in humans. For example, in ~50% of the population there is a deletion of the GSTM1 gene, and ~16% of the population have a deletion of the GSTT1 gene.¹ Failure to express certain GST proteins may increase the risk of certain types of cancer. Details of the tissue distribution of GST isoforms are unclear. Therefore, an examination of the tissue distribution of GST's will be important for understanding how GSTs function in a chemoprotective manner.

Our objective was to assign the GST isoforms of various tissue sources and detect any possible allelic variants and/or post translational modifications of these isoforms using off-line and on-line HPLC-ESI MS. A PE-SCIEX API III triple quadrupole mass spectrometer equipped with a pneumatically assisted electrospray ion source was used for mass spectral analysis.

Tissue specimens were obtained from persons who died from gunshot wounds or motor vehicle accidents with no evidence of preexisting diseases. The tissue specimens were snap-frozen 3-12h post mortem and stored at -70 degrees. Cytosolic GST's were purified from frozen tissues by procedures utilizing epoxy-linked GSH-agarose affinity chromatographic methods.² In some cases, purification and HPLC analyses were performed in the same day due to the instability of some GST's. Synthetic peptides corresponding to unique C-terminal epitopes of GST subunits (M1-M5) were used to raise subunit specific antibodies. These antibodies were then used for western blot analysis.

ESI-MS has been used to examine the primary structure of rat and mouse liver GSTs.^{3,6} In the present study, the multiple subunits of human GST's were detected in different tissues. This information is presented in Table 1 along with the expected and obtained molecular weights. ESI-MS obtained from four different forms of GST's are shown in Figure 1. We found no evidence of GSTs being phosphorylated, methylated or glycosylated. Two of the Alpha class (GSTA1 & GSTA2) and two of the Mu class subunits (GSTM3 and GSTM4) were acetylated at the N-terminus. The molecular masses obtained for GSTM1, GSTM2 and GSTP1 are in close agreement with their estimated masses deduced from their amino acid sequences.

In most of the examined tissues GSTM2, GSTM5 and GSTM4 isoforms are minor components of the total GST composition. GSTP1 is the predominant isoform in heart, lung and brain. GSTM1 was found to be a major Mu class subunit in liver and adrenal but not in the other tissues examined. GSTM3 was also shown to be brain and teste-specific. The absence of the GSTM1 peak in Figure 1 is seen from tissues of person with the GSTM1 null genotype.

The results demonstrate that ESI-MS along with the information obtained from the use of peptide specific antisera, allows for a fast and reliable analysis of GSTs. The intrinsic changes of the distribution pattern of these isoforms in different tissues and under various conditions, including malignant and other diseased states, can also be determined using this technique.

ESI-MS Evaluation of Post-translational Modifications to Histone Proteins Through the Cell Cycle

Mary S. Weir Lipton, David L. Springer, Noelle F. Metting, Charles G. Edmonds
Macromolecular Structure and Dynamics and Molecular Biosciences Departments
Pacific Northwest National Laboratory, Richland, WA 99352

During the cell cycle, which results in the faithful replication and packaging of genomic DNA and the production of two genetically identical daughter cells, chromosomes undergo major structural transitions ranging from the fully dispersed active state in S phase to the fully condensed inactive state in metaphase. A large body of data already exists on the alteration of chromatin structure through the cell cycle and the accompanying post-translational modifications of histone proteins. However, the accumulation of these observations into a coherent picture demonstrating the function and interaction of these modifications remains elusive. It has been known for sometime that ionizing radiation causes a division delay in mammalian cells predominately at the G₂-M transition. To obtain populations of cells in unperturbed G₂ and those arrested in G₂, HeLa cell cultures were synchronized after their release from a double thymidine block at the G₁/S border and cells were harvested at points through the mitotic process. The histones were extracted and purified from these cells and analyzed by ESI-MS.

The figure below compares ESI-MS spectra of H4 proteins from these studies. The 15+ charge state is shown contains among other related peaks at m/z 754.8. The form of histone H4, predominant at two hours after release, has a mass of 11305 Da, and differs from the predicted mass for the principle species by 70 daltons. Putatively, this corresponds to the addition of one acetyl and two methyl modifications ($42.04 + 14.03 + 14.03 = 70.1$). However, at eight hours after release, a number of other modifications of the histone

Mass spectrum corresponding histone H4 isolated from a free cycling HeLa cell line harvested at the G₁/S and the G₂/M borders. Additional post-translational modifications are seen in the cell traversing the G₂/S border.

appear. A peak at m/z 761.3 corresponds to a protein with a mass incremented by 98 Da. This increment can correspond to either a covalent addition of 2 acetyl and 1 methyl groups, or the noncovalent association of a PO₄⁻ group. The predominant form of the histone is represented by a peak at m/z 765.0 and has a mass incremented from the peak at m/z 761.3 by 56 Da which corresponds to the addition of 1 acetyl group and 1 methyl group. A third peak at m/z 767.8 corresponds to a protein whose mass is incremented by 42 Da over the previous peak. This corresponds to the addition of an acetyl group.

Further characterization of the extent and location of the post-translational modifications to histone proteins is possible by coupling liquid chromatography to mass spectrometry (LC-MS). All of the fragments expected for histone H2B, listed in the, were identified in our proteolytic digest with mass precision within 1 Da or less. Two exceptions are peptide fragment 2 and 3. It is unclear at the moment why the mass of fragment 2 varied from that expected by almost 3 Da, but the 25 Da increment in the mass of peptide fragment 3 correlates well with the mass increment found for the intact protein and is thought to be due to a sequence variant. Additionally, we have identified up to 4 acetylations and 1 phosphorylation of the histone, all occurring, as expected, in the N-terminal peptide. In order to determine the location of the post-translational modifications in peptide fragment 1 and the sequence variant in peptide fragment 3 we have extended these studies to LC-MSⁿ and MSⁿ experiments. While these experiments are still in their infancy, we have determined to this point that the sites of acetylation are varied and an N terminal acetylation can be identified.

Biomedical Mass Spectrometry: Blood, Sweat and Urine

Catherine Fenselau,
Structural Biochemistry Center, University of Maryland Baltimore County (UMBC)
Baltimore MD 21228

The title for this plenary lecture comes from a speech given by Winston Churchill in 1940. This date seems appropriate as a baseline for the development of biomedical mass spectrometry, since the first commercial instruments were manufactured around that time, for use in monitoring petroleum refining. The capability to analyse intact volatile organic compounds in petroleum distillates was eventually extended to other volatile molecules, most notably in lipid biochemistry and natural products structure elucidation. As indicated in Figure 1, these areas supplied both instrumentation and trained personnel to apply mass spectrometry to biomedical problems. The field also traces its lineage through isotope ratio studies. Although biomedical mass spectrometry has provided the stimulus for many developments in instrumentation and automation, most practitioners use instruments provided by commercial manufacturers, thus enhancing reproducibility from lab to lab. This means our work is intertwined with the efforts of our colleagues in the ASMS who develop new techniques for ionization, ion analysis and computer support. The development of the area has been generously supported by Federal and other funding for instruments and research. A relationship is suggested in Figure 1 between biomedical mass spectrometry and the applications of mass spectrometry in biotechnology and to biopolymer studies. Historically the biomedical community has nurtured and catalysed the development of techniques for high mass analysis (1,2).

This talk presented an overview of long-term work in my laboratory addressing the pharmacology of a family of chemotherapeutic nitrogen mustards used world-wide against a variety of cancers. This was intended to represent a small selection of the many kinds of problems being addressed by the large and active community of biomedical investigators. Pharmacology is the study of the interactions of drugs with living systems, and studies were summarized of the distribution, metabolism and pharmacokinetics of cyclophosphamide, melphalan and chlorambucil (3-6 and others). The importance to the field of the development of interfaces for gas chromatography and mass spectrometry, and of commercial production of computer-supported GCMS systems was emphasized. This technology has allowed important qualitative and quantitative contributions to be made to biomedical science. It also has greatly expanded commercial instrument sales, jobs for trained mass spectroscopists and the membership of ASMS (7). As the field exploded, a new journal was launched to serve the interests of biomedical mass spectroscopists (8).

The impact of fast atom bombardment was recognized with a history of the analysis of monomeric insulin (9); characterization from the speaker's lab of guanosinemonomophosphate cross-linked by phosphoramidate mustard, part of the mode of action of these mustards (10); and studies of the mechanisms of conjugation of phosphoramidate mustard and melphalan with the tripeptide glutathione (11,12). A stable isotope-labelling study of the enzyme-catalysed conjugation of glutathione with cyclophosphamide was carried out using laser ablation, electron ionization and delayed extraction on a time-of-flight mass spectrometer (13).

The advent and commercialization of matrix assisted laser desorption and electrospray ionization (and with the latter a reliable interface for HPLC and mass spectrometry) have provided tools for recent efforts to address mechanisms by which patients receiving therapeutic mustards develop resistance to their action (14-16).

The hypothesis has been tested that metallothionein, present in every cell, whose synthesis is inducible by exposure to antitumor alkylating agents, inactivates these drugs by covalent sequestration. Continuous monitoring was carried out, using electrospray, of the reaction in vitro of metallothionein and chlorambucil, which confirmed that covalent sequestration occurs without loss of metal ions (16). The ability to follow the flux of metal ions into and out of metal-binding proteins has allowed us to characterize Zn⁺⁺ transfer between metallothionein and carbonic anhydrase and other metalloproteins. The transfer of Zn⁺⁺ to carbonic anhydrase has been found to occur more rapidly from chlorambucil-alkylated metallothionein than from metallothionein (17).

Advances in understanding the genetic machinery for the synthesis of thionein (apometallothionein) (18) have identified a regulatory role for a nucleic acid binding protein (metallothionein regulatory element), which requires Zn⁺⁺. This has led us to postulate that alkylation by therapeutic mustards may enhance release of zinc ions to the regulatory protein, which then activates transcription of thionein. In support of this hypothesis, electrospray mass spectrometry was used to demonstrate Zn⁺⁺ transfer between metallothionein and a model nucleic acid binding protein, g32. Further studies are underway of the role of Zn⁺⁺ in the mechanism of induction.

Thus mass spectrometry (of various kinds) has been the key technique used through twenty-five years to study the distribution, metabolism and pharmacokinetics of therapeutic nitrogen mustards, and their interactions with peptides, nucleic acids and proteins. In conclusion, the slogan for the centennial year of the Boston marathon was presented, "One Hundred Years of Blood, Sweat and Cheers", to suggest that the next 50 years of biomedical mass spectrometry will be even more interesting and exciting than the first 50 years.

WORKSHOP OF THE INTEREST GROUP ON THE HISTORY OF MASS SPECTROMETRY; MAY 13, 1966; JOINT MEETING OF THE INTEREST GROUP AND THE PLANNING COMMITTEE FOR THE 50TH ANNIVERSARY
Subject: Plans for the Group at future ASMS Meetings
Reported by Charles M. Judson, Chairman of the Interest Group

Attendance was 20, larger than recent meetings of this group, probably because for the first time in recent years, we had an announcement in the program.

First subject of discussion was "Is the workshop format suitable for this group, and what are subjects suitable for a workshop?" Subjects suggested were:

1. Archiving techniques.
2. How have advances in technology contributed to growth of mass spectrometry?
3. The time-line of mass spectrometry, selecting a limited period.
4. History of methods for introduction of gases, liquids and solids.

It was suggested that invitation of an archivist to lead the Archiving discussion would be better done at an east coast location and would not be suitable for the 1997 meeting in Palm Springs. The Chairman will select another topic from the list and identify a panel of facilitators as needed.

The discussion then moved to topics for oral or poster papers for future meetings. The following were suggested, in addition to the topics proposed for workshops:

1. Continuation of history of methods of mass analysis
 - Ion traps
 - Omegatrons, ICR and FTICR
 - Linear RF Analysers (Bennett Tube, etc.)
2. History of methods of ionization
 - Electron ionization (a non-trivial history)
 - Spark ionization
 - Surface Ionization
 - Chemical ionization
 - Field ionization, field desorption
 - Secondary ionization by particles
 - Laser ionization
 - Glow discharge and ICP
 - Spray ionization
3. Contributions of the petroleum industry to the development of mass spectrometry (Does any other industry merit such attention?)

It was agreed that we should suggest that oral papers on any aspect of the history of mass spectrometry should be encouraged for all future years. Mike Grayson has already suggested to the Program Chairman that "History of MS" should be one of the topic descriptions in the short abstracts used to group papers.

Mike Grayson suggested that the Executive Committee might not be willing to support an oral session on history of mass spectrometry two years in a row, and that this topic should be spread out over the five years remaining before the anniversary year. The chairman suggested that people directly knowledgeable about history of mass spectrometry are rapidly becoming unavailable, and that some of these topics should be presented while suitable speakers are still available. The Interest Group Chairman will request to the new Program Chairman an oral session on history of mass spectrometry for 1977, possibly a half session, or a single oral paper which could fit in some related session, and at a minimum a commitment for an oral session in 1978.

Mike Grayson suggested that the Committee for the 50th Anniversary will suggest that the 2002 meeting be in Philadelphia where the Museum of Chemical Instrumentation will be located.

Funding of the Group by the Society was discussed. The Society has funded membership in the Heritage Foundation, and offered to support Al Yerger's work to report on Calutrons, which has been paid only in part. Mike Grayson will contact the executive committee regarding any future needs for funding.

The subject of reprinting historical documents was discussed. Larry Philips suggested that CD ROMS would be more suitable than reprints. This subject will need to be reviewed in more detail, both as to documents to be reproduced, and mechanism of reproduction. Possibly this should be a workshop subject, with a subcommittee making recommendations.

The chairman commented that the suggestion of getting persons who attended the 1953 meeting to come to the anniversary meeting was not going to be easy, and suggested that it might be easier to get a written report or a tape or video interview from them. He proposed to try before the 1977 meeting to get a list of people living who might have attended the 1953 meeting, and start on finding their current addresses.

The discussion continued until 2:00 and there was no time for a formal meeting of the 50th Anniversary Committee, but Mike Grayson ended the meeting with some comments about the plans of the Anniversary Committee.

Frank Field suggested that the first meeting was 1952 and not 1953. The Chairman will circulate to the Anniversary Committee and to Frank the documentation that the first meeting of E-14 was 1953.

Young Mass Spectrometrists Interest Group

The Peer Review Process: How to be an Effective Reviewer

The topic of this year's Young Mass Spectrometrists Interest Group was the peer review process as it relates to serving as a reviewer for publications and/or grant proposals. We, as younger members of the mass spectrometry community, are increasingly called upon to serve as peer reviewers for scientific literature; often with little or no guidance as to what constitutes a technically sound and thorough review. Similarly, serving on a study section is an important aspect of service to the scientific community for which little (or no) formal training is offered. The goal of this workshop was to learn from established reviewers, the protocol which should be followed in order to produce a sound scientific review which will be of use to members of the scientific community. A brief business meeting preceded the panel discussion. Audience members were asked for topics of future Young Mass Spectrometrists Interest Group meetings which would benefit their professional development. Steven Hofstadler was elected as the new Interest Group Coordinator succeeding Dave Dearden who served as the coordinator from 1994-1996.

A panel of distinguished members of the mass spectrometry community was assembled to share their insights into what they see as key features of a good review and how one becomes a good reviewer. The panel was comprised of: Sue Weintraub (University of Texas Health Science Center, a frequent member of NIH study sections), Catherine Fenselau (University of Maryland Baltimore County, Associate Editor of *Analytical Chemistry*), Gary Glish (University of North Carolina Chapel Hill, Associate Editor of *Journal of the American Society for Mass Spectrometry*), and Michael Gross (Washington University, Editor-in-Chief of *Journal of the American Society for Mass Spectrometry*). Panelists gave a brief overview of the review process, highlighting key aspects which lay the foundation for a sound and thorough review.

Sue Weintraub began by describing five properties of a good peer review of a grant proposal. An important aspect of serving as a reviewer is to keep one's mind open to novel and unfamiliar areas of research. Just because the proposed research may involve techniques with which the reviewer is not completely familiar does not mean the proposal is not worthy of detailed consideration. Consequently, the reviewer must do everything possible to educate him/herself to insure that their level of expertise is adequate to fully understand and critique the scope and relevance of the proposed research. If techniques or concepts are proposed with which the reviewer is not familiar, it is their responsibility to seek out the necessary resources to educate themselves. The ability to devote an adequate amount of time to the review is a critical aspect of a thorough review. One can not expect to fully comprehend and critique a grant proposal if only a cursory read-through is given. Thus, multiple read-throughs of a proposal, or group of proposals (ideally with enough time between readings to fully "digest" the material), is highly desirable. Consistency as a reviewer is essential due the highly competitive nature of the review process; consistency results from making sure that the above guidelines are adhered to. Finally, it is important to keep in mind that the product of one's review is the written critique; it is advantageous to concisely state which aspects of the proposed research need further development and which areas appear particularly exciting from a scientific standpoint. A concise critique lets the author of the proposal know how effectively their ideas were communicated to the review panel.

Following Dr. Weintraub's presentation, and a number of questions from the audience, the other panelists gave brief descriptions of what qualities they look for in the peer review of manuscripts. Again, the key features were open mindedness, expertise, time, consistency, and critique. Dr. Fenselau stressed the importance of a thorough critique, as it is the goal of the peer review process to improve the quality of the scientific literature. Dr. Glish added that time is of the essence in the review of manuscripts and it is a disservice to the scientific community to sit on a review for six weeks before giving it a cursory read-through and a "publish as is" critique. Dr. Gross described the type of papers he likes to see published in *Journal of the American Society for Mass Spectrometry* and suggested alternative journals in which work outside the scope of the Journal might be published. A question came up related to how papers are handled which have been rejected from non-mass spectrometry journals because they were deemed by the editor to be outside the scope of a particular journal. The panel agreed that if a paper is rejected from a non-mass spectrometry journal on these grounds, it can be submitted along with the original review and letter from the editor and may be accepted without additional review (provided the authors have addressed any key questions raised by the reviewers).

Following additional questions from the audience and a solicitation from the chairman for topics for next year's meeting of the Young Mass Spectrometrists interest group the meeting was adjourned.

Respectfully Submitted,

Steven A. Hofstadler
Young Mass Spectrometrists Interest Group
Workshop Chairman

Summary 96 ASMS Energy and Petrochemicals Workshop
Dean V. Davis - 76 Products Company
555 Anton Blvd., Costa Mesa, CA 92626

Approximately 50 people attended the Energy and Petrochemicals workshop at the 96 ASMS meeting. The workshop started with a brief business meeting. The membership was polled on a number of questions regarding the current policies of the convention organizers. In all cases the members were happy with the way petroleum related activities are currently being handled within the society.

The chair asked for suggestions for or volunteers to become the next chair of the group, none were offered. Hence the current chair polled the membership about their feelings on how the group was operating and whether he should request permission from ASMS to stay on as chair. The membership by show of hands indicated unanimous support for the chair remaining in office for two more years.

The topic of the workshop was to examine cross correlation for parameters measured by MS methods versus the same data generated by other techniques and to explain any differences. Dean Davis began the discussion by asking if anyone in the audience had compared total aromatics in gasolines by ASTM D5580 (GC) and ASTM 5769 (GC/MS). As he understood it, the 5580 value is consistently higher than the 5769 value. The conventional wisdom is that the uncalibrated C10, C11, C12 benzenes in 5769 are being underestimated and that paraffin >C12 maybe incorrectly detected as C9+ aromatics in 5580. The combined effects would thus account for the differences seen. Vince Nero commented and showed some data that using a slightly different way of calculating the uncalibrateds in 5769 provided different data. This data was consistently the same as the average of the ASTM D1319 (FIA) method from the new ASTM RFG Interlaboratory Cross-check program. He was however unaware of how it compares with 5580, which is not being used often, except in California. Dean Davis took this opportunity to inform the membership that the changes Vince was recommending along with others had arisen out of discussion at the prior years ASMS workshop. These had been forwarded to ASTM and would be incorporated in the next version of the 5769 method due out later this year. After the new method is issued a round robin was scheduled to take place. Many members of the audience would participate in this the round robin.

The last thing discussed was possible uses by the group of the new ASMS web page facilities. Most people felt something similar to a bulletin board would be most useful. This would be a place where people could interactively retrieve and post information. The chair not being an internet expert agreed to investigate some possibilities and let the membership know the results.

At the conclusion of the meeting the chair asked for information in order to update the groups mailing list. This list is maintained by the chair and a current copy is sent to the membership every year. Anyone who wants to be on this list can contact the chairperson at his E-mail address Standvd@Products.Unocal.Com.

FTMS INTEREST GROUP WORKSHOP

Instrumental Developments in FTMS—Both Major and Minor

The third annual workshop of the FTMS interest group focused on recent results in FT-ICR research. Short presentations were given by a variety of industrial and academic chemists. Gökhan Baykut of Bruker Instruments began the session by discussing Bruker's commercial MALDI-FTMS. The sample probe assembly is similar to that used on their MALDI-TOF mass spectrometers and includes a video camera for viewing the sample inside of the vacuum chamber. Peptide mass spectra with resolutions $>500,000$ were shown. Paul Speir of Bruker followed with a discussion of Bruker's electrospray FTMS systems. He showed example spectra taken with a shielded magnet. While the shielding greatly reduces the magnetic field experienced by the environment outside of the magnet, it does not affect spectral quality.

The afternoon's third speaker, Kevin Goodner from John Eyler's group at the University of Florida, discussed WinICR. This is an off-line data processing program that he and Cliff Watson have written. It can process FT-ICR data files obtained from most commercial instruments, as well as Bruker TOF files. The program is available free of charge by contacting Kevin. The next talk, by Ziqiang Guan from Fred McLafferty's group at Cornell University, dealt with instrument set-ups used in photodissociation experiments. He spoke on co-aligning an excimer laser (193 nm) and a CO_2 laser (10.6 μm) and on the selection of optical materials. Dr. Guan showed IR/CAD spectra of peptides which included z fragmentation patterns. The following speaker, Michael Easterling from Jon Amster's group at the University of Georgia, discussed their use of FT-ICR for internal (in-cell) MALDI. For efficient ion detection, this group uses quadrupolar excitation (QE) to geometrically shrink the ion beam prior to ion excitation. Their pre-amplifier is mounted inside of the cell vacuum chamber to allow immediate amplification of the image current produced by the ion beam.

Guo-Zhong Li from the High Field Magnet Laboratory at Florida State University spoke on their optical system used for laser-induced fluorescence experiments in an FT-ICR. He discussed the experiment's pulse sequence, which involves QE to shrink the ion cloud. Off-resonance QE can also be used to axialize the ions. Electrospray FT-ICR with an in-bore ESI source was the topic of member of David Laude's group at the University of Texas at Austin. His work indicates that if the desolvating skimmer voltage on the ESI source is turned down, adduct ions are only seen at lower charge states; the reasons why higher charge states do not readily form adducts are unknown. The afternoon's eighth speaker, Kent Gillig from David Russell's group at Texas A&M University, spoke on their FT-ICR ion mobility spectrometer. This instrument includes a dual cell FT-ICR followed by a drift cell, TOF flight tube, and multi-channel plate detector. It allows them to combine ion chemistry and structural determination studies.

The next speaker was Carl James from NIH. He spoke on the magnetron radii of ions during QE experiments. Gordon Anderson of the Pacific Northwest Laboratory followed with a presentation on ICR-2LS Version 1. This PC program allows manipulation of ICR data files and also has waveform calculation capabilities. James Bruce is a co-

author of the program. Investigating photodissociation with an FT-ICR was the topic presented by Scott Tonner from Terry McMahon's group at the University of Waterloo. Scott has studied blackbody induced dissociation using radiation coming off the walls of the cell; the kinetics of photodissociation are also being measured. John Stults of Genentech presented MALDI data from his IonSpec FT-ICR system. The instrument's ultrahigh resolving power was able to separate ^{34}S from ^{32}S isotopes in peptides. Lower trapping voltages were used to limit coalescence of peaks.

Marshall Pope from David Deardon's group at Brigham Young University discussed a simple modification that was used to convert their Analytica of Branford electrospray system into a microspray system. The cost was \$65 for the conversion, which includes a metal desolvating tube that can be heated. The nozzle-skimmer distance can be tuned while spraying samples. To minimize contamination problems, each user has their own desolvating capillary which can be switched without breaking vacuum. This design does not charge up as much as glass tube systems, is easy to use with a wide variety of solvents, cuts down on the need for drying gas, minimizes tuning effects, and increases sensitivity. The afternoon's final speaker, Carlito Lebrilla of the University of California at Davis, discussed the role of the collision gas in external MALDI FT-ICR. His group has found that it is easier to get high resolution spectra with no gas. They believe that neutrals produced by the laser are traveling down the vacuum chamber into the FT-ICR cell and are collisionally cooling their own ions.

Interest group members are encouraged to provide feedback to Carolyn Cassidy (CCASSADY@MIAMI.MUOHIO.EDU or 513-529-2494) concerning topics for the 1997 workshop as well as any other information that they feel would be of interest to the group.

FTMS Interest Group Coordinator

DESORPTION/IONIZATION INTEREST GROUP WORKSHOP

"DELAYED EXTRACTION IN MALDI- AND ESI-TOF MS "

The workshop was opened Monday, 15 May 1996, at 12:30 PM with approximately 150 attendees present. The format consisted of a brief introduction, four 15-minute presentations, and a 20 minute period of open discussion. The invited speakers were Robert Brown (Utah State University), Marvin Vestal (PerSeptive Biosystems/ Vestec), Werner Ens (University of Manitoba), and Igor Chernushevich (University of Manitoba). In addition, Paul Kowalski (Bruker Instruments) was allowed 5 minutes to show some recent results.

Interest Group Coordinator, Doug Barofsky, opened the workshop with an encouragement for Group members to fill out the ASMS suggestions forms that had been circulated while they were seating themselves.

Doug Barofsky briefly introduced the topic of delayed extraction by pointing out that it was first described as time-lag focusing by Wiley and McLaren in 1955 (Rev. Sci. Instrum. 26, 1150). Nonetheless, it was considered to be of little import for the present day forms of TOF MS. John Lennon and Robert Brown changed this conception in 1994 when they reported dramatically improved resolution and sensitivity in MALDI TOF mass spectra obtained with the aid of delayed ion extraction (42nd ASMS Conference, Chicago). In the ensuing two years, the potential for applying the technique has greatly expanded, and commercial versions have become available.

Robert Brown described the principles behind delayed ion extraction. He used mass spectra obtained in his laboratory to illustrate the effects of varying the delay time and the magnitude of the extraction potential on resolution, mass accuracy, background signals, and sensitivity in a linear MALDI TOF instrument. He also spoke about the use of delayed extraction in his laboratory to investigate the MALDI process itself. In contrast to post source metastable decomposition that occurs on the microsecond time scale, in-source decays occurring on the time scale of hundreds of nanoseconds can be observed with the aid of delayed extraction. This early metastable ion decay might be associated with the ionization reaction.

Marvin Vestal focused his presentation on the applications of delayed ion extraction in conjunction with a reflectron. He presented results from MALDI TOF mass spectrometers ranging in lengths from 1.3 m (a linear instrument) to 6.4 m (a reflector instrument). He showed how the use of internal calibrants that bracket the masses of interest makes it possible to determine masses with sufficient accuracy to distinguish between amino acid modifications in peptides. He further indicated that the overall mass accuracy obtainable through the combined use of delayed extraction and ion reflection is comparable to that possible with MALDI FTICR MS even though the resolving power possible in the TOF case is only in range of 3,000 to 10,000.

Werner Ens briefly described how delayed extraction is implemented for MALDI TOF in Manitoba and then reminded the audience that it has broader application, namely as a means to focus ions orthogonally extracted out of an electrospray beam. On this cue, he yielded the podium to his colleague, Igor Chernushevich.

Igor Chernushevich described the electrospray interface used in Manitoba for orthogonal ion injection into a TOF mass spectrometer, including the recent installation of a RF-only quadrupole section in front of the ion extraction chamber that increases sensitivity and resolution and greatly reduces mass and m/z discriminations. He reviewed the focusing principle involved in this application of delayed pulsed extraction and indicated that resolving powers in excess of 10,000 are now possible.

Paul Kowalski showed four overviews that, as had been done in the preceding talks, highlighted some the excellent spectrometric characteristics that are possible on a MALDI instrument equipped with delayed extraction.

Following the presentations, there was only a small amount of discussion among the presenters on technical points.

The workshop was adjourned at 2:00 PM.

Polymeric Materials Interest Group Meeting

About 70 people attended the Wednesday lunchtime interest group meeting. An attempt was made in advance to have speakers using a variety of techniques, but, in the end, all who volunteered were investigating various aspects of MALDI (matrix-assisted laser desorption/ionization). Feedback I heard in advance of the meeting included (1) "I'd like to hear more about using MALDI to analyze polymers" and (2) "We seem to be spending too much time discussing MALDI of polymers. I hope this year the topics will be broader." Last year we had a fairly broad discussion of a variety of technical approaches. The broadness was limited this year by the inability of a number of our active industrial researchers to attend because of budget issues within their companies.

Although I solicited feedback at the meeting and encouraged E-mail or other correspondence to me after the conference, I received no input concerning suggestions for future ASMS conferences or this interest group. I also requested short summaries from the speakers to help make this report as accurate as possible, but none were received. Below is a summary of our technical program.

J. Scrivens, ICI: Jim discussed the analysis of mixtures of polymers (same polymer; variety of average molecular weights, with a range of about 1-30 kd). He obtains accurate relative areas for the distributions using a very low matrix:sample ratio. He has done this experiment on a number of polymers. Equal weights of the polymers are analyzed. The issue of accuracy in the calculation of average molecular weights for synthetic polymers using MS, and the comparison of MS values with those obtained by more traditional methods (GPC, NMR, VPO) has been a lively area of investigation and discussion.

K. Owens, Drexel University: Kevin discussed the many aspects required for successful MALDI and the roles of the matrix. He indicated that desorption and ionization must often be optimized separately. He discussed slow crystal formation in the deposition of the MALDI solution. He also showed results for polystyrene. In this case, the matrix (dihydroxy-benzoic acid), used successfully for a sample with a lower average molecular weight (1,250 d), was unsuccessful with 5 kd polystyrene. Sinnapinic acid was successful with this material, but failed with 68 kd polystyrene. 3-indole-acrylic acid was successful with polystyrene of all molecular weights.

C. Kassis, University of North Carolina: Camille showed results in which the addition of a non-ionic surfactant improved the results for analysis of polymers. Surfactants with a lower critical micelle concentration were useful at a lower concentration. She also discussed the use of gel permeation chromatography (size exclusion chromatography) preceding MALDI analysis to analyze polymers. This is a technique also mentioned by others. She used an LC Transform apparatus. The matrix was pre-coated on the metal disk used for GPC column effluent deposition.

C. McEwen, DuPont: Chuck discussed the analysis of polymers with high polydispersity. This has been a topic of high interest, because these materials have often failed to produce good results using MS techniques. He showed that if you use selective extraction (time-of-flight instrument) or analyze GPC fractions, you can detect higher mass oligomers than were observed in the full mass spectrum of the unseparated polymer. Issues such as the dynamic range of the technique and "detector fatigue" were discussed.

S. Hanton, Air Products and Chemicals, Inc.: Scott showed a comparison of results for polytetramethylene glycol (supposedly with an average MW of about 1,000 d), analyzed using FAB and MALDI and compared these to GPC and NMR. The MALDI results were usually much higher than for the other techniques, although this was substantially solvent-dependent. Chuck suggested the possibility of dimer formation (Scott used a matrix:sample ratio of 500:1, however). Chuck also said he generally gets good results for this type of polymer although he said some results at his company were similar to Scott's. They agreed to do a collaborative study. The possibility of cationization discriminating against lower mass oligomers was also mentioned. A discussion about using different cations was completed by Scott adding that his study of Li, Na and K produced only a 5% difference (Li produced the lowest average MW).

D. Schriemer, University of Alberta: Dave showed results for MALDI of polystyrene up to 930 kd. The species were cationized with silver. For 1.5 Md, the doubly charged species was detected. Peaks were approximately 100 kd wide. The results agree with GPC. He said that the amount of sample loaded must be decreased greatly at higher MWs. At the high end, he was using a matrix:sample ratio of 8M:1! He also showed resolution of oligomers at 46 kd using time-lag focusing. There was also a discussion of the time-to-mass domain conversion necessary to calculate correct quantitation to compare with GPC results. A number of comments were made by other participants about their similar procedure for doing this. It has not been obvious in the past couple of years, as people have reported results at odds with GPC, whether they were calculating their MALDI peaks areas correctly.

K. Marcus, Clemson University: Ken was the only speaker not discussing MALDI. He showed results for an RF glow discharge MS instrument built in his lab. He used it for the analysis of non-conductive polymers. He claimed that it produced useful information in bulk polymer analysis for end groups, co-polymers, and inorganic species that might be present. For PTFE (Teflon) he obtained a SIMS-like spectrum, but with a much stronger signal. The technique can also be used to sputter through surface layers to do depth profiling.

Summary: It appears that progress has been made in the last two years in the understanding of how to analyze synthetic polymers using mass spectrometric techniques. There is a lot of activity in both MALDI and electrospray and there is considerable interest in comparing the results of these techniques in appropriate cases. Direct laser desorption, usually used in conjunction with FTMS has also produced some excellent results recently. The challenges of a wide variety of chemistry and the broad molecular weight ranges present require more study.

Dave Parees, Air Products and Chemicals, Inc., workshop organizer

SPECIAL SESSION WORKSHOP

"Forensic Applications of Mass Spectrometry"

A special workshop on forensic applications of mass spectrometry was held on Wednesday afternoon, May 15. The objective of this workshop was to promote interest in the forensic sciences and to illustrate areas in which mass spectrometry is used. Approximately eighty people were in attendance representing industry, academia, government laboratories, and instrument manufacturers. The workshop was structured around informal presentations from invited speakers, followed by question and answer periods.

The workshop began with a presentation of research in progress by Stacy Barshick (Oak Ridge National Laboratory) on the decomposition chemistry of human remains. Although not the best lunchtime topic, the audience found it morbidly fascinating. The talk described how mass spectrometry can play a vital role in determining the products associated with the decomposition of human remains. Knowledge of human decomposition chemistry was shown to be a critical need in forensic investigations for determining time since death and assisting in cadaver recovery efforts. The challenge for mass spectrometry in this application would be to identify and quantify the most accurate biomarker (or ratio of biomarkers) for determining time since death and for remote sensing to assist field searches for cadaver recovery.

Mark Miller (Federal Bureau of Investigation) spoke next on drug analysis and toxicology. Although techniques such as thin layer chromatography, immunoassay, HPLC, and GC were described as being useful for screening purposes, mass spectrometry remains the preferred method for confirmation and quantification. Two example cases, cocaine laced Pony Malta and EDTA preservative in blood tampering, were used to illustrate the challenges in toxicological trace analysis applications. The major challenges for toxicological assays described were the development of lower cost tandem mass spectrometry instrumentation and the exploration of faster, more direct sample preparation and analysis methods.

The detection and trace analysis of explosives and post-explosion residues was presented by Jehuda Yinon (Weizmann Institute of Science). The difficulties in explosives analysis were described including variations in analyte (vapor or particulate versus solid, liquid or residue) and matrices (air, water, soil, post-explosion debris). Atmospheric sampling methods or ion mobility mass spectrometers were said to be the methods of choice for real-time analysis of hidden explosives. In contrast, GC or LC MS methods were found to be better for post-explosion and environmental contamination applications. The challenge was put forth to the mass spectrometry community to develop better LC methods, improve MS sensitivity and investigate better sampling and collection methods for explosives and post-explosion residue collection and detection.

Several other snapshots of research in progress were also presented by colleagues at Oak Ridge National Laboratory. Chris Barshick spoke on the analysis of gun shot residues using inductively coupled plasma mass spectrometry (ICP-MS). Conventional methods such as scanning electron microscopy, atomic adsorption spectroscopy and ICP-optical spectroscopy were

compared to ICP-MS. The major advantages of ICP-MS included ppt detection levels, >10% accuracy for elemental quantification and the ability to analyze > 90% of all elements. Future projects of forensic interest could involve the effects of weathering, analysis of lead-free primers and the determination of when a firearm was last fired.

Doug Duckworth also presented work using ICP-MS for the analysis of glass. A statistical analysis was performed on two glass samples with different refractive indices (mirror and pane glass) using ICP-MS. The glass samples were microwave digested prior to ICP-MS analysis. Elemental quantification at 1 - 100 ppm levels were obtained and the results were subjected to discriminant analysis. The findings were conclusive that by ICP-MS, mirror and pane glass samples can be differentiated. This work is of forensic interest in crime scene/burglary cases and automobile/hit and run accidents. A major challenge in this work will be the ability to discriminate samples with similar refractive indices.

The chemical characterization of fingerprints was presented by Keiji Asano. This work was undertaken because of a local child abduction case. Although the child was witnessed to be in the suspect's vehicle and the suspect's fingerprints were found, the child's fingerprints were not detected in the vehicle used in the abduction. Using mass spectrometry, differences in the chemical profiles taken from children and adults were readily apparent. The chemical variations were mainly due to differences in fatty acid content; children have larger quantities of lower molecular weight while adults contain more high molecular weight fatty acid esters. In addition to fatty acids, cholesterol, steroids, and nicotine were detected in some fingerprint samples. Future work in this area could involve determining the ability to differentiate suspects based on the chemical composition of their fingerprints.

The workshop appeared to be well-received as evident by the number of attendees remaining following the presentations. Those who remained for continued discussions were interested in knowing how to get involved in the area of forensics and the availability of funding for research. Although no clear "inside track" was defined, the enthusiasm of these individuals for this work remained. Finally, the organizers would like to thank all the speakers for leading the discussions, the participants for their interaction, and ASMS for allowing us to hold this special session.

FUNDAMENTALS INTEREST GROUP WORKSHOP

Ion Binding Energies and Thermochemistry

Organized by Robert C. Dunbar, Wednesday, May 15, 1996

Robert C. Dunbar (Case Western Reserve University) led into the topic with an outline overview of thermochemical approaches using spectroscopy, association, dissociation (threshold, thermal and competitive), reactions (bracketing and equilibrium), and computation. Eleven participants gave presentations.

Peter B. Armentrout (University of Utah) discussed two recent examples of work designed to resolve controversial thermochemistry in the literature. Reexamination of the reactions, M^+ ($M = \text{Ru, Rh, and Pd}$) + $\text{C}_2\text{H}_6 \rightarrow \text{MCH}_3^+ + \text{CH}_3$, yields $M^+-\text{CH}_3$ bond energies in much better agreement with theoretical work of Bauschlicher et al. (J. Chem. Phys. 1989, 91, 2399) than the original experimental work of Mandich et al. (J. Am. Chem. Soc. 1984, 106, 4403). Examination of the kinetic energy dependence of the $\text{Nb}^+ + \text{CH}_4 \rightarrow \text{NbCH}_2^+ + \text{H}_2$ reaction reveals a small threshold, consistent with Hettich and Freiser (J. Am. Chem. Soc. 1987, 109, 3543) and inconsistent with Bauschlicher et al. (J. Phys. Chem. 1992, 96, 6969).

John Bartmess (University of Tennessee, Knoxville). **Current Status of Thermochemical Compilations.** At long last, the "new" gas phase basicity scale will be submitted to J. Phys. Chem. Ref. Data by June 15th, and will be included in the updated version of the NIST positive ion database 19A, available by late summer/fall. The negative ion database 19B is likewise being revised on that time table. These will be available on an NIST Web site to be given in sci techniques mass-spec, and in the Spectaker, when available.

David V. Dearden (Brigham Young University) FTICR amine exchange equilibrium techniques were used to study the recognition of chiral amine guests by protonated chiral crown ether hosts. Comparison of the equilibrium constants for exchange of the two enantiomeric amines with an achiral reference measures recognition by the host. Results were obtained for recognition by protonated (R,R)- and (S,S)-dimethyldiketopyrindino-18-crown-6 of R- and S- α -(1-naphthyl)ethylamine. Comparison of the recognition of chiral sec-butylamine, cyclohexylethylamine, and phenylethylamine reveals the importance of the pi-pi stacking interaction. This host-guest system is consistent with the 4-point binding model of Cram.

Ralph Dougherty (Florida State University). Classical theories of ion-molecule collision rates were shown to fail because orbital overlap occurs at distances greater than the impact parameter, b_c . When the orbitals overlap, the electrons on the ion and molecule exchange. A first order perturbation molecular orbital (PMO) theory for both ion-molecule collisions and electron-transfer (ET) reactions was presented. The new collision theory utilizes Langevin theory and the Mulliken approximation for the resonance integral. The ET theory is the semiclassical theory using a Marcus model with PMO estimates of the matrix element. Applications illustrating inverted region gas-phase ET, dissociative ET, and proton transfer were presented.

Kelly Griffith (Creighton University). Treating open shell systems, and especially ions, computationally is a difficult problem. Specifically one must be concerned with the stability of the UHF wave function, which may be prone to a phenomenon known as symmetry breaking. In the species $(\text{O}_4)^+$, symmetry breaking manifests as the artifactual localization of charge onto specific atoms (which results in a lower HF energy). In other species there can be breaking of the higher electric moments. Building correlation onto a symmetry broken UHF wave function may repair the break, but not always. It is an open question of how best to deal with the problem, and the solution may be different for various species.

Luke Hanley (University of Illinois at Chicago). We are developing a method for extracting ion fragmentation energetics from surface-induced dissociation data which is conceptually similar to that used by Peter Armentrout for threshold CID measurements. By measuring the kinetic energy distribution of the scattered ions, we can estimate the amount of energy deposited into the surface. A functional form of the cross section is then assumed and the energy resolved mass spectra are fit using our model. Preliminary tests of the method with $\text{Cr}(\text{CO})_6^+ \rightarrow \text{Cr}^+$ SID data are. This method does not require us to make assumptions about kinetic to internal energy transfer efficiencies, Arrhenius factors, or effective surface masses.

Stephen Kass (University of Minnesota). Density functional calculations are very popular these days because they scale favorably relative to *ab initio* procedures and they explicitly include electron correlation. We have recently discovered that potential energy surfaces can be very basis set dependent (6-31+G** vs aug-cc-pVDZ), that transition state frequencies often appear to be considerably too small, and that in the reaction of fluoride with ethyl fluoride there is no anti elimination transition state on the potential energy surface with many different functionals; a result that clearly is in error and is of some concern.

Terrance B. McMahon (University of Waterloo) described pulsed ionization high pressure techniques for the determination of thermochemical properties. The technique involves the generation of ions at high pressures (~5 torr) of an inert bath gas such as CH_4 , where roughly 10^6 thermalizing collisions will take place. With no electric fields in the source a true thermal distribution of ion energies is obtained. The approach to equilibrium and accurate equilibrium constants are observable. The technique was illustrated for gas phase $\text{S}_\text{N}2$ reactions of Cl^- with alkyl bromides. The reaction exothermicity, the well depths of the entrance and exit channel complexes, and the height of the transition state were all readily determinable.

Helmut Schwarz (Technical University of Berlin). **On the Origin of the Unparalleled $\text{BDE}(\text{Pd}^+-\text{CH}_2\text{I})$.** State-of-the-art *ab initio* studies demonstrate that the reaction $\text{PD}^+ + \text{CH}_3\text{I} \rightarrow \text{PdCH}_2\text{I}^+ + \text{H}$ is endothermic by ca. 20 kcal/mol, which translates into a bond dissociation energy (BDE) of ca. 83 kcal/mol for the $\text{Pd}-\text{CH}_2\text{I}$ bond. This figure is in agreement with an experimental bracket of $69 \text{ kcal/mol} < \text{BDE}(\text{Pd}^+-\text{CH}_2\text{I}) < 92 \text{ kcal/mol}$. Based on these findings, the previously studied $\text{Pd}^+/\text{CH}_3\text{I}$ system was re-investigated, and double-resonance experiments demonstrate that the formation of PdCH_2I^+ occurs stepwise via PdCH_3^+ as a reactive intermediate.

Robert Squires (Purdue University). described progress toward the determination of the absolute heat of formation of carbonyl fluoride, $\text{CF}_2=\text{O}$. This molecule plays an important part in the atmospheric degradation of HFCs. The experimental thermochemistry for CF_2O has been called into question by recent *ab initio* calculations. CID threshold measurements are being carried out with CF_3O^- in a flowing afterglow-triple quadrupole apparatus in order to establish the fluoride affinity of CF_2O , $\text{FA}(\text{CF}_2\text{O})$. Combining the preliminary value for $\text{FA}(\text{CF}_2\text{O})$ with the heat of formation and gas-phase acidity of CF_3OH determined in other work gives a heat of formation for CF_2O that is in good agreement with theory.

Chrys Wesdemiotis and Michael J. Nold (University of Akron). The kinetic method (R. G. Cooks et al., Mass Spectrom. Rev. 13 (1994) 287) has been used to obtain information on the gas phase basicities of small biomolecules. This method does not provide proton affinities but rather basicities (ΔG), i.e. thermodynamic values that contain both enthalpic and entropic contributions. The following ΔG values have been determined (all in kJ/mol): 2-phenyl-5-oxazolone, 914; cyclo-Leu-Gly (a diketopiperazine), 874; Gly-Leu, 932, and Leu-Gly, 948. The cyclic dipeptide binds H^+ more weakly than linear peptides with the same amino acid residues. The sequence of a linear dipeptide significantly affects its basicity.

QUANTITATION INTEREST GROUP WORKSHOP

"Quantitative LC/MS in the Pharmaceutical Industry"

Craig Abolin, Sandoz Research Institute, East Hanover, NJ; Thomas Oglesby, Taylor Technology, Inc., Princeton, NJ; Walter Korfmacher, Schering-Plough Research Institute, Kenilworth, NJ; Kelvin Chan, Wyeth-Ayerst, Princeton, NJ; Kathy Halm, Glaxo Wellcome, Research Triangle Park, NC.

Summary- Since the introduction of Atmospheric Pressure Ionization (API) sources, LC/MS has revolutionized quantitative analysis in the Pharmaceutical industry. Conventional detection technologies based on competitive binding, UV light absorbance or derivatization followed by GC/MS do not offer the combination of fast method development, specificity, sensitivity, high throughput, and near universal applicability of LC/MS. Because many of the newer drugs under development share many of the physicochemical characteristics of biochemicals (<2Kdalton, polar and ionic in solution), LC/MS is ideally suited to become the dominant quantitative technology used in the Pharmaceutical industry. Because of this major technology shift, an appreciation of the strengths and weaknesses of quantitative LC/MS technology is essential. This Workshop was designed to promote discussion among novice and veteran practitioners of the art of quantitative LC/MS.

Craig Abolin "Standard Curves, Calibration Models and Goodness of Fit" Using standard plotting conventions, a standard curve is constructed by plotting the detector response on the Y-axis and concentration (the independent variable) on the X-axis. The simplest calibration model that fits the concentration-response relationship is usually preferred. The simplest linear model and four nonlinear models were discussed [Wagner (Quadratic-Log), Quadratic, Log-log and Power].

To detect nonlinearity in a standard curve data set, a plot of the RRF vs. calibrator concentration was suggested (Figure 1). In Figure 1, nonlinearity can be seen as a systematic deviation from a slope of 1. For nonlinear systems such as in Figure 1, a calibration curve can be constructed using a power function of the form $Y = a + bX^c$, where Y is typically the area ratio, a is the intercept, b is the slope and c is the exponent. A weighting factor of $1/X^2$ was suggested to reduce high concentration bias during the regression analysis. To visually compare the goodness of fit between weighting schemes or models, a residual plot can be constructed as in Figure 2. Small ($\pm 15\%$) random deviations from the expected value indicated a good model and a good fit. For nonlinear systems, the coefficient of determination (r^2) was not considered a robust indicator of goodness of fit. During the discussion period, it was generally agreed that electrospray tended to be more nonlinear than atmospheric pressure chemical ionization.

Thomas Oglesby "Nonlinearity Issues" HPLC/ESI/MS/MS results were shown for an assay employing a coeluting stable isotope analogue as an internal standard. The assay was apparently linear ($R=0.999-1.00$) with precision (%CV) better than 2%. Under slightly different instrumental conditions, the assay displayed nonlinear behavior reminiscent of saturation of the ESI process. It was demonstrated, however, that the nonlinear behavior originated from other causes including offset voltages, multiplier voltages and pulse-counting parameters. It was concluded that in order to maintain linearity, it is essential to control all hardware and software parameters in conjunction with using a coeluting stable isotope analogue internal standard.

Kelvin Chan "Biological Matrix Effects" Kelvin showed an example of the effect of poor chromatography on LC/MS/MS results. The retention time of the analyte was near the void volume allowing coeluting metabolites to interfere with the assay. In this case, the metabolites shared the same nominal parent and product ions as the analyte. The suggested solution was to use better chromatography for the analyte ($k' \geq 3$) to ensure separation of the analyte from polar metabolites.

An example of the effect of using non optimal internal standards was shown. The internal standard was a structural analog of the analyte. Using blood from two different monkey species, the relative recovery of the analytes differed dramatically. Differential recovery of the analyte and internal standard (by at least a factor of 10) was observed and resulted in unreliable quantitation. The suggested solution was to replace the analog internal standard with a stable isotope internal standard containing $^{13}C_n$ and/or 2H_n where the total $n \geq 4$.

Walter Korfmacher "Non-GLP Drug Discovery Support--Use of The Rat For PK Screening". Walter mentioned that the utility of the rat is its size--it is small enough that a small amount of drug is needed for dosing, but large enough for serial bleeding when the PK assays are performed by a sensitive technique such as LC-API/MS/MS. He then went on to discuss the advantages of working in a non-GLP environment such as Drug Discovery. These advantages included: (1) quantitative methods do not need validation; (2) QC samples are not needed; (3) MS system and software do not need validation.

Dr. Korfmacher also described the utility of using HPLC-API/MS/MS in early drug discovery applications. These advantages included: (1) rapid method development; (2) metabolite identification; (3) the ability to analyze the low volume samples obtained in the serial bleeding of rats. A short discussion followed his presentation. The discussion was cut short so that the final speaker would have time for presentation and discussion.

Kathy Halm "Non-GLP Drug Discovery Support Using The Dog Model For Simultaneous PK Screening of Drug Candidates" Ms Halm described the "N-in-One" approach to dosing several compounds IV simultaneously for pharmacokinetic screening of compound half-life in the dog. APCI LC/MS methods for multiple compounds were rapidly developed and applied to quantitate plasma levels for subsequent pharmacokinetic analysis of clearance, volume of distribution and half-life. API LC/MS has been critical to supporting the needs of Drug Discovery where selectivity, sensitivity and rapid analytical turnaround are necessary to support the selection of candidates for development. Discussion centered around the design of the experiments and limitations of the methodology.

ENERGETICS OF METAL ION COORDINATION CHEMISTRY

A Workshop Sponsored by the Metal Ion Coordination Interest Group

A brief business meeting was conducted by Peter B. Armentrout (University of Utah). Suggestions for plenary speakers, topics for oral sessions, and topics for future workshops were solicited. (Those who were unable to attend the workshop but would like to provide such suggestions are welcome to contact me.) It was the intent of the workshop to concentrate on a single area and permit participation of all attending by allowing sufficient time for more extensive discussion. The topic of energetics of metal ion coordination chemistry was chosen because there are several methods that have recently been developed or recently applied to metal ion coordination chemistry for molecules from the simple to the complex. Five speakers, chosen to represent different types of experimental techniques, participated in the workshop.

Blas Cerda (University of Akron) described recent work in the laboratory of **Chrys Wesdemiotis**. Their work involves the application of Cook's kinetic method to measure the binding affinities of alkali metal ions to the DNA and RNA bases. A key development in this work is the inclusion of entropy effects in the data analysis. As it is usually applied, Cook's kinetic method assumes that entropy effects can be ignored, a reasonable assumption if the two dissociating species are similar. In the present work, this cannot be achieved and hence the entropy effects are measured by determining the branching ratios for dissociation at two effective temperatures. Trends in the results were discussed and some details can be found in the abstracts for posters.

Mary T. Rodgers (University of Utah) described recent developments in studies of threshold collision induced dissociation (CID) performed in collaboration with **Peter B. Armentrout**. Using studies of $\text{Li}^+(\text{H}_2\text{O})_x$ clusters ($x = 1-5$) as an example, Rodgers described the methods used for determining accurate thermochemistry, in particular the assumptions regarding the estimation of kinetic shifts in the thresholds. The use of a phase space limit to determine the molecular parameters for the transition state was described. Good agreement between the CID results and those obtained by Kebarle using high pressure mass spectrometry was obtained for $x = 2-5$, but the value measured for $\text{Li}^+(\text{H}_2\text{O})$ did not agree with an extrapolated value in the earlier work. This has implications for the lithium ion affinity scale presently used in the literature which is anchored to this extrapolated value.

Terry B. McMahon (University of Waterloo) described a new laser ablation high pressure mass spectrometer developed in his laboratory. This apparatus provides an intense pulsed source of atomic metal ions which allows much more accurate studies of the temperature dependence of equilibria involving metal ions. *van't Hoff plots* (plots of $\ln K$ vs $1/T$) allow the determination of enthalpies and entropies of association. Examples of work conducted so far included equilibria of several different atomic transition metal ions associating with such weakly binding ligands as argon and carbon dioxide.

Rob Dunbar (Case Western Reserve University) spoke about several methods utilized in his laboratory to measure metal ion complex bond energies. First was the determination of rate energy curves by photoelectron-photoion coincidence (PEPICO) or time resolved photodissociation (TRPD). Using theory to provide needed background information, this method can provide the most accurate thermochemical values. Cyclopentadienyl nickel ions were provided as an example. Second, radiative and collisional association methods were described. Such techniques have the advantage of being applicable to larger systems (in fact are more suitable there), although the range of bond energies accessible is somewhat narrow. This method has been applied to systems such as $\text{Cr}^+(\text{aromatics})$ and $\text{Au}^+(\text{C}_6\text{F}_6)$. Third is the method of thermal dissociation (called ZTRID by Dunbar and BIRD by Evan Williams). Using the blackbody radiation present everywhere is sufficient to induce dissociation over a sufficiently long timescale. This method is excellent for larger systems and weakly bound clusters, but again the range of bond energies accessible is somewhat limited. Applications to species such as $\text{Si}(\text{C}_2\text{H}_5)_4^+$ were described.

Marshall Pope (Brigham Young University) talked about efforts in **Dave Dearden's** laboratory to perform collision-induced dissociation in their Fourier transform ion cyclotron resonance mass spectrometer. Work on the test systems of $\text{Cr}(\text{CO})_x^+$ and $\text{H}^+ [\text{O}(\text{CH}_3)_2]_2$ were described. Unfortunately, the sensitivity of this experiment appears to be quite limited and discussion focused on how the performance could be improved.

BIOMEDICAL APPLICATIONS INTEREST GROUP WORKSHOP

DNA and Protein Sequencing by MS

This workshop was held on Thursday, May 16 from 12:30 to 2:00 pm. Approximately 90 people attended the workshop. A short business meeting was chaired by Jackson O. Lay prior to the workshop. Attendees were requested to fill out the interest group questionnaires and return them to him at the end of the workshop or to the ASMS questionnaire box. Especially solicited were opinions as to whether or not the interest group should be further subdivided into more specialized areas. Little interest was expressed by attendees in further subdividing the interest group.

The workshop was organized around presentations by four speakers: Paul Chiarelli from Loyola University, Rong Wang from Rockefeller University, Matthias Mann from the European Molecular Biology Laboratory (EMBL), and Eckhard (Edi) Nordhoff from Odense University. DNA and protein sequencing using mass spectrometric techniques can and does cover a wide variety of approaches ranging from primarily biological/biochemical approaches to primarily instrumental, with complete coverage of the topic impossible in the hour and a half time period. The protein sequencing speakers were selected to illustrate approaches to a specific problem, a general approach relying heavily on biological/biochemical methodology and a primarily mass spectrometric approach.

Paul Chiarelli presented the results of a study of the characterization of the products of cross-linking polypeptides using the novel cross-linking reagents bis(3,5-dibromosalicyl)fumarate and 3,3',4,4'-benzophenone tetra(3,5-dibromosalicylate). The specific example used to illustrate the approach was cross-linked hemoglobin.

Rong Wang discussed approaches to ladder sequencing using both chemical and enzymatic methods. In this technique, chemical or enzymatic reactions produce a peptide mixture (ladder peptides) with sequential truncations from either the amino (N) or carboxy (C) termini of the peptide. The resulting peptide mixture is analyzed by MALDI, with the amino acid sequence being determined by mass differences. He also discussed current strategies and methods and problems associated with each method. For generating N-terminal ladder peptides, there are three different methods: (1) using terminating reagent in normal stepwise Edman degradation reaction; (2) using a shorten coupling reaction time in automated amino acid sequencer; (3) using volatile protein degradation chemicals with sequential addition of peptide samples. The utility of ladder sequencing was demonstrated with an example of determining the identities of biotransformed products from dynorphin in human plasma. For generating C-terminal ladders, he discussed the use of a nucleophilic reagent- to control the process. He noted that a combination of V8 and carboxypeptidase Y was often the best enzymatic combination to use for C-terminal ladder sequencing.

Matthias Mann discussed sequencing proteins isolated from PAGE gels. He pointed out that, since for the most part a complete sequence is not needed, the first question to ask is "What do you need the sequence for?" This determines what sequence information is required. For identification from a data base, one usually only needs to identify 2-3 amino acids in two peptides. For a homology search, several stretches longer than 7 amino acids are needed. While for cloning, several stretches longer than 6 amino acids are needed with accuracy being paramount.

Mann noted that trypsin is the enzyme of choice for MS/MS determinations, because after reduction and in the gel, trypsin will digest virtually every protein. The resultant peptides have a positively charged residue at the C-terminus which simplifies interpretation. He also noted that N- and C-terminal ions are often missing, but that usually an a_1b_2 pair is present. From the MW, one can then find the y_{n-2} ion which can serve as a good starting point. For cloning information, he recommended use of Don Hunt's C-terminal methylation procedure. Y ions predominate in the MS/MS spectra, and a comparison of the MS/MS spectra of the modified and unmodified peptides can be used to determine which ions are y ions (shift by 14 or 28 dalton). The use of 50:50 ^{18}O : ^{16}O water during the digestion step can also be used to identify y ions. Trypsin will incorporate 50% ^{18}O in the C-terminus which will result in a shift of all y ions by 2 dalton.

Edi Nordhoff discussed DNA sequencing using the Sanger technique and MALDI/TOF MS. He noted that the major problem with MS analysis is that detection sensitivity and signal resolution for larger oligodeoxyribonucleotide ions is still insufficient for most routine sequencing applications. Ion fragmentation is one of the major problems with base loss being the major fragmentation reaction. Among the four different deoxyribonucleotides, dA, dC, and dG are very fragile, whereas dT is rather stable. The N-glycosidic bond of the purine bases can be significantly stabilized if N7 is replaced by carbon. This modification is compatible with the Sanger sequencing reaction. Improved signal-to-noise and spectral resolution has been observed for the detection of the larger sequencing products of a 78 nt long template sequence when dA/G were replaced by their 7-deaza-derivatives. 2'-F-dCTP also exhibits dramatically less prompt base loss than does dCTP upon MALDI-MS, if 2,5-dihydroxybenzoic acid instead of 3-hydroxypicolinic acid is used as the matrix. These results indicate that 2'-F-dCTP is a potential alternative for dCTP in DNA-Sanger-sequencing by MALDI. Incorporating 2'-F-dCTP into the growing DNA-strand and combined with 7-deaza-dA/GTP and a stabilized primer sequence (carrying exclusively T and 7-deaza-A as nucleobases) a considerably increased ion stability has been observed. However, the incorporation of 2'-F-dCTP causes nonspecific premature termination too abundant to tolerate. He noted that further studies are now underway to determine whether the latter limitation can be overcome by the using other DNA-polymerases.

Respectfully submitted,

Kenneth B. Tomer

Kenneth B. Tomer

ION TRAP INTEREST GROUP WORKSHOP

"Ion Traps or (Triple) Quads: How to Decide"

Thursday, May 16, 12:30 - 2:15 PM

The second annual meeting of the Ion Trap Interest Group began with a brief business meeting. **Rick Yost** (University of Florida), interest group coordinator, distributed a suggestion form to solicit ideas for the 1997 Conference (including workshop, oral session, and plenary topics). **Gary Glish** (University of North Carolina) announced the next Sanibel Conference will be on Quadrupole Ion Trap, January 25-28, 1997, on Sanibel Island, FL. Finally the questions of whether the interest group should be exclusive (quadrupole ion traps only) or inclusive (all types of ion traps, including Fourier transform ion cyclotron resonance traps, which are the topic of another interest group) was discussed. It was concluded that the interest group would continue to focus primarily on quadrupole ion traps.

The workshop, focusing on comparing the new generation of ion trap instruments with the old familiar approaches such as quads and triple quads, was of widespread interest, as reflected in the attendance by over 450 conferees. **Rick Yost** provided a brief perspective on the evolution of the ion trap; new features and capabilities include low cost, small size, high sensitivity (including efficient MS/MS), and versatility (including MSⁿ, high resolution, and choice of internal or external ionization). Key analytical issues to be addressed during the workshop were identified: sensitivity, dynamic range, quantitation (including the use of co-eluting internal standards), tandem mass spectrometry, and "conventional" spectra.

Mark Hail (Bristol-Myers Squibb) initiated the discussion on decision criteria and key analytical issues, based on their recent decision to purchase an LC/MS/MS ion trap (the Finnigan LCQ) for small molecule pharmaceuticals and peptides. Key advantages of the ion trap were excellent full-scan data, data-dependent MSⁿ acquisition, and ability to fragment hard-to-fragment ions, particularly via stepwise MSⁿ. Limitations included the low-mass-cutoff in daughter scans (loss of daughter ions of <30% of the parent ion mass) and lack of parent and neutral loss scans. **Gary Glish** rose to point out that the low-mass-cutoff can be overcome in part by dropping the parent ion's *q* value, as well as the improvement in fragmenting hard-to-fragment ions achieved by pulsing in a more massive collision gas.

The first speaker to address ion traps for GC/MS and GC/MS/MS applications was **Alvin Fox** (University of South Carolina), who has compared GC/MS/MS on the ion trap (Finnigan GCQ) and the triple quad (Fisons Quattro) for detection of muramic acid in particulates. The ion trap offers higher abundance for higher *m/z* ions, providing enhanced sensitivity for selection of parent ions for MS/MS. The sensitivity and quantitation capabilities of the ion trap (using co-eluting isotopically labelled internal standards) permitted the ion trap to replace the triple quad in this application.

Bert Lynn (Mississippi State University) discussed optimization of GC/MS/MS conditions on the Varian Saturn ion trap for pesticide residues at low ppb levels. He pointed out the

advantage of switching MS/MS steps for screening and targeted compound analysis. In response to a question from **Craig Abolin** (Sandoz), Bert indicated a limited dynamic range of approximately two decades.

Kenny Morand (Procter & Gamble) summarized quantitation data for various ion trap and quadrupole GC/MS and GC/MS/MS instruments employing co-eluting isotopically labelled internal standards. In some cases, the precision was poorer with the ion trap.

The discussion turned to LC/MS and LC/MSⁿ with a presentation by **Matt Sweeney** (Finnigan MAT), who showed MS¹⁰ data on vitamin B12 (cyanocobalamin).

Jack Henion (Cornell University) compared CE/MS performed on ion traps using homemade interfaces (Finnigan ITMS and Varian Saturn II) with triple quads (Sciex API III). He showed much better S/N ratios for the ion trap data, but indicated that CE/MS was still difficult, with lots to learn to make it practical (independent of the ion trap itself).

Bob Voyksner (Research Triangle Institute) compared LC/MS performance on a homemade electrospray/ion trap system (Finnigan ITMS) and a quadrupole. The ion trap system delivered better S/N.

David Arnott (Genentech) presented LC/MS/MS data comparing ion traps (Finnigan LCQ) with triple quads (Finnigan TSQ) for peptide sequencing. For CID of tryptic digest peptides (doubly charged) the two instruments were equivalent. CID of singly charged peptides or peptides with ≥ 3 charges has yet to be explored, although rearrangements are seen for higher charge states with both ion traps and triple quads. A lively discussion ensued in response to a question from **Jack Henion** regarding the trade-offs between flexibility and ease-of-use for MSⁿ instruments and the need for "research-grade" software.

Bob Strife (Procter & Gamble) discussed the utility of MSⁿ for structure elucidation of surfactants, pointing out that only one of several possible MSⁿ experiments is commonly used, the sequential daughter scan.

Peter Roepstorff (Odense University) compared nanospray/MS/MS results for peptides using ion traps (a prototype Bruker-Franzen Esquire) and triple quads (Finnigan TSQ). The ion trap's higher resolution was valuable for assigning charge states; it was slightly more sensitive, but otherwise equivalent to the triple quad in providing daughter spectra of tryptic digest peptides. It was also pointed out that N-terminal derivatization can minimize the ion trap's problems with low-mass-cutoff at 30% of the parent ion *m/z*.

Finally, **Jun Qin** of Rockefeller University provided a perspective into the ion trap's future by discussing MALDI/MSⁿ on the ion trap (Finnigan ITMS), pointing out that the ion trap is an ideal marriage with the pulsed ionization event of MALDI. **Mark Hail** pointed out the potential of MALDI/MSⁿ for higher mass peptides.

ASMS Business Meeting, Portland, OR

The business meeting was held on May 12, 1996 at the Portland Convention Center in conjunction with the 44th ASMS Annual Conference. President Christie Enke chaired the business meeting and opened proceedings at 4:00 pm by welcoming all participants. Presentations made by members of the ASMS Board of Directors are summarized below.

President's Report (Christie Enke)

The American Society for Mass Spectrometry has continued to grow at an impressive rate. Our membership is presently over 3000. The number of papers presented here in Portland is nearly double the number in Tucson only 6 years ago (more than 1500, up from 800). The increasing volume of material to be presented creates a continuing challenge for the Vice-president for Programs to organize an accessible program. While the almost overwhelming richness of our programs is part of the wonderful inter-disciplinary interchanges that help fuel the rapid development of mass spectrometry, it can also lead to a feeling that one's own special interests are becoming more and more "diluted". It is in this context that the Interest Groups become increasingly important in providing cohesion and leadership in their areas. The Board's program to support and strengthen this function continues.

In addition to the annual conference, most of us have become used to, if not dependent on our journal - JASMS. The number of papers being published by our membership is an indication that JASMS is rapidly becoming our other major means of communication, bringing us year-round contact with some of the best research in the field. Another rapidly expanding communication medium is the ASMS home page. It provides an easy and quick means of keeping up to date on the latest Society information.

President Enke mentioned that he had enjoyed being our president these last two years and expressed his appreciation for all the support from the membership.

Vice-President for Programs' Report (Veronica Bierbaum)

The Vice-President for Programs reviewed the scientific and social program for the 44th annual conference. This is the largest ASMS conference ever, in terms of both presentations and attendance, and represents the first venture into a convention center. Veronica expressed appreciation to everyone present for their contributions to the conference, in particular, the Program Review Committee, the Oral Sessions Chairs, the Workshop Organizers, the

presenters of tutorial lectures, the plenary lecturers, all speakers and poster presenters, and the ASMS Staff.

Vice-President for Arrangements' Report (Charles McEwen)

The Vice-President for Arrangements presented the sites and dates for the ASMS Conferences for the next four years. Palm Springs, CA will be the site of our next meeting in 1997 (June 1-6), and this meeting will be held at the Convention Center. 1998 and 1999 Conferences will be in Orlando, FL (Marriott, May 30-June 4, 1998) and Dallas, TX (Loews Anatole, June 13-18, 1999). He also reported that Long Beach, CA (Convention Center, June 11-16, 2000) is being considered as the Conference site for the year 2000.

Treasurer's Report (Jane Gale)

The Treasurer reviewed the budget of the society; approximately one third of total expenses go for running the society, another third for the annual conference and one sixth for JASMS. The budgets for all other activities constitute the remaining one sixth of our expenses. In general, income matches expenses on a department by department basis, although in 1995 there were overall losses in both our operations and Journal budgets. These were offset by profits realized in all other departments, so that we finished the year with a net profit of \$18,000. Historically, the Society has been operating at or close to break-even, as befits a non-profit organization. In order to assure financial stability in the face of unanticipated losses, however, our retained earnings have grown commensurate with our membership and the complexity of our activities. We therefore maintain a balance roughly equal to the combined budgets of our journal and our annual conference. These retained earnings are invested in a very low risk stocks and bonds program managed by the Glenmede Corporation.

Member-at Large for Measurements and Standards' Report (Sharon Lias)

Sharon Lias, Member at Large for Measurements and Standards, reported that the Measurements and Standards Committee is continuing work on an update of the 1991 JASMS article, "Standard Definitions of Terms Relating to Mass Spectrometry." Committee member Phil Price is soliciting suggestions for new terms to be included from the Society membership.

Member-at Large for Education's Report (Robert Boyd)

Robert Boyd, Member-at-Large for Education, summarized the work of the Education Committee over the past year. He thanked the members of the Education Committee (John Amster, Pam Crain, Joe Grabowski and Al Yergey) for their assistance. The 1995 Fall

Workshop on EC-MS was very successful, thanks to the efforts of Pierre Thibault who organized the program, with contributions from Barry Karger, Jack Henion, Martin Mazereeuw, Andy Tomlinson and Curt Monnig, and with the essential on-site assistance of Cindi Lilly of the ASMS office. The 1996 Short Courses were highly successful, with a record total enrollment for 5 courses. This success was due to the efforts and talents of Rick Yost and Jodie Johnson (MS/MS), Al Yergey, Bob Voyksner and Don Chace (LC/MS), Dave Dahl and Tony Appelhaus (Ion Optics and SIMION), Dan Kassel, John Stults and Pierre Thibault (Peptides and Proteins), and Larry Phillips and the Baltimore-Washington Mass Spectrometry Discussion Group (Interpretation of Mass Spectra).

Member-at Large for Publication's Report (Anne Giordani)

Anne Giordani, Member-at-Large for Publication, reported that ASMS now has a "home page" on the World Wide Web <<http://www.asms.org>>. The most up-to-date information about ASMS and its activities is available on the ASMS home page. More and more, ASMS will be communicating electronically with its membership. Anne Giordani urged all members to make sure that ASMS has their correct e-mail addresses by checking the membership directory that is published in the August issue of JASMS. Additions and corrections are best e-mailed to ASMS <asms@asms.org>.

Anne also thanked the members of the original JASMS Editorial Board for their six years of service to the Society in this capacity. As of 1996, rotating three-year terms for the Editorial Board have been established. The current members of the Editorial Board are: Klaus Biemann, Michael T. Bowers, Jennifer S. Brodbelt, A.L. Burlingame, Richard M. Caprioli, R. Graham Cooks, Christie G. Enke, Catherine C. Fenselau, Alex G. Harrison, Ronald A. Hites, Keith R. Jennings, Hilka I. Kenttamaa, Barbara S. Larsen, David A. Laude, Chava Lifshitz, Joseph A. Loo, Alan G. Marshall, Scott A. McLuckey, Robert C. Murphy, N.M.M. Nibbering, David H. Russell, Richard D. Smith, Charles L. Wilkins, and Richard A. Yost.

JASMS Editor-in-Chief's Report (Mike Gross)

Mike Gross, JASMS Editor-in-Chief, reviewed the status of JASMS. "JASMS Online" is now available for publishing "Fast Track Articles." Articles will appear in the electronic edition of JASMS, on the Internet <<http://www.elsevier.com/locate/jasmonline>>, within two weeks of final acceptance. JASMS continues its healthy growth in the number of articles submitted while continuing to maintain its strong "Impact Factor" as calculated by ISI (second only to "Analytical Chemistry" among the analytical chemistry journals). Due to the scientific quality of JASMS, and its wide circulation to ASMS members, Mike urged everyone to consider JASMS when

choosing where to publish their research. He also reminded members that to insure archival access to JASMS, they should urge their home institutions to subscribe.

Secretary's Report (Hee-Yong Kim)

The Secretary announced the results of the election for the four Board positions which will become vacant on July 1, 1996. The new Board members are Robert J. Cotter (Vice President for Programs), Paul C. Goodley (Treasurer), Robert D. Voyksner (Member-at-Large for Measurements and Standards) and Paul Vouros (Member-at-Large for Education). Among the 2,303 ballots sent out 747 members actually voted, representing 32.4% voter turn-out. The secretary thanked all candidates for their willingness to stand for election.

Following the above reports, President Enke welcomed incoming officers and then called for any new business. There being none, President Enke thanked all, announced the Tutorial sessions and formally closed the Meeting at 4:30 pm.

Award Presentations and Lectures

The Award Ceremony was held on Thursday night (May 16) from 7:30 to 9:30 pm following the Salmon Bake dinner. As the Conference Wrap-up, the Vice President for Programs thanked all who made this conference successful. She honored the outgoing president, Christie Enke, and thanked him for his leadership and service. President Enke then introduced the winners of the ASMS Research Awards sponsored by Finnigan Corporation (presented to John Yates by Phil Warren) and by a number of ASMS Corporate Members and ASMS (presented to Xue-jun Tang by President Enke). Following these presentations, the Best Student Paper Awards for articles published in the International Journal of Mass Spectrometry and Ion Processes sponsored by Elsevier and Finnigan Corporation were presented to Klaus Dreisewerd and Sergey Nizkorodov by Graeme Whitley and John Todd. Jane Gale then announced twenty-five Student Travel Stipend Recipients. President Enke subsequently made a presentation to each of the outgoing Board Members (Past President, Henry Fales; Treasurer, Jane Gale; Robert Boyd, MAL for Education; and Sharon Lias, MAL for Measurements and Standards), and thanked them for their outstanding service to the Society. Also thanked were Judith Sjöberg and her staff at the ASMS office for 15 years of service. President Enke then presented the Distinguished Contribution to Mass Spectrometry Award to Frank Field and Burnaby Munson for the development and application of Chemical Ionization Mass Spectrometry. The 44th ASMS Annual Conference officially ended with the conclusion of the award lecture presented by Frank Field and Burnaby Munson at 9:30 pm.

891		Sequencing	8, 31, 222	351, 461, 550, 565, 568	
Relaxation, Radiative	1233	331, 352, 355, 365, 398		595, 597, 599, 656, 840	
Residual Gas Analysis		400, 401, 402, 405, 406		876, 924, 966, 1000	
510		407, 488, 564, 574, 602		1078, 1168, 1182, 1216	
Resolution	24, 649	603, 667, 669, 670, 690		1229, 1272, 1291, 1303	
746, 821, 1132, 1327		702, 728, 735, 906, 942		1413	
RF Glow Discharge	383	983, 1110, 1185, 1187		Substitution	680
892, 1159		1239, 1331, 1339, 1341		Supercritical Fluid	180
RNA	1, 405, 1373, 1405	1433, 1435		Supercritical Fluid	
RRKM	476	Silanes	87, 429, 472	Extraction	548
Saccharides	223, 224	SIMS	23, 26, 72, 385	Surface Analysis	22, 25
225, 415		521, 630, 814, 841, 842		272, 521, 629, 630	
Salts	210, 575, 684, 995	874, 881, 1098, 1157		1143, 1156, 1345	
Sampling	200, 419	1158, 1327		Surface-Induced	
422, 525, 528, 868, 877		SIMS, Liquid	131, 323	Dissociation	462, 463
900, 995, 1013, 1095		568, 584, 590, 680, 802		464, 465, 466, 467, 468	
Saponins	1303	803, 804, 806, 807, 840		469, 470, 471, 705	
Scattering	1254	885, 888, 1262, 1293		1166	
Secondary Electron		1391, 1449		Surfactants	163, 803
Emission	1343	SIMS, Organic	22, 25	806, 807, 876, 927	
Secondary Electron		28, 813, 946, 1143		1096, 1203, 1204, 1269	
Multiplier	79	SIMS, Static	22, 28	1271, 1275	
Secondary Ion Emission		521, 629, 630, 813, 893		Taxanes	597
630, 801, 813, 946		894, 946, 1142, 1143		Terpines	539, 545, 546
Secondary Ion Imaging	24	1156		Thermochemistry	87
26, 946		Solvation	1221, 1224	91, 92, 103, 106, 172	
Selected Ion Flow Tube	46	Solvents	207, 270	461, 471, 1225	
429, 434, 1010, 1226		645, 659, 904, 1016		Thermospray	177
Selected Ion Monitoring		1023, 1087, 1374		187, 958, 1272	
237, 519, 522, 611, 612		Space Charge	129, 130	Thioesters	522, 1050
622, 627, 712, 852		144, 502, 767, 825, 829			
958, 972, 973, 1076		Sputtering	11, 22, 472		
Selected Reaction		813, 817, 892, 1162			
Monitoring	545, 625				
671, 856, 970, 979					
1297, 1312, 1324					

INDEX OF KEYWORDS					
Keyword	Page	Keyword	Page	Keyword	Page
Time-of-Flight MS	2, 14	Trace Analysis	14, 20		
15, 28, 29, 35, 37, 51		150, 165, 200, 288, 296			
54, 59, 78, 81, 137, 138		510, 511, 519, 548, 587			
139, 167, 213, 214, 215		595, 839, 844, 848, 849			
216, 227, 232, 269, 270		864, 865, 871, 872, 877			
276, 277, 278, 279, 281		878, 930, 955, 1156			
329, 345, 350, 353, 357		1295, 1402			
358, 398, 399, 400, 402		Transfer Line	1144		
407, 411, 425, 479, 513		Ultra High Vacuum	1095		
529, 530, 531, 533, 547		Velocity Distribution	268		
591, 604, 607, 634, 638		Volatile Organic Analysis			
645, 648, 649, 652, 669		47, 48, 49, 56, 286, 397			
673, 679, 686, 729, 731		422, 514, 520, 525, 526			
736, 751, 786, 787, 789		527, 546, 864, 865, 868			
790, 791, 793, 794, 795		869, 870, 1268			
796, 797, 798, 799, 805		Work Function	61, 99		
811, 814, 839, 841, 860		Xenobiotics	184, 258		
874, 881, 893, 894, 896		311, 391, 397, 548, 584			
897, 904, 911, 912, 984		625, 882, 968, 1283			
985, 993, 996, 994		Zwitterion	806, 1385
